Thrombocytopenia in Pregnancy

Shruti Chaturvedi and Keith R. McCrae

Abstract

Thrombocytopenia is a common hematologic problem in pregnant women. The most common cause of thrombocytopenia is gestational thrombocytopenia, which is usually mild, is not associated with bleeding or neonatal thrombocytopenia, and resolves spontaneously postpartum. Gestational thrombocytopenia, however, may be hard to discern from immune thrombocytopenia (ITP), another cause of isolated thrombocytopenia during pregnancy, although thrombocytopenia due to ITP is often more severe and occurs earlier in pregnancy. Preeclampsia is the most common medical disorder of pregnancy and is associated with a constellation of symptoms including hypertension and proteinuria; thrombocytopenia is generally mild, but reflects the severity of underlying preeclampsia. The syndrome of hemolysis, elevated liver enzymes and low platelets (HELLP) is thought by some to be a variant of preeclampsia as it shares some manifestations but also displays unique ones, particularly liver involvement and microangiopathic hemolytic anemia. HELLP may be difficult to discern from primary thrombotic microangiopathies such as thrombotic thrombocytopenic purpura (TTP) and the atypical hemolytic uremic syndrome (aHUS), which are not unique to pregnancy but occur with increased frequency in this setting. Accurate diagnosis of the cause of thrombocytopenia during pregnancy is important, as treatment varies depending on the etiology. Careful consideration of the timing of onset of thrombocytopenia, and associated hematologic and other manifestations, needs to be considered in the differential diagnosis. Though thrombocytopenic disorders may severely compromise the outcomes of some pregnancies, prompt diagnosis and appropriate therapy often lead to successful pregnancy outcomes.

Introduction

Thrombocytopenia, defined as a platelet count less than 150,000/μL, is the second most common hematologic abnormality in pregnancy after anemia, occurring in up to 6–10 % of pregnancies (Sainio et al. 2000; McCrae 2006; Sullivan and Martin 1995). Platelet counts <100,000/μL are less common and are observed in less than 1 % of pregnancies (Rodeghiero et al. 2009). Although most cases of thrombocytopenia in pregnancy are mild and have no adverse outcome for the mother or fetus, moderate to severe thrombocytopenia may lead to bleeding during delivery, and occasional cases may be related to a life-threatening systemic disorder such as a thrombotic microangiopathy (McCrae 2010). Treatment goals are dynamic—in the first and second trimester the goal is to keep the platelet count in a safe range to prevent spontaneous bleeding, while during delivery, procedural risks and the risk of trauma during parturition necessitate a higher platelet count. Moreover, because therapeutic interventions

used to treat thrombocytopenic disorders in pregnant women may have toxicities unique to pregnancy, management approaches must be carefully considered.

Disorders That Cause Thrombocytopenia in Pregnancy

There are several potential causes of thrombocytopenia in a pregnant woman. Some of these are specific to pregnancy, others are exacerbated by pregnancy, whereas others may have no relationship to pregnancy at all (Table 1). Gestational thrombocytopenia, hypertensive disorders including preeclampsia, and immune thrombocytopenia (ITP) are the three most frequently encountered causes of thrombocytopenia in the pregnant patient (Table 2) (Burrows and Kelton 1990b; Gernsheimer and McCrae 2007). Thrombotic thrombocytopenic purpura and the HELLP syndrome are rare but must not be missed since they are associated with high maternal and fetal mortality. The evaluation of a pregnant woman presenting with thrombocytopenia is outlined in Table 3.

Table 1 Causes of thrombocytopenia in pregnancy

Pregnancy-specific conditions	Conditions associated with or exacerbated by pregnancy	Nonpregnancy-associated conditions
Gestational thrombocytopenia (70–80 %) Hypertensive disorders (preeclampsia) (15–20 %) HELLP syndrome (<1 %) Acute fatty liver of pregnancy (<1 %)	Thrombotic thrombocytopenic purpura Hemolytic uremic syndrome Disseminated intravascular coagulation (due to HELLP, amniotic fluid embolism, etc.) Type IIB von Willebrand disease-associated thrombocytopenia	Pseudo-thrombocytopenia Immune thrombocytopenia Drug induced thrombocytopenia Congenital thrombocytopenia Hypersplenism Antiphospholipid antibody syndrome Viral infections Nutritional deficiencies (folate, vitamin B12) Bone marrow disorders including aplastic anemia and hematologic malignancies

Table 2 Characteristics of thrombocytopenic disorders in pregnancy

	Gestational thrombocytopenia	Immune thrombocytopenia	Preeclampsia	HELLP syndrome	Thrombotic thrombocytopenic purpura	Atypical HUS
Incidence during pregnancy (%)	5–9	<1	5–8	0.5–0.9	<1	<1
Pathogenesis	Dilutional, increased platelet clearance	Autoimmune	Abnormal placentation	Abnormal placentation, complement regulatory protein mutations in some	Congenital or acquired severe ADAMTS13 deficiency	Complement activation, complement regulatory protein mutations
Timing in pregnancy	Onset late second or third trimester	Any, most common cause in first trimester	Onset in late second or third trimester (>20 weeks gestation)	70 % in late second or third trimester, 30 % postpartum	Second or third trimester	Usually postpartum
Platelet count	Usually >70,000/μL	<100,000/μL, may be severe	Any	Any <100,000/μL	Any <150,000/μL	Any <150,000/μL
Other important laboratory findings	None		24 h urine protein > 0.3 g/24 h	MAHA, LDH > 600 U/L or bilirubin > 1.2 mg/dL, AST > 70 U/L	ADAMTS13 activity <10 %	MAHA, ADAMTS13 not severely reduced
Neonatal thrombocytopenia	No	Yes	No[a]	No[a]	No[a]	No[a]
Resolves postpartum	Yes	May resolve	Yes	Yes	Not without plasma exchange (acquired TTP) or plasma infusion (congenital TTP)	Postpartum onset in most cases

[a]May be associated with thrombocytopenia in the setting of fetal distress and premature delivery

Table 3 Diagnostic evaluation for thrombocytopenia in pregnancy

History
Prior thrombocytopenia or bleeding especially with previous pregnancies, drug intake, autoimmune disorders, systemic illness
Physical examination
Bleeding manifestations, blood pressure (preeclampsia), and abdominal tenderness (HELLP and acute fatty liver of pregnancy)
Laboratory tests
In all patients
Complete blood count
Peripheral blood smear
Reticulocyte count
Liver function tests
Viral screening (hepatitis B virus, hepatitis C virus, human immunodeficiency virus)
When clinically indicated
Lupus anticoagulant and antiphospholipid antibodies
ADAMTS13 activity and inhibitory antibody
Thyroid function testing
Mutations in complement regulatory genes (atypical hemolytic uremic syndrome)
Haptoglobin, lactate dehydrogenase
Direct antiglobulin test (appropriate to rule out Evans syndrome)
Von Willebrand type IIB testing
Disseminated intravascular coagulation testing—prothrombin time, activated partial thromboplastin time, fibrinogen, fibrin split products

Gestational Thrombocytopenia

Gestational thrombocytopenia, also called incidental thrombocytopenia of pregnancy, is the most common cause of thrombocytopenia in pregnant women, accounting for 70–80 % of cases (Burrows and Kelton 1993a; Sainio et al. 2000; McCrae 2006). Normal pregnancy is associated with a physiologic fall in the platelet count that is about 10 % lower than in nonpregnant women (Boehlen et al. 2000; Jensen et al. 2011). It has been speculated that these changes may reflect dilution, decreased platelet production, or accelerated platelet clearance (Provan et al. 2010). The majority of women still have platelet counts within the normal range; however, some women develop counts that fall into the thrombocytopenic range, becoming particularly apparent in the late second or third trimesters. Although there is no established minimum platelet count for gestational thrombocytopenia, most experts agree that this diagnosis is less likely when platelet counts fall to less than 70,000/μL. There are reports of women with more severe thrombocytopenia that did not respond to corticosteroid therapy and resolved postpartum, consistent with gestational thrombocytopenia (Win et al. 2005).

Because there is no diagnostic testing available for gestational thrombocytopenia, it is a diagnosis of exclusion. Patients with a history of primary or secondary ITP, thrombocytopenia preceding pregnancy, an identifiable cause for thrombocytopenia other than pregnancy, or thrombocytopenia that improves with steroid therapy are generally not considered to have gestational thrombocytopenia.

Gestational thrombocytopenia is not associated with adverse maternal or fetal outcomes. The degree of maternal thrombocytopenia is generally not severe enough to increase the risk of bleeding with delivery, although platelet counts less than 75–80,000/μL may compromise the ability to give epidural anesthesia (Provan et al. 2010; van Veen et al. 2010). A brief trial of ITP-directed therapy (corticosteroids or intravenous immunoglobulin) may be considered in patients with platelet counts in the 50,000–70,000/μL range and may have diagnostic and therapeutic utility (McCrae 2010). In the absence of response to steroids, platelet transfusions may be used to raise the platelet count to a "safe" level for epidural catheter placement. Gestational thrombocytopenia is self-limited and resolves 1–2 months after delivery. It may recur in subsequent pregnancies. Importantly, unlike ITP, it is not associated with a higher rate of fetal or neonatal thrombocytopenia compared to non-thrombocytopenic women. When this occurs, it may be due to coincident neonatal alloimmune thrombocytopenia due to maternal exposure and sensitization to fetal platelet antigens (Burrows and Kelton 1988; Curtis 2015).

Immune Thrombocytopenia

ITP is an uncommon cause of thrombocytopenia in pregnancy, occurring in between 1 in 1000 and 1 in 10,000 pregnancies and accounting for about 3 % of pregnant women with isolated thrombocytopenia (Gernsheimer and McCrae 2007). About a third of women with pregnancy-associated ITP are first diagnosed during pregnancy, while two-thirds have a preexisting diagnosis of ITP (Webert et al. 2003). Despite improved understanding of pathophysiology, the factors that cause ITP and may cause worsening during pregnancy are incompletely understood.

The clinical features of ITP in a pregnant woman are similar to those in nonpregnant patients, with bruising, mucosal bleeding, petechiae, and sometimes spontaneous bleeding whose severity usually reflects the degree of thrombocytopenia. ITP can occur at any time during pregnancy; however it is the most common cause of thrombocytopenia in the first and early second trimesters (Gill and Kelton 2000). It is more frequently associated with platelet counts $<$100,000/μL (Provan et al. 2010) and occasionally presents with severe thrombocytopenia and bleeding. Patients with ITP more often have a prior history of ITP or other autoimmune disorders that may be helpful in making this diagnosis.

Management of ITP in Pregnancy

The goal of treatment of ITP in pregnancy is to prevent bleeding. Therefore, treatment is generally not required in the first or second trimester unless the patient has a platelet count less than 20,000–30,000/μL, symptomatic bleeding, or

an elective procedure requiring a higher platelet count. In the third trimester, a higher platelet count is desirable for delivery, especially if the patient desires epidural anesthesia. Recent guidelines recommend a platelet count of at least 75,000/μL for safe placement of an epidural catheter (Provan et al. 2010). It may be advisable to maintain a platelet count of at least 50,000/μL beyond the mid-third trimester in case an emergency cesarean section is required (McCrae 2010). Figure 1 summarizes the management of ITP in pregnancy.

As with nonpregnant patients, corticosteroids are first-line therapy for ITP in pregnancy (Neunert et al. 2011; Provan et al. 2010). We usually start with a low dose of 10–20 mg prednisone daily and titrate to maintain a platelet count >30,000/μL. Prednisolone and prednisone are preferred to dexamethasone, which crosses the placenta more easily. Corticosteroids may have unique toxicities in pregnancy, such as gestational diabetes, pregnancy-induced hypertension, and psychosis. These agents have also been associated with placental abruption, premature rupture of the membranes, and adverse pregnancy outcomes (Kelton 2002; Laskin et al. 1997). Some reports have associated exposure to high-dose corticosteroids in the first trimester with developmental abnormalities such as cleft lip and palate (Carmichael et al. 2007; Czeizel and Rockenbauer 1997; Laskin et al. 1997). Given these potential adverse effects, steroids should be used sparingly and at the lowest possible dose. Corticosteroids should be tapered, with close monitoring in the postpartum period to avoid a rapid fall in the platelet count.

For patients who respond suboptimally, or not at all, to reasonably tolerated doses of corticosteroids, intravenous immunoglobulin (IVIg) at a dose of 1 g/kg (in single or divided doses) can be used (Provan et al. 2010). Indeed, some have cogently argued that due to the toxicity of corticosteroids, IVIg should be used as the first-line therapy for pregnancy-associated ITP. The duration of response to IVIg is short, lasting 2–3 weeks, and repeated infusions are usually required to maintain adequate platelet counts. For patients who do not respond to corticosteroids or IVIg as single agents, combinations of these therapies may be effective, particularly when higher-dose "pulse" steroids are used (e.g., methylprednisolone 1 g/kg for 2 consecutive days). This approach, along with platelet transfusions, may be needed close to delivery (Koyama et al. 2012; Webert et al. 2003).

Occasionally, a patient may be refractory to treatment with corticosteroids and IVIg. For these refractory patients, toxicity and teratogenicity of alternative agents limit their use. Splenectomy, although rarely necessary, may safely be performed laparoscopically in the mid-second trimester to avoid early pregnancy loss or obstruction of the surgical field by the gravid uterus closer to term (Griffiths et al. 2005). The recommended pre-splenectomy vaccines (meningococcal, pneumococcal, and *Haemophilus influenzae* B vaccines) are all inactivated and can be safely administered during pregnancy (Keller-Stanislawski et al. 2014; Chu and Englund 2014).

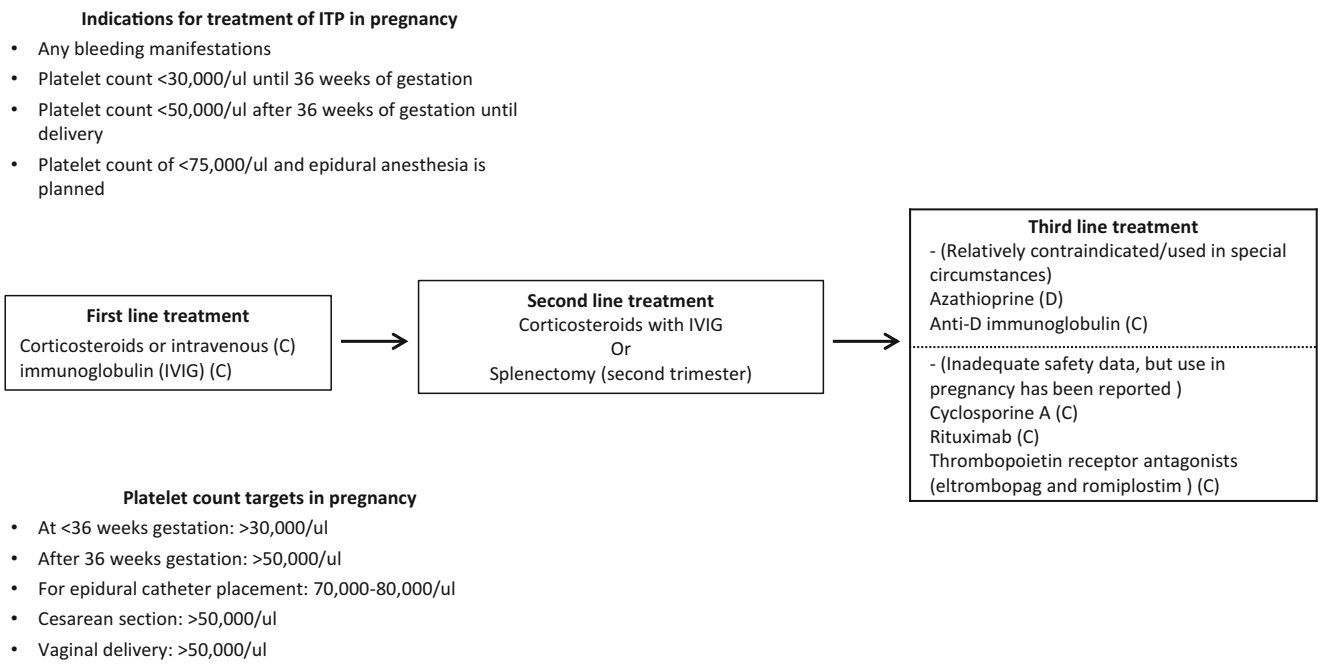

Fig. 1 Management of ITP in pregnancy. *Letters in brackets* indicate FDA-designated pregnancy category. (C) = studies in animals show risk, but inadequate studies in human fetuses. Benefit may justify risk; (D) = evidence of risk in human fetuses. Benefit may justify risk; (X) = studies in animals or human fetuses demonstrate abnormalities. Risk of harm outweighs benefits

Azathioprine has been used safely in pregnant women with renal transplants, systemic lupus erythematosus, and inflammatory bowel disease (Erkman and Blythe 1972; Price et al. 1976), suggesting that it is reasonably safe for use in pregnancy-associated ITP. Some studies report associations of maternal azathioprine with intrauterine growth restriction, preterm delivery, and immune impairment of the neonate (Sukenik-Halevy et al. 2008; Gisbert 2010). It is labeled as pregnancy category D by the US Food and Drug Administration (FDA), indicating that there is positive evidence of fetal risk, but benefits may outweigh the risk in case of serious or life-threatening disease. Its delayed effect, however, limits its use as a steroid-sparing agent. Cyclosporin A has also been used safely in pregnancy. In general, cytotoxic agents are associated with a risk of teratogenicity and should be avoided if possible.

There is limited data regarding the use of rituximab in pregnancy. There are several reports of its successful use in pregnancy-associated ITP (Gall et al. 2010; Klink et al. 2008). Rituximab crosses the placenta and may cause a delay in neonatal B-cell maturation. This resolves by 4–6 months, and reports to date have not showed any clinically significant infections in the offspring (Klink et al. 2008; Gall et al. 2010). One retrospective study identified 153 pregnancies associated with rituximab exposure for various indications, with known outcomes (Chakravarty et al. 2011). There were 90 live births, of which 22 were preterm. Eleven neonates had hematologic abnormalities (lymphopenia, neutropenia, or B-cell depletion) that were not associated with infectious complications (Chakravarty et al. 2011). Rituximab has been designated pregnancy category C by the FDA (Chakravarty et al. 2011).

There are isolated case reports of the use of thrombopoietin receptor antagonists (eltrombopag and romiplostim) for refractory ITP in pregnancy (Alkaabi et al. 2012; Decroocq et al. 2014); however their effects on the fetus are unknown, and their use cannot be recommended in pregnancy. Short-term therapy with danazol in combination with high-dose IVIg and corticosteroids has been used for refractory thrombocytopenia in the third trimester (Orisaka et al. 2005). However, danazol has been observed to cause birth defects and has been designated category X by the FDA; its use should therefore be avoided.

Risk of Neonatal Thrombocytopenia

Anti-platelet antibodies can cross the placenta and cause fetal and neonatal thrombocytopenia. The development and severity of neonatal thrombocytopenia depend on many poorly understood factors including the stage of pregnancy (greatest in the third trimester), maturity of the fetal reticuloendothelial system, and immunoglobulin subclass (highest for IgG1) (Kane and Acquah 2009). There is no consistent correlation between neonatal thrombocytopenia and the severity of maternal thrombocytopenia, the level of maternal platelet-associated immunoglobulin, whether or not the mother has undergone splenectomy, or several other parameters (Kelton 2002; Stavrou and McCrae 2009; Burrows and Kelton 1993b). In fact, the best predictor of neonatal thrombocytopenia is a history of thrombocytopenia in an older sibling (Christiaens et al. 1997).

Thrombocytopenia, with a platelet count <50,000/μL, occurs in approximately 10 % of newborns of mothers with ITP, whereas platelet counts <20,000/μL occur in approximately 4 % (Burrows and Kelton 1993b). There is no safe and reliable indirect method to measure the fetal platelet count. Neonates with severe thrombocytopenia may experience bleeding complications, the most feared of which is intracranial hemorrhage. Because of a perceived increased risk of intracranial hemorrhage as a consequence of head trauma during vaginal delivery, in previous decades nearly all pregnant patients with ITP were managed with cesarean section. However, more recent data have shown that (a) the risk of fetal intracranial hemorrhage in offspring of mothers with ITP is extremely low (Burrows and Kelton 1993b), and (b) this risk is not substantially increased by vaginal delivery (Cook et al. 1991). Therefore, maternal ITP is not an indication for cesarean delivery, and the delivery method should be guided by maternal indications only. Antenatal determination of the fetal platelet count by percutaneous umbilical cord blood sampling (or cordocentesis) is not recommended since it is associated with a 1–2 % risk of fetal loss, at least as high as the risk of intracranial hemorrhage due to maternal ITP (Stavrou and McCrae 2009). It must be noted that low-dose maternal corticosteroids do not increase neonatal platelet count and should not be used with this objective (Christiaens et al. 1990).

The neonatal platelet count should be measured on a cord blood or peripheral blood sample immediately after delivery. If completely normal, this does not need to be rechecked, but parents should be counseled to watch for bruising petechiae or signs of bleeding. For neonates with thrombocytopenia, platelet counts should be checked regularly for the first week, since the platelet nadir is frequently observed at 2–5 days of life (Burrows and Kelton 1990a). Neonates with platelet counts <50,000/μL should undergo a transcranial ultrasound to rule out intracranial hemorrhage, even if asymptomatic. Platelet transfusions and IVIg may be used to treat neonates with platelet counts <30,000/μL, or those with active bleeding (Gibson et al. 2004).

Thrombotic Thrombocytopenic Purpura and Other Thrombotic Microangiopathies

Thrombotic Thrombocytopenic Purpura (TTP)

Thrombotic thrombocytopenic purpura (TTP) is a life-threatening systemic disorder characterized by microangiopathic hemolytic anemia (MAHA), thrombocytopenia, and varying degrees of renal, neurologic, and other organ

dysfunctions (Kremer Hovinga 2017 in this volume). It is caused by a deficiency of ADAMTS13, a von Willebrand factor-cleaving protease. Deficiency of ADAMTS13 is usually acquired, resulting from neutralizing autoantibodies (Tsai and Lian 1998), although congenital ADAMTS13 deficiency (Upshaw-Schulman syndrome) accounts for a minority of cases, many of which may present for the first time during pregnancy (Lotta et al. 2010). Although TTP is not pregnancy specific, it occurs with increased frequency during pregnancy, predominantly in the second and third trimester (Scully et al. 2014; Martin et al. 2008; Kremer Hovinga et al. 2010). Although the pathophysiology underlying this association is not well understood, it may be related to the increases in fibrinogen, factor VIII, VWF, and factor VIIa (Stirling et al. 1984) and the decrease in ADAMTS13 activity that occurs during normal pregnancy. In one study, the mean ADAMTS13 activity decreased from 94 % (range 40–160 %) in the first trimester to 64 % (range 22–135 %) in the second and third trimesters (Mannucci et al. 2001); however these levels are well above the 5–10 % levels associated with TTP.

TTP is a challenging diagnosis to make in pregnancy, since its clinical features overlap with other pregnancy-specific conditions such as preeclampsia, HELLP syndrome, and acute fatty liver of pregnancy (AFLP) that often manifest with MAHA and thrombocytopenia. Measuring ADAMTS13 activity and inhibitory antibody helps in confirming the diagnosis; however these tests may not be immediately available. Due to the importance of prompt initiation of therapy for this disorder, any patient with unexplained MAHA and thrombocytopenia should be considered to have TTP and started on daily plasma exchange, which has a response rate of approximately 80 %. The role of corticosteroids in pregnancy-associated TTP has not been evaluated in randomized trials. Although they are commonly used in conjunction with plasma exchange in the nonpregnant patient with TTP, there may be an increased risk of complications in pregnant individuals. TTP can cause thrombosis in the placental circulation and result in fetal growth restriction, intrauterine fetal death, and preeclampsia. Therefore all pregnant women with a history of TTP should be followed by a high-risk obstetrician and undergo regular fetal growth scans and uterine artery Doppler monitoring. The British Committee for Standards in Hematology guidelines also advise thromboprophylaxis with aspirin and low molecular weight heparin in a patient treated for TTP once the platelet count reaches 50,000/μL (Scully et al. 2012).

Women with Upshaw-Schulman syndrome (congenital ADAMTS13 deficiency) frequently have acute episodes of TTP during pregnancy, and these are associated with high fetal mortality. Indeed, patients with congenital TTP are disproportionately represented in pregnancy-associated TTP (Moatti-Cohen et al. 2012; Scully et al. 2014). It is important to distinguish congenital from acquired TTP, as regular plasma infusions may prevent acute attacks and permit a normal pregnancy outcome in congenital TTP, while acquired TTP should be treated with daily plasma exchange for days or even weeks to induce remission (Scully et al. 2014; von Auer et al. 2015). It is important to note that, unlike preeclampsia, eclampsia, and HELLP syndrome, delivery does not lead to resolution of TTP.

There is an increased risk for TTP in subsequent pregnancies; however these pregnancies can be successfully managed with close monitoring and care. One series reported successful outcomes in 18 pregnancies in women with a history of congenital TTP who were managed with prophylactic plasma infusions and close monitoring (Scully et al. 2014). In another series of 10 women with acquired TTP, recurrent TTP occurred in 2 of 16 pregnancies, while 13 (81 %) pregnancies resulted in normal births (Jiang et al. 2014). Patients with a history of TTP may be at higher risk of preeclampsia.

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is a thrombotic microangiopathy that is pathophysiologically distinct from TTP, but shares overlapping clinical features. HUS is typically associated with the presence of acute renal failure, which is less commonly observed in TTP (Coppo et al. 2006) (Kremer Hovinga 2017 in this volume). Levels of ADAMTS13 are generally not severely reduced in most patients with HUS. Prior to the availability of ADAMTS13 testing, it was nearly impossible to definitively distinguish HUS from TTP. While TTP/HUS is estimated to occur in 1:25,000 pregnancies (Dashe et al. 1998), contemporary estimates of the incidence of HUS per se during pregnancy are not available.

There are several variants of HUS. One type, D+ HUS, is caused by infection with Shiga toxin-producing *E. coli* (typically types O157:H7 and O104:84). However, the commonest type of HUS encountered during pregnancy is atypical HUS (aHUS), which is associated with activation of the alternate complement pathway (Fakhouri et al. 2010; Nester and Thomas 2012). Patients with atypical HUS may have mutations in complement regulatory proteins such as factor H, factor I, membrane cofactor protein, or thrombomodulin, among others, as well as activating mutations in complement factors B and C3. Factor H-reactive antibodies may cause acquired factor H deficiency. In a retrospective cohort of 100 women with atypical HUS, 21 % had pregnancy-associated atypical HUS of which 79 % presented in the postpartum period (Fakhouri et al. 2010). Complement abnormalities were detected in 18 of the 21 patients with pregnancy-associated atypical HUS. Overall outcomes were poor with 4.8 % and 7.7 % associated with fetal loss or preeclampsia, respectively. Seventy six percent of patients developed end-stage renal disease despite plasma exchange. However, this data was accumulated prior to the availability of eculizumab, a

humanized monoclonal anti-C5 antibody that is highly effective in treating atypical HUS.

Preeclampsia and the HELLP Syndrome

These disorders are discussed together, because they share similar clinical characteristics and pathophysiology. Preeclampsia affects up to 6 % of all first pregnancies (American College of Obstetricians and Gynecologists [ACOG] practice bulletin 2002), accounts for 21 % cases of thrombocytopenia at delivery, and is the most common cause of pregnancy-associated mortality worldwide. ACOG criteria for the diagnosis of preeclampsia include the following: (1) blood pressure of 140 mmHg systolic or 90 mmHg diastolic or higher that occurs after 20 weeks of gestation in a woman with previously normal blood pressure, and (2) proteinuria, defined as urinary excretion of 0.3 g of protein or higher in a 24-h specimen that usually correlates with a 1+ or greater reading on dipstick (ACOG practice bulletin 2002). Multiple organ systems are affected in preeclampsia, reflecting systemic endothelial dysfunction, although the kidneys are affected most severely. Predisposing factors include age <20 years or >30 years, a high body mass index, chronic hypertension, as well as maternal and paternal genetic factors (McCrae 2010; Mostello et al. 2008). Thrombocytopenia is observed in about 50 % of patients with preeclampsia and generally parallels the severity of preeclampsia.

The HELLP syndrome develops in 10–20 % of women with severe preeclampsia and affects 0.5–0.9 % of all pregnancies (Haram et al. 2009; Kirkpatrick 2010). Criteria for the diagnosis of HELLP syndrome include hemolysis (abnormal peripheral smear, LDH > 600 U/L, or bilirubin > 1.2 mg/dL), aspartate aminotransferase > 70 U/L, and a platelet count < 100×10^9/L (Sibai 2011). The risk of severe complications in the HELLP syndrome parallels the severity of thrombocytopenia, although severe complications such as hepatic rupture and hemorrhage can occur even without severe thrombocytopenia.

Abnormal placentation, the process by which fetal trophoblast cells invade the maternal decidua and remodel the maternal uterine spiral arteries, is central to the pathogenesis of preeclampsia, in which both the depth of trophoblast invasion and the extent of remodeling of the spiral arteries are reduced. This may reflect deficiencies in trophoblast function, including failure of trophoblast cells to alter their pattern of integrin expression toward an endothelial phenotype and deficient protease activity, among others (Young et al. 2010). As pregnancy advances, insufficient placentation results in progressive uteroplacental ischemia that induces the systemic manifestations of preeclampsia. As early as the first trimester, patients who are destined to develop preeclampsia exhibit elevated levels of soluble vascular endothelial cell growth factor (VEGF) receptor type 1 (sFlt1) (Maynard et al. 2005), as well as endoglin, an endothelial cell-derived member of the tumor growth factor-β (TGF-β) receptor family (Venkatesha et al. 2006). Increased levels of sFlt1 and endoglin mRNA are present in preeclamptic placentae, suggesting this is the source of these proteins. sFlt1 binds and neutralizes VEGF and placental growth factor (PLGF), and endoglin blocks the binding of TGF-β to endothelial cells. One outcome of these actions is to decrease expression of endothelial nitric oxide (NO) synthase leading to reduced NO production and exacerbation of the hypertensive manifestations of preeclampsia. Functional deficiency of VEGF/PLGF also results in endothelial dysfunction particularly that of the glomerular endothelium, leading to the characteristic endothelial swelling and "glomerular endotheliosis" lesions of preeclampsia and in some cases the development of a thrombotic microangiopathy (Myatt and Webster 2009). Mutations in genes regulating the activity of the alternative complement system (factor H, factor I, and membrane cofactor protein) were detected in 4 of 11 patients with HELLP syndrome and renal involvement (Fakhouri et al. 2008), suggesting that, as in atypical hemolytic uremic syndrome (aHUS), excessive complement activation may be involved in the pathogenesis of HELLP in some patients.

The mainstay of treatment for preeclampsia and HELLP syndrome is delivery of the fetus. Prompt delivery is indicated in women beyond 34 weeks of gestation, or with fetal distress or severe maternal disease (Lindheimer et al. 2010). For pregnancies <34 weeks of gestation and in which the maternal and fetal status is stable, delivery may be attempted after administering beclomethasone to accelerate fetal lung maturity (Roberts and Dalziel 2006). In addition to medical stabilization and prompt delivery, most patients require additional antihypertensive medications and should receive magnesium sulfate for seizure prophylaxis. The use of high-dose corticosteroids and plasma exchange remain controversial, but some series indicate that these may improve the outcomes of severe HELLP (Woudstra et al. 2010; Eser et al. 2005).

Women with preeclampsia or HELLP are at increased risk for development of recurrent disease and poor pregnancy outcome in subsequent pregnancies (Dildy et al. 2007). A meta-analysis suggests that aspirin has modest efficacy in prevention of preeclampsia, although no difference in the incidence of fetal death was demonstrated (Askie et al. 2007). In recent years, it has become increasingly apparent that patients with preeclampsia are at increased risk for cardiovascular disease and death during long-term follow-up (Cirillo and Cohn 2015).

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy is a rare disorder that usually presents in the third trimester of pregnancy with nausea, vomiting, malaise, right upper quadrant pain, and cholestatic

liver dysfunction (Fesenmeier et al. 2005). It occurs in 1:7000–1:20,000 deliveries and has a maternal mortality rate of around 15 %. Approximately 50 % patients with AFLP meet the criteria for preeclampsia, but overlap with HELLP may also occur. Most patients develop DIC due to acquired antithrombin deficiency, with thrombocytopenia and deficiencies of fibrinogen and other clotting factors (Castro et al. 1999). Due to the coagulopathy, bleeding is common, despite only mild thrombocytopenia. Other complications include hypoglycemia, infection, renal insufficiency, and encephalopathy. Some cases of acute fatty liver, as well as HELLP, may be associated with fetal mitochondrial fatty acid oxidation defects, most commonly due to deficiency of long-chain 3-hydroxyacyl-coenzyme A dehydrogenase. Treatment involves supportive care with blood product support for the underlying coagulopathy (McCrae 2006). Delivery of the fetus leads to improvement in AFLP within 2–3 days and should be seriously considered in pregnancies beyond the period of viability, fetal distress, or life-threatening maternal disease. Plasma exchange, with or without continuous hemofiltration, has also been reported to improve outcomes in severe AFLP (Jin et al. 2012; Yu et al. 2014).

Miscellaneous Causes of Thrombocytopenia

In this section, we will briefly discuss several miscellaneous causes of thrombocytopenia in pregnancy. These, and other causes that are not discussed, are listed in Table 1.

In all individuals with thrombocytopenia, whether pregnant or non-pregnant, the peripheral blood film should be examined to evaluate for ethylenediaminetetraacetic acid (EDTA)-dependent platelet clumping, causing "pseudothrombocytopenia." In such cases, determination of the platelet count in a tube containing a non-EDTA anticoagulant such as citrate-tris-pyridoxalphosphate (CPT) may eliminate clumping and lead to more accurate readings (Podda et al. 2012).

Disseminated intravascular coagulation (DIC) may arise from a number of events in pregnant women. Placental abruption, amniotic fluid embolism, and uterine rupture cause fulminant DIC due to the rapid release of tissue factor-rich material that causes profound activation of coagulation, with consumption of coagulation factors and severe hypofibrinogenemia. DIC may, however, develop more gradually in the case of retained fetal products, and thrombocytopenia may be the presenting feature (McCrae and Cines 1997).

The antiphospholipid syndrome may be associated with immune thrombocytopenia or a microangiopathic thrombocytopenia (Asherson et al. 2007). Treatment strategies similar to primary ITP, with corticosteroids and IVIg, may be employed when platelet count is <30,000/μL, with azathioprine, rituximab, or other interventions reserved for refractory cases (Gernsheimer and McCrae 2007). Treatment of thrombocytopenia in these patients must be balanced with the risk of thrombosis and pregnancy loss. In women with a persistent lupus anticoagulant or antiphospholipid antibodies and no prior history of thrombosis, daily low-dose aspirin may be started if the platelet count is greater than approximately 50,000/μL. If a history of prior spontaneous abortion or thrombosis is present, the patient should be treated with aspirin and low molecular weight heparin. A stable platelet count >50,000/μL is usually considered safe for anticoagulation (Gernsheimer and McCrae 2007).

Type IIB von Willebrand disease is characterized by a mutant von Willebrand factor (VWF) molecule that binds to its primary platelet receptor, glycoprotein Ib, with increased affinity, thereby inducing platelet agglutination, accelerated platelet clearance, and thrombocytopenia (Grainick et al. 1985). Levels of endogenous VWF increase during pregnancy (Stirling et al. 1984), and thrombocytopenia induced by the mutant VWF may become more apparent (Rick et al. 1987). In some patients, platelet counts can fall to as low as 20,000–30,000/μL, with improvement after delivery. Desmopressin can worsen thrombocytopenia and should not be used. Platelet transfusions along with a VWF-containing factor VIII concentrate have been used to maintain safe platelet counts and prevent hemorrhage during delivery (Hepner and Tsen 2004; Ieko et al. 1990). Phenotypically similar to type IIB von Willebrand disease is platelet-type von Willebrand disease or pseudo-von Willebrand disease. This is an autosomal dominant disorder characterized by gain of function mutations of the glycoprotein Iba (GP1BA) gene, resulting in enhanced binding of VWF to the platelet surface receptor, and accelerated platelet clearance. Distinguishing the two conditions may be difficult but has important clinical implications; patients with platelet-type von Willebrand disease need to be treated with platelet transfusions rather than VWF replacement because of their inherent platelet defect and thrombocytopenia. The commonly used ristocetin-induced platelet aggregation is unreliable in view of the physiological increases in platelet activation and adhesion in pregnancy (Ranger et al. 2012); however, platelet aggregation studies in the presence of normal plasma VWF from cryoprecipitate have been successfully used to make this diagnosis (Enayat et al. 2006). Confirmatory diagnosis can also be made by genotypic analysis.

Drug-induced thrombocytopenia may result from a variety of prescription drugs, as well as illicit medications, such as cocaine. While *infiltrative marrow disorders* (e.g., hematologic malignancies, metastatic cancer, invasive fungal or other infections) and bone marrow failure syndromes (e.g., aplastic anemia, myelodysplasic syndrome, and

myelofibrosis) can cause cytopenias, including thrombocytopenia, these are uncommon in women of childbearing age. *Severe nutritional deficiencies*, such as folate or vitamin B12 deficiencies, can present with thrombocytopenia, usually along with other cytopenias, but these are similarly rare in pregnant women. *Congenital thrombocytopenias*, such as the May-Hegglin anomaly, may first be detected during pregnancy and may be detected through identification of abnormal platelet morphology on review of the peripheral blood film of the patient and family members.

Take-Home Messages

- Gestational thrombocytopenia, hypertensive disorders of pregnancy, and immune thrombocytopenia are the most common causes of low platelet counts in a pregnant woman.
- Time of onset during pregnancy, careful clinical and laboratory evaluation, and attention to associated clinical findings need to be considered to make an accurate diagnosis of the cause of thrombocytopenia in a pregnant woman.
- Treatment depends on etiology and is aimed at preventing hemorrhage—platelet count targets depend upon the period of gestation and planned procedures.
- HELLP syndrome and TTP/HUS are life-threatening diagnoses that must be excluded in all patients.

Thrombocytopenia in the Newborn

Robert Carr, Timothy Watts, and Catherine Rea

Abstract

Thrombocytopenia is common in preterm and sick newborn infants. Establishing the cause and deciding at what threshold to transfuse donor platelets is a recurrent clinical challenge. A healthy baby will have a platelet count that is in the *normal range* ($>150 \times 10^9$/L) at birth, but there is evidence that the progenitor pool is limited and thrombopoiesis vulnerable to disruption and exhaustion, particularly at very early gestational ages.

This chapter gives an overview of current understanding of the *physiology of platelet production and function* in the newborn and describes the aetiology and natural history of conditions that lead to *thrombocytopenia in clinical practice*. The relationship between *thrombocytopenia and clinical bleeding* remains poorly defined, with appropriate thresholds for platelet transfusion subject to debate. Current UK *transfusion guidelines* are presented, along with ongoing studies, to establish an evidence base for what remains often pragmatic practice. This chapter ends with a look towards therapeutic *alternatives to transfusion* of donor platelets for prevention and treatment of thrombocytopenia in the newborn.

Introduction

Thrombocytopenia is common in neonates admitted to critical care, particularly in low gestational age babies. As this group of patients are at high risk of clinically significant and potentially damaging bleeding (Wilson-Costello et al. 2007; Stoll et al. 2015), prophylactic transfusion of platelets is common in neonatal practice. However, predictors of clinically important bleeding remain uncertain, and hence there is a lack of international consensus regarding appropriate thresholds for triggering platelet transfusion, a therapy that brings its own dangers (Stainsby et al. 2008; Roberts et al. 2008; Christensen 2011).

Normal Ranges

The definition of thrombocytopenia in the newborn is controversial. Most commonly the 'normal' range for platelet count is considered to be the same as for children and adults ($150–450 \times 10^9$/L) so that babies with platelet counts below 150×10^9/L would be considered to be thrombocytopenic, regardless of their gestational age at birth. The basis for this are studies of fetal blood obtained by cordocentesis, which have shown that the mean platelet count has reached 150×10^9/L by the end of the first trimester and rises to between 175 and 250×10^9/L by the end of the second trimester (Holmberg et al. 1983; Forestier et al. 1986,

1991). This definition is further supported by studies of platelet counts in babies born at term that show that over 98 % have values above 150 × 10^9/L at birth (Burrows and Kelton 1990a, 1993; Sainio et al. 2000).

An alternative view is that definitions should be based on reference ranges from representative patients (Christensen 2011). Wiedmeier and colleagues (2009) reported reference ranges in 2008, based on the 5th to 95th centiles for platelet counts from a large cohort of almost 50,000 neonates born between 22 and 42 weeks gestation, measured in the first 90 postnatal days. They found that platelet counts were generally lower the more preterm the baby is, with a 5th centile of 104 × 10^9/L in babies <32 weeks gestation, whereas in babies >32 weeks it was 123 × 10^9/L. They suggested that platelet counts of 100–150 × 10^9/L should be considered normal in the most preterm infants. Other studies similarly suggest a relationship between platelet count and gestational age (Aballi et al. 1968; Sell and Corrigan 1973; Van den Hof and Nicolaides 1990; Haque and Bahakim 1991; Obladen et al. 2000), although results have not been consistent.

A caution to ascribing these data to a 'normal' range is that they are based on babies in neonatal units, who by virtue of their circumstances would generally not have normal haematological values. If they are premature, they will usually have pathological reasons for their premature birth, most of which are known to have an impact on blood values, such as infection, bleeding or placental problems. Following birth they will often be clinically unstable and subject to significant physiological stresses which, in turn, would be expected to affect their haematological indices. None the less, these studies provide an important reference to guide clinical practice.

Overall there remains reasonable international consensus that thrombocytopenia in the neonate should be defined as a platelet count of less than 150 × 10^9/L. This can be further broken down into mild when the platelet count is 100–150 × 10^9/L, moderate 50–100 × 10^9/L and severe when <50 × 10^9/L.

Following the birth of a healthy full-term baby, there is frequently a rise in platelet count over the first 2–3 postnatal weeks (Christensen 2011; Weidmeier et al. 2009; Aballi et al. 1968; Obladen et al. 2000). Earlier studies suggest that after this initial increase, the platelet count reaches a plateau (Aballi et al. 1968; Sasanakul et al. 1993; Appleyard and Brinton 1971). Weidmeier et al. (2009) in their large cohort study of unselected term and preterm infants showed a sinusoidal pattern of platelet counts after birth and during the first 90 postnatal days, with an initial peak at 2–3 weeks, followed by a relative fall and a secondary peak at 6–7 weeks. However, as the study was based on infants who had blood counts as part of a clinical inpatient or outpatient visit, the sinusoidal pattern might not represent true 'normality'. Weidemeier described the 95th centile in their cohort of babies to increase to over 700 × 10^9/L at 5–6 weeks postnatal age and suggest that in many healthy babies platelet counts rise to values generally considered to indicate thrombocytosis.

Prevalence of Thrombocytopenia

Thrombocytopenia, defined as a platelet count less than 150 × 10^9/L, is common in babies subjected to blood counts in the newborn period. The prevalence varies depending on the population studied, being more frequent in babies with significant illness and especially with lower gestation at birth. Thrombocytopenia has been reported in 1–2 % of all newborns (Dreyfus et al. 1997), rising to 18–35 % of sick babies undergoing intensive care (Roberts et al. 2008; Christensen et al. 2006; Castle et al. 1986; Metha et al. 1980). Preterm babies are particularly likely to develop thrombocytopenia. In a survey of 284 extremely low birth weight (<1000 g at birth) babies in four neonatal intensive care units across the USA, Christensen and colleagues (2006) described platelet counts below 150 × 10^9/L in 73 % of all babies and in up to 90 % of the very smallest babies. In this study, 38 % of babies had platelet counts <50 × 10^9/L. In a large multicentre study in the UK, 5 % of all babies admitted to participating neonatal units, irrespective of birth weight, developed severe thrombocytopenia, defined in this study as <60 × 10^9/L (Stanworth et al. 2009).

Platelet Physiology

Megakaryocytopoiesis in Fetus and Newborn

The study of fetal megakaryocytopoiesis is hampered by the very low numbers of megakaryocytes in fetal bone marrow and the difficulty of obtaining specimens for isolating megakaryocyte progenitors. Available evidence suggests that megakaryocytopoiesis follows a similar pattern developmentally to other haemopoietic lineages, but appears to develop later than erythropoiesis and granulopoiesis. Primitive haemopoiesis has been identified initially in the embryonic yolk sac as early as 19 days from conception, in the embryonic liver by 5–6 weeks and in the bone marrow from 11 weeks. Megakaryocytes have been demonstrated in the yolk sac by 5 weeks and in the liver and spleen by 10 weeks gestation. Megakaryocyte progenitors have been isolated from fetal blood and bone marrow from 18 weeks gestation confirming that megakaryocytopoiesis is well established by the third trimester (Graeve and De Alarcon 1989; Peault et al. 1999; Zon 1995; Huyhn et al. 1995; Zauli et al. 1993; Bruno et al. 1996).

Haemopoiesis occurs predominantly in the liver for much of the second trimester in the human fetus, but declines in the liver to negligible levels by term. Bone marrow haemopoiesis increases over the second trimester, and by 24 weeks the composition of the fetal marrow begins to resemble that of adults. By term almost all haemopoiesis is in the marrow (Peault et al. 1999; Charbord et al. 1996). It is suggested that the changes in sites of haemopoiesis during fetal life follow migration of stem and progenitor cells between tissues via the circulation. This is supported by the finding of large numbers of these cells, including MK-lineage progenitors, in the fetal circulation, which diminish with increasing gestation (Linch et al. 1982; Murray and Roberts 1995). This transitioning of the site of megakaryocytopoiesis may explain some of the vulnerability of newborns, particularly at very early gestations, to disruption of platelet production and development of thrombocytopenia.

Good evidence exists for significant differences between fetal and neonatal megakaryocytopoiesis and that found in adults (Ferrer-Marin et al. 2010). Fetal megakaryocyte progenitors appear to have greater proliferative potential than adult progenitors, producing significantly larger megakaryocyte colonies in vitro cell culture (Murray et al. 1998; Nishihira et al. 1996). In addition, the high proliferative potential cell-megakaryocyte (HPPC-MK) progenitor cell, which expresses a surface marker phenotype similar to primitive human fetal stem cells, has only been isolated from humans using in vitro clonal assays from fetal, and not adult, bone marrow (Bruno et al. 1996).

The relative numbers, metabolism and morphology of megakaryocyte lineage cells also change during fetal development and differ from adults. There is a higher proportion of immature megakaryocyte progenitors in the fetus than in term babies and in adults, and these progenitors also appear to have a higher proliferative capacity and to be more sensitive to cytokine stimulation (Zauli et al. 1993; Bruno and Hoffman 1998; Bruno et al. 1996). However, fetal and neonatal megakaryocytes are significantly smaller and of lower ploidy than adult megakaryocytes, which has been shown to be associated with the production of fewer platelets per progenitor. Fetal megakaryocytes increase in size and ploidy with increasing gestation (Graeve and De Alarcon 1989; Hegyi et al. 1991; de Alarcon and Graeve 1996).

As in adults, thrombopoietin (Tpo) is the predominant cytokine regulating megakaryocytopoiesis and platelet production in the fetus and newborn. However, there appear to be distinct developmental aspects of Tpo metabolism and its response to thrombocytopenia that may be important. Baseline Tpo levels in the immediate newborn period appear to be relatively higher than in adults (Murray et al. 1998; Walka et al. 1999). Studies attempting to elucidate the response of Tpo blood levels to thrombocytopenia in the newborn have yielded conflicting results, with some suggesting an attenuated response, with relatively low Tpo levels in the face of thrombocytopenia secondary to reduced megakaryocytopoiesis (Watts et al. 1999; Sola et al. 1999), whereas other studies have shown that newborn babies can produce high circulating Tpo levels (Colarizi et al. 1999; Sola et al. 2004).

Despite this lack of clarity about Tpo production in the newborn, there is clearer evidence regarding the response of megakaryocyte lineage cells to Tpo and other cytokine stimulation. In vitro data shows that progenitor cells in the fetus and newborn are more sensitive to Tpo stimulation than adult cells, with a greater proliferative response (Nishihira et al. 1996; Murray 1999; Sola et al. 2000). However, megakaryocytes appear to show an attenuated increase in size and ploidy, when subjected to Tpo (Pastos et al. 2006). This further supports the idea that neonates respond to thrombocytopenic stress by increasing progenitor proliferation, rather than enhancing megakaryocyte maturation and platelet production at the distal end of the megakaryopoietic pathway.

If, as these data suggest, the preterm newborn infant must rely on recruitment of additional megakaryocyte progenitors to increase platelet production in times of stress, animal studies aimed at elucidating neonatal granulopoiesis may provide explanation why maintaining normal number of both neutrophils and platelets so often fail. Quantification of fetal progenitors in newborn rodents showed significant reduction in total progenitors relative to adults (Christensen and Rothstein 1984). It has also been shown that in steady state, a higher proportion of human fetal progenitors are actively proliferating at any time, and hence there are fewer to recruit into production in the face of increased utilisation of neutrophils, particularly in response to sepsis (Christensen et al. 1986; Christensen 1988). These data have been used to explain the high frequency of neutropenia in response to neonatal sepsis. It may be surmised that the same principles may apply for platelet production and explain the relatively high incidence of thrombocytopenia in the sick neonate.

The implications of the many differences between adult and newborn megakaryocytopoiesis for the maintenance of adequate platelet numbers in the preterm and sick infant need further study. However, current evidence provides developmental reasons why thrombocytopenia is so frequent and suggests that any biological intervention to increase platelet numbers will need a prophylactic strategy based on risk, rather than a reactive strategy introduced once thrombocytopenia has developed.

Newborn Platelet Function and Primary Haemostasis

The haemostatic system in neonates is similarly distinct from that of adults. Many of the protein components of

secondary haemostasis are at significantly lower concentrations compared to adult values in the first 6 months, and normal ranges for coagulation factors have been established according to gestational age (Kuhle et al. 2003). An understanding of 'immaturity' of platelet function and primary haemostasis might inform practice and justify the use of higher transfusion thresholds for prophylactic platelets in newborns. However, neonatal platelet function and primary haemostasis has been difficult to characterise (Haley et al. 2014). This partially reflects the complexity of primary haemostasis, which is usually conceptualised as a series of steps orchestrated by the platelets (George 2000).

The first step of primary haemostasis follows vessel injury exposing collagen fibres that immobilise von Willebrand factor (vWF) molecules. Blood flow unfolds vWF from a globular circulating state and *platelet adhesion* occurs via GpIbα and platelet collagen receptors (integrin α2β1 and GpVI). Adhesion prompts transmembrane signal induction and a series of *platelet activation* events including degranulation to release ADP, calcium, coagulation factors, thromboxane A2 and serotonin (George 2000). The activated platelets undergo cytoskeletal changes, spreading to provide a negatively charged platform for coagulation complex assembly. Activated and adherent platelets expose the $\alpha_{IIb}\beta_3$ complex allowing vWF and fibrinogen-mediated *platelet aggregation* (George 2000).

Another hurdle is characterising this complex process, as available laboratory techniques have significant limitations (Haley et al. 2014). Aggregometry is a reasonably accessible and more frequently used technique, measuring changes in impedance or turbidity to reflect platelet activation by agonists (e.g. ADP, collagen, ristocetin, arachidonic acid, thrombin-reactive peptide). Aggregometry studies indicate that platelets derived from cord blood of term babies have reduced responsiveness to agonists compared to those of adults (Sola-Visner 2012; Israels et al. 1990). However, large volumes of blood are required for aggregometry, limiting its use to the study of cord blood-derived platelets, which may not be functionally equivalent to those derived from postnatal peripheral blood (Del Vecchio et al. 2015; Saxonhouse et al. 2010).

Flow cytometry has the advantage of using smaller sample volumes (Del Vecchio et al. 2015). Following application of platelet agonists, monoclonal antibodies can be used to quantify the expression of activation markers such as P-selectin. This technique supports evidence from aggregometry studies, with platelets from peripheral blood of both term and preterm babies showing comparative hyporesponsiveness (Rajasekhar et al. 1994, 1997; Del Vecchio et al. 2015; Bednarek et al. 2009). This is more pronounced at lower gestational age (Sitaru et al. 2005), and the effect persists into the second week after birth (Bednarek et al. 2009; Sitaru et al. 2005; Rajasekhar et al. 1997).

Evidence for a hyporesponsive platelet phenotype in neonates might encourage clinicians to be more cautious in thrombocytopenic neonates and raise platelet transfusion thresholds. However, aggregation and flow cytometry only assesses a particular element of platelet function, not the entire complex process of primary haemostasis. Both technologies also fail to reflect the physiological conditions under which it occurs. For example, in vivo, factors such as the haematocrit, blood proteins and shear stress are known to modulate primary haemostasis (Israels et al. 2001; Shenkman et al. 1999).

The platelet function analyser (PFA-100) attempts to mimic flow and shear stress by aspirating blood through a narrow aperture in a membrane coated with either collagen and ADP or epinephrine. Time to aperture closure provides an assessment of platelet aggregation. Studies using this technique demonstrate shorter closure times in cord blood samples from term neonates compared to adults suggesting enhanced primary haemostasis (Israels et al. 2001). This is replicated in peripheral blood samples, although the effect is less pronounced than in cord blood, highlighting a possible difference in the functionality of platelets derived from each source (Saxonhouse et al. 2010). Supporting studies using flow chambers measure platelet adhesion to a coated surface under arterial shear stresses and also demonstrate increased deposition of neonatal platelets on an extracellular matrix (Shenkman et al. 1999). This appears to be mediated by higher concentrations of vWF in neonatal plasma and a higher concentration of the highest-molecular-weight multimers compared to adult blood (Weinstein et al. 1989). These laboratory studies indicating enhanced primary haemostasis are supported by studies demonstrating shorter bleeding times in healthy term and preterm babies in comparison to adults (Andrew et al. 1990; Del Vecchio et al. 2008).

In summary, measures of primary haemostasis in neonates indicate that it is comparatively enhanced compared to adults. Therefore, despite the hyporesponsive phenotype of neonatal platelets seen with aggregation and flow cytometry studies, it can be concluded that the apparent 'immaturity' of neonatal haemostasis probably does not, in itself, justify raised platelet transfusion thresholds for neonates with thrombocytopenia.

Thrombocytopenia in Clinical Practice

In the vast majority of newborns with thrombocytopenia, low platelet counts are largely the consequence of other significant morbidities, for example, prematurity, infection and/or intrauterine growth restriction. It is only for the rare, specific diagnoses, such as fetal and neonatal alloimmune thrombocytopenia (FNAIT), thrombocytopenia due to maternal autoimmune thrombocytopenia (ITP) or the

hereditary thrombocytopenias, which the baby may present with thrombocytopenia and its sequelae alone.

Low platelet counts in the newborn baby may be the consequence of increased consumption, decreased production or rarely sequestration. But unlike in older children or adults, immaturity of thrombopoiesis is likely to be a common contributing factor, particularly in preterm infants. The multifactorial nature of thrombocytopenia in the newborn has meant that it has become conventionally classified by its time of onset (Table 1): fetal if already present at birth; early onset if detected soon after or developing within 72 h of birth; late onset if it develops after the immediate postnatal period. Within each category, there are specific causes, and many aetiologies follow a consistent time course. There are, in addition, causes that may present at any time in the neonatal period.

Fetal Thrombocytopenia

The most severe in utero thrombocytopenia is associated with FNAIT. Hohlfeld and colleagues (1994), in their study of over 5000 fetal blood samples, showed fetuses with FNAIT have a mean platelet count of 51×10^9/L (range 3–145 $\times$ 10^9/L). There is a high risk of intracranial haemorrhage and intrauterine death.

Haemolytic disease of the newborn, particularly when due to rhesus isoimmunisation, is also often associated with thrombocytopenia. It is likely to be secondary to fetal hypoxia driving compensatory erythropoiesis at the expense of other lineages, including megakaryocytes, as demonstrated by Koenig and Christensen (1989a), who found reduced megakaryocyte production in affected fetuses. Other fetal aetiologies are more commonly not identified until after birth and present as early-onset thrombocytopenia.

Early-Onset Thrombocytopenia

Early thrombocytopenia, defined as developing within 72 h of birth, accounts for the majority (up to 75 %) of thrombocytopenic episodes in the newborn. In most, the platelet count continues to fall after birth, reaching a nadir by day 4 or day 5 (Fig. 1); thereafter the platelet counts of most babies start to recover by day 7, and more than 85 % have normal platelet counts by the end of the second week (Castle et al. 1986; Metha et al. 1980; Christensen et al. 2006). The thrombocytopenia is usually mild to moderate, the platelet count rarely falling below 50×10^9/L, and in the majority does not require platelet transfusion support. In more severely affected babies it may persist, especially if a further insult to the fragile thrombopoiesis supervenes.

The most clearly defined cause of early-onset thrombocytopenia is placental insufficiency and chronic fetal hypoxia, commonly associated with maternal pre-eclampsia, hypertension, diabetes and fetal growth restriction. Several groups have shown that the mechanism is impaired megakaryocytopoiesis, with reduced circulating megakaryocyte progenitors and megakaryocytes and associated with raised Tpo at birth (Murray and Roberts 1996; Watts et al. 1999; Watts and Roberts 1999) (Fig. 2). These babies frequently have other associated haematological abnormalities, such as neutropenia, polycythaemia and nucleated red cells in the peripheral circulation at birth (Philip and Tito 1989; McIntosh et al. 1988). The neutropenia has also been shown to be secondary to impaired granulocytopoiesis (Koenig and Christensen 1989b, 1991). Babies born under these conditions have been shown to have raised erythropoietin levels (Salvesen et al. 1993), leading researchers to conclude that the constellation of abnormalities are due to hypoxia-related EPO-driven excess of erythropoiesis from multipotent

Table 1 Causes of *acquired* neonatal thrombocytopenia

Onset	Impaired production	Consumption
Fetal	Congenital infection (e.g. CMV, toxoplasma, rubella, parvovirus) Bone marrow replacement, e.g. congenital leukaemia, neuroblastoma Rhesus disease	Congenital infection (e.g. CMV, toxoplasma, rubella) Alloimmune (FNAIT) Autoimmune (maternal ITP, SLE) Haemophagocytic lympho-histiocytosis (HLH)
Early onset	Chronic fetal hypoxia (e.g. pregnancy-induced hypertension, intrauterine growth restriction, maternal diabetes) Congenital infection (e.g. CMV, toxoplasma, rubella, parvovirus) Metabolic disease	Perinatal hypoxia-ischaemia (DIC-related) Perinatal bacterial or fungal infection Congenital infection (e.g. CMV, toxoplasma, rubella, parvovirus) Alloimmune (FNAIT) Autoimmune (e.g. maternal ITP, SLE) Kasabach-Merritt syndrome (secondary to haemangiomas)
Late onset	Prolonged thrombocytopenia after sepsis and necrotising enterocolitis Congenital infection Metabolic disease	Late-onset sepsis Necrotising enterocolitis Acquired viral infection (e.g. CMV) Congenital infection Kasabach-Merritt syndrome

CMV cytomegalovirus, *FNAIT* fetal and neonatal alloimmune thrombocytopenia, *ITP* immune thrombocytopenia, *SLE* systemic lupus erythematosus

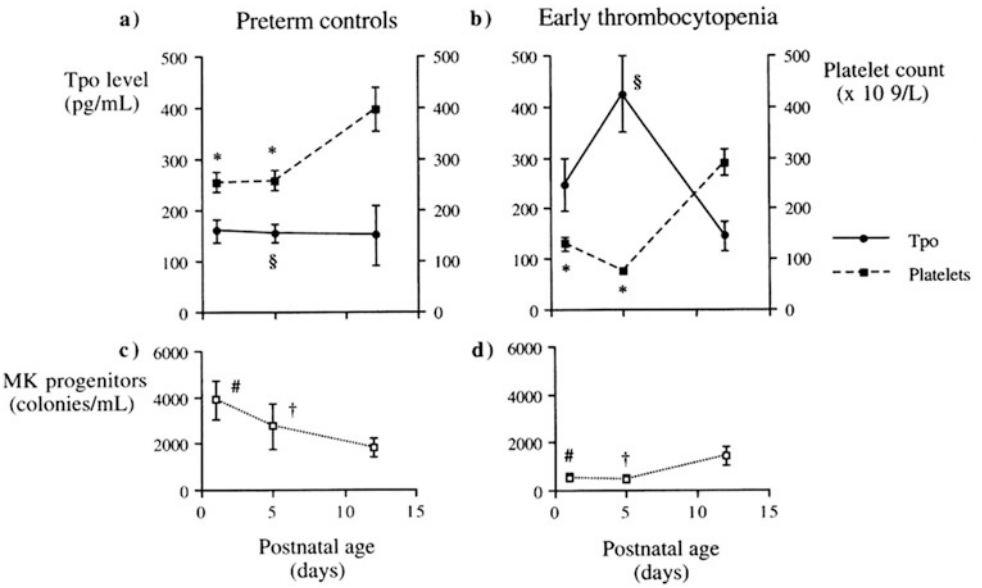

Fig. 2 Serial plasma thrombopoietin (Tpo), platelets and megakaryocyte (MK) progenitors in 28 preterm babies from uncomplicated pregnancies with and without early thrombocytopenia. (*Published: Watts TL, Murray NA, Roberts IAG. Pediatric Research 1999*)

progenitor cells, at the expense of the neutrophil and megakaryocyte lineages (the so-called lineage-steal hypothesis). That this may occur in fetal and early neonatal life, but not in other clinical circumstances of EPO excess, provides additional evidence that the capacity of the progenitor pool may be more limited in the fetus and preterm infant, as outlined in the above section on fetal megakaryocytopoiesis.

Christensen et al. (2006) found that the cause of thrombocytopenia could not be identified in almost 50 % of the babies in their study of extremely low birth weight (birth weight <1000 g) newborns. This is also the experience of most neonatologists. Early-onset thrombocytopenia is most frequent in the most prematurely born preterm babies in their first few days, when they are at their most unstable. It has been described in association with more general factors that are likely to be indicators of severity of illness in premature babies, such as antepartum haemorrhage, umbilical arterial or venous catheter insertion, respiratory distress syndrome, mechanical ventilation and phototherapy for hyperbilirubinaemia.

It seems likely that otherwise unexplained, early-onset thrombocytopenia is a final common outcome from multiple insults in the sick newborn: (1) underlying vulnerable megakaryopoiesis, with developmental difficulty in upregulating platelet production; (2) impairment in megakaryocytopoiesis in babies with placental insufficiency; (3) systemic inflammation related to perinatal infection or chorioamnionitis in the absence of frank infection; (4) frequent phlebotomy in babies with high numbers

of circulating megakaryocyte progenitors might also deplete reserves for platelet production.

Late-Onset Thrombocytopenia

Late-onset thrombocytopenia is most commonly associated with acquired systemic infection or necrotising enterocolitis. The presentation follows a distinct pattern, frequently of sudden onset and is often severe, requiring at least one and often many platelet transfusions (Zipursky et al. 1976; Mondanlou and Ortiz 1981; Baer et al. 2009). It usually has a self-limiting course, commonly lasting 5–7 days, although it may be prolonged and persist even after the precipitating cause is treated (Murray 1999; Roberts and Murray 2003). Babies who have had significant early thrombocytopenia may be more likely to have persistent thrombocytopenia if they develop additional late thrombocytopenia with intercurrent sepsis. This may be related to reduced megakaryocytopoiesis (Cremer et al. 2013).

Late-onset bacterial infection occurs in 25–41 % of very low birth weight (<1500 g) babies (Stoll et al. 1996; Carr et al. 2009), and thrombocytopenia accompanies bacterial infection in 50–75 % of these episodes, irrespective of causative organism (Baer et al. 2009; Carr et al. 2015). Postnatally acquired viral infections may also precipitate thrombocytopenia, though CMV is now a less frequent cause where the policy is to give only CMV-negative or leucodepleted blood products. Necrotising enterocolitis (NEC), a condition occurring in low birth weight preterm infants and characterised by ischaemic bowel necrosis but with uncertain aetiology (Lin and Stoll 2006), precipitates thrombocytopenia in more than half of cases which can be particularly severe and refractory (Hutter et al. 1976; Kenton et al. 2005; Baer et al. 2009; Stanworth et al. 2009).

Thrombocytopenia Associated with Thrombosis or Coagulopathy

Consumptive thrombocytopenia may occur at any time, associated with activation of the clotting cascade leading to local thrombosis or disseminated intravascular coagulation.

Thrombotic events are relatively common in the newborn period and are frequently associated with a consumptive thrombocytopenia. The most common presentation is secondary to large vessel thrombosis from vascular access devices such as umbilical arterial or venous lines, usually in the preterm baby. Spontaneous thrombosis may also occur, more commonly in babies with predisposing factors such as perinatal hypoxia-ischaemia and polycythaemia. Renal vein thrombosis is an example of this and classically presents with the triad of a renal mass, haematuria and thrombocytopenia. Treatment is often expectant, due to concerns of haemorrhage in newborn period, although thrombolysis and anticoagulation are used in some circumstances.

Neonatal thrombocytopenia may also be associated with concomitant coagulopathy typical of disseminated intravascular coagulation (DIC), the most common circumstance being in severe perinatal hypoxia-ischaemia. But evidence is often lacking for the presence of DIC in many episodes of thrombocytopenia, and it appears to be a contributory factor in only a minority (10–20 %) (Castle et al. 1986; Metha et al. 1980; Gross et al. 1982). Although DIC is often cited as being associated with neonatal sepsis, there are a number of studies that suggest this is commonly not the case (Zipursky et al. 1976; Corrigan 1974; Aronis et al. 1998). In necrotising enterocolitis, DIC has been shown to be present in only about one in four babies affected (Sonntag et al. 1998).

Immune Thrombocytopenias

Fetal and Neonatal Alloimmune Thrombocytopenia (FNAIT)

FNAIT occurs when the mother forms an antibody to a fetal human platelet antigen (HPA) inherited from the father. The antibody crosses the placenta, initiating fetal platelet destruction. This condition is exactly analogous to haemolytic disease of the newborn (HDN). Unlike the majority of disease states associated with neonatal thrombocytopenia, FNAIT carries a significant risk of severe haemorrhage as a consequence of the antibody also interfering with platelet function (Ghevaert et al. 2007; Williamson et al. 1998).

Half of HPA1a-positive babies born to HPA1a-immunised mothers are thrombocytopenic ($<150 \times 10^9$/L), and 50 % of those have platelet counts of less than 20×10^9/L at birth. A low platelet count increases the risk of major and life-threatening haemorrhage, but this is variable depending on the antibody specificity (Ghevaert et al. 2007; Williamson et al. 1998).

Incompatibility between maternal and fetal HPA occurs in 1 in 350 pregnancies, but FNAIT only occurs in about 1 in 1000 live births (Curtis 2015; Turner et al. 2005). There have been 36 HPA antigens described so far that have been shown to lead to antibody production causing FNAIT (Curtis 2015). HPA1a is the commonest antigen, causing 80–85 % of cases in white populations, but rarely in non-white. Platelets are negative for HPA1a in 2–2.5 % of Caucasians (Williamson et al. 1998; Davoren et al. 2004; Knight et al. 2011). The polymorphic variant is carried on the β3 subunit of the $\alpha_{IIb}\beta_3$ integrin, which is the major fibrinogen receptor and is involved in platelet activation and aggregation responses

that are central to platelet thrombus formation. It is the involvement of HPA antigens in such crucial platelet functions that are likely to be the reason that these babies so frequently have bleeding complications associated with their thrombocytopenia. Other common antigens include HPA5b, seen in 10–15 % of cases of FNAIT, and which is more common in African populations. Antibodies with anti-HPA-5b specificity appear to increase the risk of haemorrhage. In one series, four cases with this specificity had intracranial haemorrhage at a platelet count that was either in the normal range or considered to be safe (Ghevaert et al. 2007).

Unlike haemolytic disease of the newborn, FNAIT commonly develops during first pregnancies (up to 50 % of the time) often in the absence of obvious isoimmunisation events such as fetomaternal bleeding. This raises the question as to how sensitisation occurs. There is evidence that it may be from shedding of trophoblasts from fetal chorionic villae in the placenta into the maternal circulation, as these cells express integrin beta3, that also forms part of the glycoprotein that contains HPA1a on platelets (Curtis 2015; Kumpel et al. 2008). Another key feature of this condition is the strong association between the formation of the antiplatelet antibodies and maternal expression of the HLA class II antigen DRB3*01:01, present in 99 % of anti-HPA1a-producing women (Williamson et al. 1998; Bussel 2009). It appears that DRB3*01:01 enhances HPA1a antigen presentation and the immune response to it (Curtis 2015).

A fetus affected by FNAIT may develop thrombocytopenia from as early as 20 weeks gestation. In untreated pregnancies, 10–20 % develop intracranial haemorrhage which may lead to intrauterine death or significant disability and a third resulting in cerebral palsy (Roberts et al. 2008; Sharif and Kuban 2001; Ward et al. 2006). In an important minority of cases, intracranial haemorrhage may occur postnatally; hence early-diagnosis essential and postnatal platelet support is of critical importance.

The mainstay of management of a baby with FNAIT in the newborn period is to transfuse with HPA-compatible platelets. Both the baby and mother should be HPA typed and the mother tested for alloantibodies. The National Blood Service in the UK keeps stocks of platelets negative for HPA1a or HPA5b on the shelf ready for urgent use. If appropriately matched platelets are not immediately available, pooled un-typed platelets should be given. As the risk of bleeding is high in this condition, standard practice is to keep the platelet count above 50, or 100×10^9/L in the presence of significant bleeding. If repeated transfusions do not achieve reasonable platelet increments, intravenous immunoglobulin (IVIG) should be added (te Pas et al. 2007). A cranial ultrasound must always be performed at presentation.

In subsequent pregnancies, excellent outcomes have been achieved with active management. Because of the dangers of intrauterine cordocentesis and transfusion, the accepted treatment is now the provision of weekly IVIG from 12 to 20 weeks of gestation, with careful ultrasound monitoring for evidence of fetal bleeding. Later in gestation, steroid therapy may be added (van den Akker et al. 2007; Berkowitz et al. 2006; Pacheco et al. 2011).

There has been interest in recent years in the development of a prophylactic treatment (Curtis 2015). This is analogous to anti-D antibody prophylaxis in rhesus haemolytic disease, where the antibody administered to the mother induces antibody-mediated immune suppression, leading to failure of the mother to produce destructive red cell antibodies, most likely through rapid clearance of D-positive cells from the maternal circulation.

An FNAIT prophylaxis programme requires both screening mothers for an at-risk HPA type and an effective anti-HPA antibody. Most research into this has looked at HPA1a, screening for pregnant women who are HPA1a negative. Screening can now be done rapidly and reasonably cost-effectively (Garner et al. 2000). As far as prophylactic anti-HPA1a antibody is concerned, there are a number of approaches being actively investigated (reviewed: Curtis 2015). A number of groups have worked with animal models which show promise; a recent study in healthy volunteers of a recombinant anti-HPA1a IgG antibody showed reduced clearance of platelets following antibody administration, suggesting this may be a suitable model for prophylaxis, and an international collaborative project is looking at purifying large quantities of anti-HPA1a antibody from positive women previously immunised by NAIT-affected pregnancies. Should sufficient antibody be obtained, prophylaxis trials are planned (Kjeldsen-Kragh et al. 2007; Kjelsen-Kragh et al. 2012).

Neonatal Autoimmune Thrombocytopenia

Autoantibodies against maternal platelets that cause maternal thrombocytopenia are present in 1-2 per 1000 pregnancies (Gill and Kelton 2000; Kelton 2002). The most common clinical circumstances are in maternal ITP and SLE. In maternal ITP only 10 % of babies develop thrombocytopenia. Major bleeding complications are rare, with intracerebral haemorrhage thought to develop in no more than 1 % (Burrows and Kelton 1990b; Valat et al. 1998). As neonatal bleeding is not likely, there is no necessity to counsel against vaginal delivery for the baby's well-being. The severity of fetal and neonatal thrombocytopenia in ITP tends to correlate with the severity of maternal thrombocytopenia and is consistent in subsequent pregnancies (Valat et al. 1998).

When maternal thrombocytopenia is known to be associated with autoimmune disease, all babies should

have platelet counts measured on cord blood samples or from the baby soon after birth. If the platelet count is normal, then no further testing is necessary. If the platelet count is $<150 \times 10^9$/L at birth, repeat testing should be carried out over subsequent days as the platelet count will often fall further. The usual natural history of the thrombocytopenia is for the platelets to then recover by 7–10 days after birth. The treatment threshold should be according to the standard guidelines (Table 3), with IVIG recommended as first line, unless there is significant bleeding in which case pooled platelets can be given (Ballin et al. 1988).

Thrombocytopenia and Clinical Bleeding

Newborns, particularly preterm infants, are at high risk of bleeding, but the evidence implicating thrombocytopenia directly in most bleeding episodes in the newborn period is conflicting. Haemostasis depends on the complex interplay between platelets (number and function), vascular physiology and coagulation. All aspects of this triad are potentially vulnerable in the newborn period, and the relative contribution of a low platelet count is far from clear.

Preterm neonates frequently develop significant bleeding complications in the absence of thrombocytopenia and coagulopathy. It is likely that some episodes are more the consequence of vascular fragility and haemodynamic instability. For example, the pathogenesis of both intraventricular and pulmonary haemorrhage is often associated with reperfusion injury after a hypoxic-ischaemic insult related to perinatal or postnatal illness.

Attempts to define the uncertain relationship between a low platelet count and clinically significant bleeding in the newborn have been hampered by lack of an agreed classification of bleeding severity, and no consistent definition of severity of thrombocytopenia. These uncertainties were addressed in a systematic way for the first time by the UK PlaNeT-1 study.

PlaNeT-1 was a prospective, year-long observational cohort study involving seven regional neonatal intensive care units in the UK. The study documented platelet counts and bleeding episodes occurring in all babies whose platelet counts fell below 60×10^9/L. Episodes of bleeding were recorded, based on a consistent classification scale, along with contemporaneous platelet counts and platelet transfusions (Stanworth et al. 2009; Muthukumar et al. 2012; Venkatesh et al. 2013).

Five percent of all babies admitted to the study of neonatal units developed a platelet count $<60 \times 10^9$/L. One third (34 %) of babies whose platelet count fell below 60×10^9/L subsequently had a nadir count of less than 20×10^9/L. Only 9 % developed bleeding classified as severe. Minor haemorrhage was common (73 %), but 18 % of babies had no haemorrhage of any severity recorded. Although these data suggest that minor haemorrhage is a frequent consequence of severe thrombocytopenia, nadir platelet counts were actually highest in the babies with major haemorrhage and lowest in babies with no haemorrhage recorded.

An important and novel finding of the PlaNeT-1 study was that major haemorrhage was most strongly associated with lower gestational age, and a postnatal age less than 2 weeks. The most common episodes of minor haemorrhage described were haematuria, bleeding from the endotracheal tube, nasogastric tube and skin. The insights gained from the PlaNeT-1 study have also led to the development of a more consistent classification of bleeding severity for use in future treatment trials (Table 2) (Curley et al. 2014).

In summary, (1) the degree of thrombocytopenia was not a useful predictor of haemorrhage risk, and (2) there was no evidence that minor bleeding episodes predicted the development of major haemorrhage.

Table 2 Definitions of bleeding grades

Minor	Any bleed from the skin, umbilical cord, skin around stoma, surgical scar, mucosa Pink frothy secretions or old blood from the endotracheal tube Cranial USS: germinal matrix haemorrhage (Papile grade 1)
Moderate	Frank blood from stoma Macroscopic haematuria Cranial USS: intraventricular haemorrhage without ventricular dilatation (Papile grade 2) Fresh blood from endotracheal tube, without ventilatory changes
Major	Macroscopic rectal blood Fresh blood from endotracheal tube with ventilator changes Cranial USS: intraventricular haemorrhage with ventricular dilatation (Papile grade 3) or with parenchymal infarction (Papile grade 4)
Severe	Life-threatening major bleed with haemodynamic instability requiring volume boluses or red cell transfusion within 24 h Fatal major bleeding

USS ultrasound scan, *ETT* endotracheal tube, *IVH* intraventricular haemorrhage
Reference: Curley et al. (2014)

It should be noted that none of the babies described in the PLaNeT study had a diagnosis of FNAIT. It is clear that FNAIT, in which impaired platelet function coexists with severe thrombocytopenia, is frequently complicated by life-threatening haemorrhage (Ghevaert et al. 2007; Williamson et al. 1998).

Platelet Transfusion

Indications

Platelet transfusion is common in neonatal practice, but the evidence base to guide the use and thresholds of platelet transfusion is poor (Roberts et al. 2008; Christensen 2011; Curley et al. 2014). Neonatologists are understandably fearful of the consequences of bleeding and will give prophylactic transfusions in non-bleeding babies to avoid this (Josephson et al. 2009; Del Vecchio et al. 2001). Surveys in both the UK and the USA have shown that there is a wide range of transfusion thresholds used between units and between practitioners, with thresholds generally higher in the USA than Europe (Chaudhary and Clarke 2008; Josephson et al. 2009; Cremer et al. 2011).

Surprisingly, no studies have provided evidence of clinical benefit from platelet transfusion, or a clear link with fewer bleeding complications. Indeed there are several studies that have correlated a high number of platelet transfusions to excess morbidity and mortality in preterm babies (Del Vecchio et al. 2001; Kenton et al. 2005; Baer et al. 2007). Although the explanation for this may well be that sicker babies receive more platelet transfusions, it would be wise to sound a note of caution in the excessively liberal use of platelet transfusions in non-bleeding babies.

There are a number of consensus guidelines for platelet transfusion that have been published. The British Committee for Standards in Haematology published guidance in 2004, which relate transfusion decisions to platelet thresholds and clinical stability (Table 3) (Gibson et al. 2004). These guidelines are currently undergoing revision.

The only randomised controlled trial of prophylactic platelet transfusion at different thresholds was published over 20 years ago (Andrew et al. 1993). This study randomised babies to have their platelet count kept above 50 or above 150 $\times$ 10^9/L and showed no benefit in keeping platelets at the higher threshold with regard to any outcomes including bleeding. However, this study no longer reflects current practice, as many neonatologists use a prophylactic platelet transfusion threshold well below 50 $\times$ 10^9/L. The UK guideline (Gibson et al. 2004) suggests a threshold for preterm babies without clinical haemorrhage of 30 $\times$ 10^9/L and term babies of 20 $\times$ 10^9/L (Table 3).

A randomised controlled study is, at the time of writing, underway in the UK with 50 participating neonatal units. The Platelets for Neonatal Transfusion Study 2 (PlaNeT-2) is designed to compare the safety of a higher or lower transfusion threshold (Curley et al. 2014). This study randomises non-bleeding preterm neonates <34 weeks of gestation at birth to receive platelet transfusions below the threshold of either 25 $\times$ 10^9/L or 50 $\times$ 10^9/L. It is a reflection of existing variability in platelet transfusion practice and lack of supportive evidence that during the planning stage, concerns were expressed in equal measure, that the lower threshold placed babies at too high a risk of bleeding, and that the upper threshold was too conservative and would expose babies to excessive transfusion.

An alternative approach to the use of a simple platelet count as the arbiter of whether to give a platelet transfusion has been investigated in a study that takes into account the effect that platelet size has on platelet function and the effectiveness of the platelet plug (Gerday et al. 2009). In this study babies were randomised to the use of the 'platelet mass index', being the product of the platelet count and the mean platelet volume, compared to the platelet count alone for deciding whether to transfuse platelets. It was found that babies in the platelet mass directed transfusion group had fewer transfusions, with no detectable difference in bleeding outcomes.

A more extensive review of transfusion practice, and the practical provision of platelets for transfusion to newborn infants, is covered in a recent review (Carr et al. 2015).

Table 3 UK Platelet transfusion guidelines

Platelet count	First postnatal week Without significant haemorrhage	After first week Without significant haemorrhage	Any postnatal age With significant haemorrhage[a]
<20–30 $\times$ 10^9/L	Transfuse all infants	Transfuse all infants	Transfuse all infants
<50 $\times$ 10^9/L	Transfuse if high risk[b]	Do not transfuse	Transfuse
50–100 $\times$ 10^9/L	Do not transfuse	Do not transfuse	Transfuse
>100 $\times$ 10^9/L	Do not transfuse	Do not transfuse	Do not transfuse

[a]Significant haemorrhage includes grade 2+ intraventricular haemorrhage, pulmonary haemorrhage with respiratory deterioration and gastrointestinal bleeding (Some clinicians may treat 'moderate' haemorrhage as 'significant')

[b]High risk includes birth weight <1000 g, gestation <28 weeks, clinical instability, previous haemorrhage, abnormal coagulation, systemic sepsis or necrotising enterocolitis

Reference: Gibson et al. (2004)

Risks and Complications

Platelet transfusion, in common with the use of other blood products, is not without risk. Adverse incidents that involve the transfusion of blood products are relatively common. Data from the UK Serious Hazards of Transfusion (SHOT) national haemovigilance scheme shows that the there is a disproportionate burden of incidents in the newborn population, with 16 % of reported incidents occurring to neonates <28 days of life (Stainsby et al. 2008). Most of these reports are from practical errors. Infection is also well described. Bacterial contamination is more likely with platelets than with other products, and transfusion-transmitted viral and other infections are also clearly a risk (Baer et al. 2007; Curley et al. 2014).

Alternatives to Platelet Transfusion

Thrombopoietin Analogues

Tpo analogues are used in a variety of clinical settings in thrombocytopenic adults, and they have been approved for use in the USA for treatment of severe refractory immune thrombocytopenia (Kuter 2010; Journeycake 2012; Arnold 2013). There has been interest in the idea of using Tpo analogues to reduce the incidence or severity of neonatal thrombocytopenia (Sallmond et al. 2010; Ferrer-Marin et al. 2010).

There are several reasons why this approach is attractive. Many episodes of neonatal thrombocytopenia are severe and prolonged, and these babies may have very many transfusions. There is evidence for a developmental limitation in the newborn to the megakaryopoietic response to stress. Some researchers have concluded that there may in addition be a suboptimal Tpo response to thrombocytopenia, which may be particularly relevant in babies with early thrombocytopenia and reduced megakaryocytopoiesis. Conversely, neonatal progenitors appear to be more sensitive to Tpo stimulation, so may be an effective target for therapeutic stimulation.

There are, however, many factors that raise doubts about this form of therapy entering standard neonatal practice. Most important is the timeframe for an adequate increase in peripheral blood platelets following Tpo analogue treatment, which is unlikely to be rapid enough to be useful for the majority of thrombocytopenic episodes. In adults, platelets start to increase at 4–6 days but only reach a peak at 10–14 days after treatment (Kuter 2010). By this time most neonatal thrombocytopenic episodes will have already resolved spontaneously. Differences between newborn and adult megakaryocytopoiesis may prolong this response time further in the newborn.

There are other reasons for caution. Initial studies of recombinant Tpo led to the development of neutralising antibodies which cross-reacted with endogenous Tpo, leading to refractory thrombocytopenia and aplastic anaemia, although more recent synthetic analogues appear not to induce antibodies. The analogous use of the neutrophil cytokines, GM-CSF and G-CSF, for stimulation granulopoiesis to prevent or treat neutropenia and so reduce sepsis has not translated into clinical benefit (Carr et al. 2009; Kuhn et al. 2009; Carr 2013). Tpo receptors are present on some non-haemopoietic cells, including in the nervous system, raising the possibility of unintended toxicities following their use in the newborn (Dame et al. 2003), and there have been studies that have shown that Tpo may have proapoptotic and differentiation-blocking effects on the developing brain (Ehrenreich et al. 2005; Samoylenko et al. 2008). Finally, the effects of potent biological simulators of haemopoietic stem cells early in life raise anxieties about unpredictable long-term consequences, though this has not occurred following the now extensive use of erythropoietin or of G- and GM-CSF in newborns.

None the less, prolonged thrombocytopenia is a clinical challenge in a number of preterm infants, and for these Tpo therapy might be effective and lead to clinical benefit. More research and clinical trials in the area are warranted.

Donor-Independent Platelets for Transfusion

A number of research groups are investigating the possibility of producing megakaryocytes and platelets ex vivo, with the goal of donor-independent platelet transfusions, with improvements in safety and quality. The aim is to produce self-sustaining cultures of stem cells, primitive or more mature megakaryocyte progenitor cells, that will continuously produce megakaryocytes and platelets for transfusion, obviating the need for platelet donation. Although various cell lines have been successfully established, current obstacles to the development of these systems include difficulties with sufficient yield of platelets for clinical application (Lambert et al. 2013). However, the small blood volumes of preterm infants and their added vulnerability to multiple donor exposure would make them ideal early beneficiaries.

Conclusion

Thrombocytopenia in the neonatal period is common. It most frequently occurs in extremely preterm babies but is often only mild to moderate and self-limiting. However, concerns about the high risk of bleeding and the potential major sequelae of death or neurodisability are strong drivers for replacement therapy, with frequent and repeated platelet transfusions.

The underlying cause of neonatal thrombocytopenia in the preterm population is usually multifactorial. As increasingly premature infants survive, the various patterns of thrombocytopenia related to common clinical circumstances have been defined by careful clinical observation. Now there is need for greater understanding and definition of normal developmental physiology to underpin prevention and treatment strategies to reduce the risk and consequences of too few platelets (Box 1).

Box 1: Future Research Perspectives

Aetiology

Biology and homeostasis of fetal/neonatal megakaryopoiesis

Mechanisms of thrombocytopenia, in particular the pathogenesis of:

Early thrombocytopenia in the absence of placental dysfunction

Prolonged postnatal thrombocytopenia

Clinical

Standardisation of platelet function assays and establishing neonatal normal ranges

Defining clinically appropriate platelet transfusion thresholds

Therapies

Thrombopoietin for prevention or treatment of thrombocytopenia

Antibody prophylaxis for fetal and neonatal alloimmune thrombocytopenia (FNAIT)

Donor-independent platelets for transfusion

In the meantime, the mainstay of treatment in neonatal thrombocytopenia remains platelet transfusion, and careful ongoing studies to define safe transfusion thresholds are important to achieve consensus on clinical management. However, we can also look forward to novel treatments: antibody prophylaxis for mothers at risk of developing the alloantibodies responsible for neonatal alloimmune thrombocytopenia, thrombopoietin or other agents to enhance endogenous platelet production and the prospect of off-the-shelf in vitro platelets produced in quantities sufficient for small babies.

Take-Home Messages

- A normal platelet count at birth is $>150 \times 10^9$/L.
- Thrombocytopenia is most common in preterm infants, in whom the progenitor pool appears limited.
- Neonatal platelets have an immature functional phenotype as measured by aggregometry, but in vitro and clinical measures of primary haemostasis which indicate enhanced haemostatic activity compared with adults. Available evidence on function does not justify raised platelet transfusion thresholds.
- The relationship between platelet count and clinical bleeding risk remains poorly defined, with no international consensus on appropriate transfusion thresholds.
- Fetal and neonatal alloimmune thrombocytopenia (FNAIT) is a clearly defined syndrome associated with life-threatening haemorrhage caused, uniquely, by antibodies with specificity for functional platelet antigens.
- There is ongoing research into alternatives to donor platelets, such as thrombopoietin analogues, but platelet transfusion to prevent bleeding is likely to remain the mainstay of management for the foreseeable future.

Thrombocytopenia in Patients with Solid Tumors or Hematologic Malignancies

Caroline I. Piatek and Howard A. Liebman

Abstract

Thrombocytopenia is a common finding in patients with cancer and is most frequently the result of systemic cancer treatment. The mechanism by which cancer therapies cause thrombocytopenia is varied, leading to differing incidences and patterns of thrombocytopenia. In addition to megakaryocyte cytotoxicity, various cancer drugs have been associated with immune thrombocytopenia, thrombotic microangiopathy, and splenomegaly. Decreased platelet production due to direct tumor involvement of the bone marrow is more common in patients with hematologic malignancies compared to those with solid tumors. Splenic sequestration of platelets is an important cause of thrombocytopenia in both hematologic and solid cancers and may result from several different mechanisms. Disseminated intravascular coagulation is a common cause of thrombocytopenia in cancer patients and is associated with poor survival. Immune thrombocytopenia (ITP) is mostly often described in patients with chronic lymphocytic leukemia and also appears to be associated with inferior survival. Management of thrombocytopenia includes supportive care. Platelet transfusions are administered to patients with bleeding or at high risk of bleeding. The use of thrombopoietin receptor agonists may decrease the need for delays or dose reductions in patients receiving systemic cancer treatment. However, their use in this setting is still considered investigational.

Introduction

Thrombocytopenia is a frequent complication of cancer and may be due to a variety of causes. It is associated with an increased bleeding risk and increased healthcare costs (Wu et al. 2009; Liou et al. 2007). Thrombocytopenia may limit the delivery of cancer treatment on time and at the optimal dose, which may negatively impact patient outcomes (Elting et al. 2001; Bonadonna et al. 1995). Systemic cancer treatment is the most frequent cause of thrombocytopenia in cancer patients. Although megakaryocyte cytotoxicity is the most commonly recognized mechanism of thrombocytopenia resulting from cancer agents, the mechanism of thrombocytopenia varies. Other important causes of thrombocytopenia in cancer patients include direct tumor involvement of the bone marrow, splenomegaly, disseminated intravascular coagulation (DIC), and immune thrombocytopenia (ITP) (Table 1). Management includes supportive care with the administration of platelet transfusions for those with bleeding or at high risk of bleeding. Dose delays and dose reductions may be implemented with subsequent treatment cycles. Several small trials have explored the use of thrombopoietin (TPO) receptor agonists to mitigate thrombocytopenia in cancer patients receiving chemotherapy. However, their use is currently not considered to be standard.

Thrombocytopenia Due to Direct Cancer Effect

Solid Tumor Involving the Bone Marrow

Bone marrow metastasis is uncommon in patients with solid tumors (Kopp et al. 2011). It signifies advanced disease and a dismal prognosis with a median survival of less than 2 months (Hung et al. 2014). Although reported with nearly all tumor types, the most common cancers to metastasize to the bone marrow are the stomach, lung, breast, and prostate (Chou et al. 2015).

Bone marrow infiltration by metastatic carcinoma can result in extramedullary hematopoiesis, predominantly involving the spleen. Premature splenic release of hematopoietic cells may lead to leukoerythroblastosis (nucleated red blood cells, tear drop red blood cells, and immature myeloid cells) in the peripheral blood. Therefore, in patients with unexplained cytopenias and/or leukoerythroblastosis, a bone marrow biopsy should be performed to evaluate for marrow infiltration by metastatic carcinoma (Fig. 1a, b).

Clinical manifestations of bone marrow metastases are nonspecific. Bone pain is the most common presenting symptom, occurring in 43–63 % of patients (Kim et al. 2007; Hung et al. 2014). Other common symptoms include fever (36 %) and bleeding (21 %) (Hung et al. 2014). Laboratory findings in the majority of patients include peripheral cytopenia, leukoerythroblastosis, and markedly elevated alkaline phosphatase (Hung et al. 2014). Thrombocytopenia is observed in 77 % of patients with bone marrow metastases, and platelet count less than 50×10^9/l is an independent predictor of inferior survival (Hung et al. 2014; Chou et al. 2015).

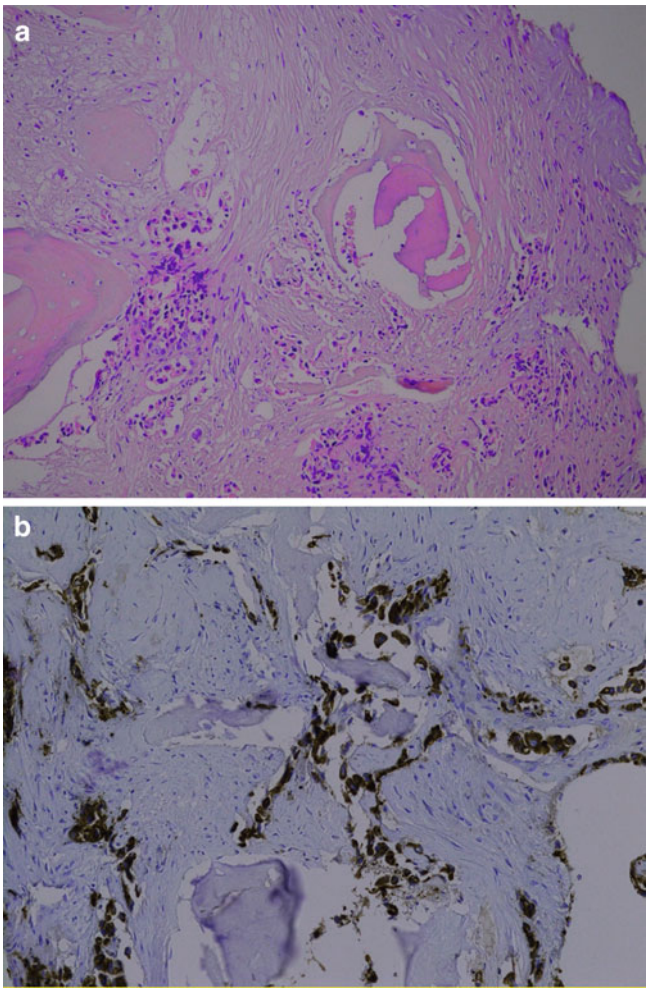

Fig. 1 (**a** and **b**) Bone marrow involvement with metastatic carcinoma of the breast. (**a**) Hematoxylin and eosin stain of a bone marrow trephine biopsy demonstrating clusters of pleomorphic cells with hyperchromatic nuclei embedded in a markedly fibrotic background. (**b**) Bone marrow trephine biopsy showing clustered AE1/AE3 positive carcinoma cells (*dark brown* staining) in a markedly fibrotic background

Hematologic Malignancies Involving the Bone Marrow

Thrombocytopenia is one of the most frequent laboratory abnormalities in hematologic malignancies. It is most often due to decreased platelet production as a result of bone marrow infiltration by malignant cells (Kuznetsov et al. 1992). Thrombocytopenia is incorporated into the staging system of a number of hematologic malignancies due to its negative prognostic significance. For example, a platelet count less than 100×10^9/L at the time of diagnosis of chronic lymphocytic leukemia (CLL) denotes advanced disease and is associated with a very poor outcome (Rai et al. 1975; Binet et al. 1981).

Splenomegaly Due to Tumor Involvement or Portal or Splenic Vein Thrombosis

One third of the total platelet mass is located in a spleen of normal size. With splenomegaly, 50–90 % of the total platelet mass is sequestered in the spleen, leading to a decrease in peripheral platelet counts (Aster 1966). Portal

hypertension is the most commonly recognized etiology of splenomegaly in patients with solid tumors. Portal hypertension may be due to a number of etiologies, including prehepatic portal hypertension (thrombosis, tumor invasion, or extrinsic compression by tumor), intrahepatic portal hypertension (cirrhosis or oxaliplatin-associated hepatic sinusoidal injury), or post-hepatic hypertension (Budd-Chiari syndrome). Splenomegaly also appears to be a common finding after resection of hepatic metastases. This phenomenon may result from the same growth factors and cytokines that stimulate liver regeneration which can also stimulate spleen growth. In one study, there was an increase in spleen volume in 78 % of patients following partial hepatectomy for colorectal metastases. There was an average increase in spleen volume of 40–45 % at 6 months after surgery with a decrease in spleen size to near-baseline size at 9 months (Jacobs et al. 2012). There was an inverse correlation between spleen size and platelet count following hepatectomy (Ando et al. 2004).

Splenomegaly is an important cause of thrombocytopenia in hematologic malignancies. Radionuclide scanning reveals differential patterns of splenic cellularity and vascularity in various hematologic disorders. Splenomegaly was attributed primarily due to increased splenic vascularity with polycythemia vera, increased splenic cellularity with chronic myeloid leukemia (CML) and CLL, and both increased splenic vascularity and cellularity in myelofibrosis and hairy cell leukemia (Zhang and Lewis 1989).

Although splenectomy and partial splenic embolization are not commonly performed in patients with solid or hematologic malignancies, such approaches may result in a sustained increase in platelet count and decreased platelet transfusion requirements (Berman et al. 2004; Kauffman et al. 2008; Bhatia et al. 2015).

Thrombocytopenia Due to Cancer Treatment

Systemic Cancer Therapy

Systemic cancer therapy is the most common cause of thrombocytopenia in cancer patients, resulting in thrombocytopenia in nearly two-thirds of patients with solid tumors (Wu et al. 2009). Thrombocytopenia leads to dose reductions in 15 % of cycles and cycle delays in 6 % of cycles in patients receiving chemotherapy for solid tumors. Bleeding is observed in 9 % of patients and is more common in patients with a prior bleeding history, baseline platelet count of less than 75×10^9/l, bone marrow metastases, poor performance status, or with administration of cisplatin, carboplatin, carmustine, or lomustine (Elting et al. 2001). Severity of thrombocytopenia based on National Cancer Institute Common Terminology Criteria for Adverse Events, version 4.0 (Table 2) (National Cancer Institute 2010).

Thrombocytopenia with traditional chemotherapy agents is most frequently the result of megakaryocyte cytotoxicity. The typical pattern of thrombocytopenia due to megakaryocyte cytotoxicity is a platelet nadir 7–17 days after drug administration with a return to baseline platelet count in 3–4 weeks. Prolonged thrombocytopenia may be seen with agents that induce bone marrow and stem cell injury, such as busulfan and melphalan (McManus and Weiss 1984). Because of the associated risk of stem cell toxicity and impact on stem cell collection, melphalan is avoided in multiple myeloma patients who are candidates for autologous stem cell transplant.

Thrombocytopenia occurs in over 75 % of patients with colorectal cancer treated with oxaliplatin, 5-fluorouracil, and leucovorin (Andre et al. 2004; Colucci et al. 2005). Although megakaryocyte cytotoxicity is the most commonly recognized mechanism of oxaliplatin-related thrombocytopenia, oxaliplatin has been described to cause thrombocytopenia through splenic sequestration from the sequelae of hepatic sinusoidal injury and immune mediation. Combination therapy with oxaliplatin frequently leads to morphologic changes in the liver, which include sinusoidal obstruction, sinusoidal fibrosis, and veno-occlusive lesions (Rubbia-Brandt et al. 2004). Oxaliplatin-mediated hepatic sinusoidal obstruction has been shown to correlate with increased spleen size and thrombocytopenia. In a retrospective study of 136 patients with early-stage colorectal cancer, there was an increase in spleen size in 86 % of patients receiving adjuvant treatment with 5-fluorouracil and oxaliplatin. There was no change in spleen size in patients who received 5-fluorouracil alone. In nearly a quarter of patients, there was a greater than 50 % increase in spleen size. An increase in spleen size correlated with the cumulative dose of oxaliplatin. There was a significant correlation between the degree of spleen size increase and the reduction in platelet count. Thrombocytopenia due to splenomegaly improved to near-baseline levels 2–3 years after completion of oxaliplatin (Overman et al. 2010).

Table 2 Grading of thrombocytopenia based on National Cancer Institute Common Terminology Criteria for Adverse Events, version 4.0 (National Cancer Institute 2010)

Grade	Platelet level
1	<LLN—75×10^9/l
2	<75–50×10^9/l
3	<50–25×10^9/l
4	<25×10^9/l

LLN lower limit of normal

ITP has also been described with oxaliplatin. Platelet destruction is mediated by oxaliplatin-dependent antibodies to platelet antigens, leading to a sudden drop in platelet count to less than 10×10^9/l and bleeding manifestations within several hours of oxaliplatin infusion (Dold and Mitchell 2003; Curtis et al. 2006). This complication typically occurs after at least 12 cycles of oxaliplatin and may be preceded by hypersensitivity reaction (skin rash, pruritis, chills, and bronchospasm) (Jardim et al. 2012; Bautista et al. 2010). ITP has also been described with fludarabine and irinotecan with differing patterns of total drug exposure and time to platelet nadir following the last dose (Table 3) (Leach et al. 2000; Hegde et al. 2002; Jiang et al. 2014; Bozec et al. 1998; Mirtsching et al. 2014). Alemtuzumab is an anti-CD52 antibody used in the treatment of hematologic malignancies and multiple sclerosis. It is associated with a distinct form of ITP characterized by its delayed onset. In a phase 2 trial of alemtuzumab for the treatment of multiple sclerosis, 6 of 216 (2.8 %) of patients developed ITP. The median time from initial and last alemtuzumab exposure was 24.5 months and 10.5 months, respectively (Cuker et al. 2011). Management of ITP associated with cancer therapy includes discontinuation of implicated drug. Standard treatments of ITP, including steroids and IV immunoglobulin, may be administered to patients with bleeding manifestations or platelets less than 10×10^9/l with favorable outcomes reported.

Thrombotic microangiopathy (TMA) encompasses a spectrum of disorders which are characterized by microvascular thrombosis, hemolytic anemia, platelet consumption, and end-organ damage. While the clinical manifestations overlap, the pathophysiology of TMAs varies based on the underlying etiology. The major subtypes are thrombotic thrombocytopenia purpura and hemolytic uremic syndrome. A variety of secondary causes of TMA have also been described, including infections, collagen vascular disease, malignancies, surgery, stem cell transplant, and drugs.

Nucleoside analogs gemcitabine and mitomycin are the most commonly implicated chemotherapy agents in drug-induced TMA. The estimated incidence of drug-induced TMA is 0.015–0.31 % with gemcitabine and 2–15 % with mitomycin (Fung et al. 1999; Humphreys et al. 2004; Lesesne et al. 1989). Gemcitabine- and mitomycin-induced TMAs are thought to be result of direct endothelial cell injury and occur at higher cumulative doses (Groff et al. 1997; Humphreys et al. 2004; Lesesne et al. 1989). The clinical presentation is characterized by hemolytic anemia, presence of schistocytes, thrombocytopenia, renal insufficiency, elevated LDH, and normal levels of serum metalloproteinase ADAMTS13 (Lesesne et al. 1989; Pisoni et al. 2001; Shah et al. 2013).

Drug-induced TMA has also been reported with several targeted cancer agents, including anti-VEGF agents bevacizumab, sunitinib, and aflibercept (Eremina et al. 2008; Bollee et al. 2009; Izzedine et al. 2007). In a phase I study combining bevacizumab and sunitinib, 5 of 25 patients developed TMA, leading to the abandonment of this combination (Feldman et al. 2009). In contrast to TMA associated with gemcitabine or mitomycin, TMA observed with anti-VEGF agents does not appear to be dose-dependent. Bevacizumab-induced TMA is thought to be the result of inhibition of vascular endothelial growth factor signaling in the kidney (Eremina et al. 2008). In a series of six patients who underwent renal biopsy for evaluation of TMA following bevacizumab, common features included proteinuria and elevated creatinine. However, other manifestations were varied (Eremina et al. 2008).

The optimal management of drug-induced TMA has not been established. Plasma exchange is often employed but is generally not effective. For gemcitabine-induced TMA, the American Society of Apheresis guidelines list plasma exchange as a category IV indication (published evidence demonstrates or suggests apheresis to be ineffective or harmful) based on grade 2C evidence (weak recommendation, low-quality or very low-quality evidence) (Schwartz et al. 2013). Case reports have reported successful treatment with anti-CD20 antibody rituximab for gemcitabine- and mitomycin-induced TMA (Gourley et al. 2010; Shah et al. 2013). Eculizumab is a monoclonal antibody against complement protein C5 which is approved for the treatment of paroxysmal nocturnal hemoglobinuria and atypical hemolytic uremic syndrome. Successful treatment of gemcitabine-induced TMA with eculizumab has also been reported (Al Ustwani et al. 2014).

A variety of other mechanisms of thrombocytopenia have been described with new anticancer agents (Table 4). The onset and duration of thrombocytopenia may be an important indicator of a differing mechanism of thrombocytopenia. In patients with relapsed refractory multiple myeloma

Table 3 Patterns of immune thrombocytopenia with various cancer treatments

Cancer treatment	Exposure	Typical time to onset of thrombocytopenia and/or bleeding from last dose	Platelet nadir	Other associated features
Oxaliplatin	>12 cycles	Within several hours	$<10 \times 10^9$/l	May follow hypersensitivity reaction
Fludarabine	3 cycles	5–12 days	$<10 \times 10^9$/l	–
Irinotecan	4 cycles	Immediately	$<10 \times 10^9$/l	Hemodynamic instability
Alemtuzumab	2.5 cycles	10.5 months	$<10 \times 10^9$/l	–

Table 4 Mechanisms of thrombocytopenia for various cancer treatments and drugs

Mechanism of thrombocytopenia	Anticancer therapy
Stem cell toxicity	Alkylating agents, radiation
Megakaryocyte cytotoxicity	Traditional chemotherapeutic agents
Delayed megakaryocyte maturation	Histone deacetylase inhibitors, trastuzumab emtansine (T-DM1)
Prevention of platelet budding	Bortezomib
Apoptosis	BCL2 inhibitors
Immune-mediated	Fludarabine, irinotecan, oxaliplatin, alemtuzumab
Thrombotic microangiopathy	Mitomycin C, gemcitabine, bevacizumab, sunitinib
Hepatic sinusoidal injury leading to splenomegaly	Oxaliplatin

treated with proteasome inhibitor bortezomib, there is a 60 % decrease in the mean platelet count during treatment followed by rapid recovery between treatments. Mechanistic studies have shown that bortezomib inhibits nuclear factor kappa B, thereby preventing platelet budding from the megakaryocyte (Lonial et al. 2005).

Antiapoptotic BCL-2 family proteins are important for thrombopoiesis and platelet survival. BCL2 inhibitors induce apoptotic death of platelets, leading to a dose-dependent and dose-limiting thrombocytopenia (Vogler et al. 2011; Debrincat et al. 2015). Thrombocytopenia is the most common dose-limiting toxicity of histone deacetylase (HDAC) inhibitors. Mechanistic studies show that HDAC inhibitors delay megakaryocyte maturation through inhibition of GATA binding protein-1 (GATA-1) gene expression in megakaryocytes but do not cause platelet apoptosis (Matsuoka et al. 2007; Bishton et al. 2011). Thrombocytopenia with trastuzumab emtansine (T-DM1) also appears to be due to delayed megakaryocyte differentiation (Uppal et al. 2015).

Radiation Therapy

Acute hematological toxicities are a common finding in patients receiving radiation. The major risk factors for radiation therapy interruptions due to grade 3/4 thrombocytopenia include concurrent chemotherapy (odds ratio [OR] 45.5; $p < 0.001$), increasing percentage of bone marrow irradiation (OR 4.1 for each 20 %; $p < 0.001$), and presence of brain metastases (OR 7.3; $p = 0.01$). Other significant risk factors include leukemia or lymphoma, bone metastases, bone marrow metastases, and prior chemotherapy (Mac Manus et al. 1997). There is an increase in OR of 1.8 for each additional prior line of myelosuppressive chemotherapy (Knox et al. 1997).

Acute hematological toxicities are commonly reported in patients receiving pelvic radiation combined with chemotherapy (Keys et al. 1999; Ajani et al. 2008). A major contributing factor is the large volume of bone marrow irradiated as approximately 50 % of hematopoietically active bone marrow in the body is included within conventional treatment fields (Ellis 1961). Advances in radiation therapy are aimed at maximizing the radiation dose to the tumor while minimizing the radiation exposure to normal tissue, thereby increasing efficacy and decreasing toxicities of treatment. Compared to three-dimensional conformal radiotherapy, intensity-modulated radiation therapy has been showed to decrease volume of bone marrow irradiated, resulting in decreased incidence and severity of acute hematologic toxicity in cervical cancer patients undergoing concurrent chemoradiotherapy (Hui et al. 2014).

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a well-recognized complication of solid and hematologic cancers. DIC is observed in approximately 7 % of patients with solid tumors and approximately 15 % of patients with acute leukemia (Sallah et al. 2001; Dixit et al. 2007). Cancer-associated DIC may be divided into three subtypes based on the predominant pathologic and clinical manifestations: hyper-fibrinolytic, procoagulant, and subclinical (Thachil et al. 2015). The hyper-fibrinolytic form, which is predominantly seen in acute promyelocytic leukemia (APL) and metastatic prostate cancer, is characterized by activation of the fibrinolytic pathway, leading to widespread bruising and bleeding. In APL, early hemorrhagic death from DIC remains an important cause of death in this highly curable disease (Lehmann et al. 2011; Park et al. 2011; McClellan et al. 2012). The procoagulant form of DIC results from excess thrombin generation leading to microvascular and macrovascular thrombosis. It is most commonly seen in adenocarcinomas or pancreatic cancer. Subclinical DIC, which may be seen in a variety of solid tumors, describes DIC diagnosed based on laboratory abnormalities in the absence of clinical manifestations.

In a prospective study of 1117 patients with solid tumors, DIC was found in 76 (6.8 %) patients and was associated with an inferior survival. Risk factors for cancer-associated DIC included older age, male gender, advanced malignancies, breast cancer, and tumor necrosis on pathology specimen. Nearly all patients with cancer-associated DIC presented with platelets less than 150×10^9/l; the median platelet at presentation was 53×10^9/l. Other laboratory findings included prolonged PT in 60 %, prolonged PTT in 53 %,

and fragmented red blood cells in 66 % of patients. Median fibrinogen was 129 mg/dl (Sallah et al. 2001).

The cornerstone of DIC management is to treat the underlying cancer. Further management is based on the clinical manifestations. Patients with bleeding manifestations are treated with platelets, cryoprecipitate, or plasma. Thrombotic manifestations are managed with anticoagulation, preferentially with low molecular heparins.

Immune Thrombocytopenia

ITP is characterized by antibody-mediated peripheral destruction of platelets. Although ITP has been recognized in nearly all lymphoproliferative disorders, it is most commonly described with Hodgkin lymphoma, large granular lymphocyte (LGL) leukemia, and CLL. ITP has been reported in approximately 1 % of patients with Hodgkin lymphoma (Xiros et al. 1988). Platelet count less than 150×10^9/l is observed in 20 % of patients with LGL leukemia. Commonly recognized mechanisms of thrombocytopenia in patients with LGL leukemia include splenomegaly, ITP, and suppression of megakaryopoiesis by LGL cytotoxic lymphocytes (amegakaryocytic thrombocytopenia) (Dhodapkar et al. 1994; Lai et al. 2008).

CLL is characterized by immune dysregulation with common manifestations including autoimmune hemolytic anemia (AIHA), pure red cell aplasia, and ITP (Diehl and Ketchum 1998). ITP is reported in 2–5 % of patients with CLL and its onset may precede, coincide, or follow the diagnosis of CLL (Visco et al. 2008). Compared to CLL patients without ITP, those with ITP have a higher frequency of unmutated immunoglobulin heavy-chain variable region (IgVH) gene (82 % versus 46 %, $p < 0.01$), positive direct antiglobulin test (22 % versus 5 %, $p < 0.001$), AIHA (16 % versus 3 %, $p < 0.001$), and inferior survival (5-year overall survival 64 % versus 82 %, $p = 0.01$). Unmutated IgVH status is a well-recognized negative prognostic marker in patients with CLL and thus is thought be a contributing factor to these survival differences (Visco et al. 2008).

Management

General Management

Patients with solid tumors or hematologic malignancies with "adequate bone marrow function," typically defined as a platelet count of 75–100 $\times 10^9$/l, are generally able to receive full-dose anticancer therapy. Dose delays or reductions are often considered for patients with platelet counts that do not meet this threshold. However, the specific platelet thresholds for dose initiation, delay, or reductions vary based on the anticancer therapy. In contrast, patients with hematologic malignancies involving the bone marrow typically receive full-dose therapy with platelet transfusion support.

According to the American Society of Clinical Oncology clinical practice guidelines, prophylactic platelet transfusion is recommended at a platelet threshold of 10×10^9/l for non-bleeding cancer patients. Higher transfusion thresholds are typically used in patients with active bleeding, high risk for bleeding, fever, hyperleukocytosis, rapidly declining platelet count, or coagulation abnormalities (Schiffer et al. 2001). Antifibrinolytic agents may be used as adjunctive therapy as they have been reported to decrease the number of platelet transfusions, red blood cell transfusions, and bleeding episodes in several small randomized trials of patients with hematologic malignancies (Wardrop et al. 2013).

Role of Thrombopoietin Receptor Agonists in Solid Tumors

Endogenous TPO is a key regulator of megakaryocyte production and maturation (Kuter 2010). TPO receptor agonists, romiplostim and eltrombopag, are widely used in the management of chronic ITP. TPO receptor agonists bind the TPO receptor, thereby activating and stimulating the production of megakaryocytes and inhibiting antibody-mediated apoptosis of megakaryocytes and platelets. There is no evidence to date of TPO receptor expression by tumor cells in preclinical studies, validating the potential safety when used in cancer patients (Erickson-Miller et al. 2010, 2012).

The use of TPO receptor agonist therapy has been explored in several small studies of cancer patients undergoing chemotherapy. In this clinical scenario, the goal of TPO receptor agonist therapy is to avoid platelet nadirs that result in interruptions in treatment or lead to bleeding events without causing thrombocytosis and increased thrombotic risk. The timing and duration of platelet nadir with the specific chemotherapy regimen as well as the time needed for eltrombopag to take effect needs are important considerations in determining appropriate dosing regimen. Pharmacokinetic/pharmacodynamic modeling suggests that eltrombopag administration 5 days before and after chemotherapy results in improved platelet count stability compared to 10 days before or 10 days after chemotherapy (Hayes et al. 2013). This pharmacokinetic/pharmacodynamic modeling should be kept in mind when interpreting clinical trial data exploring TPO receptor agonist therapy in patients receiving chemotherapy.

In a randomized, double-blind, multicenter phase 2 study, patients receiving first-line carboplatin/paclitaxel were randomized to receive 50–100 mg of oral eltrombopag once daily for 10 days following chemotherapy administration. The failure to meet the primary outcome (a difference in platelet count from day 1 in cycle 2 to platelet count in cycle 2 with eltrombopag compared placebo) was likely attributable to suboptimal dosing (Kellum et al. 2010). In a small, blinded, placebo-controlled trial with eltrombopag in patients with solid tumors receiving gemcitabine alone or in combination with cisplatin or carboplatin, patients were randomized to receive oral eltrombopag 100 mg once daily for 5 days before and 5 days after chemotherapy starting with cycle 2. Eltrombopag use was found to be associated with fewer dose reductions or delays (Winer et al. 2015).

Role of Thrombopoietin Receptor Agonists in Hematologic Malignancies

TPO agonists are ineffective in myeloablative states and thus are not used in patients with acute myeloid leukemia (AML) receiving intensive chemotherapy. The administration of pegylated recombinant human megakaryocyte growth and development factor (PEG-rHuMGDF) has been shown to have no effect on the duration of severe thrombocytopenia or the platelet transfusion requirement in patients receiving myeloablative chemotherapy for AML (Schiffer et al. 2000). The major concern with the use of romiplostim in patients with MDS is the progression to AML based on early trial results (Kantarjian et al. 2010). However, there were similar rates of progression of AML at the time of final analysis (Giagounidis et al. 2014).

Approach to Patients Requiring Anticoagulation for Venous Thromboembolism

Venous thromboembolism (VTE) is a frequent complication of cancer, and importantly, thrombocytopenia does not appear to be protective against the development of VTE (Heit et al. 2000; Vu et al. 2015). The optimal management of cancer-associated VTE in patients with concomitant thrombocytopenia is not well established. Management is largely guided by expert opinion with the aim to balance the risks of recurrent VTE and bleeding during episodes of thrombocytopenia. Low molecular weight heparin (LMWH) therapy remains the standard of care for cancer-associated VTE (Lyman et al. 2015). Vitamin K antagonist therapy should be avoided in patients with severe thrombocytopenia due to its prolonged anticoagulant effect. The International Society on Thrombosis and Haemostasis approach to the management of cancer-associated VTE in patients with thrombocytopenia is presented in Fig. 2 (Carrier et al. 2013). Retrospective data support the safety of this general approach (Babilonia et al. 2014; Miao et al. 2015; Kopolovic et al. 2015). In a retrospective study of 74 cancer patients with a platelet count less than 100×10^9/l at the time of acute VTE diagnosis, 30 patients completed 3 more months at therapeutic LMWH doses with two non-major clinically relevant bleeding events but no major bleeding events. This was in spite of a median platelet nadir of 44×10^9/l (interquartile range: 13–65) and 14 patients having a platelet count nadir of less than 30×10^9/l among this group of 30 patients (Kopolovic et al. 2015). Based on this limited data, full-dose anticoagulation may be considered in selected patients with a platelet count as low as 30×10^9/l. However, well-designed clinical trials are needed

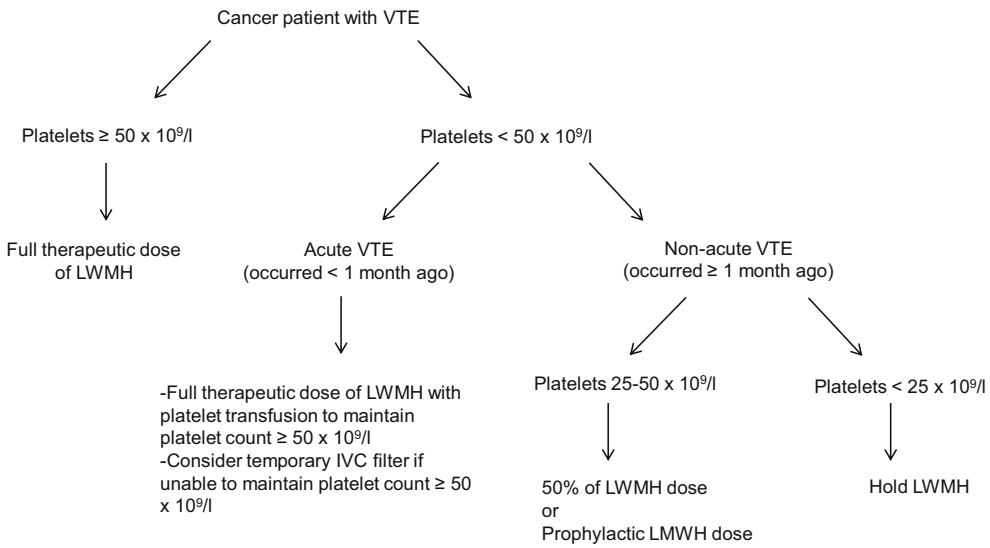

Fig. 2 International Society on Thrombosis and Haemostasis guidelines for the management of venous thromboembolism in cancer patients with concomitant thrombocytopenia (Carrier et al. 2013). *VTE* venous thromboembolism, *LMWH* low molecular weight heparin, *IVC* inferior vena cava

to evaluate the appropriate doses of therapeutic anticoagulation in cancer patients with VTE and concomitant thrombocytopenia.

Take-Home Points

- Thrombocytopenia is a common complication in patients with cancer.
- Systemic cancer treatment is the most common cause of thrombocytopenia in cancer patients.
- The mechanism of thrombocytopenia varies with the cancer treatment.
- Bone marrow involvement with tumor, splenomegaly, disseminated intravascular coagulopathy, and immune thrombocytopenia are other important causes of thrombocytopenia in cancer patients.
- The management of thrombocytopenia in cancer patients includes dose delays or reductions of anticancer therapy and supportive care.

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

Johanna A. Kremer Hovinga

Abstract

Thrombocytopenia and microangiopathic hemolytic anemia (MAHA) with schistocytes on the blood smear are key findings in thrombotic microangiopathies (TMAs). Initial clinical evaluation of patients focuses on the distinction between primary and secondary TMA forms associated with underlying diseases or systemic disorders.

Primary TMAs, the focus of this chapter, include thrombotic thrombocytopenic purpura (TTP; acquired or hereditary), Shiga toxin-mediated hemolytic-uremic syndrome (STEC-HUS), and complement-mediated or atypical HUS (hereditary or acquired). Mortality and morbidity resulting from acute TMA episodes are considerable and therefore urgent treatment is necessary, preferably directed at the underlying pathophysiology. Two factors can help to distinguish between the primary TMA forms. Age at presentation is important because HUS is typically diagnosed in children and TTP in (young) adults. Renal involvement may also help because kidney injury is prominent in HUS but usually absent or only moderately present in TTP, where neurological symptoms are more frequent.

A severe ADAMTS13 deficiency (<10 % of that in normal plasma) indicates a diagnosis of TTP. ADAMTS13 deficiency can be autoantibody-mediated (acquired TTP) or the result of *ADAMTS13* gene mutations (hereditary TTP, Upshaw–Schulman syndrome). STEC-HUS is preceded by an infection with Shiga toxin-producing *Escherichia coli* (e.g., *E. coli* O157:H7) or *Shigella dysenteriae* leading to bloody diarrhea. Complement-mediated HUS is the consequence of excessive activation of the alternative pathway of the complement system as a result of mutations in complement regulators or complement factors (hereditary forms) or the presence of autoantibodies against complement regulators (acquired forms).

Plasma exchange (PEX) with fresh frozen plasma replacement is the treatment of choice for TTP, which has the highest acute mortality rate of all TMAs (exceeding 90 % in the pre-plasma therapy era). PEX is usually supplemented by immunosuppressant drugs, corticosteroids, and/or rituximab to tackle ADAMTS13 autoantibodies. In TMA cases with normal or only moderately reduced ADAMTS13 activity, prominent renal involvement, and no history of bloody diarrhea, anti-complement treatment should be considered within the first week of presentation.

Introduction

Acute thrombotic microangiopathies (TMAs) are life-threatening disorders characterized by microangiopathic hemolytic anemia (MAHA) with schistocytes (Fig. 1) on the peripheral blood smear, consumptive thrombocytopenia, and variable degrees of ischemic organ dysfunction as a result of microvascular thrombosis, primarily affecting the brain and kidneys (Moake 2002; Lämmle et al. 2005; Sadler 2008; Kremer Hovinga and Lämmle 2012; George and Nester 2014). TMAs are rare disorders with an annual incidence of all forms of 11.3×10^{-6} (Terrell et al. 2005).

Depending on the primary organ dysfunction observed, acute TMAs are referred to as thrombotic thrombocytopenic purpura (TTP) when neurological manifestations are predominant, or as hemolytic-uremic syndrome (HUS) in the presence of acute renal insufficiency. Furthermore, distinction can depend on the specialty of the involved consultant, be it a hematologist (TTP) or a nephrologist (HUS), as well as on patient's age, as HUS is mainly found in children, whereas TTP is predominately a disease of (young) adults. The clinical overlap between TTP and HUS is, however, considerable (Amorosi and Ultmann 1966; Rock et al. 1991; Thompson et al. 1992; Vesely et al. 2003).

The primary or idiopathic forms of TTP and HUS must be distinguished from secondary TMAs with underlying or associated disorders, such as drug-induced TMAs, preeclampsia and eclampsia/HELLP syndrome in pregnancy, TMA associated with stem cell transplantation, neoplasia, autoimmune disorders (e.g., systemic lupus erythematosus), and human immunodeficiency virus (HIV) infection (Table 1). These secondary TMA forms are beyond the scope of this chapter. Note, however, that TMA can be associated with severe acquired ADAMTS13 deficiency in patients with systemic lupus erythematosus and that pre-eclampsia often complicates pregnancy in patients with hereditary TTP and congenital ADAMTS13 deficiency (Scully et al. 2006; Fujimura et al. 2009; von Krogh et al. 2014).

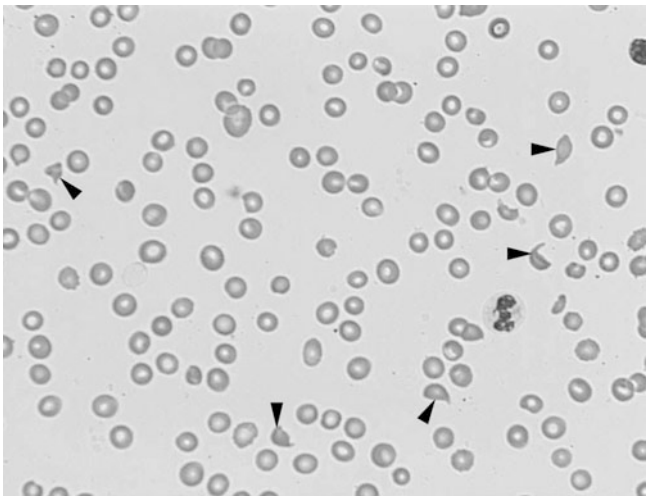

Fig. 1 Peripheral blood smear of a patient presenting with an acute TTP episode. Schistocytes are indicated by *arrowheads*; note the severe thrombocytopenia. Further laboratory work-up revealed the following results: platelet count 8×10^9/L, hemoglobin 46 g/L, LDH 2655 U/L (normal range <480 U/L), total bilirubin 105 μmol/L (3–26 μmol/L), creatinine 91 μmol/L (59–116 μmol/L). The direct antiglobulin test (direct Coombs test) was negative. ADAMTS13 activity was <5 % in the presence of an ADAMTS13 inhibitor of 3 BU/mL, proving a diagnosis of acute acquired TTP as a result of severe autoantibody-mediated ADAMTS13 deficiency. The patient was treated with daily plasma exchange and prednisone, and was splenectomized on day 29 as a result of a plasma refractory state. He has remained in remission, despite the reappearance of a severe functional ADAMTS13 inhibitor 3.4 years after splenectomy (Kremer Hovinga et al. 2004b)

During the past decade, a number of pathophysiological processes underlying TTP and HUS have been unraveled. This has provided the rationale for long-standing, empirical therapies but also directed the development of new treatment strategies such as rituximab for acquired TTP, development of recombinant ADAMTS13 for hereditary TTP, and anti-complement therapy in atypical HUS (aHUS).

This chapter focuses on the clinical presentation, pathophysiological findings, and treatment options for TTP and HUS.

Epidemiology

Thrombotic Thrombocytopenic Purpura

Annual incidence rates for idiopathic TTP were estimated to be $3.7–4.43 \times 10^{-6}$ (Török et al. 1995; Terrell et al. 2005) and that of acquired TTP with severe ADAMTS13 deficiency caused by anti-ADAMTS13 autoantibodies as

Table 1 Forms of thrombotic microangiopathy with underlying pathophysiology and primary management options

Primary forms of thrombotic microangiopathy		
	Cause	Treatment
Thrombotic thrombocytopenic purpura (TTP)		
Hereditary TTP (Upshaw–Schulman syndrome)	Congenital ADAMTS13 deficiency Homozygous or compound heterozygous *ADAMTS13* gene mutations	Plasma infusion Recombinant ADAMTS13 in the future
immune-mediated, acquired TTP	Acquired ADAMTS13 deficiency as a result of inhibitory and noninhibitory anti-ADAMTS13 autoantibodies In roughly one-third of patients, ADAMTS13 activity is normal or only mildly reduced	Plasma exchange with replacement of plasma Immunosuppression (corticosteroids, second line rituximab, splenectomy)
Hemolytic uremic syndrome (HUS)		
Shiga toxin-mediated HUS	Infection, mainly enteric, with Shiga toxin-producing bacteria, mainly *E. coli* (predominately serotype O157:H7 followed by O26, O145;O128, etc.) and *S. dysenteriae type 1*	Supportive care
Post-pneumococcal infection HUS	Pneumococcal neuraminidase exposes usually cryptic Thomsen–Friedenreich antigen on red blood cells and glomeruli	Supportive care
Atypical HUS	Mutations in complement regulators CFH (20–30 %), CFI (5–10 %), MCP (5–10 %), THBD (3–5 %) or in complement factors (gain-of-function) C3 (5–10 %) and CFB (1–4 %) Mutations in DGKE (rare)	Plasma infusion or exchange Anti-C5 antibody or other anti-complement treatment
Atypical HUS	Anti-complement factor H antibodies in homozygous deletion of CFHR 1/3	Plasma infusion or exchange Immunosuppression Anti-C5 antibody or other anti-complement treatment
Secondary forms of thrombotic microangiopathy (TMA)		
	Cause	Treatment
Pre-eclampsia and eclampsia/HELLP syndrome	Many theories Typical pregnancy complication in many female hereditary TTP patients Mutations in complement factors and regulators as risk factors in some patients/families	Control of blood pressure and urgent delivery Early preventive administration of plasma
Drug-mediated TMA	Quinine (direct via quinine-dependent antibodies) Ticlopidin (in some by induction of anti-ADAMTS13 antibodies) VEGF inhibition Gemcitabine, others	Cessation of drug Supportive care
Connective-tissue disease-associated TMA	Systemic lupus erythematosus and others About half of cases overlap with TTP and severe acquired ADAMTS13 deficiency Frequently noninhibitory anti-ADAMTS13 antibodies	Treatment of underlying illness Plasma exchange Immunosuppression
Hematopoietic stem cell transplantation-associated TMA	Calcineurin inhibitors Graft-versus-host disease towards endothelium? Dysregulation of the complement system?	Mild forms: Calcineurin inhibitors Supportive care Severe forms: Grim prognosis Anti-C5 antibody or other anti-complement treatment
Neoplasia-associated TMA	Advanced carcinoma (typically of stomach, breast, or prostate)	Chemotherapy may be tried, prognosis generally grim Supportive care
HIV-associated TMA	Ongoing uncontrolled HIV infection In some cases classical TTP with severe acquired ADAMTS13 deficiency	Highly active antiretroviral therapy (HAART) Plasma exchange

2.17×10^{-6} (95 % CI 2.00–2.34) (Reese et al. 2013). The latter study confirmed the clinical observation that acquired TTP is rare in children under 18 years of age (annual incidence rate 0.09×10^{-6} compared with 2.88×10^{-6} in adults) as well as the observation that blacks are more often affected than non-blacks (ratio 7.1:1), as are women (female to male ratio 3.2:1) (Reese et al. 2013).

The true prevalence of hereditary TTP as a result of congenital ADAMTS13 deficiency, also known as Upshaw–Schulman syndrome (USS, OMIM #274150), is unknown. A proportion of <5 % of all TTP cases with severe ADAMTS13 deficiency has been put forward (Galbusera et al. 2009). Worldwide, more than 150 affected patients are known to be alive. A population screening in healthy

Japanese adults, stratified according to their plasma ADAMTS13 activity, revealed a considerable number of heterozygous *ADAMTS13* mutation carriers in this population (Kokame et al. 2011). The authors hypothesized that the true prevalence of hereditary TTP could be up to threefold higher than the estimate based on recognized patients. The point prevalence of hereditary TTP in central Norway, a region with many USS patients, was 16.7×10^{-6} (von Krogh et al. 2016). This number was reflected by an allelic frequency of the two most prevalent *ADAMTS13* mutations in the population, *c.4143_4144dupA* and p.R1060W, of 0.04–0.33 %, and 0.3–1 %, respectively. For the latter mutation, a somewhat lower allelic frequency of 0.06 % was documented in a population study in the Netherlands (de Vries et al. 2015).

Hemolytic Uremic Syndrome

HUS is predominately observed in children below 5 years of age. More than 90 % of cases develop secondary to infections with Shiga toxin (Stx)-producing *E. coli* (STEC), *Shigella dysenteria* and *Streptococcus pneumonia* (Tarr 2009; Noris et al. 2012). For different countries in Europe and the Americas, annual incidence rates of infectious HUS of 2×10^{-6} to 7.1×10^{-6} children per year have been reported (Gianviti et al. 1994; Decludt et al. 2000; Banatvala and Zwi 2000; Elliott et al. 2001; Gerber et al. 2002; Schifferli et al. 2010). In the majority of cases, these infections are mild and self-limiting; however, about 10–15 % of affected patients subsequently develop STEC-HUS (Wong et al. 2000; Tarr et al. 2005).

Apart from large outbreaks, often attracting public attention (Buchholz et al. 2011; Frank et al. 2011), most occurrences are sporadic. In Switzerland, infections with Stx-producing bacteria are reportable, with roughly 200 cases reported every year (the resident population of Switzerland is eight million). About 10–20 % of all individuals, but up to 80 % of children below the age of 5 years (Tarr 2009), develop a severe course with bloody diarrhea and hemorrhagic colitis. Of these, 10–15 % subsequently develop STEC-HUS (Wong et al. 2000; Tarr et al. 2005). Consequently, STEC-HUS is also referred to as diarrhea-associated (D^+HUS) or typical HUS.

The most common bacteria implicated in STEC-HUS is *E. coli* serotype O157:H7, which accounts for up to 70 % of cases in North America and western Europe (Ochoa and Cleary 2003; Barton Behravesh et al. 2011; Scallan et al. 2011; Locking et al. 2011; Gould et al. 2013). Several non-O157:H7 strains (i.e., O111:H8, O103:H2, O121, O145, O113, or O104:H4, in the German 2011 outbreak) were also implicated (Gerber et al. 2002; Bundesamt and Gesundheit 2008; Buchholz et al. 2011; Trachtman 2012). Infections with *Shigella dysenteriae* type 1 are frequently identified in STEC-HUS in developing countries. Healthy cattle are the major reservoir of *E. coli* O157:H7 and, consequently, consumption of contaminated meat or unpasteurized dairy products are among the most common modes of food-borne transmission.

About 10 % of HUS cases are classified as atypical because they are not caused by Stx-producing bacteria or *Streptococcus pneumonia*. Mutations in genes encoding complement system proteins [gain-of-function mutations in complement factor genes *C3* and *CFB*, as well as loss-of-function mutations in complement regulatory protein genes *CFH*, *CFI*, *MCP* (also known as *CD46*), or in the thrombomodulin gene *THBD*] are identified in 50–70 % of aHUS and have been found in sporadic and familial cases (Noris and Remuzzi 2009; George and Nester 2014). Rare cases have been attributed to acquired complement dysregulation caused by antibodies to CFH and CFB (Noris and Remuzzi 2009).

Pathophysiology

Thrombotic Thrombocytopenic Purpura

The pathophysiological hallmark of acute TTP is occluded microvasculature caused by von Willebrand factor (VWF)–platelet-rich thrombi. These thrombi are the consequence of insufficient processing of newly secreted, unusually large, and extremely adhesive VWF multimers (Sadler 2006). In a substantial number of patients, a severe deficiency of the von VWF-cleaving protease, also known as ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin type 1 motifs-13), prevents physiological processing of unusually large VWF multimers into smaller, less-adhesive and sticky VWF molecules.

At present, two forms of severe ADAMTS13 deficiency (<10 % of normal activity) are distinguished. In USS (Upshaw 1978; Schulman et al. 1960) or hereditary TTP, severe ADAMTS13 deficiency is the result of compound heterozygous or homozygous mutations in the *ADAMTS13* gene (Levy et al. 2001; Kokame et al. 2002, 2008; Schneppenheim et al. 2003, 2006; Assink et al. 2003; Matsumoto et al. 2004a; Veyradier et al. 2004; Donadelli et al. 2006). Obligatory heterozygous *ADAMTS13* mutation carriers typically have an ADAMTS13 activity that is about 50 % of the normal and are generally considered to be healthy, although mild thrombocytopenia during pregnancy or infections has been reported in some cases (Kremer Hovinga and Meyer 2008; Mansouri Taleghani et al. 2013).

The *ADAMTS13* gene is located on chromosome 9q34, in close neighborhood to the *ABH blood group locus*, and encodes a multidomain protein of 1427 amino acids. More than 100 different causative *ADAMTS13* mutations,

including missense (~62 %), nonsense (~12.5 %), splice site (~8 %), and frame-shift (deletions and insertions; 17.5 %) mutations, spreading over all ADAMTS13 protein domains, have been identified in USS. The majority of mutations are confined to single families; consequently, homozygous mutation carriers are mainly observed in offspring of consanguineous marriages. Exceptions are two recurring mutations, *c.4143_4144dupA* in exon 29 and p.R1060W in exon 24, which have been observed in several unrelated families (Schneppenheim et al. 2003, 2006; Assink et al. 2003; Pimanda et al. 2004; Tao et al. 2006; Donadelli et al. 2006; Hrachovinova et al. 2006; Manea et al. 2007; Garagiola et al. 2008; Camilleri et al. 2008) and have a widespread geographical distribution. The frameshift mutation *c.4143_4144dupA* has been described in families originating from central and northern Europe, and was found to account for many cases in Scandinavia and around the Baltic Sea (Schneppenheim et al. 2006; Hyla-Klekot et al. 2013; von Krogh et al. 2016). Distribution of the second mutation, *c.3178 C>T* (p.R1060W), is even more extended and is the predominant mutation in British patients, but has also been reported in patients from Turkey, central Europe, Scandinavia, France, and Italy, as well as in North Americans of European descent (Tao et al. 2006; Camilleri et al. 2008; Lotta et al. 2010). The mutation was also found in the North American population of the NHLBI GO Exome Sequencing Project and the CEPH sample in the 1000 Genomes Browser (listed as single nucleotide polymorphism rs142572218).

The clinical phenotype of hereditary TTP is variable. There seems to be a dichotomous distribution of disease onset with a number of patients presenting with a first acute TTP episode before the age of 5 years (early onset), whereas others remain asymptomatic into early adulthood and suffer from the first acute episode between 20 and 40 years of age or later (late onset) (Furlan and Lämmle 2001), often triggered by a first pregnancy (Fujimura et al. 2009; Moatti-Cohen et al. 2012; Scully et al. 2014; von Krogh et al. 2014). In analogy to hemophilia, where patients with levels of blood-clotting protein FVIII:C of less than1 % usually have a severe, those with 1–5 % a moderate, and patients with >5 % a mild disease course, it was hypothesized that the severity of the clinical phenotype (defined by the timepoint of the first acute TTP episode, frequency of recurrence, and need for prophylactic plasma infusion) is controlled by the presence and amount of residual ADAMTS13 activity (Meyer et al. 2008b; Lotta et al. 2012). Residual ADAMTS13 activity was essentially found in carriers of the *c.3178 C>T* (p.R1060W) mutation, with the highest values in p.R1060W homozygotes. In these patients ADAMTS13 activities ≥10 % were associated with an asymptomatic course up to the seventh decade (Meyer et al. 2008b). A simple *ADAMTS13* genotype–phenotype correlation is, however, questioned by the variable clinical courses of homozygous *c.4143_4144dupA* patients, even within families (Schneppenheim et al. 2006; von Krogh et al. 2016).

It is intriguing to speculate on modifier genes, especially in the complement system, given the overlapping clinical pictures of TTP and HUS. Noris et al. (2005) reported on such an additional *CFH* mutation, previously described in aHUS in a hereditary TTP patient with primarily renal involvement. The *CFH* mutation was lacking in other family members with congenital ADAMTS13 deficiency having no renal involvement. In a recent study by Fan et al. (2016) on 32 hereditary TTP patients, of whom 13 had (severe) renal involvement up to end-stage renal disease (ESRD) and kidney transplantation, the missense sequence variants (single nucleotide polymorphisms) in complement factor and regulatory genes, reported to be associated with an increased risk for aHUS, were not more common in USS patients with renal insufficiency compared with USS patients without. However, 1/13 patients with renal involvement had a novel C3 mutation, p.K155Q located in the C3 macroglobulin-like 2 domain, where other predisposing aHUS mutations cluster. Although complement aberrations could contribute to renal involvement, there have to be other, as yet unrecognized, factors shaping the phenotype in congenital ADAMTS13 deficiency.

Acquired TTP is an autoimmune disorder with circulating anti-ADAMTS13 autoantibodies, leading to a severe ADAMTS13 deficiency. Initial retrospective studies found a severe ADAMTS13 deficiency in 87–100 % of patients clinically diagnosed with idiopathic (or classical) TTP (Furlan et al. 1998a; Tsai and Lian 1998). Subsequent studies on less-selected patient cohorts, however, reported lower frequencies of between 33 and 80 % [for a review see (Kremer Hovinga and Lämmle 2012)] with a pooled average of ~60 % (Furlan et al. 1998a; Tsai and Lian 1998; Veyradier et al. 2001; Vesely et al. 2003; Matsumoto et al. 2004b; Kremer Hovinga et al. 2004a; Zheng et al. 2004; Peyvandi et al. 2004; Böhm et al. 2005; Scully et al. 2008). There has been ample debate on the reasons for this variable correlation between severe ADAMTS13 deficiency and clinical diagnosis of acute TTP. Possible explanations are differences in the assays used for ADAMTS13 activity determination, single versus multicenter studies using different diagnostic criteria, and variable attention to underlying secondary causes of TMA such as TMA after stem cell transplantation or associated with drugs or advanced cancers, where ADAMTS13 activity is usually normal or only mildly reduced (Kremer Hovinga et al. 2010; Peyvandi et al. 2004, 2008; Vesely et al. 2003; Veyradier et al. 2001; Zheng et al. 2004).

The prerequisite of a positive antibody assay in the context of severe ADAMTS13 deficiency (whether functional

inhibitor assay or ELISA) is the presence of free, circulating anti-ADAMTS13 antibodies. In the majority of patients, strong functional ADAMTS13 inhibitors can be demonstrated by Bethesda-like assays (Furlan et al. 1998a, b; Tsai and Lian 1998). Some 10-25 % of cases have only noninhibitory anti-ADAMTS13 antibodies, which are also present in 4–15 % of healthy blood donors and in a number of hereditary TTP patients on regular plasma prophylaxis; however, in the latter these antibodies do not seem to interfere with ADAMTS13 recovery or ADAMTS13 plasma half-life (Fujimura et al. 2011; Kremer Hovinga and Meyer 2008). Noninhibitory anti-ADAMTS13 antibodies have been postulated to act through ADAMTS13 clearance (Scheiflinger et al. 2003; Rieger et al. 2005, 2006; Thomas et al. 2015). Because ADAMTS13 antigen values are severely reduced in the majority of acquired TTP patients, the latter mechanism is probably important for all types of anti-ADAMTS13 antibodies (Rieger et al. 2006; Feys et al. 2006; Thomas et al. 2015). Unexpectedly high ADAMTS13 antigen levels in samples from patients with severe ADAMTS13 deficiency in the presence of anti-ADAMTS13 antibodies prompted the measurement of circulating immune complexes of anti-ADAMTS13 antibody and ADAMTS13 (Rieger et al. 2006). These were subsequently found to be a dominant aspect of acquired TTP and present during acute episodes and relapses but also in remission, even years after the previous acute TTP episode (Froehlich-Zahnd et al. 2012; Ferrari et al. 2012, 2014).

Anti-ADAMTS13 antibodies are mainly IgG isotypes and predominantly of subclass IgG_4, followed by subclasses IgG_1, IgG_2, and IgG_3 (Ferrari et al. 2009). High levels of IgG_4 were found to be associated with an increased risk of relapse and, in relapsed cases, IgG_4 was often the only anti-ADAMTS13 isotype. On the other hand, the presence of IgA and/or IgG_1 at presentation with acute TTP was associated with adverse outcome in a small number of patients (Ferrari et al. 2007, 2009).

ADAMTS13 autoantibodies frequently use the VH1-69 and VH1-3 heavy chain gene segments (Pos et al. 2009; Schaller et al. 2014). Somatic mutation rates of characterized monoclonal anti-ADAMTS13 antibodies are compatible with affinity maturation (Schaller et al. 2014; Luken et al. 2006; Pos et al. 2009). In longitudinal studies of patients over a number of relapses, functional maturation (from noninhibitory to inhibitory anti-ADAMTS13 antibodies) and/or epitope spreading was also demonstrated, suggesting continuous development and shaping of the autoimmune response to ADAMTS13 in acquired TTP (Froehlich-Zahnd et al. 2012; Thomas et al. 2015).

The principal epitope of anti-ADAMTS13 antibodies lies within the ADAMTS13 spacer domain and was fine-mapped to positively charged amino acids Arg568 and Arg660, as well as to Phe592, Tyr661, and Tyr665 (Jin et al. 2010; Pos et al. 2010, 2011). Anti-spacer domain antibodies are present in 97–100 % of patients with severe acquired ADAMTS13 deficiency (Klaus et al. 2004; Luken et al. 2005; Zheng et al. 2010; Thomas et al. 2015), and inhibitory anti-ADAMTS13 antibodies were only found among anti-spacer domain antibodies (Thomas et al. 2015). Roughly two-thirds of patients also have antibodies that react with other ADAMTS13 domains. So far, epitopes of these latter antibodies have not been fine-mapped.

As in other autoimmune diseases, there is evidence for a certain genetic predisposition for the development of pathogenic ADAMTS13 antibodies. The major histocompatibility complex (MHC) class II allele HLA DRB1*11 was found to be over-represented in acquired TTP patients in different European countries, whereas the HLA DRB1*04 allele was more prevalent among healthy controls, suggesting a protective effect of the latter MHC class II allele (Coppo et al. 2010a; Scully et al. 2010). Furthermore, a pair of identical twin sisters, not having the HLA DRB1*11 allele, developed acute TTP as a result of severe autoantibody-mediated ADAMTS13 deficiency a little over a year apart (Studt et al. 2004). Heterozygous *ADAMTS13* mutation carriers have been observed among patients diagnosed with acute TTP caused by severe acquired ADAMTS13 deficiency (in 11 % and 9.6 % of the studied acquired TTP populations, respectively) (Meyer et al. 2007; Camilleri et al. 2008). Seven of these heterozygous ADAMTS13 mutation carriers had ADAMTS13 IgG antibodies, which were found to be functional ADAMTS13 inhibitors in six of the seven patients. Given the low prevalence of *ADAMTS13* mutations in the general population, the number of heterozygous mutation carriers among patients diagnosed with acquired TTP seems remarkable and hints to a role of heterozygous sequence variants either in facilitating a drop in ADAMTS13 to below a critical threshold, relevant to set off an acute TTP episode, or in the development of ADAMTS13 autoantibodies.

Hemolytic Uremic Syndrome

Pathological-anatomical findings in STEC-HUS and aHUS are thickening of arterioles and capillary walls as a result of endothelial swelling and detachment, accumulation of subendothelial cell debris and protein deposits, and narrowing of vessel lumens, fortified by obstructing platelet thrombi.

Enterohemorrhagic bacteria release Shiga toxins (Stxs) into the gut, from where they are absorbed across the epithelium into the blood stream. They bind to endothelial cells, predominately in the small vessels of gut, kidney, and brain, leading to bloody diarrhea, renal insufficiency, and neurological complications (Bielaszewska and Karch 2005; Karch

et al. 2006). Comparison of *Stx* genotypes in isolates from patients with uncomplicated STEC diarrhea and from patients who developed STEC-HUS associated *Stx2* with severe disease course [for a review see (Karch et al. 2006)].

Shiga toxins are the major virulence factor of enterohemorrhagic bacteria and belong immunologically to two major families, Stx1 and Stx2. In *E. coli*. Stx1 is 56 % homologous to Stx2 and differs only by one amino acid from *S. dysenteriae* type 1 Stx. Besides the major toxin types Stx1 and Stx2, a number of sequence variants, particularly for *Stx2* (e.g., *stx2a*, *stx2c*, and *stx2d*) have been described (Karch et al. 2006). Stxs are composed of five glycolipid-binding B subunits, which facilitate binding to globotriaosylceramide (Gb3) on epithelial and endothelial cells, and one enzymatically active A subunit that inhibits protein synthesis by cleaving ribosomal RNA, eventually leading to apoptotic cell death. Besides Stxs, there are a number of other virulence factors that contribute to the pathogenicity of STEC, such as intimin (encoded by *E. coli* attaching and effacing gene, *eae*), an adhesin (encoded by *saa*), or enterohemolysin (encoded by *ehxA*). Their roles in human disease, however, are still under investigation.

The complement system is part of the innate immune system. The C3 and C5 convertase complexes are formed via three pathways: classical, lectin and alternative pathways, leading finally to the generation of the lytic membrane attack complex C5b-9. Host cells are normally protected by membrane-anchored or fluid-phase complement regulators that inactivate and dissociate the C3 and C5 convertases (George and Nester 2014; Nester and Thomas 2012; Noris and Remuzzi 2009). Atypical HUS is linked to uncontrolled activation of the complement system, either as a result of gain-of-function mutations in C3 or *CFB*, or through insufficient complement regulation. Most prevalent are *CFH* mutations, accounting for roughly 25 % of identified mutations in aHUS, followed by mutations in membrane cofactor protein *MCP* (5–10 %), *CFI* (5–10 %), *C3* (5–10 %), and *CFB* (1–4 %) (George and Nester 2014; Nester and Thomas 2012; Noris and Remuzzi 2009). In addition, components of coagulation and other pathways can modulate complement activation. Sequence variants or mutations in the thrombomodulin gene (*THBD*, 3–5 %) (Delvaeye et al. 2009), the plasminogen gene (*PLG*) (Bu et al. 2014), or the diacylglycerol kinase-ε gene (*DGKE*) (Lemaire et al. 2013) have been implicated in small numbers of aHUS patients. In addition, homozygous deletions of *CFH-related proteins 1* and *3* are associated with autoantibody formation against CFH and are identified in about 6 % of aHUS patients.

Mutations are often heterozygous, and phenotypic penetrance among carriers of *CFH, CFI*, *MCP*, and *THBD* mutations have been reported to be 40–50 % (Caprioli et al. 2006; Delvaeye et al. 2009). It was suggested that mutations in complement system genes are risk factors rather than causes of aHUS. In many patients, additional genetic risk factors have been identified, suggesting that more than one risk factor is required for overt phenotypic manifestation in aHUS. Overall complement regulation can be maintained in the presence of reduced action of one or two regulators; however, situations associated with complement activation and inflammation, such as infection or pregnancy, confer additional risk factors and precede acute syndromic presentation in up to half of mutation carriers (Caprioli et al. 2006; Delvaeye et al. 2009).

Clinical Presentation and Diagnosis

In 1966, Amorosi and Ultman reviewed their own 16 TTP cases as well as cases reported in the literature. They summarized the most prevalent clinical signs into the famous TTP pentade of MAHA, thrombocytopenia, neurological manifestations, renal insufficiency, and fever (Table 2). There were no established therapies and mortality exceed 90 %. Nowadays, with good treatment options available and high mortality in untreated patients, acute TTP can be diagnosed on the basis of the concomitant presence of (severe) thrombocytopenia and MAHA with schistocytes on the blood smear, without another apparent explanation (George 2000, 2010). Only a minority of patients presents with the full pentade of signs and organ manifestations nowadays. However, myocardial ischemia and ischemia of intestinal organs are increasingly recognized in patients and can influence management (e.g., hospitalization in intensive care rather than a normal ward when cardiac involvement is present) (Sane et al. 2009; Benhamou et al. 2015; Hughes et al. 2009; McDonald et al. 2009; Swisher et al. 2007).

Basic laboratory work-up should include a full blood count with differential markers of hemolysis (reticulocyte count, haptoglobin, lactate dehydrogenase, bilirubin, and direct Coombs test, which should be negative) and of organ involvement (cardiac troponin, creatinine, possibly S100b as neurological marker). Prior to the first administration of plasma-containing blood products, a blood sample should be withdrawn for ADAMTS13 activity measurement. At the beginning of the millennium, ADAMTS13 assays were cumbersome and confined to specialized research laboratories, today a wide range of commercial assays, which are generally easy to perform and have short turnaround times, are available and results are usually on hand within a few days. An ADAMTS13 activity of <10 % of the normal confirms a diagnosis of acute TTP. The presence of a functional ADAMTS13 inhibitor and/or of anti-ADAMTS13 antibodies allows the distinction between acquired and congenital severe ADAMTS13 deficiency. Roughly one third of patients clinically diagnosed with acute TTP in the absence of an apparent

underlying disorder have normal or only mildly to moderately reduced ADAMTS13 activity. In a number of the latter patients, usually with a good response to plasma exchange (PEX) treatment, the presence of anti-ADAMTS13 antibodies was demonstrated. These even evolved into functional ADAMTS13 inhibitors over subsequent TTP episodes in one patient (Froehlich-Zahnd et al. 2012; Kremer Hovinga and Lämmle 2012). This suggests that ADAMTS13 may be specifically involved in the disease in the absence of a severe ADAMTS13 deficiency, as assessed by current routine assays.

Patients with a severe acquired ADAMTS13 deficiency are a distinct group of patients that usually have a lower platelet count, less severe or no renal involvement, and a high risk of relapse in survivors (Kremer Hovinga et al. 2010; Coppo et al. 2010b).

Hereditary TTP can present in early childhood or later in life. Concise exploration of case histories revealed that many patients had exchange transfusions within the first days of life [28 % of Japanese patients (Fujimura et al. 2011, 2009) and 44 % of Norwegian patients (von Krogh et al. 2016)]. During childhood, episodes of (mild) thrombocytopenia and/or hemolytic anemia are frequently documented in the context of mild infections (Schneppenheim et al. 2003). Later in life, pregnancy is an important risk factor for a first acute TTP episode (typical constellation of late disease onset). This is particularly true for carriers of the *ADAMTS13* p.R1060W mutation, where acute TTP episodes are rarely seen outside of situations with increased risk (Lotta et al. 2012; Scully et al. 2014; Moatti-Cohen et al. 2012). Nearly all women with hereditary TTP develop pregnancy complications; thrombocytopenia is usually present during the second and third trimester, and pre-eclampsia and eclampsia/HELLP are frequently observed.

A diagnosis of hereditary TTP is based, according to the criteria of the hereditary TTP registry (www.ttpregistry.net, ClinicalTrials.gov identifier NCT01257269), on a suitable patient and/or family history with $\geq$1 acute TTP episodes; an ADAMTS13 activity of <10 % of the normal in the absence of a functional ADAMTS13 inhibitor on two or more occasions at least 1 month apart; molecular analysis of the *ADAMTS13* gene revealing bi-allelic *ADAMTS13* mutations; and/or a plasma infusion trial documenting full recovery and a plasma half-life of infused ADAMTS13 of 2–4 days (Furlan et al. 1999; Meyer et al. 2008a).

The diagnosis of infection-associated HUS is based on the patient's age [typically <5 years of age (Wong et al. 2000) but can also be observed in adults (Dundas et al. 1999)], a history of prodromal diarrhea that turns bloody after 1–2 days, and an overt clinical triade of thrombocytopenia, MAHA, and often severe renal insufficiency that becomes apparent after 5–7 days. Serotype-specific enzyme immunoassays are available for the detection of *E. coli* O157

directly from stool samples. Nowadays, PCR assays for *Stxs* and multiplex PCR assays for other virulence factors (e.g., intimin and enterohemolysin) on stool specimens are standard practice.

About two-thirds of patients require dialysis during the acute phase (Decludt et al. 2000; Banatvala and Zwi 2000; Elliott et al. 2001; Gerber et al. 2002) and, although renal function recovers in the majority of survivors, an average of 25 % (range 0–64 %) (Garg et al. 2003) demonstrate long-term renal sequelae (such as reduced glomerular filtration rate, hypertension, or proteinuria) and 3 % present with end-stage renal disease (ESRD) (range 0–17 %) (Garg et al. 2003) requiring long-term renal replacement therapy. Neurological symptoms, including stroke, seizure, and coma, are present in 25–30 % of cases. Mortality rates during the acute phase of STEC-HUS have been reported to be 3–5 % and death is nearly always associated with extrarenal disease, particularly severe neurological involvement (Tonshoff et al. 1994; Siegler and Oakes 2005; Garg et al. 2003).

The distinction between acquired TTP and aHUS is more difficult, as no objective single test is available to confirm the clinical diagnosis of aHUS. A diagnosis is established in the presence of MAHA, thrombocytopenia, serum creatinine level >200 μmol/L (>2.25 mg/dL), negative stool examination for Stx-producing bacteria, and ADAMTS13 activity of >10 %. Molecular analysis of complement factor genes are now available from a number of commercial and research labs; however, documentation of such mutations is not necessary to establish a diagnosis of aHUS. Until recently, prognosis of aHUS has been grim with a mortality rate of 25 % during the acute phase, and ESRD or serious neurological sequelae in up to 50 % of surviving patients (Taylor et al. 2004; Schieppati et al. 1992; Constantinescu et al. 2004).

Treatment and Outcome

For clarity, uniform criteria for patient outcomes are required. The following definitions are in accordance with the Oklahoma TTP-HUS registry (Kremer Hovinga et al. 2010; Vesely et al. 2003) and are widely used today to assess treatment in TTP:

- Response to treatment is defined as achievement of a normal platelet count of $\geq 150 \times 10^9$/L and normalization of lactate dehydrogenase (LDH) values during PEX.
- Remission is defined as no PEX for 30 days, which is usually associated with resolution of laboratory and clinical abnormalities.
- Exacerbation is defined as recurrence of thrombocytopenia and/or MAHA within 30 days of the last PEX session, necessitating resumption of daily PEX.
- Relapse (i.e., a new episode) is defined as recurrence of thrombocytopenia and/or MAHA after achievement of remission.

When Amorosi and Ultman described the famous pentade of TTP in 1966, the mortality in their series of more than 250 patients exceeded 90 %. For patients treated with corticosteroids, mortality was 77.5 % (9/40 patients survived), and 65 % among patients splenectomized early.

Plasma Therapy

In the late 1970s, Bukowski et al. (1977), Byrnes and Khurana (1977), and Upshaw (1978) first reported successful treatment of acute TTP episodes by PEX with replacement of plasma and by plasma infusion. Thereby, they demonstrated that an important aspect of TTP treatment is replacement of a missing plasma factor.

Between 1982 and 1989, the Canadian Apheresis Study Group performed the first randomized trial on 102 patients presenting with acute TTP, comparing PEX with replacement of fresh frozen plasma (FFP) with FFP infusions (Rock et al. 1991). PEX/FFP was superior to FFP infusion, with response rates of 47 % after seven procedures (one cycle) and of 78 % at 6 months, versus 25 % and 49 % in the infusion arm, respectively. Mortality at 6 months in the PEX/FFP arm was 22 % compared with 36 % in the plasma infusion arm. In a parallel study, Bell and coworkers (Bell et al. 1991) treated 108 patients either with PEX and corticosteroids ($n = 54$) or with corticosteroids alone, depending on the severity of disease. Overall survival was 91 %. Relapse was the predominant problem and occurred in 64 % of patients. Relapse was responsible for all deaths observed (10/108 patients), indicating that supplementation of plasma therapy with corticosteroids is associated with higher survival rates than PEX/FFP alone. Corticosteroids alone were effective in 52 % of milder TTP cases. Additional support for the beneficial effect of adjunctive treatment with immunosuppressant drugs stems from indirect evidence from the Oklahoma TTP-HUS registry. Following the introduction of corticosteroids by default in 2005/2006 a reduction in treatment-associated complications in TTP patients with ADAMTS13 of <10 % was directly correlated with a reduction in the number of PEX/FFP sessions required to achieve remission (Som et al. 2012). PEX/FFP is now usually supplemented with corticosteroids (oral prednisone at 1–2 mg/kg body weight or 125–250 mg of intravenous

methylprednisolone) and has become the mainstay of TTP treatment, with survival rates of nearly 90 % (Kremer Hovinga et al. 2010). In addition, patients should receive folic acid because of the increased requirements of the proliferating erythropoiesis and megakaryopoiesis.

The recommended volume exchanged per PEX session is one volume of the patient's estimated plasma volume, which corresponds to 40 mL/kg body weight per session, although a number of centers initiate treatment with 1.5 volumes (60 mL/kg body weight) for the first one to three sessions, followed by exchanges of one plasma volume daily thereafter. PEX/FFP is continued until remission is achieved, defined as a platelet count $\geq 150 \times 10^9$/L on two consecutive days, normalized LDH activity, and no new manifestations of organ dysfunction. Disappearance of the ADAMTS13 inhibitor and recovery of ADAMTS13 activity is not seen in all patients and seems not to be mandatory for achieving remission. Discontinuation of PEX is the only way to know whether a stable remission has been achieved. Given the initially high numbers of early exacerbations, some centers taper rather than stop PEX abruptly, although tapering of PEX does not seem to reduce relapse rates (Bandarenko and Brecher 1998). When PEX is stopped, tapering of corticosteroids is usually started and completed within 6–12 weeks of the last PEX session.

More intensified PEX/FFP regimens should be reserved for severe cases or patients initially refractory to plasma treatment. Escalation beyond 1.5 plasma volumes per session is not recommended as process efficacy progressively declines with increased recycling of infused plasma. Alternatives are PEX twice per day or plasma infusions between PEX sessions. Although it is recommended to avoid (gross) platelet transfusions, platelets may be given for invasive procedures.

The high mortality without appropriate treatment creates an urgency to initiate treatment before the ADAMTS13 activity is available, thereby performing PEX also on patients without severe acquired ADAMTS13 deficiency, considered by certain experts as not having "true TTP". It should be kept in mind, however, that ADAMTS13 activity was not available for patient stratification in the landmark study by Rock et al. (1991), although it is often claimed that the study consisted mainly of "true TTP" patients because of the exclusion of patients not able to support plasma infusions as a result of severe renal insufficiency. ADAMTS13 was later determined in a subset of 41/102 (40.2 %) patients, of which most, but not all, were found to have mild to medium levels of ADAMTS13 inhibitors (between 0.2 and 2 BU/mL) (Tsai et al. 2001). In addition, the Oklahoma TTP-HUS registry has demonstrated that the response to PEX in idiopathic TTP patients was similar in the subgroup without severe ADAMTS13 deficiency to those with severe ADAMTS13 deficiency (Kremer Hovinga et al. 2010; Vesely et al. 2003).

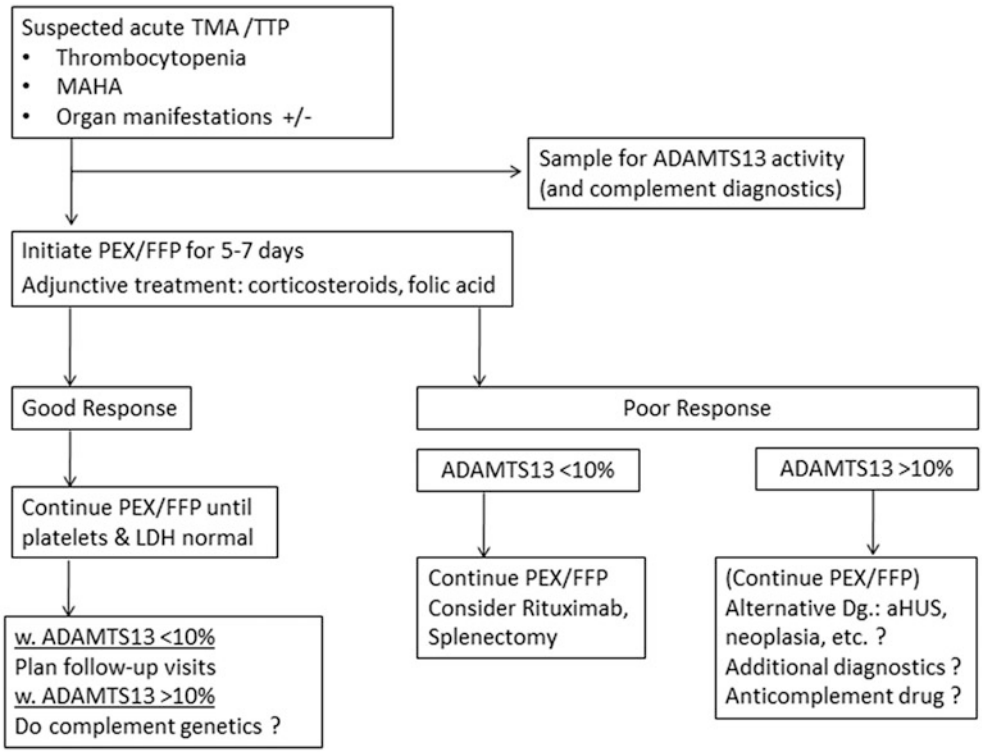

Fig. 2 TMA treatment algorithm. Adapted from (Cataland and Wu 2014)

Therefore, all patients clinically diagnosed with idiopathic TTP should be subjected to PEX/FFP treatment for 5–7 days. After this time, the ADAMTS13 activity result should be back from the laboratory and can help to guide next steps (see Fig. 2).

The initial infusion and PEX studies used fresh frozen plasma as replacement fluid (Rock et al. 1991; Bell et al. 1991). Subsequently, different plasma products (e.g., cryo-poor plasma, solvent/detergent plasma, and amtosalen UVA-treated plasma) were compared with FFP in small studies and found to be equivalent in treating TTP (Mintz et al. 2006; Pehta 1996; Scully et al. 2007).

Rituximab and Splenectomy

Rituximab is a humanized monoclonal antibody against CD20, a B cell surface marker expressed in increasing concentrations from late pro-B cells to mature B cells, but not present on plasma blasts or plasma cells. Rituximab was approved for the treatment of non-Hodgkin's lymphomas but is increasingly used for off-label indications, particularly to treat various autoimmune disorders. It rapidly depletes over 95 % of CD20-positive B cells from the circulation, thereby reducing autoantibody production.

First reports on the use of rituximab to treat acquired TTP appeared 2002 (Chemnitz et al. 2002; Gutterman et al. 2002). Although there are no randomized controlled trials, rituximab has since been used in several TTP cohorts of 30–40 patients as first-line treatment within the first days of presentation supplementing PEX/FFP (Scully et al. 2011; Westwood et al. 2013); in patients with insufficient response or refractory to PEX/FFP (Froissart et al. 2012); to treat relapses; and preemptively to correct ADAMTS13 values <10 % in remission to prevent future relapses (Hie et al. 2014; Westwood et al. 2013). All cases demonstrated a reduction in the relapse rate to 10–25 % and/or to postpone relapses, which again were successfully treated with rituximab (Scully et al. 2011; Froissart et al. 2012; Westwood et al. 2013; Hie et al. 2014). Scully et al. (2011) treated 40/86 (46.5 %; females 65 %) patients presenting with acute acquired TTP (34 de novo, 6 relapsed) with rituximab within 3 days of presentation, and observed shorter hospitalization times and a reduced relapse rate compared with 40 historical controls (females 82.5 %; relapsed 22.5 %). Unfortunately, the outcome of the remaining 46 patients, labeled as screen failures, was not reported. Because long-term follow-up data are missing, it is unknown, whether upfront rituximab prevents chronic relapsing TTP or (only) postpones relapses. Confirmation in a prospective randomized controlled trial is eagerly awaited.

Treatment escalation in patients refractory to or exacerbating on PEX/FFP is more readily accepted, as the treating physician is required to modify therapy. In the pre-rituximab era, these patients often received vincristine or cyclophosphamide.

The most difficult decision, given the lack of prospective randomized controlled trials and possible overtreatment, is whether patients in remission (with reappearance of anti-ADAMTS13 antibodies and severe ADAMTS13 deficiency) should be treated preemptively with rituximab to correct ADAMTS13 deficiency and hopefully prevent possible relapses (Westwood et al. 2013; Hie et al. 2014). Of note, a severe ADAMTS13 deficiency alone does not (always) seem to be sufficient to bring about acute TTP episodes. Jin et al. (2008) reported severe ADAMTS13 deficiency in 6/13 (46.1 %) patients on long-term follow-up without occurrence of relapses. A similar observation was reported for the Oklahoma TTP-HUS registry (Lim et al. 2015). Survivors of acute TTP episodes with severe ADAMTS13 deficiency are taking part in long-term follow-up programs with regular ADAMTS13 activity measurement. Of 52 patients in this program, 20 (38.5 %) had at least on one occasion in remission a severe ADAMTS13 deficiency, which recovered spontaneously in 75 % of cases. Six patients experienced a relapse on average 4 years after documentation of a severe ADAMTS13 deficiency.

Possible overtreatment is an important aspect because, although rare, the risk of progressive multifocal leukoencephalopathy (PML) seems to be higher in rituximab-treated patients with autoimmune disorders (5/100,000) than in the normal population (0.3/100,000) although no causal association has yet been proven (Molloy and Calabrese 2012). In addition, repeated administration of rituximab has been associated with the development of hypo-gammaglobulinemia in a considerable proportion of patients (Hie et al. 2014; Kaplan et al. 2014; Makatsori et al. 2014) and is associated with increased risk of serious infection (Kaplan et al. 2014; Makatsori et al. 2014). In this context, note that it has not been formally studied whether less-intensive rituximab treatment (i.e., only one or two weekly infusions instead of four) in TTP would result in similar responses as the current regimens employed. The presence of immune complexes between ADAMTS13 and anti-ADAMTS13 antibodies months to years into remission after an acute TTP episode (Ferrari et al. 2014) could represent the missing link to the observed long-term morbidity and reduced life-expectancy in survivors of acute TTP episodes with severe ADAMTS13 deficiency (Deford et al. 2013) and vindicate more aggressive treatment of the ongoing autoimmune response in the future.

In most studies, patients receive four weekly doses of rituximab (375 mg/m^2), following the typical B cell neoplasia regimen of rituximab every seven days. The French TMA reference network has adapted this scheme and administers four doses of rituximab within 15 days from the day a patient

is considered refractory to plasma treatment. In acute TTP, PEX/FFP has usually to be continued following the first rituximab administration(s). Rituximab is removed by PEX. McDonald et al. found that the median fall in rituximab level per PEX session was 65 %, although all patients achieved CD19-positive B cell counts of <1 % (McDonald et al. 2010). Therefore, rituximab is usually given immediately following a PEX session and the next session is protracted as much as possible and timed the next day.

Besides rituximab, splenectomy has been successfully employed in refractory and relapsing TTP for decades. Splenectomy reduces the relapse rate by 85 % and often leads to durable remission (Kremer Hovinga et al. 2004b; Kappers-Klunne et al. 2005; Dubois and Gray 2010), even in rituximab-pretreated patients. It has been shown that the spleen harbors a notable reservoir of pathogenic ADAMTS13-specific switched memory B cells and plasma blasts in frequently relapsing TTP patients treated with or without rituximab (Schaller et al. 2014), providing a rational for splenectomy in frequently relapsing TTP patients.

Personal Approach and Management of TMA and TTP Patients

TTP is a medical emergency with a high mortality rate if appropriate treatment is not quickly initiated. I initiate PEX/FFP in a patient with thrombocytopenia and MAHA (schistocytes on the blood smear, negative direct antiglobulin test, elevated levels of LDH, bilirubin, reticulocytes, and a haptoglobin level below the detection limit) without an apparent alternative explanation for the findings (clinical history, exclusion of disseminated intravascular coagulation).

PEX/FFP has to be performed on several consecutive days; therefore, placement of a central venous catheter is necessary in most cases to facilitate the high volume of plasma exchanged at high rate flow rates. Formally, PEX/FFP can be performed on plasma filtration systems as well as on centrifugal machines. The latter can pack red cells in the machine to a hematocrit of 80 % or higher (compared with 35–60 % in filtration systems) and remove >80 % of plasma. They process ~1.5 patient blood volumes to remove 1.2 plasma volumes, whereas filtration systems need to process three to four patient blood volumes to achieve similar plasma removal. Of note, all published treatment series in TTP have used centrifugal separators (Szczepiorkowski et al. 2010). Furthermore, red cells in TTP are often fragile, particularly at presentation of an acute episode, and tend to be more readily damaged on the membranes of filtration systems. Furthermore, in centrifugal separators, citrate can be used as anticoagulant (compared with heparin in filtration systems), which is a further advantage in severely thrombocytopenic patients. To prevent citrate accumulation and toxicity, which is particularly important when replacing large volumes using FFP, we add a calcium infusion to the return line.

Plasma is currently the only source of ADAMTS13. In TTP, PEX is universally performed with replacement of large volumes of plasma. Which donor plasma product is used has little importance as all plasma products are equally efficacious in TTP. The product used at our hospital for years was FFP, with the addition of solvent/detergent plasma since about 2015. Given the high incidence of an underlying autoimmune pathophysiology in TTP, patients receive corticosteroids (typically 1–2 mg/kg body weight) in addition to PEX/FFP and, as supportive measures, folic acid and a proton-pump inhibitor.

PEX/FFP is performed until a normal platelet count ($>150 \times 10^9$/L) is documented on two consecutive days. Usually, the patient is supervised for a further 2–3 days in hospital. Tapering of steroids is started and is complete after 6–12 weeks. During the first few months, outpatient follow-up with laboratory investigations is every week, then once a month for 2–3 months, and then every 3 months. After 1 year, follow-up visits were extended to once every 6 months and after 2 years to once a year. Recent findings of reduced life expectancy and high morbidity in TTP survivors, as well as more widespread use of preemptive rituximab treatment in patients with reappearance of severe acquired ADAMTS13 deficiency, has resulted in a change in our follow-up program. We now recommend follow-up visits every 3 months long-term, beyond the first year.

Before the administration of any blood products, a sample should be withdrawn for ADAMTS13 activity (and possibly complement factor) determination; however, PEX/FFP should not be delayed until the results are available. My decision to initiate PEX is thus not based on ADAMTS13 activity, but on clinical criteria (platelet count, MAHA, neurologic symptoms) although ADAMTS13 activity level is used as supportive evidence, especially during management and to plan patient follow-up, as relapses happen primarily in patients who initially presented with a severe ADAMTS13 deficiency (Kremer Hovinga et al. 2010). During follow-up, ADAMTS13 activity determination is standard at our center and patients often demonstrate fluctuating levels of ADAMTS13 activity; we have seen spontaneous recovery of severe ADAMTS13 deficiency in two patients. Consequently, so far we have not preemptively treated patients with severe ADAMTS13 deficiency without overt TTP.

Fairly typical in severe acquired ADAMTS13 deficient TTP is the initial response to PEX/FFP, with a clear increase or even normalization of the platelet count, which then drops again, sometimes together with new signs of tissue/organ ischemia after about 1 week. Re-investigation of ADAMTS13

inhibitors typically demonstrates an increase in the inhibitor titers (Fontana et al. 2004), a phenomenon sometimes referred to as inhibitor boosting. This seems to be unique to acquired TTP and is not seen in other autoimmune disorders treated with PEX. Many of these patients become plasma-refractory and require escalation of treatment. A more intense PEX/FFP regimen with increased replacement volume per session (from 1 to 1.5 plasma volumes) and plasma infusions between PEX/FFP sessions is an option, but nowadays these patients usually receive rituximab. As in most other centers, I use the dose established for B cell neoplasias (i.e., 375 mg/m^2) and usually give a complete course of four weekly doses. Because PEX/FFP needs to be continued, at least initially, and rituximab is removed by PEX/FFP, rituximab is administered directly after a PEX/FFP session, and the subsequent PEX/FFP session postponed until the next day to allow as large as possible an interval. Despite the fact that a considerable amount of rituximab is removed by the next PEX/FFP session, complete depletion of peripheral CD19-positive B cells is achieved in virtually all patients.

In patients with an acute TMA episode and a normal or only mildly reduced ADAMTS13 activity and (pronounced) renal involvement, anti-complement treatment is given, especially in children and young adults. In the absence of renal involvement, PEX/FFP is continued for at least another week and the search for an underlying disorder, mainly occult neoplasia, is intensified.

As pointed out before, survivors of acute episodes of TTP and severe acquired ADAMTS13 deficiency are at high risk of subsequent relapse, which occurs in nearly half the patients (Kremer Hovinga et al. 2010). Once a patient presents with a relapse, splenectomy or a more intense immunosuppressive regimen with rituximab, is used to prevent further relapse. Our in-house results on long-term relapse prevention are better with splenectomy, but I leave the choice to the patient, and most prefer to try rituximab first. Rituximab is chosen when other autoimmune disorders (i.e., systemic lupus erythematosus) are present in addition to acquired TTP. During follow-up visits after the first acute episode these possibilities are discussed with the patient, who is vaccinated against pneumococcal and meningococcal infection, as well as *Haemophilus influenza,* as soon as corticosteroids have been sufficiently reduced.

Treatment of Hereditary TTP and aHUS

In hereditary TTP, acute episodes can be effectively prevented by regular plasma infusions every 2–3 weeks (Upshaw 1978). However, the clinical course in the majority of hereditary patients is less predictable except for patients with the p.R1060W mutation, who seem to be largely asymptomatic outside special situations of increased risk such as pregnancy, heavy alcohol intake, or (severe) infection. Although some patients remain asymptomatic for years, others have frequent bouts. The initial notion that, once a first acute episode has occurred, frequent relapses follow does not seem to be true for all patients, making it difficult for the treating physician to decide when to start plasma-prophylaxis to prevent long-term morbidity.

In contrast to hemophilia, where one-third of patients regularly treated with FVIII-containing products develop inhibitory alloantibodies, so far only 1 of about 120 congenital ADAMTS13-deficient patients on regular plasma prophylaxis has been reported to have developed a treatment-relevant inhibitory alloantibody (Raval et al. 2014). Noninhibitory anti-ADAMTS13 antibodies have been observed in some patients on regular prophylaxis; however, these antibodies do not seem to interfere with ADAMTS13 recovery or ADAMTS13 plasma half-life (Fujimura et al. 2011; Kremer Hovinga and Meyer 2008).

Early administration of plasma or plasma-containing blood products is important for successful pregnancy outcomes in hereditary TTP: Fujimura and colleagues reported 15 pregnancies in nine USS patients, resulting in seven (47 %) live births, all preterm except for one in a woman on plasma prophylaxis (Fujimura et al. 2011). Scully and colleagues reported on eight miscarriages and 54 pregnancies in 23 USS patients, six of whom were homozygous and 17 compound heterozygous carriers of ADAMTS13 p.R1060W. Successful outcomes with live-births were noted in 36 (58 %) pregnancies. In 26/36 successful pregnancies, patients had received plasma treatment (Scully et al. 2014). In a population with a somewhat different ADAMTS13 mutational spectrum, von Krogh and coworkers reported a successful outcome of 6/15 (40 %) pregnancies in nine patients (von Krogh et al. 2014).

For many years, plasma therapy was the only option in aHUS because of the lack of anti-complement therapy. Today, the first anti-complement agent, eculizumab, is available and inhibits activation of C5 to C5a and C5b, thereby preventing generation of the terminal complement complex C5b-9. Ecuizumab has been approved by the FDA and EMA for the treatment of aHUS, diagnosed on nonspecific criteria (acute TMA with ADAMTS13 >5 %). Following a number of case reports, prospective studies in predominately adult aHUS patients with long diseases courses, chronic kidney disease, and often overt TMA dependent on regular PEX showed eculizumab to be well tolerated and (very) effective; many patients were able to halt regular plasma therapy (Legendre et al. 2013; Licht et al. 2015).

More single case reports and small case series have been published on successful anti-complement treatment in the absence of complement mutations, in Stx-associated HUS,

transplant rejection, allogenic stem-cell transplantation-associated TMA, and even hereditary TTP. The use of eculizumab outside clinical trials should currently be restricted to patients with an established diagnosis of aHUS, preferably with identified underlying complement mutation(s). The high treatment costs, the fact that eculizumab has to be continued for a very long time (possibly indefinitely), as well as the increased risk of meningococcal infection (requiring vaccination before treatment initiation) all need to be considered.

Novel Drugs Under Evaluation

Von Willebrand Factor A1 Domain Targeted Therapy

Platelet–von Willebrand factor (VWF) interaction is a central paradigm in TTP. Involved moieties are glycoprotein Ib/IX on platelets and the VWF A1 domain. To date, two compounds blocking the VWF A1 domain have been tested in acquired TTP. Development of the first compound, ARC1779, an aptamer specifically binding to the VWF A1 domain, was halted after early termination of the phase II trial as a result of difficulties in patient recruitment (intention to enroll 100, terminated after nine patients were enrolled) and financial issues. Although only seven TTP patients had received ARC1779, proof of principle for the VWF A1 domain blocking approach and valuable information were gained (Jilma-Stohlawetz et al. 2011; Cataland et al. 2012).

The second compound, capalcizumab, is derived from single-chain antibodies naturally occurring in Camelidae. It was assessed in a phase II, multicenter, randomized placebo-controlled study in patients with acquired TTP (the TITAN trial). After randomization (1:1) patients received, besides standard of care, either capalcizumab or placebo in conjunction with, and for 30 days following daily PEX/FFP. Time to platelet recovery was significantly shorter in the capalcizumab compared with the placebo arm and biomarkers reflecting ischemic organ damage tended to normalize more rapidly (Peyvandi et al. 2016). The incidence of exacerbations (defined as recurrence of thrombocytopenia during the period of daily PEX/FFP or within 30 days of stopping PEX/FFP) was reduced in the capalcizumab arm, despite the fact that many patients had persistent severe ADAMTS13 deficiency. The results indicate that the anti-VWF A1 domain compound protects against platelet consumption in the microvasculature. Because the underlying autoimmune disorder is not treated, the increased relapse rate after stopping caplacizumab in this arm was not a surprise. Given the mode of action, bleeding-related adverse events were more common in the caplacizumab arm (53 % versus 38 % in the placebo arm); however, most bleeding events were mild and did not require intervention. Serious bleeding events were similar in both treatment arms. Caplacizumab is currently being further evaluated in a phase III study, the HERCULES trial (clinicaltrials.gov NCT02553317).

Recombinant ADAMTS13 (BAX930)

Lack of ADAMTS13 is the hallmark of hereditary TTP and of most cases of acquired TTP. Early in vitro experiments on hereditary TTP (Antoine et al. 2003) and acquired TTP (Plaimauer et al. 2011) demonstrated that addition of recombinant ADAMTS13 was an effective measure for restoring VWF-cleaving activity in these plasmas, even in the presence of ADAMTS13 inhibitors, where the required amount of recombinant ADAMTS13 was dependent on the titer of the functional ADAMTS13 inhibitor. Subsequently, effectivity and feasibility were proven in various animal models of hereditary and acquired TTP (Schiviz et al. 2012; Plaimauer et al. 2015; Tersteeg et al. 2015). A phase I trial of recombinant ADAMTS13 (BAX930) in patients suffering from hereditary TTP has been performed in 2016 and results are awaited (clinicaltrials.gov NCT02216084).

Anti-complement Agents

A number of studies are underway with different anti-complement agents in aHUS and other complement-mediated disorders. These agents can act through blocking C5 cleavage by C5 convertase (e.g., coversin, which is also effective in patients resistant to eculizumab as a result of *C5* polymorphisms; clinicaltrials.gov NCT02591862), blocking interaction of C5a with its receptor C5aR (e.g., CCX168; clinicaltrials.gov NCT02222155 and NCT02464891), interfering with the lectin pathway (e.g., OMS721, a fully human monoclonal antibody targeting MASP-2; clinicaltrials.gov NCT02222545), or selectively inhibiting components of the classical complement pathway (e.g., TNT009, a selective inhibitor of C1s; clinicaltrials.gov NCT02502903).

Outlook

Evidently, the pathophysiological insights into TTP and HUS gained during the past two decades have already had a tremendous impact on treatment and outcome in affected patients and have helped to remove some of the grimness of these rare diseases. There is, however, ample room for improvement as mortality and long-term morbidity are still considerable. The prospect of a number of promising novel therapies under investigation is very stimulating.

Severe ADAMTS13 deficiency in remission in patients with acquired TTP is a strong risk factor; however, spontaneous recovery of ADAMTS13 activity has been observed in a number of patients (Jin et al. 2008; Lim et al. 2015), and often

a second hit such as infection, regnacy or other events reflected by formation of neurtophile extracellular traps is needed to set off an acute TTP episode (Fuchs et al. 2012; Miyata and Fan 2012). To prevent overtreatment, biomarkers to identify patients at risk of imminent relapse would be highly desirable. This is also true for the positive confirmation of aHUS diagnosis with appropriate biomarkers and identification of patients who would benefit from long-term anti-complement therapy or for whom tapering of such agents would be safely possible. The ultimate goal is to further advance therapeutic regimens in TTP and HUS, thereby improving daily life, long-term outcome, and morbidity in affected patients.

Thrombotic Thrombocytopenic Purpura Foundation (Project ID 1009), by the ISTH 2007 Presidential Fund, and by an investigator-initiated project grant from Baxalta (Project H10-000600) for the hereditary TTP registry (www.ttpregistry.net, ClinicalTrials.gov identifier NCT01257269)

Take Home Messages

1. Acute thrombotic microangiopathies are life-threatening disorders characterized by (severe) thrombocytopenia and microangiopathic hemolytic anemia. Primary forms, thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS), must be distinguished from secondary forms with underlying conditions or disorders.
2. ADAMTS13 activity <10 % of that in normal plasma:
   - Proves a diagnosis of TTP
   - Identifies patients at high risk of relapse
   - ADAMTS13 functional inhibitor or ADAMTS13 antibodies help to distinguish between acquired and hereditary TTP
   - Presence of an ADAMTS13 functional inhibitor or ADAMTS13 antibodies provides the rational for immunosuppressive treatment (corticosteroids, rituximab, splenectomy)
3. At present, ADAMTS13 activity >10 % of normal does not rule out the need for plasma exchange; however, alternative diagnoses have to be looked for and anti-complement treatment should be considered in cases with prominent renal injury.
4. HUS may follow infection by enterohemorrhagic bacteria (diarrhea-positive HUS) or result from excessive activation of the alternative complement pathway as a result of mutations in complement factors or complement regulators.

Thrombocytosis and Essential Thrombocythaemia

Search Strategy and Evidence-Based Diagnosis

Samah Alimam and Claire N. Harrison

Abstract

Thrombocytosis is a common occurrence in general medical and surgical patients and can have a primary or secondary cause. Investigating a patient with thrombocytosis requires a systematic approach. Secondary thrombocytosis is often self-limiting and not associated with any thromboembolic complication or vasomotor symptoms. Essential thrombocythaemia is a clonal myeloproliferative neoplasm, which is associated with broad clinical sequelae and serious complications such as haemorrhage and thrombosis. Discovery of the *JAK2*-V617F, *MPL* and *CALR* genes has deepened understanding of the pathogenesis of the disorder as well as providing targets for therapy and guidance for prognosis. Subjects with essential thrombocythaemia are risk stratified and managed accordingly. Unless contraindicated, antiplatelet therapy is given to all patients and cytoreductive therapy is reserved for those who are high risk (i.e., over the age of 60 years or with previous history of a thromboembolic event).

Introduction

Platelets, first noted by Bizzozero in 1882, are discoid anucleate cell fragments circulating in the peripheral blood. They are responsible for maintaining vascular integrity, haemostasis and assisting with the acute and chronic inflammatory response (Ribatti and Crivellato 2007). Through commitment of multipotent haemopoietic stem cells to the megakaryocyte lineage, circulating platelets are produced, a relationship first described by James Wright in 1906 (Deutsch and Tomer 2006). Haemopoietic stem cells give rise to the early myeloid progenitors; megakaryocytes develop from a committed proliferating progenitor, a colony-forming unit-megakaryocyte. Once the colony-forming unit-megakaryocytes stop proliferating, they enter endomitosis (undergo DNA replication in the absence of cellular division), giving rise to classical polyploid cells with a single polylobulated nucleus – mature megakaryocytes (Cazzola 2008).

With increasing access to diagnostic techniques in medicine, thrombocytosis is a commonly encountered clinical phenomena; the defined threshold for clinically significant thrombocytosis is accepted as a sustained platelet count greater than 450×10^9/L (Schafer 2004; Harrison et al. 2010). Depending on pathogenesis, it can be defined as primary, secondary or, in a small number of individuals, as hereditary thrombocytosis (Fig. 1). Because the diagnosis has implications for long-term management and prognosis, it is imperative to establish the cause in a subject with a persistent thrombocytosis.

Platelet production is regulated by the action of thrombopoietin interacting with its receptor. Thrombopoietin has a central role in megakaryocytopoiesis (platelet production) and thrombocytosis. Through binding to the thrombopoietin receptor, MPL (also termed c-MPL; cellular homologue of retrovirus complex inducing myeloproliferative leukaemia, CD110), thrombopoietin signals to the haemopoietic stem cells to commit to the megakaryocyte progenitor cell line and stimulates the proliferation and differentiation of megakaryoblasts into megakaryocytes. The thrombopoietin

The data in this chapter is supported by a Medline search using the following key words: platelets, thrombocytosis, thrombopoietin, essential thrombocythaemia, myeloproliferative neoplasms, *JAK2*, *CALR*, *MPL*, epigenetics, risk stratification, thrombosis, haemorrhage and cytoreductive therapy.

receptor is expressed on CD34-positive cells, megakaryocytes, platelets and endothelial cells. Platelet production is driven by the combined effects of satisfactory thrombopoietin gene expression, thrombopoietin concentration and adequate number of c-MPL-bearing cells (Fig. 2a). Thrombopoietin is expressed primarily by the liver, but also by the kidney, spleen and bone marrow. When platelet numbers are low, plasma levels of thrombopoietin increase to expand megakaryocytopoiesis and platelet production (Fig. 2b, c); thrombopoietin enhances megakaryocyte proliferation through JAK2 (Janus kinase 2) and STAT5 (signal transducer and activator of transcription 5) activation. Likewise, when the platelet count rises, more thrombopoietin binds to platelet c-MPL receptors and less ligand is available for megakaryocyte receptors, leading to slowed megakaryocytopoiesis (i.e., negative feedback loop) (Cazzola 2008).

In the normal state, liver is the predominant thrombopoietin-producing organ, with little influence from external signals (Jelkmann 2001). In steady state, the plasma level of thrombopoietin is low at 10–12 mol/L. Unlike hepatic thrombopoietin, bone marrow stromal cells respond to thrombocytopenia and upregulate thrombopoietin gene expression. Functional thrombopoietin receptors remove thrombopoietin via absorption and internalisation of the cell surface complex.

Secondary Thrombocytosis

The key driver of secondary thrombocytosis is often an inflammatory or reactive process. Patients are usually diagnosed coincidentally and are often asymptomatic. Secondary thrombocytosis has a lower incidence of complications than primary thrombocytosis. In a study of 890 subjects, Rose and colleagues described secondary thrombocytosis to be the principal diagnosis in over 94 % of subjects, with an infectious aetiology contributing to over 50 % of cases (Rose et al. 2012). Because platelets are key acute-phase reactants, their number increases in response to various stimuli, including infections, inflammatory conditions and bleeding, all of which can cause a short-term elevation of platelet count. In chronic infections, iron deficiency and neoplasms, the thrombocytosis may be more persistent (Griesshammer et al. 1999). Secondary thrombocytosis in children is also driven by similar reactive causes, although in certain population groups haemolysis secondary to thalassemia or sickle cell disease must be also be considered. As the differential diagnosis is broad, it is not surprising that any investigation of thrombocytosis must begin with exclusion of potential secondary causes, as outlined in Fig. 1; this requires a though history and examination of the patient, in addition to review of all full blood count and biochemistry parameters before exclusion of an underlying clonal disorder.

The pathophysiology of secondary thrombocytosis is as varied as the differential diagnosis. The inverse relationship between platelet count and thrombopoietin in healthy subjects is lost in secondary thrombocytosis, where levels of the hormone are higher than expected (Cerutti et al. 1997). A number of studies have suggested that thrombopoietin behaves as an acute-phase protein and its increase is responsible for thrombocytosis (Ceresa et al. 2007). Furthermore, acute-phase inflammatory mediators such interleukin (IL)-1, IL-4, IL-6, IL-11 and tumour necrosis factor (TNF) are all involved in stimulating megakaryocytopoiesis via hepatic

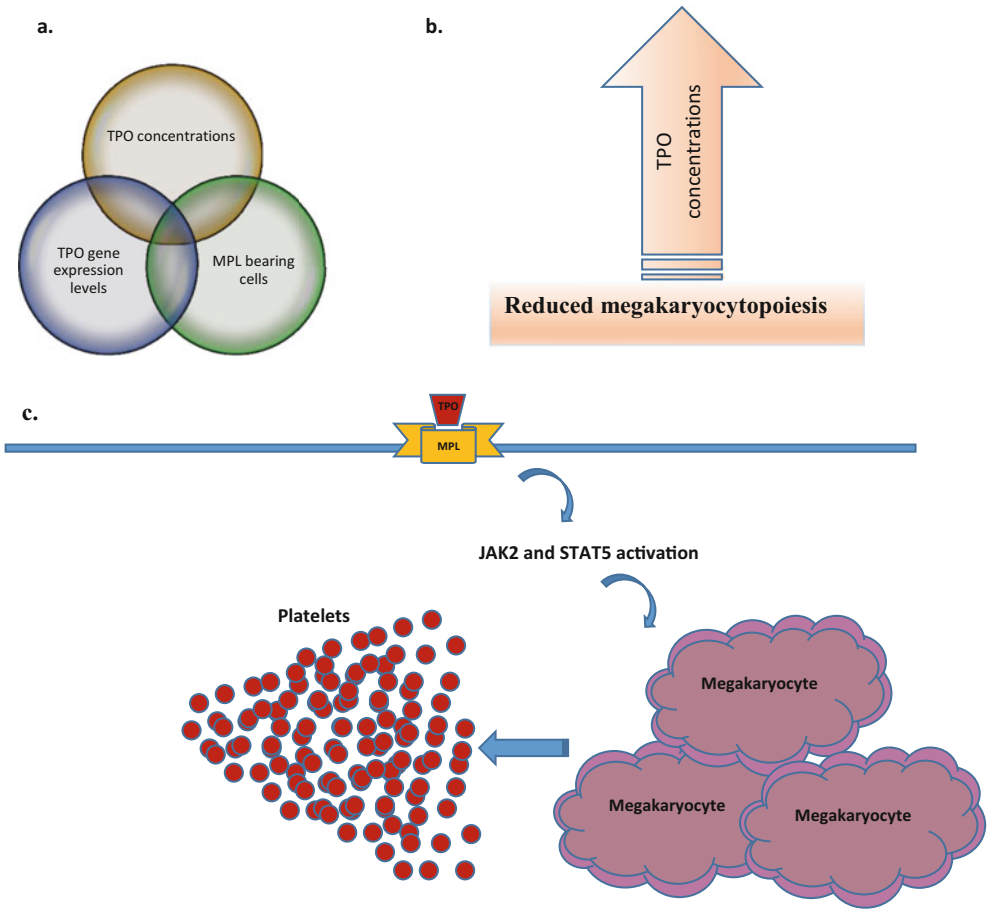

Fig. 2 (**a**) Key components in platelet production and thrombocytosis. (**b**) Response of thrombopoietin to reduced megakaryocytopoiesis. (**c**) Action of thrombopoietin on MPL, leading to megakaryocyte proliferation and platelet production. *TPO* thrombopoietin, *MPL* thrombopoietin receptor, *JAJ2* Janus kinase 2, *STAT5* signal transducers and activators of transcription 5

thrombopoietin production (Avraham 1993; Ceresa et al. 2007). A number of studies have demonstrated that subjects with secondary thrombocytosis have elevated levels of IL-6, C-reactive protein (CRP), ferritin and other acute-phase reactants compared with clonal thrombocytosis. Tefferi and colleagues noted that over 75 % of subjects with secondary thrombocytosis had elevated CRP levels compared with 10 % of clonal thrombocytosis patients (Tefferi et al. 1994). Therefore, thrombopoietin behaves as an acute-phase protein and is involved in thrombocytosis of inflammatory disorders; other acute-phase reactants cooperate with thrombopoietin in inducing an elevated platelet count (Ceresa et al. 2007) (Fig. 3).

Iron deficiency is a common cause of thrombocytosis; although the pathophysiology remains unclear, elevated erythropoietin levels have been reported (Akan et al. 2000; Balcik et al. 2002). A number of investigators have assessed the effect of erythropoietin on the thrombopoietin receptor (MPL). Although it does not interact directly with MPL, erythropoietin may enhance the effect of thrombopoietin, stimulating platelet production (Broudy et al. 1995; Balcik et al. 2002). Routine investigations to exclude an underlying iron deficiency are therefore fundamental in any diagnostic work-up for thrombocytosis; however, the presence of iron deficiency does not exclude clonal thrombocytosis.

Although, the clinical complications seen with primary thrombocytosis are less frequent in reactive thrombocytosis, a number of studies have shown that thrombocytosis is an independent risk factor for thromboembolic events in cancer subjects (Zakai et al. 2004; Khorana et al. 2005). Not surprisingly, management of secondary thrombocytosis centres on treating the underlying cause and management of any potential complications.

Spurious Thrombocytosis

Spurious thrombocytosis is a rare cause of elevated platelet count; it is characterised by the presence of platelet-like structures in the peripheral blood. Some automated blood counters report these structures as platelets and therefore produce an incorrect count. Many pathogens, cryogloblins and red blood cell fragments can be misread as platelets. A peripheral blood smear and thorough history should be sufficient to make this diagnosis.

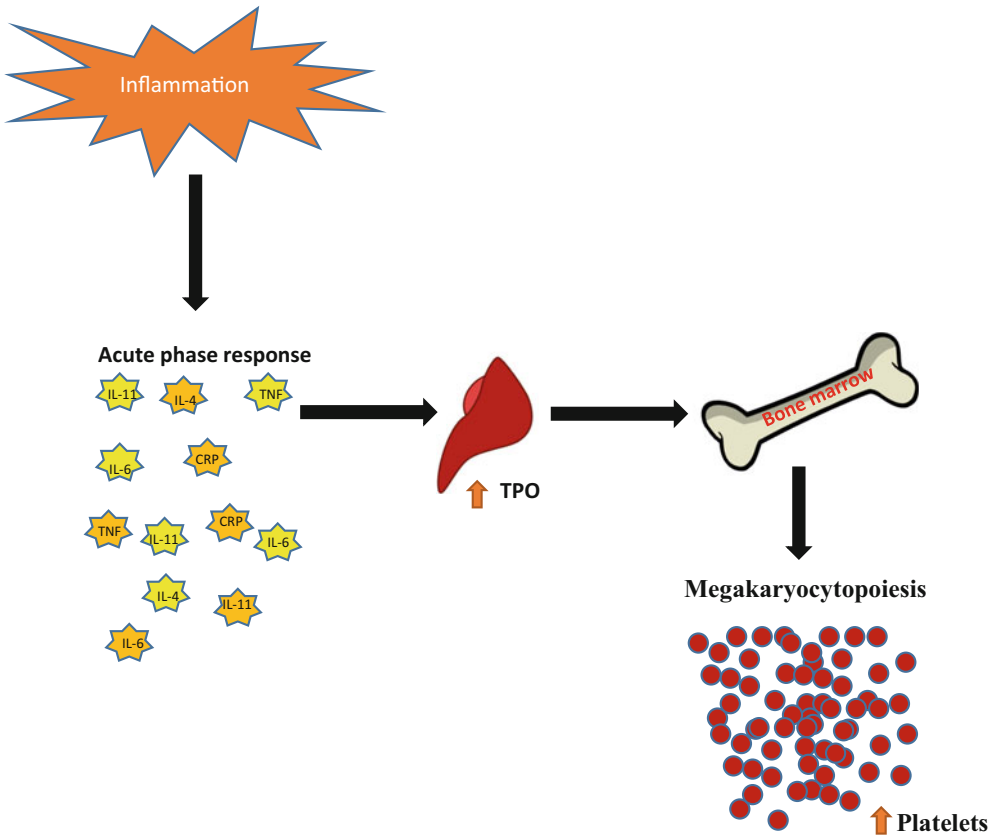

Fig. 3 Proposed mechanism for reactive thrombocytosis. Proposed mechanism of increased thrombopoietin (*TPO*) production in response to inflammatory mediators such as IL-2, IL-4, IL-6, IL-11, tumour necrosis factor (*TNF*) and C-reactive protein (*CRP*), resulting in enhanced megakaryocytopoiesis and increased platelet production

Hereditary Thrombocytosis

Hereditary thrombocytosis (HT) is a polyclonal, heterogeneous autosomal dominant disorder that results in overactivation of the thrombopoiesis pathway, resulting in thrombotic and haemorrhagic complications similar to those seen in essential thrombocythaemia (Skoda and Prchal 2005). Germline mutations in families with hereditary thrombocythaemia have been identified in the *MPL* gene encoding the thrombopoietin receptor. The first *MPL* mutation described was that of substitution of serine in position 505 with asparagine (S505N) in the transmembrane domain of MPL protein, discovered in a family with autosomal dominant thrombocytosis (Skoda 2009). The other commonly described mutations are outlined in Table 1.

The mutations in *MPL* result in loss of the inhibitor upstream reading frames, resulting in increased production of thrombopoietin and, consequently, of platelets (Ghilardi and Skoda 1999). Not all mutations arise within the thrombopoietin receptor or *MPL* gene. Mead and colleagues reported a germline *JAK2*-V617L mutation in a British patient with thrombocytosis and cardiovascular events, and no bone marrow changes suggestive of myeloproliferative neoplasms (Mead et al. 2012); this highlights the number of potential gene mutations contributing to thrombocytosis. However, less than 10 % of pedigrees have a known mutation because, although some disease-causing genes have been reported, the majority remain unidentified (Skoda 2009). There have been infrequent reports of progression

Table 1 Common mutations described in hereditary thrombocytosis (Skoda 2009; Mead et al. 2012)

of thrombocytosis to myelofibrosis and acute myeloid leukaemia in subjects with HT (Posthuma et al. 2010)

Clonal Thrombocytosis

Figure 1 outlines the differential diagnosis of clonal thrombocytosis. Clonal thrombocytosis should be a diagnosis of exclusion when there is persistent thrombocytosis in the absence of reactive causes and/or presence of a clonal marker. The following section focusses on myeloproliferative neoplasms and essential thrombocythaemia.

Myeloproliferative Neoplasms

Myeloproliferative neoplasms (MPNs) are characterised by clonal expansion of the different myeloid cells, the commonest forms being essential thrombocythaemia (ET), polycythaemia vera (PV), primary myelofibrosis (PMF) and Philadelphia-positive chronic myeloid leukaemia (CML), in addition to the other disorders outlined in Fig. 4. Although all MPN disorders are phenotypically diverse, thrombocytosis can be a feature of any MPN. During the last 20 years there have been major advances in the understanding of MPNs and description of a number of acquired mutations that drive disease pathogenesis. This chapter focusses on ET; however, it is important in the diagnostic work-up to consider all the MPNs.

The MPNs overlap in phenotype and mutational drivers. CML is a MPN defined by the *BCR-ABL* fusion gene, arising from the Philadelphia translocation, and must not be missed in the diagnostic work-up of any thrombocytosis. PV and PMF share the same clonal markers as ET and are distinguished clinically, biochemically and histologically. The hallmark of PV is erythrocytosis with an elevated haematocrit, whereas PMF is characterised histologically by bone marrow fibrosis and, in advanced disease, profound constitutional symptoms.

Essential Thrombocythaemia

Essential thrombocytosis (ET) was first described in 1934 by Epstein and Goedel. ET is a Philadelphia-negative MPN characterized by persistent thrombocytosis (Epstein and Goedel 1934). It is commonly diagnosed in the sixth decade of life and has an incidence of 0.4–2.5 per 100,000 per year (Rozman et al. 1991). ET has a higher prevalence in females, with a second peak in women in the third decade of life. ET is extremely infrequent in childhood; diagnoses in rare cases occur in the second decade of life (Dame and Sutor 2005). Life expectancy is normal and mirrors the general population in the first decade of diagnosis. However, ET is associated with thromboembolic complications, progression to myelofibrosis and acute myeloid leukaemia, with reduced life expectancy after the first decade (Wolanskyj et al. 2006; Barbui et al. 2011).

ET is characterised by clonal proliferation by mutually exclusive mutations in *JAK2*, calreticulin (*CALR*) or *MPL*; however, a proportion of subjects do not harbour an identified mutation and are termed "triple negative" (TN). The diagnosis of ET is based on the WHO criteria, which encompasses laboratory, molecular, clinical and histological criteria as outlined in Fig. 5. In addition to thrombocytosis, ET can be associated with an elevated white cell count, which has prognostic significance. ET must be distinguished from PV, early pre-fibrotic myelofibrosis and myelodysplastic syndrome. Low ferritin in the presence of normal haemoglobin levels points to a diagnosis of PV, whereas anaemia, splenomegaly and elevated lactate dehydrogenase, or a leucoerythroblastic peripheral smear with or without teardrop poikilocytes, suggest myelofibrosis. Bone marrow histology aids in differentiating between the three pathologies,

ET has a heterogeneous clinical phenotype, ranging from the asymptomatic patient to profound symptomology impacting considerably on quality of life. The clinical course of ET manifests with microcirculatory disturbances and arterial and venous thromboses (Landolfi et al. 2008). Microcirculatory disturbances, arising from platelet thrombi in end arterial circulations, result in vasomotor symptoms, often presenting as erythromelagia, headaches, visual disturbances and chest pain (van Genderen and Michiels 1997; Michiels et al. 2006). Splenomegaly, weight loss, fatigue and pruritus are other frequent clinical presentations.

I.	Sustained platelet count > 450 x 10^9/l.
II.	Bone marrow biopsy demonstrating proliferation of megakaryocytes with increased number of enlarged and mature forms. No significant increase of left shift of granulopoiesis or erythropoiesis.
III.	Not meeting WHO criteria for PV, PMF, CML, MDS or other myeloid neoplasm.
IV.	Presence of *JAK2*V617F, *CALR* or other clonal marker or no evidence of reactive thrombocytosis.

Fig. 5 WHO criteria for diagnosis of essential thrombocythaemia; all four components must be met (Vardiman et al. 2009). *PV* polycythaemia vera, *PMF* primary myelofibrosis, *CML* chronic myeloid leukaemia, *MDS* myelodysplastic syndrome

Arterial and venous thromboses are serious complications of ET and are described in up to 25 % of patients. Arterial thrombosis presenting as stroke or transient ischemic attack is the most common, although peripheral vascular and coronary artery thromboses are also well described. Venous thrombosis usually occurs in unusual sites such as cerebral sinus and splanchnic veins. The risk of thrombosis remains high throughout the disease state and risk of recurrent thromboembolic events is as high as 20 % (Wolanskyj et al. 2006). It is interesting to note that there is an absence of correlation between platelet count and vasomotor symptoms or thromboembolic complications (Campbell et al. 2012). Enhanced platelet, leukocyte and endothelial activation has been consistently demonstrated in ET subjects and is the proposed pathogenetic link between activated platelets and thrombotic complications (Patrono et al. 2013).

Thrombocytosis, paradoxically, is also associated with bleeding complications. Over 10 % of subjects develop a major haemorrhagic event, including gastrointestinal, intracranial and urogenital bleeding (Finazzi et al. 2012). A number of studies have demonstrated impaired platelet function in ET subjects (Finazzi et al. 1996; Trelinski et al. 2008), although these do not correlate well with bleeding risk. Furthermore, extreme thrombocytosis is a cause of acquired von Willebrand disease as a result of increased adsorption of the large multimers, which can further exacerbate the risk of bleeding.

Evolution of ET to post-ET myelofibrosis occurs in up to 30 % of subjects, with risk increasing after the second decade (Wolanskyj et al. 2006; Passamonti et al. 2008). Bone marrow histology is crucial in confirming the transformation. Progression to acute myeloid leukaemia, diagnosed in the presence of >20 % blast cells in the peripheral blood smear or bone marrow aspirate, is noted in less than 10 % of subjects; however, the risk increases with advancing age and with previous cytoreductive therapy (Kiladjian et al. 2006; Wolanskyj et al. 2006; Passamonti et al. 2008).

Histology

The peripheral film smear is usually normal in ET; any evidence of left shift, teardrops or dysplasia suggests an alternative diagnosis. Bone marrow histological confirmation of the underlying pathology remains integral in the diagnosis of MPNs and specifically in distinguishing between the three Philadelphia-negative MPNs in view of their overlapping phenotype. ET histology is characterised by the presence of single or clustered large to giant mature megakaryocytes with deeply lobulated staghorn-like nuclei, normal or slightly increased cellularity and the absence of or minimum reticulum fibrosis (Fig. 6) (Vardiman et al. 2009; Harrison et al. 2010). Dysplastic megakaryocytes, erythroid hyperplasia and significant reticulum fibrosis are against the diagnosis of ET and suggest a diagnosis of PV, PMF or myelodysplastic syndrome. Because of the subjective nature of bone marrow pathology and interpretation, it is advisable to avoid categorising into pre-fibrotic MF versus true ET unless other features are present. It is better to focus on establishing a firm diagnosis of one or other because it has a considerable impact on prognosis and management (Wilkins et al. 2008).

Janus Kinase 2

The Janus kinase family of tyrosine kinases includes *JAK1*, *JAK2*, *JAK3* and *TYK2*. JAK is characterized by four functional domains: FERM, SH2, pseudokinase (JH2) and the tyrosine kinase domain (JH1) (Fig. 7). The JH2 domain lacks kinase activity and therefore acts as a negative regulator of JAK protein kinase function (Jatiani et al. 2010). The JAK proteins play important roles in hematopoietic cell signalling by the cytokines, erythropoietin, thrombopoietin, granulocyte macrophage colony-stimulating factor, and granulocyte colony-stimulating factor receptors in hematopoietic cells. Signalling is activated when these receptors bind their

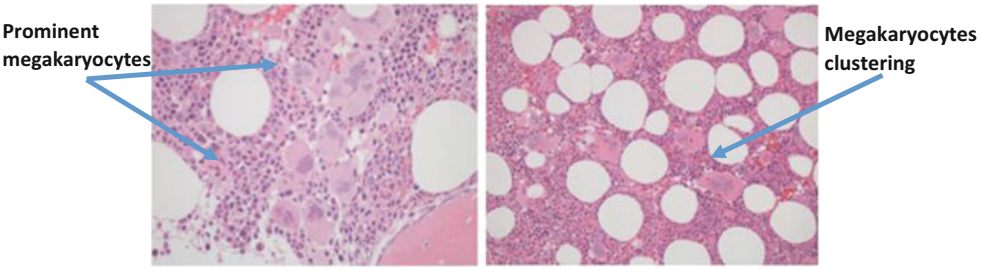

Fig. 6 Classical histological features of bone marrow trephine in essential thrombocythaemia, demonstrating prominent (*left*) and clustered (*right*) large megakaryocytes

Fig. 7 Janus kinase, demonstrating the four domains and site of *JAK2*-V617F mutation (Jatiani et al. 2010). *PK* phosphokinase, *TK* tyrosine kinase

cognate ligands (Spivak 2010), resulting in phosphorylation and subsequent activation of their downstream transcription factors, STATs. The activated STATs dimerise and translocate to the nucleus, where they activate or repress target gene promoters, as shown in Fig. 8 (Jatiani et al. 2010).

The acquired gain-of-function mutation in exon 14 of the *JAK2* gene, with a substitution of a valine for a phenylalanine at position 617 (V617F) in the negative autoregulatory JH2 pseudokinase domain (Baxter et al. 2005), has become instrumental in the understanding of MPN pathophysiology. The mutation disrupts the inhibitory role of the JH2 domain on the JH1 domain, whereby the activation loop of JH1 adopts a conformation such that it can be phosphorylated by an adjacent *JAK2*-V617F molecule (Baxter et al. 2005; Jatiani et al. 2010). This promotes cell proliferation and resistance to cell death, as well as hypersensitivity to hematopoietic growth factors and cytokines signalling through receptors utilising JAK (Spivak 2010).

The *JAK2*-V617F mutation is prevalent in up to 50 % of ET subjects (Antonioli et al. 2005). More recently, mutations outside of exon 14 and 12 (more commonly seen in PV), *JAK2*-V625F and *JAK2*-F556V, have been discovered in subjects with ET. Although both are gain-of-function mutations that result in activation of the JAK–STAT pathway, their clinical significance and correlations remain under scrutiny (Milosevic Feenstra et al. 2015). Germline *JAK2* mutations have also been described in familial thrombocytosis, as discussed earlier in the chapter.

ET subjects with *JAK2*-V617F are older, with higher haemoglobin and white cell count, and lower platelet and serum erythropoietin levels than those with *CALR* mutations (Rumi et al. 2014). The *JAK2* allele burden has not demonstrated any survival impact or transformation to leukaemia, although an increase in allele burden is associated with a higher incidence of splenomegaly, transformation to myelofibrosis and increased incidence of arterial embolic events.

Thrombopoietin Receptor

As described previously, proliferation and differentiation of *MPL* is regulated by thrombopoietin. ET subjects have a somatic gain-of-function mutation in exon 10 of *MPL*, resulting in substitution of tryptophan at codon 515 with leucine (*MPL*-W515L), lysine (*MPL*-W515K) or alanine (*MPL*-W515A) (Skoda 2009). The mutation, located within the juxtamembrane region of the protein, causes activation of the receptors in the absence of ligand, resulting in exaggerated cytokine-independent growth and hypersensitivity with overphosphorylation of the JAK2, STAT3 and STAT5 proteins. A number of additional somatic mutations have also been described in ET, including W515S, W515R, S204P, L510P, A519Y and S505N, commonly seen in familial thrombocytosis. Further mutations outside exon 10 of *MPL*, including T1191, S204F and Y591D, are all gain-of-function mutations, although their clinical significance remains unclear (Skoda 2009; Milosevic Feenstra et al. 2015)

The *MPL* mutations are found in 3–5 % of ET subjects, who are usually older with more marked thrombocytosis, lower haemoglobin and reduced bone marrow cellularity compared with triple-negative ET subjects or those harbouring a *JAK2* or *CALR* mutation (Nangalia and Green 2014). To date, there is no evidence in the literature to suggest a survival difference between subjects who harbour the *MPL* mutation and those with a *JAK2* or *CALR* mutation (Nangalia and Green 2014).

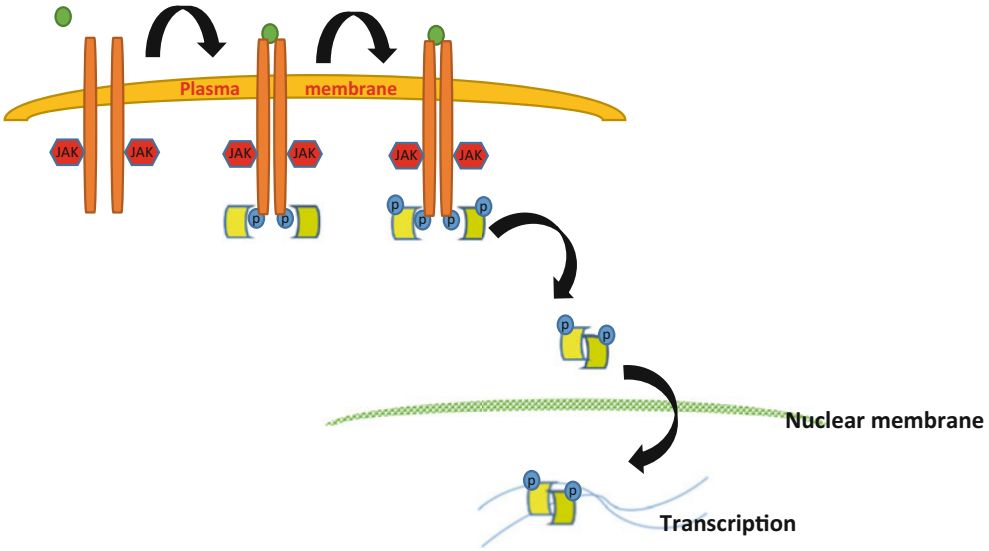

Fig. 8 Tyrosine kinase activity of the JAK pathway. Tyrosine kinase is activated when a regulatory molecule ( ) binds and the two cytokine receptor molecules ( ) come closer, bringing the JAK molecules ( ) together. This leads to phosphorylation, which further activates JAK and phosphorylates the receptors, leading to binding of STAT ( ). When STAT binds to the receptor, it is also phosphorylated by JAK. Once phosphorylated, the STATs combine to form a dimer and an active transcription factor. indicates phosphorylation

Calreticulin

This decade has seen a great shift in the understanding of MPN, with the discovery of somatic frame shift mutations at exon 9 of the *CALR* gene (Nangalia et al. 2013). CALR is an endoplasmic reticulum calcium-binding chaperone. A number of mutations within exon 9 of the *CALR* gene have been described, including type 1 (52 base pair insertion) and type 2 (5 base pair insertion) mutations; other minor mutation anomalies have also been described, such as 46 and 48 base pair deletions (Palandri et al. 2015). All mutation types result in a single base pair frameshift and alteration of the C-terminal sequence of the protein. Consequently, mutant proteins lack the usual C-terminal endoplasmic retention signal, resulting in disturbances in calcium binding (Nangalia et al. 2013). Although the mechanism of how *CALR* mutations drive the pathogenesis of ET remains unclear, JAK–STAT hyperactivation remains integral to the disease process (Rampal et al. 2014); for example, mutant *CALR* has been demonstrated to drive the JAK2–STAT pathway via activation of the thrombopoietin receptor (Chachoua et al. 2015).

CALR mutations account for approximately 30 % of cases of ET. Both variants of *CALR* mutations are associated with a higher platelet count, lower haemoglobin and lower leukocyte count than *JAK2* mutations (Rotunno et al. 2014; Rumi et al. 2014). More specifically, male gender is associated with type 1 *CALR* mutations and younger age with type 2 variants; furthermore, platelet count is significantly higher in subjects with type 2 versus type 1 *CALR* mutations. Long-term analyses have not demonstrated any differences in overall survival between ET subjects with *CALR* mutations and those with *JAK2* or *MPL* mutations.

Triple Negative

Subjects who lack the *JAK2*, *CALR* and *MPL* mutations are termed triple negative (TN); their diagnosis is through clinical and histological findings. TN subjects can have mutations outside the usual driver mutations sites or have a hereditary element to their disease (Milosevic Feenstra et al. 2015). Long-term outcome remains unclear; although subjects have fewer thromboembolic events, there is a suggestion of higher rates of blast transformation (Tefferi et al. 2014). It is interesting to note that, in this cohort, hyperactivity of the JAK–STAT pathway has been demonstrated despite the absence of a driver mutation (Rampal et al. 2014).

Epigenetic Regulators

Somatic mutations in the genes implicated in epigenetic regulation have become integral in understanding the complexity of MPNs. Regulators of DNA methylation and chromatin structure in haematopoietic progenitors are mutated in

a number of myeloid malignancies, including MPNs (Nangalia and Green 2014). Unlike mutations in *JAK2*, *CALR* and *MPL*, which are usually mutually exclusive, mutations in epigenetic regulators can co-occur with these so-called phenotypic driver mutations. Epigenetic modifiers include tet methylcytosine dioxygenase 2 (TET2), isocitrate dehydrogenase 1 (IDH1), IDH2, additional sex combs-like 1 (ASXL1), enhancer of zeste homologue 2 (EZH2) and DNA methyltransferase 3A (DNMT3A). DNA methylation has an important role in cell differentiation, as it can regulate the expression of particular genes without affecting the DNA sequence. Because it is reversible, DNA methylation has a potential role in targeted therapy (Milosevic and Kralovics 2013). The TET protein first identified less than a decade ago is responsible for the conversion of 5-methylated cytosine into the hydroxymethylated form and is mutated in 4 % of ET subjects. Although, overall, TET mutation is associated with increased risk of disease transformation, its specific effect in ET remains unknown (Tefferi et al. 2009; Nangalia and Green 2014). Mutations in IDH1/2, which catalyze conversion of isocitrate to alpha-ketoglutarate, occur in less than 1 % of ET patients. Such mutations are a predictor of overall poor survival and increased risk of transformation to leukaemia. Mutations in DNMT3A, a DNA methyltransferase, and ASXL1, an activator and inhibitor of transcription, are seen in as many as 5–8 % MPN subjects; however, both are more common in PMF (Milosevic and Kralovics 2013).The order of acquisition of such mutations is of great interest and now widely accepted to have significant clinical implications; for example, subjects in whom *JAK2* mutation is acquired first are more likely to develop PV and have higher risk of thrombosis than subjects that acquired the *TET2* mutation first (Ortmann et al. 2015) .

Risk Stratification

Risk stratification forms an important basis for discussion of prognosis with subjects and planning for initiation of therapy (see Fig. 9). It should be a tailored approach. Because of the increased thromboembolic risk associated with advancing age, subjects over the age of 60 years or with a prior thrombohaemorrhagic event fall into the high risk category, regardless of symptoms (Tefferi et al. 2001; Marchioli et al. 2005). The low risk category includes subjects under the age of 60 years, platelet count less than 1500×10^9/L and without a history of thromboembolic events. The intermediate category is compiled of subjects who are between the ages of 40 and 60 years and have no previous thromboembolic events but might possess one or more cardiovascular risk factors (Harrison et al. 2010; Barbui et al. 2011).

Activated granulocytes have a central role in endothelial injury so it is not surprising that a high white cell count is associated with an increased risk of thrombosis (Carobbio et al. 2008; Landolfi et al. 2008). This was highlighted in a number of studies, including the PT-1 study, where a white cell count within the upper limit of normal was associated with a greater incidence of thrombotic events (Campbell et al. 2012). The IPS-ET thrombosis model, currently under evaluation, further builds on this and incorporates the presence/absence of the *JAK2*-V617F mutation to predict survival (Barbui et al. 2012; Passamonti et al. 2012). The role of *JAK2* mutation in thrombotic risk is still under discussion; however, the accepted consensus is that *JAK2* mutation is associated with an increased risk of thrombosis, especially compared with subjects harbouring the *CALR* mutation (Cheung et al. 2006; Rumi et al. 2014). It is foreseeable that mutational status, including *CALR*, *MPL* and epigenetic markers, will come to play a central role in prognosis and in guiding pharmacological management.

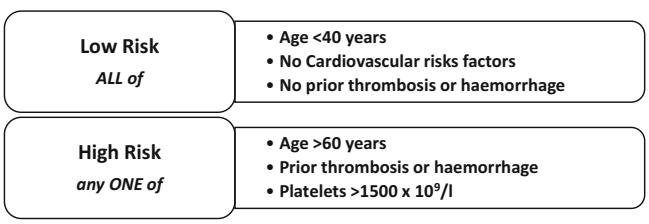

Fig. 9 Risk stratification in essential thrombocythaemia (Harrison et al. 2010)

Treatment

Risk stratification guides treatment strategies for patients with ET (Fig. 9). Antiplatelet therapy (low dose aspirin) is recommended for all patients where there are no contraindications (Harrison et al. 2010). In view of the bleeding risk in extreme thrombocytosis (platelet count $>1000 \times 10^9$/L), antiplatelet therapy should only be used with caution. Cytoreductive therapy is indicated in high-risk patients, as outlined above.

Initiation of cytoreductive therapy is dependent on risk stratification, profound constitutional symptom burden and tolerability of therapy. Subjects above the age of 60 years should be offered hydroxycarbamide, a drug that has proven efficacy in high-risk patients (Cortelazzo et al. 1995; Harrison et al. 2005). Hydroxycarbamide is well tolerated, although it continues to be associated with mouth and leg ulcerations, immunosuppression, nail changes and conflicting reports of increased risk of leukaemia. It is teratogenic and should be avoided in men and women who are of childbearing age. In older patients who are intolerant of other therapies, radioactive phosphorus and busulphan can

	<60 years	> 60 years
•**First line**	•Interferon	•Hydroxycarbamide
•**Second line**	•Anagrelide •Hydroxycarbamide	•Buslphan •Anagrelide •Pipobroman •Intrferon

Fig. 10 Summary of cytoreductive drugs used in essential thrombocythaemia

be used; however, both can increase the risk of progression to acute leukaemia over a period of long-term use.

In high-risk patients under the age of 60 years, the favoured regimens are anagrelide or interferon, or indeed hydroxycarbamide (Fig. 10). Anagrelide has demonstrated benefit in platelet control (Gisslinger et al. 2013). It is reserved for younger patients and those without cardiovascular compromise, because of the side effects of arrhythmias. Anagrelide is also associated with a risk of bone marrow fibrosis and progression to MF (Campbell et al. 2009). Interferon alpha, usually delivered in injectable form, has demonstrated efficacy in improving platelet count, constitutional symptoms and splenomegaly and in reducing JAK2 and CALR allele burden (Tefferi and Barbui 2015). It can be associated with side effects such as flu-like symptoms and mood and endocrine disturbances.

How to Approach a Case of Thrombocytosis

In the clinical setting it is important to distinguish reactive and spurious thrombocytosis from clonal thrombocytosis, as summarised in Fig. 11. A thorough history and examination can help guide initial investigations. Evidence of raised acute-phase reactants, inflammation, bleeding or recent surgery suggests that reactive thrombocytosis is a possibility, although it does not exclude an underlying MPN. Low serum ferritin is indicative of iron deficiency, which should be corrected and platelet count monitored; in addition, it is important to monitor the haematocrit because an elevation after correction of iron deficiency suggests PV as a diagnosis. The peripheral blood smear is invaluable in guiding the diagnostic pathway. If there is evidence of a leucoerythroblastic film or dysplasia, a MPN or MDS diagnosis should be sought and molecular analysis with bone marrow investigations undertaken early. If platelet count remains elevated, molecular analysis of *JAK2*-V617F, *CALR* and *MPL* are recommended; identification of a mutation does not always distinguish ET from other MPN disorders so bone marrow histology and cytogenetics are recommended, especially in the presence of abnormal peripheral blood film. If the bone marrow histology reveals fibrosis, WHO grade $\geq$1 myelofibrosis must be considered. If there is evidence of dysplasia or ring sideroblasts, myelodysplastic syndrome is another potential diagnosis. Where there is absence of mutation and MPN remains a suspected diagnosis, bone marrow histology and cytogenetics should be performed. It is important to always consider the possibility of CML, so analysis of BCR-ABL should be performed where there is strong suspicion or where diagnosis is unclear. The role of epigenetic mutation analysis in the clinical setting remains undetermined.

In subjects who have a prolonged history of thrombocytosis with a family history, hereditary thrombocytosis should be considered and investigation undertaken for the mutations outlined in Table 1.

Summary

- Thrombocytosis is frequently encountered in medical and surgical subjects; it is cytokine mediated and reversed on cessation of cause.
- Reactive thrombocytosis is not associated with the same clinical sequelae as those seen in myeloproliferative neoplasms.
- Hereditary thrombocytosis is a rare cause of familial thrombocytosis and is associated with mutations in the thrombopoietin receptor and *JAK2* gene.
- There are a number of clonal causes for thrombocytosis, including essential thrombocythaemia (ET), polycythaemia vera and myelodysplastic syndrome.
- ET is a clonal myeloproliferative neoplasm.
- Common driver mutations in ET include *JAK2*-V617F, *MPL*-W515L/K and *CALR*.
- *JAK2*-positive subjects are older, have higher platelet counts and lower haemoglobin levels and are at increased risk of thrombosis.
- *CALR*-positive subjects are younger, have lower haemoglobin levels and higher platelet counts.
- Epigenetic mutations have an increasing role in diagnosis and prognostication.

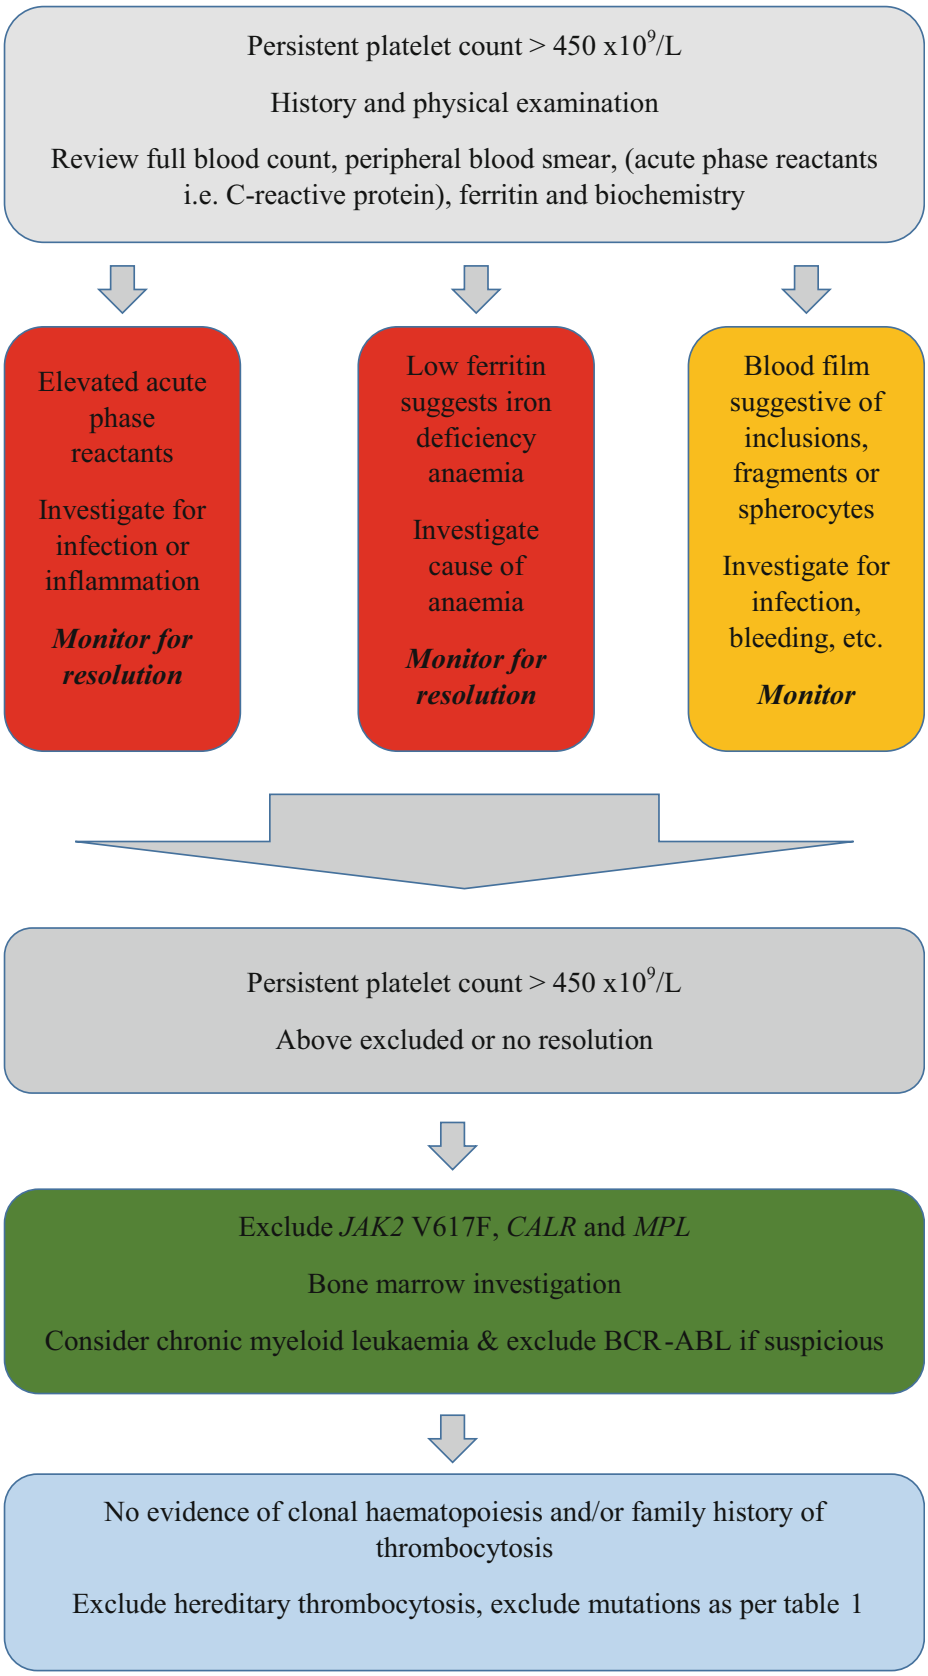

Fig. 11 Diagnostic pathway for investigating a patient with thrombocytosis

- Age over 60 years, cardiovascular risk factors, high leukocyte count and presence of the *JAK2*-V617F mutation are independent predictors of thromboembolic events.
- ET subjects over the age of 60 years or those with a previous history of thromboembolic or haemorrhagic event are classified as high risk.
- Treatment of ET is based on risk stratification. All patients, unless contraindicated, should be offered antiplatelet therapy (i.e., aspirin 75 mg daily). Cytoreductive therapy is reserved for high-risk patients or those who have gross constitutional symptoms.

Take Home Messages

- Thrombocytosis is commonly encountered in clinical practice; it is important to exclude secondary causes.
- Myeloproliferative neoplasms should be considered in patients where a secondary cause for the thrombocytosis has not been identified.
- Thrombocytosis is most commonly associated with essential thrombocythaemia but can also occur in other myeloproliferative neoplasms.
- Clonal drivers can be identified in the majority of patients with essential thrombocythaemia; JAK2-V617F in 50%, CALR in 30% and MPL in up to 5% of patients.

Platelet Adhesive Protein Defect Disorders

Shinji Kunishima and Hirokazu Kashiwagi

Abstract

This chapter describes inherited platelet disorders linked to defects in the major platelet adhesion receptors, GPIb/IX/V and $\alpha_{IIb}\beta_3$. Bernard–Soulier syndrome is caused by abnormalities of the GPIb/IX/V complex, characterized by thrombocytopenia, giant platelets, prolonged bleeding time, and ristocetin-induced platelet agglutination. Glanzmann thrombasthenia is the result of a quantitative and/or qualitative defect in integrin $\alpha_{IIb}\beta_3$, characterized by prolonged bleeding time and absent platelet aggregation in response to multiple physiological agonists, but with normal platelet count and morphology.

Introduction

When a blood vessel is injured and bleeding occurs, platelets adhere to the exposed subendothelium, become activated and release their granule content, and form aggregates. Platelet adhesion occurs through binding of the platelet membrane glycoprotein (GP) Ib/IX/V to von Willebrand factor (VWF), which binds to the subendothelium; subsequent platelet aggregation takes place by activation of integrin $\alpha_{IIb}\beta_3$ and fibrinogen binding (Fig. 1). In addition, there are other important adhesion receptors on platelets (i.e., GPVI and α2β1) that also mediate platelet adhesion. This chapter describes platelet disorders linked to defects in the major platelet adhesion receptors. Studies have provided us with much information on the structure–function relations of receptors, but also insights into the molecular mechanisms of primary hemostasis (Table 1). The reader may refer to some excellent reviews (Gresele et al. 2015; Nurden and Nurden 2014, 2015).

Bernard–Soulier Syndrome

In 1948, Bernard and Soulier described an infant who had a severe mucocutaneous bleeding tendency with prolonged bleeding time and abnormally large platelets, but normal platelet count and clot retraction (Bernard and Soulier 1948). His sister was similarly affected and died from bleeding at a younger age. Both the parents and the other sister were asymptomatic. Similar case reports accumulated in the following years (Weiss et al. 1974; Kanska et al. 1963; Cullum et al. 1967) and the classical diagnostic criteria of autosomal recessive inheritance, thrombocytopenia, giant platelets, prolonged bleeding time, and normal clot retraction was proposed (Alagille et al. 1964; Bithell et al. 1972).

Clinical Features

Bernard–Soulier syndrome (BSS) is a very rare disorder with an estimated prevalence of one in one million (Lopez et al. 1998). However, it is likely to be more prevalent than previously believed, because patients are often misdiagnosed with immune thrombocytopenia (ITP), undiagnosed, or underreported.

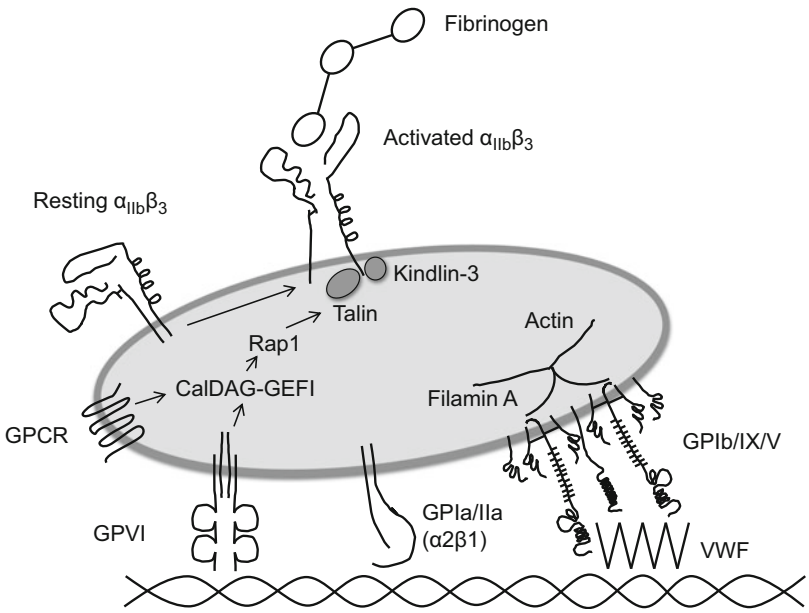

Fig. 1 Major platelet membrane glycoproteins and their ligands, with the principal inherited platelet disorders indicated

Table 1 Principal inherited platelet adhesive protein defect disorders

Disorder	Inheritance	Bleeding tendency	Platelet count	Platelet size	Molecule	Defective gene	Platelet characteristics
Bernard–Soulier syndrome	AR	Severe	Decreased	Large	GPIb/IX/V	*GP1BA*, *GP1BB*, *GP9*	Absent ristocetin-induced agglutination
Platelet-type von Willebrand disease	AD	Moderate	Normal or decreased	Large	GPIb/IX/V	*GP1BA*	Increased ristocetin-induced agglutination
Glanzmann thrombasthenia	AR	Severe	Normal	Normal	$\alpha_{IIb}\beta_3$	*ITGA2B*, *ITGB3*	Absent aggregation in response to physiological agonists
$\alpha_{IIb}\beta_3$-related macrothrombocytopenia	AD	Absent to moderate	Decreased	Large	$\alpha_{IIb}\beta_3$	*ITGA2B*, *ITGB3*	Normal to impaired aggregation
GPVI deficiency	AR	Mild	Normal	Normal	GPVI	*GP6*	Decreased response to collagen

AR autosomal recessive, *AD* autosomal dominant

In fact, in a large cohort study enrolling 131 BSS families, almost 50 % (64 of 131) of the patients had been previously misdiagnosed as having ITP and were treated with steroids and/or intravenous immunoglobulins. Of note, splenectomy was performed in 11 % of cases (14 of 131 patients) (Savoia et al. 2014). BSS is in most cases inherited in an autosomal recessive manner; only one case has been reported as autosomal dominant (Miller et al. 1992). Several founder mutations have been identified in northern Europe, Italy, Japan, and India (Kunishima et al. 2006c; Liang et al. 2005; Noda et al. 1995; Sumitha et al. 2011; Wright et al. 1993). Consanguinity is common among affected families. Even without known consanguinity, parents of a patient homozygous for a mutation often carry the same disease haplotype enriched in a certain geographical area. Among the 207 reported BSS patients, 179 (85 %) were homozygous and 28 (13 %) were compound heterozygous for mutations in one of the *GP1BA*, *GP1BB,* and *GP9* genes (Savoia et al. 2014). Patients manifest a severe bleeding tendency from early childhood, primarily from mucocutaneous tissues. Purpura, epistaxis, menorrhagia, and gingival bleeding are common but hemarthroses and deep visceral hematomas are rare. The bleeding tendency is more severe than predicted from the degree of thrombocytopenia, because platelets are dysfunctional and unable to adhere to the exposed vascular subendothelium. According to the World Health Organization (WHO) bleeding scale (grade 0, no bleeding; 1, petechial bleeding; 2, clinically significant bleeding; 3, bleeding requiring transfusion; 4, bleeding associated with fatality), more than 50 % of the patients (77 of 139 patients) had severe bleeding classified as grades 3 and 4 (Savoia et al. 2014). As is sometimes the case for other congenital bleeding disorders, a bleeding tendency is not always remarkable in

newborns or infants. Heterozygous carriers of BSS are generally asymptomatic with normal platelet function, but sometimes have mild thrombocytopenia and large platelets.

Laboratory Features

The diagnostic features are thrombocytopenia, giant platelets, prolonged bleeding time, and absent ristocetin-induced platelet agglutination. Skin bleeding times are moderately to severely prolonged (<20 min). Platelet counts in many cases are moderate to severe. The mean platelet count was 51×10^9/L (range 5×10^9–175×10^9/L) (Savoia et al. 2014). Because routine automated blood cell counting systems use the impedance method, in which blood cells are differentiated by their size and do not recognize giant platelets as platelets, they underestimate not only the platelet count but also the mean platelet volume . In this regard, optical or immunological counting is superior to conventional impedance counting (Briggs et al. 2007). Nevertheless, manual platelet counting in a calculating chamber or on peripheral blood smears is still the gold standard.

Giant platelets on peripheral blood smears are the most characteristic morphological feature of BSS. Most platelets are as large as red blood cells and the mean platelet size (determined as platelet diameter on peripheral blood smears) is twice as large as that of controls (4.8 μm, range 2.9–7.5 μm, and 2.4 μm, range 1.9–3.4 μm, respectively) (Noris et al. 2013; Savoia et al. 2014). Mean platelet volume, as measured by hematology analyzers, is also increased in BSS, giving values almost twice those of controls (Noris et al. 2013). It has been suggested that the large platelet size is a result of increased membrane deformability, which results in swelling in the plasma milieu and a tendency to readily spread on glass slides (Frojmovic et al. 1978; White et al. 1984). This is mostly caused by the defective linkage between the cytoplasmic domain of GPIbα and filamin A, leading to decreased interaction of platelet membrane and cytoskeleton. In fact, (1) giant platelets and thrombocytopenia in a mouse model of BSS can be rescued by the exogenous expression of GPIbα (Ware et al. 2000); (2) knockdown of filamin A results in production of large platelets from embryonic stem cell-derived megakaryocytes (Kanaji et al. 2012); and (3) patients with 22q11.2 microdeletion syndromes, who are haploinsufficient for the GPIbβ gene, have large platelets (Liang et al. 2007; Naqvi et al. 2011; Van Geet et al. 1998). The physical linkage between GPIb/IX/V–filamin A–actin is the major but not only determinant of platelet size. Giant platelets are also found in variants with missense mutations in the extracellular domain of GPIbα that result in the expression of dysfunctional receptors (Li et al. 1995; Miller et al. 1992; Savoia et al. 2001; Ware et al. 1993) and in type 2B von Willebrand disease (VWD) (Nurden et al. 2010; Federici et al. 2009), in which abnormal von Willebrand factor spontaneously binds to GPIb/IX/V. These findings raise the possibility that normal megakaryocytopoiesis and platelet morphogenesis are affected not only by physical interaction between GPIb/IX/V and the cytoskeleton, but also by GPIb/IX/V-mediated signal transduction. In fact, the demarcation membrane systems of megakaryocytes are irregular and vacuolar (Hourdille et al. 1990; White 1998), and proplatelet formation from megakaryocytes is defective in homozygous and heterozygous BSS (Balduini et al. 2011; Vettore et al. 2011), a mouse model of BSS (Poujol et al. 2002), and type 2B VWD (Nurden et al. 2010). Thickened marginal bands as a result of an increased number of microtubules have been observed in BSS patients and a mouse model of BSS (Balduini et al. 2009; Strassel et al. 2009).

Absence of ristocetin-induced platelet agglutination constitutes another laboratory hallmark of BSS and this abnormality is not corrected by the addition of normal plasma, a procedure the allows BSS to be distinguished from VWD. This is because the antibiotic ristocetin induces binding of VWF to GPIb/IX/V in the absence of platelet activation or high shear rates (Berndt et al. 1992); therefore, VWF fails to bind to BSS platelets deficient in GPIb/IX/V on the platelet membranes. Platelet aggregation in response to physiological agonists such as collagen, ADP, and epinephrine, as well as clot retraction, is normal. However, platelet aggregation in response to thrombin is decreased because the high affinity thrombin binding site containing GPIbα is absent and thus the capacity of α-thrombin to activate platelets through the platelet thrombin receptor PAR-1 is deficient (De Marco et al. 1994; De Candia et al. 2001). Prothrombin consumption and thrombin generation are markedly decreased because of the defective binding of factor XI and α-thrombin to platelets (Bernard and Soulier 1948; Caen and Bellucci 1983). However, functional studies of BSS platelets are difficult to perform, because of thrombocytopenia and because of the difficulty in isolating the giant platelets from red blood cells and lymphocytes. Flow cytometry-based platelet aggregation analysis has the advantage of requiring less sample for analysis (Giannini et al. 2007).

Molecular Abnormalities

Molecular abnormalities of BSS platelets were first suggested in 1969 after observing that there was a delay in the electrophoretic mobility of platelets caused by decreased sialic acid content (Grottum and Solum 1969). Later, it was found that this was caused by the lack of platelet membrane GPIb (Nurden and Caen 1975). In 1973, it was found that platelets failed to aggregate in the presence of the antibiotic

ristocetin or bovine fibrinogen (Caen and Levy-Toledano 1973; Howard et al. 1973). The platelet function abnormality was also demonstrated by the finding that platelets failed to adhere to rabbit aortic subendothelium (Weiss et al. 1974). Subsequently, GPIb (missing from BSS platelets) was identified as a platelet receptor for VWF (Hagen et al. 1980). Biochemical analysis of the surface-labeled platelet glycoproteins by two-dimensional sodium dodecyl sulfate–polyacrylamide gel electrophoresis showed that BSS platelets are deficient in GPIbα, GPIbβ, GPIX, and GPV (Clemetson et al. 1982; Berndt et al. 1983). However, with the exception of rare variant cases, the component subunits of the GPIb/IX/V complex are residually and heterogeneously expressed on the platelet membranes (Arai et al. 1994; Drouin et al. 1988; Kunishima et al. 1994). Flow cytometric determination of each subunit on the platelet surface is a practical and convenient method for diagnosis of BSS. The most deficient subunit in platelets is often found to indicate the genetic basis: patients with residual GPIbβ and GPIX are often associated with a *GP1BA* mutation, and those with residual GPIbα and GPIbβ are often associated with a *GP9* mutation (Kunishima et al. 2002a; Kunishima and Saito 2006). Severely decreased expression of GPIbα and GPIX suggests a *GP1BB* mutation. Flow cytometry also allows evaluation of platelet size, and double-labeling of GPIb/IX/V and $\alpha_{IIb}\beta_3$ permits comparative expression levels.

Genetic Defects

The genes encoding for GPIbα (*GP1BA*), GPIbβ (*GP1BB*), GPIX (*GP9*), and GPV (*GP5*) are located on chromosomes 17p13.2, 22q11.21, 3q21.3, and 3q29, respectively. Gene structures are similar to each other and each subunit belongs to the leucine-rich repeat (LRR) protein family (Andrews et al. 2003; Bryckaert et al. 2015; Li and Emsley 2013; Lopez 1994). After the cloning of genes encoding each of the three subunits in the late 1980s (Hickey and Roth 1993; Hickey et al. 1989; Lopez et al. 1987, 1988; Wenger et al. 1988; Yagi et al. 1994), the first causative gene defect was elucidated by Ware et al. (1990) and, so far, more than 100 different mutations have been identified (Andrews and Berndt 2013; Kunishima et al. 2002a; Lanza 2006; Lopez et al. 1998; Savoia et al. 2014; Ware et al. 1990) (Fig. 2). In vitro biosynthetic studies have shown that coordinated assembly of GPIbα, GPIbβ, and GPIX but not GPV is required for efficient surface expression of a functional GPIb/IX complex (Lopez et al. 1992, 1994; Dong et al. 1997, 1998). Thus, a defect in any of the three genes, *GP1BA*, *GP1BB*, or *GP9* by either homozygous or compound heterozygous mutation produces the BSS phenotype. No mutations have been reported in *GP5*. Mutations include missense and nonsense mutations and small insertions and deletions. Because each gene is compact and the entire open reading frame is contained within a single exon, no splice mutations were identified. This is one of the reasons why BSS is less prevalent than Glanzmann thrombasthenia (GT), in which splicing defects are common (Nurden et al. 2011a; Nurden 2006).

Genetic defects producing BSS can be mainly classified into two types: (1) common lack of expression of the GPIb/IX/V complex as a result of a biosynthetic defect that affects the synthesis, processing, or assembly of the complex and (2) less common expression of a dysfunctional complex that fails to bind ligand and affects physical linkage between the complex and the actin cytoskeleton.

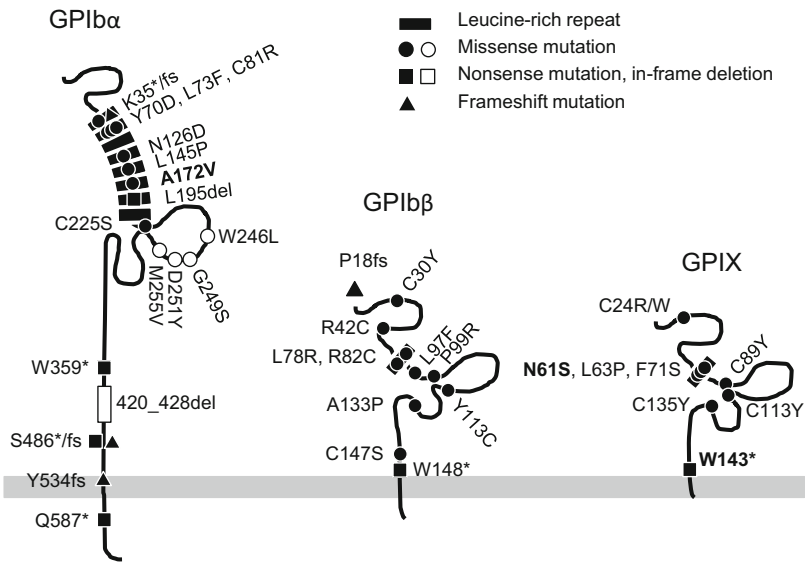

Fig. 2 GPIbα, GPIbβ, and GPIX together with mutations associated with Bernard–Soulier syndrome (*closed symbols*) and platelet-type von Willebrand disease (*open symbols*). The major founder mutations are indicated in *bold*

1. *Absent GPIb/IX/V expression*
   In BSS platelets, the expression of GPIb/IX/V is usually absent or severely decreased (Savoia et al. 2011). This is because coordinated expression of each subunit, inter-subunit interaction, disulfide association between GPIbα and GPIbβ, and interactions in the extracellular, transmembrane, and cytoplasmic domains are required for optimal assembly of the complex (Luo et al. 2007a, b; Mo et al. 2006, 2008; Luo and Li 2008). Thus, truncating mutations caused by nonsense and frameshift mutations that eliminate or alter the polypeptide sequence of a subunit not only disrupt the structural integrity of the mutated subunit but also interfere with assembly of the complex (Holmberg et al. 1997; Kunishima et al. 1994, 2002b, 2006c; Noda et al. 1995; Takata et al. 2012; Ware et al. 1990; Yamamoto et al. 2013). In some instances, truncating mutations in *GP1BA* and *GP9* are associated with residual expression of incomplete GPIbβ/GPIX and GPIbα/GPIbβ complexes, respectively. A *GP1BB* mutation is often associated with null expression of GPIbβ and severely decreased GPIbα and GPIX expression. This is because GPIbβ plays a crucial and indispensable role in expression of the complex by two GPIbβ (Cys147) molecules binding to one GPIbα (Cys500 and Cys501) to support GPIbα expression (Kunishima et al. 2006b; Lopez et al. 1994; McEwan et al. 2011; Luo et al. 2007a). A missense mutation in a subunit can lead to absent GPIb/IX/V expression through several mechanisms. Mutations at the conserved residues in the LRR motif are in many cases damaged and deteriorating (Afrasiabi et al. 2007; Clemetson et al. 1994; Dagistan and Kunishima 2007; Donner et al. 1996; Drouin et al. 2005; Kenny et al. 1998; Koskela et al. 1999; Kunishima et al. 2006a; Liang et al. 2005; Noris et al. 1997; Rand et al. 2010; Sachs et al. 2003; Sato et al. 2014; Savoia et al. 2011, 2014; Sumitha et al. 2011; Suzuki et al. 1997; Vanhoorelbeke et al. 2001; Wright et al. 1993; Zieger et al. 2009). Among these, p.Asn61Ser is the most prevalent founder mutation in northern Europe and has been reported in multiple unrelated Caucasian families (Clemetson et al. 1994; Dagistan and Kunishima 2007; Donner et al. 1996; Drouin et al. 2005; Koskela et al. 1999; Liang et al. 2005; Rand et al. 2010; Sachs et al. 2003; Savoia et al. 2011, 2014; Vanhoorelbeke et al. 2001; Wright et al. 1993; Zieger et al. 2009). In addition, mutations at the conserved cysteine residues or creating cysteines in the N- and C-terminal LRR flanking regions interfere with intramolecular disulfide bond patterns and secondary structures (Kunishima et al. 1997, 1999; Kurokawa et al. 2001; Noda et al. 1996; Simsek et al. 1994).
2. *Dysfunctional GPIb/IX/V complex*
   Some mutations in the LRR motif of GPIbα do not severely affect the stability and are associated with expression of a dysfunctional GPIb/IX/V complex. These mutations include p.Leu73Phe (Miller et al. 1992), p.Leu145Pro (Li et al. 1995), p.Ala172Val (Bolzano mutation) (De Marco et al. 1990; Ware et al. 1993), and p.Leu195del (Nancy I mutation) (de la Salle et al. 1995; Ulsemer et al. 2000) (Fig. 3).

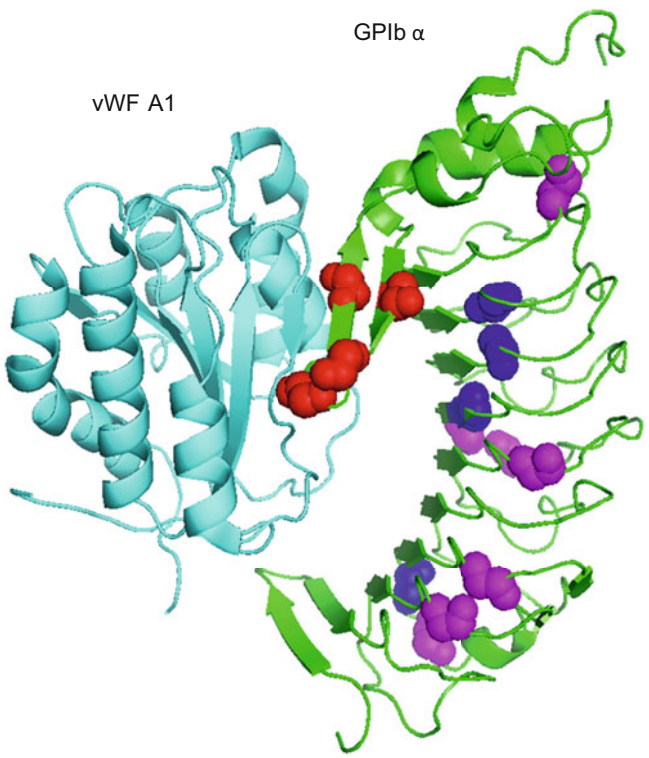

Fig. 3 Crystal structure of von Willebrand factor A1 domain–GPIbα complex (PDB 1M10). Bernard–Soulier mutations associated with absent GPIb/IX/V are shown in *magenta* and dysfunctional GPIb/IX/V are shown in *blue*. Platelet-type con Willebrand disease mutations are clustered in the β-switch region and shown in *red*

The first dysfunctional variant was described in an autosomal dominant form of BSS resulting from a heterozygous p.Leu73Phe (Miller et al. 1992). VWF binding to patients' platelets was decreased and a proteolytic fragment of GPIbα was identified on immunoblots of platelets. The p.Ala172Val mutation, also known as the Bolzano mutation, was first identified in a Italian family (De Marco et al. 1990; Ware et al. 1993). The patients' platelets had ~50 % of control levels of GPIb/IX expression. Binding of thrombin to platelets was conserved, whereas that of VWF was severely impaired. p.Ala172Val is prevalent in southern Italian populations (Savoia et al. 2001). Heterozygous patients have mild macrothrombocytopenia and may have mild bleeding symptoms; this condition was previously considered Mediterranean macrothrombocytopenia (Behrens 1975). In investigation of an Italian cohort of 216 patients with macrothrombocytopenia, 42 patients were heterozygous for p.Ala172Val, all sharing the same haplotype

(Noris et al. 2012). Patients with p.Leu145Pro (Li et al. 1995) and p.Leu195del (Nancy I mutation) (de la Salle et al. 1995; Ulsemer et al. 2000) also share similar platelet features: residual and heterogeneous expression of GPIb/IX/V and the absence of VWF binding.

Chromosome 22q11.2 Microdeletion

The 22q11.2 deletion syndrome (22q11.2DS) is one of the commonest microdeletion syndromes and encompasses DiGeorge, velocardiofacial, and conotruncal anomaly face syndromes (McDonald-McGinn and Sullivan 2011). The minimum deleted region contains *GP1BB*. Thus, patients with 22q11.2DS are obligate BSS carriers and have large platelets (Liang et al. 2007; Naqvi et al. 2011; Van Geet et al. 1998). Budarf and colleagues were the first to report BSS in a patient who had the 22q11.2DS (Budarf et al. 1995). The patient was compound heterozygous for the 22q11.2 deletion and a single point mutation that disrupts a binding site for the GATA-1 transcription factor (g.-160C>G) (Ludlow et al. 1996). This was also the first report of BSS associated with a promoter site mutation. So far, several BSS cases associated with 22q11.2DS have been described (Bartsch et al. 2011; Budarf et al. 1995; Hillmann et al. 2002; Kenny et al. 1999; Kunishima et al. 2013; Ludlow et al. 1996; Tang et al. 2004).

Acquired Bernard–Soulier Syndrome

Although very rare, acquired (or pseudo-) BSS has been described in which autoantibodies or paraproteins bind to GPIb/IX/V and impair its receptor function. It is reportedly associated with vasculitis, lymphoproliferative disorder, procainamide therapy, and Gaucher's disease (Devine et al. 1987; Kelsey et al. 1994; Stricker et al. 1985; Tornai et al. 1999). In addition, severely decreased GPIb/IX/V expression may be associated with myelodysplasia (Frigeni and Galli 2014; Berndt et al. 1988; Hicsonmez et al. 1995). In these conditions, both normal and abnormal platelet populations are present in the circulation.

Platelet-Type von Willebrand Disease

Platelet-type (or pseudo-) VWD is an autosomal-dominant bleeding disorder first described in 1982 by Weiss and colleagues (Weiss et al. 1982) and Miller and Castella (Miller and Castella 1982). Patients present mild thrombocytopenia, with or without large platelets, and a mild-to-moderate bleeding tendency (Othman and Emsley 2014; Othman et al. 2013). This disorder is characterized by an abnormally increased affinity of the platelet GPIbα for von Willebrand factor as a result of gain-of-function mutations in *GP1BA*, leading to clearance of both platelets and VWF from the circulation. Laboratory features include enhanced ristocetin-induced platelet agglutination at low concentrations of ristocetin, decreased ristocetin cofactor activity, mildly decreased VWF antigen with low VWF cofactor activity/antigen ratio, and absence of high molecular weight VWF multimers. The differential diagnosis between platelet-type VWD and type 2B VWD requires a mixing assay for ristocetin-induced platelet agglutination and genetic analysis. To date, six platelet-type VWD mutations, including five missense mutations (Enayat et al. 2012; Matsubara et al. 2003; Miller et al. 1991; Russell and Roth 1993; Woods et al. 2014) and one in frame deletion (Othman et al. 2005), have been identified. All of the missense mutations that increase the affinity of GPIbα for VWF are located at the major binding interface between the VWD A1 domain and the β-switch in the C-terminal LRR flanking region (Huizinga et al. 2002; Dumas et al. 2004; Blenner et al. 2014) (Fig. 3). The 27 base pair deletion in the GPIbα macroglycopeptide region is located outside the VWF-binding domain, suggesting allosteric modulation of VWF binding.

Glanzmann Thrombasthenia and αIIbβ3-Related Abnormalities

Glanzmann Thrombasthenia

GT is an autosomal recessive bleeding disorder caused by quantitative or qualitative abnormalities in integrin $\alpha_{IIb}\beta_3$. GT patients usually have lifelong bleeding episodes, which are typically characterized by mucocutaneous bleeding with a variable clinical presentation ranging in severity from mild bruising to fetal hemorrhages. GT was first described in 1918 by Glanzmann as "hereditary hemorrhagic thrombasthenia," which is characterized by normal platelet counts and lack of clot retraction (Stevens and Meyer 2002). In 1966, Caen and colleagues reported 15 French cases with lack of platelet aggregation and clot retraction and named the disorder "Glanzmann thrombasthenia" (Bellucci and Caen 2002). In 1972, Caen divided GT into two groups: type I GT with complete lack of platelet aggregation, low platelet fibrinogen, and a profound defect in clot retraction, and type II GT with complete lack of platelet aggregation, a substantial amount of platelet fibrinogen, and moderately defective clot retraction (Bellucci and Caen 2002). In the mid-1970s, Nurden and Caen and Phillips and coworkers demonstrated that one of the major platelet glycoproteins, which was subsequently identified as $\alpha_{IIb}\beta_3$, was absent in three cases of type I GT (Nurden and Caen 1974; Phillips

et al. 1975). In the mid-1980s, several researchers found rare variant forms of GT, in which platelet aggregation was absent despite normal expression of $\alpha_{IIb}\beta_3$ (Jung et al. 1988; Nurden et al. 1987; Tanoue et al. 1987). Although GT patients usually have normal platelet counts and morphology, several $\alpha_{IIb}\beta_3$ mutations have been found in patients with congenital macrothrombocytopenia (Nurden et al. 2011b). Moreover, congenital abnormalities in molecules closely associated with $\alpha_{IIb}\beta_3$ activation have been identified in patients with GT-like bleeding phenotypes (Nurden and Nurden 2015).

Clinical Features

GT is rare, but is the most prevalent and globally distributed congenital disorder of the platelet adhesion receptors. Although the exact number is unknown, the incidence of GT is estimated at about one in 500,000–1,000,000 individuals and is higher in ethnic groups with higher incidences of consanguinity, such as Iraqi Jews and French Gypsies (Bolton-Maggs et al. 2006). Purpura and mucosal bleeding, such as epistaxis, gingival bleeding, and menorrhagia, are common manifestations of GT (George et al. 1990; Toogeh et al. 2004). Petechiae and ecchymoses usually appear in areas of pressure or minor trauma, although spontaneous petechiae are uncommon. Epistaxis is very common and sometimes causes severe bleeding, especially in childhood. Gingival bleeding is also very common, and excessive bleeding after dental extraction may often be the first symptom shown by GT patients. Menorrhagia occurs often in female patients after menarche and could be a critical hemorrhagic problem. Gastrointestinal bleeding or hematuria can be observed, but is less common. Intracranial hemorrhages are rare and only five cases have been mentioned in the literature (Vigren et al. 2012). These bleeding tendencies are usually noticed in infancy and the majority of patients are diagnosed before the age of 5 years.

Classification

GT is defined as a congenital bleeding disorder caused by mutations in the *ITGA2B* or *ITGB3* gene, encoding αIIb or β3, respectively. GT has been classified according to the expression of $\alpha_{IIb}\beta_3$ (George et al. 1990). Severe $\alpha_{IIb}\beta_3$-deficient patients with less than 5 % of normal $\alpha_{IIb}\beta_3$ expression are classified as type I and moderate $\alpha_{IIb}\beta_3$ deficiency with 5–20 % $\alpha_{IIb}\beta_3$ expression as type II. Clot retraction is absent and platelet fibrinogen is greatly reduced in type I GT patients, whereas clot retraction and platelet fibrinogen are subnormal in type II GT. Patients with dysfunctional $\alpha_{IIb}\beta_3$ but with more than 50 % $\alpha_{IIb}\beta_3$ expression are classified as variant type.

Laboratory Findings

GT patients have normal platelet count and normal platelet morphology, markedly prolonged bleeding time, and absent or impaired clot retraction. Platelet aggregation study using a light transmission aggregometer is highly specific for the diagnosis of GT. GT platelets lack aggregation induced by all agonists except ristocetin, including ADP, collagen, epinephrine, arachidonic acid, thrombin receptor activating peptides, and thromboxane A2 mimetic. To confirm the diagnosis of GT, abnormalities in $\alpha_{IIb}\beta_3$ should be demonstrated and this is usually done by flow cytometric analysis. Quantitative analysis of surface expression of $\alpha_{IIb}\beta_3$ can be performed using a series of monoclonal antibodies against $\alpha_{IIb}\beta_3$ complex, α_{IIb}, or β_3. Dysfunction of $\alpha_{IIb}\beta_3$ can be assessed by binding of fibrinogen or ligand-mimetic antibodies, such as PAC-1. Although genetic analysis of $\alpha_{IIb}\beta_3$ is usually unnecessary for diagnosis except in the cases of variants, it can contribute to management decisions, because type I patients with a premature stop codon or truncated protein might produce alloantibodies against $\alpha_{IIb}\beta_3$ after platelet transfusion (Fiore et al. 2012; Kashiwagi et al. 2011).

Molecular Basis

The *ITGA2B* and *ITGB3* genes are located within a single 260-kilobase segment in the q21–23 band on chromosome 17. More than 200 mutations in either gene have been recorded (sinaicentral.mssm.edu/intranet/research/glanzmann) and the list is still expanding using the latest methods for genetic analysis (Buitrago et al. 2015; Nurden et al. 2015).

Large gene deletions are exceptional, although nonsense mutations, out-of-frame small deletions, and insertions that cause premature terminations of transcript are frequently identified. Many missense mutations or in-frame insertions or deletions are also described. Although the majority of mutations lead to loss of $\alpha_{IIb}\beta_3$ expression, certain mutations affect ligand binding, leading to GT variants (Fig. 4a) (Nurden et al. 2011a).

1. *Mutations leading to loss of $\alpha_{IIb}\beta_3$ expression*
   The αIIb subunit is synthesized as pro-αIIb, and pro-αIIb forms complexed with the β_3 subunit in the endoplasmic reticulum. After transfer of pro-$\alpha_{IIb}\beta_3$ complex to the Golgi apparatus, pro-αIIb is cleaved to give mature heavy and light chains of αIIb, and mature $\alpha_{IIb}\beta_3$ is moved to the platelet surface. If proper complex formation fails, residual α_{IIb} or β_3 undergoes proteasomal degradation (Duperray et al. 1989). Therefore, defects in $\alpha_{IIb}\beta_3$ expression are caused not only by nonsense or out-of-frame mutations but also by missense or in-frame mutations that affect proper $\alpha_{IIb}\beta_3$ complex formation or cellular trafficking. Although these missense or in-frame mutations are located in whole coding regions of the *ITGA2B* and *ITGB3* genes, the β-propeller domain of α_{IIb} and the β-I domain of β_3 are apparently hot spots

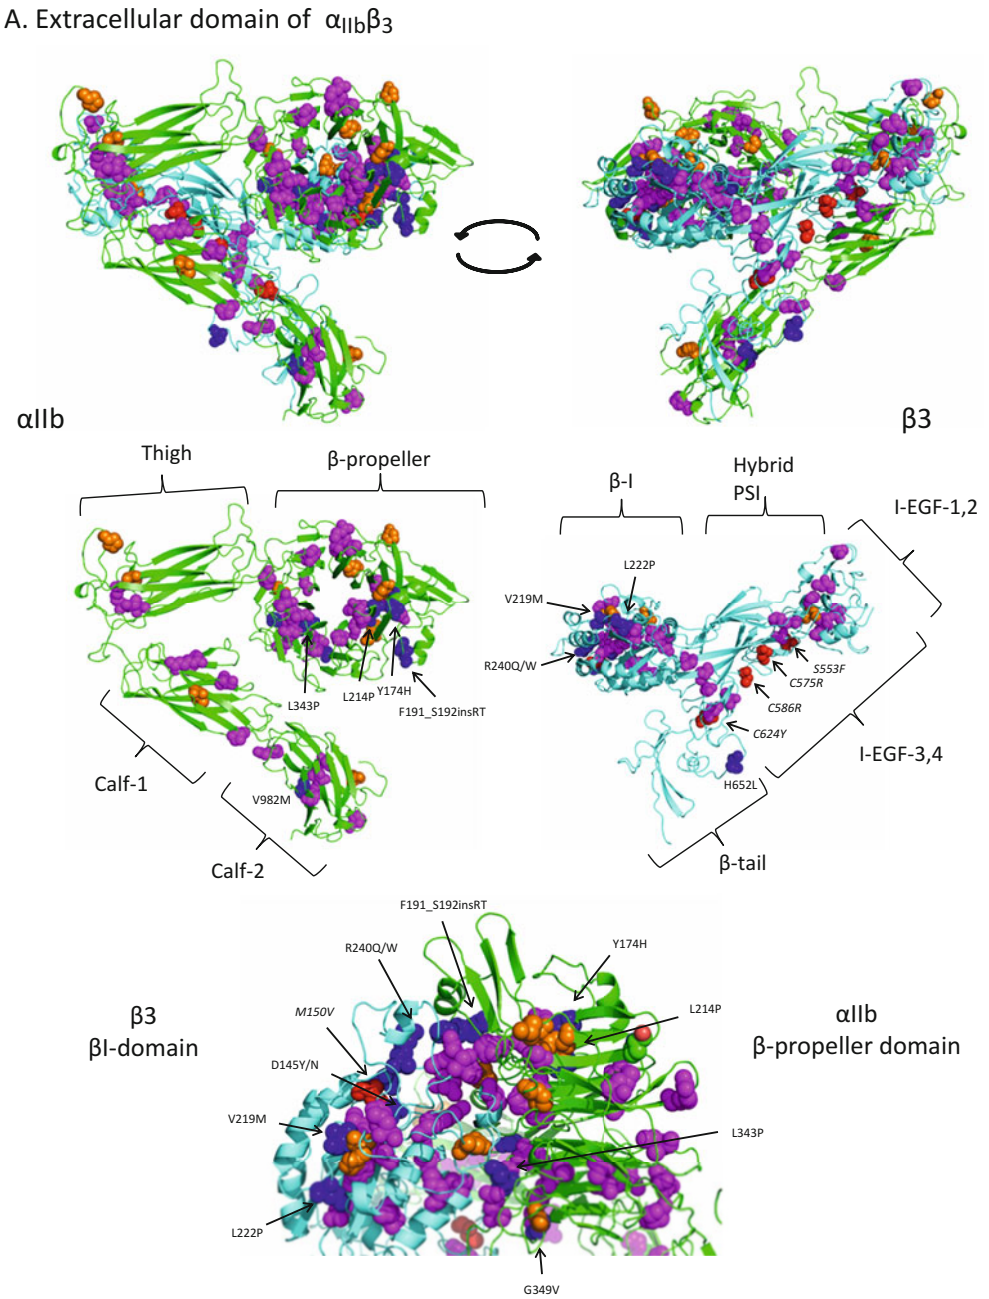

Fig. 4 Crystal structure of the extracellular domain (**a**) and transmembrane and cytoplasmic domains (**b**) of $\alpha_{IIb}\beta_3$. Amino acid substitutions identified in GT or $\alpha_{IIb}\beta_3$-associated macrothrombocytopenia are indicated. Mutations causing loss-of-expression, loss-of function, and gain-of-function are indicated as *magenta*, *blue*, and *red spheres*, respectively. *Orange spheres* indicate mutations with unknown effects. The gain-of-function mutations are also indicated in *italic*. (**c**) Gene structure and positions of mutations identified in the *FERMT3* gene

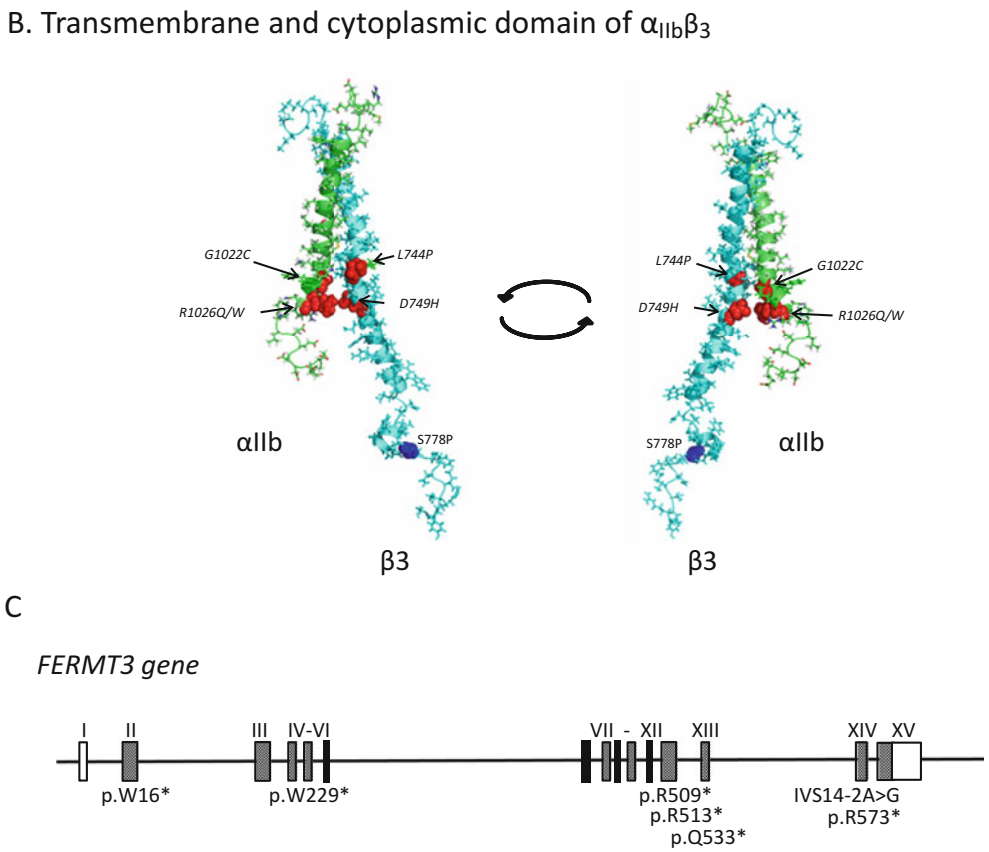

Fig. 4 (continued)

for the mutations, indicating that proper conformation and interaction of these regions is crucial for normal $\alpha_{IIb}\beta_3$ expression (Buitrago et al. 2015; Nurden et al. 2015).

2. *Loss-of-function mutations*
The β-propeller domain of αIIb and the β-I domain of β3 form a ligand-binding site and most GT variants are caused by mutations in these regions. The β-propeller domain of αIIb consists of seven four-stranded β-sheets (W1–W7) arranged in a torus around a pseudosymmetry axis (Xiao et al. 2004). The crucial regions of the αIIb for ligand binding are located within the 2-3 loop and the 4-1 loop of W3. The mutations p.Tyr174His, p.Phe191_Ser192insArgThr, and p.Leu214Pro in these regions lead to loss of ligand binding (Honda et al. 1998; Kiyoi et al. 2003). Crystal structure analysis also shows that key residues for ligand binding are located on the metal ion-dependent adhesion site (MIDAS) and the ADMIDAS (adjacent to MIDAS) domain in the β-I domain of β3 (Springer et al. 2008). Mutations in these regions, such as p.Asp145Tyr and p.Arg240Gln/Trp, make $\alpha_{IIb}\beta_3$ unstable by increasing its sensitivity to divalent cation chelation and abolishing ligand binding (Nurden et al. 2011a). Binding of talin and kindlin-3 to the β3 cytoplasmic tail is the final step of $\alpha_{IIb}\beta_3$ activation of "inside-out" signaling (Moser et al. 2008; Tadokoro et al. 2003). Three mutations leading to GT variants by impaired inside-out signaling have been found in the β3 cytoplasmic tail: p.Ser778Pro, p.Arg750*, and a splicing mutation leading to frameshift after Arg768 (Chen et al. 1992; Wang et al. 1997; Hauschner et al. 2012). Moreover, interaction between the membrane proximal to the Calf-2 domain of αIIb and the I-EGF4/β-tail domain of β3 is important for propagation of conformational signals from cytoplasmic tails. Mutations affecting ligand binding have also been identified in these regions (Kamata et al. 2005).

3. *Gain-of-function mutations*
Mutations leading to constitutive active conformation of $\alpha_{IIb}\beta_3$ have been identified in several GT patients. Cysteine residues in the I-EGF domain of β3 are a hot spot for these gain-of-function mutations, indicating the importance of the sulfide bridge in this region in maintaining the resting bent form of $\alpha_{IIb}\beta_3$. These mutations, such as p.Cys575Arg, mostly cause severe impaired surface expression of $\alpha_{IIb}\beta_3$, which could account for the bleeding

tendency (Mor-Cohen et al. 2007). However, in the case of homozygous p.Cys586Arg, platelets express ~20 % of constitutively activated $\alpha_{IIb}\beta_3$ on the platelet surface and increase fibrinogen binding (Ruiz et al. 2001). β3 p.Cys586Arg-transduced mice showed high mortality caused by bleeding, indicating that constitutive binding of fibrinogen to platelets leads to impaired platelet function and causes bleeding tendency instead of thrombosis (Fang et al. 2013).

αIIbβ3-Related Macrothrombocytopenia

Although a p.Arg1026Gln mutation in the αIIb cytoplasmic tail was reported in a GT-like patient with mild thrombocytopenia and anisocytosis (Hardisty et al. 1992; Peyruchaud et al. 1998), it was thought that mutations in the *ITGA2B* and *ITGB3* genes do not affect platelet counts and morphology until Ghevaert and colleagues found the p.Asp749His mutation in the β3 cytoplasmic tail in a family with congenital macrothrombocytopenia (Ghevaert et al. 2008). Subsequently, αIIb p.Arg1026Trp was identified in five patients from three independent Japanese families with macrothrombocytopenia (Kunishima et al. 2011). Interestingly, the salt bridge between αIIb Arg1026 and β3 Asp749 is essential for maintaining the resting state of $\alpha_{IIb}\beta_3$ (Hughes et al. 1996); disruption of the salt bridge by the mutations leads to constitutive activation of $\alpha_{IIb}\beta_3$. Several mutations in *ITGA2B* and *ITGB3* have now been identified in patients with congenital macrothrombocytopenia (Gresele et al. 2009; Nurden et al. 2011b; Kashiwagi et al. 2013). Mostly, these mutations are located in the juxtamembrane regions of αIIb or β3 and lead to constitutive $\alpha_{IIb}\beta_3$ activation with aberrant "outside-in" signaling, which may cause abnormal proplatelet formation (Kashiwagi et al. 2013; Kunishima et al. 2011; Bury et al. 2012; Kobayashi et al. 2013) (Fig. 4b).

Patients heterozygous for these mutations show mild thrombocytopenia with large platelets. Surface expression of $\alpha_{IIb}\beta_3$ is mildly to moderately decreased, but platelet aggregation is usually normal and bleeding tendency is absent or minimal. In the case of a compound heterozygote with p.Gly1022Cys and p.Arg453* in αIIb, surface expression of $\alpha_{IIb}\beta_3$ was decreased to 3–11 % with relatively severe macrothrombocytopenia (22×10^9–102×10^9/L). In the case of a compound heterozygote with αIIb p.Arg1026Gln and a 13 base pair intronic deletion (c.1440-13_1440-1del) leading to abnormal splicing of exon 15 in the *ITGA2B* gene, surface expression of $\alpha_{IIb}\beta_3$ was decreased to 12–20 % with modest thrombocytopenia (100×10^9–160×10^9/L) (Nurden et al. 2011b). We generated αIIb p.Arg1026Trp knock-in mice and showed that $\alpha_{IIb}\beta_3$ expression of homozygous knock-in platelets decreased to less than 5 % with mild macrothrombocytopenia (Kiyomizu et al. 2014). These results indicate that subjects homozygous for these activating mutations or compound heterozygous associated with $\alpha_{IIb}\beta_3$-null alleles may show a GT-like phenotype with macrothrombocytopenia. Reduced surface expression of $\alpha_{IIb}\beta_3$ appears to be the main cause of bleeding tendency, and thrombocytopenia and functional abnormalities in $\alpha_{IIb}\beta_3$ can exacerbate the symptoms.

GT-Like Variants Caused by Abnormalities in Kindlin-3 or CalDAG-GEFI

Kindlin-3 is an essential molecule for activation of β1, β2, and β3 integrins in platelets and leukocytes. Mutations of kindlin-3 coded by *FERMT3* cause a GT-like severe bleeding phenotype with immunodeficiency, named leukocyte adhesion disease (LAD)-III (Moser et al. 2008; Malinin et al. 2010). To date, at least seven mutations leading to premature termination of translation have been identified in *FERMT3* (Fig. 4c) (Crazzolara et al. 2015; Kuijpers et al. 2009; Malinin et al. 2009; Mory et al. 2008; Svensson et al. 2009). CalDAG-GEFI is a crucial signaling molecule for $\alpha_{IIb}\beta_3$ activation through activation of the small GTPase Rap1, which is an essential step for the binding of talin to the β3 cytoplasmic tail (Crittenden et al. 2004). Two mutations in CalDAG-GEFI coded by *RASGRP2*, p.Gly248Trp and p.Phe497fs*22, were found by exome sequencing of families suffering severe bleeding with impaired platelet aggregation response (Nurden and Nurden 2015; Canault et al. 2014). Expression defect mutations, p.Leu360del and p.Lys309*, were also identified in a Japanese girl with life-long bleeding tendency (Kato et al. 2015). Interestingly, CalDAG-GEFI defective platelets showed reduced but substantial aggregation response to high concentrations of agonists such as ADP and collagen; PMA-induced aggregation was normal. Susceptibility to infection was not reported in patients with CalDAG-GEFI abnormalities, in contrast to LAD-III (Canault et al. 2014; Kato et al. 2015).

Acquired Glanzmann Thrombasthenia

Acquired GT is a rare hemorrhagic disorder caused by autoantibodies, alloantibodies, or paraproteins that impair ligand binding to $\alpha_{IIb}\beta_3$. About 30 cases have been described so far, and they are often in association with lymphoproliferative or autoimmune disorders (Giannini et al. 2008; Porcelijn et al. 2008). In acquired GT, despite normal expression of $\alpha_{IIb}\beta_3$, platelet aggregation with agonists

(apart from ristocetin) is impaired, as in GT variants. Although immune thrombocytopenia (ITP) is the major concomitant, thrombocytopenia is usually mild or absent, probably as a result of a subclass of the antibodies (IgG2 or IgG4) or treatment such as splenectomy (Porcelijn et al. 2008).

Deficiency of Collagen Receptors

α2β1 (GPIaIIa) and GPVI are two major collagen receptors on platelets, and deficiency of these receptors, mostly GPVI deficiency, causes mild mucocutaneous bleeding tendency with a defective platelet aggregation response to collagen.

GPVI is a 62-kDa transmembrane protein and consists of two immunoglobulin-like domains (D1 and D2), a short mucin-like domain, a transmembrane domain, and a cytoplasmic domain. GPVI is noncovalently associated with the FcRγ chain, and ligand binding to the GPVI/FcRγ complex induces inside-out signals via the Syk/SLP-76/PLCγ2 pathway (Zahid et al. 2012). GPVI deficiency is a rare platelet disorder with mild bleeding tendency (Table 2). The first case of GPVI deficiency was reported in 1987, was associated with ITP, and showed anti-GPVI antibodies in the plasma (Sugiyama et al. 1987). Most reported subjects with acquired GPVI deficiency are female, concomitant with ITP or systemic lupus erythematosus (SLE), and have anti-GPVI antibodies either in plasma or platelet eluates (Table 2). Antibody-mediated GPVI depletion was first confirmed in mice injected with an anti-GPVI monoclonal antibody, leading to loss of GPVI expression in circulating platelets for at least 2 weeks after injection (Nieswandt et al. 2001). These antibodies cause metalloproteinase-mediated ectodomain cleavage (Andrews et al. 2007) or immune-induced internalization and degradation (Takayama et al. 2008), leading to loss of surface expression of GPVI. Congenital GPVI deficiencies caused by mutations in the *GP6* gene were firstly identified in 2009, and two missense mutations and three out-of-frame mutations have been reported to date (Fig. 5a). The p.Arg58Cys mutation in D1 abrogate collagen binding and the p.Ser195Asn mutation in D2 mainly lead to reduced

Table 2 Clinical profiles of patients with GPVI deficiency

	Age	Concomitant	Platelet count ($\times 10^9$/L)	Bleeding tendency	Autoantibody	Mutation in *GP6*	References
Deficiency							
Female	26		285	Purpura, epistaxis, menorrhagia			Moroi et al. (1989)
Male	26		100–130	Purpura, epistaxis			Ryo et al. (1992)
Acquired GPVI deficiency							
Female	58	ITP	13–140	Purpura, massive epistaxis required blood transfusion	+		Sugiyama et al. (1987)
Female	47	SLE	20–303	Purpura	+		Takahashi and Moroi (2001)
Female	25	ITP	105–135	Purpura	+		Boylan et al. (2004)
Female	20	ITP	48	Purpura	+		Kojima et al. (2006), Akiyama et al. (2009)
Female	55	ITP	2–167	Purpura, epistaxis	+		Gardiner et al. (2008)
Female	12	ITP	80–150	Purpura, epistaxis	+		Akiyama et al. (2009)
Female	22	SLE	4–441	Bleeding diathesis	+		Nurden et al. (2009)
Congenital GPVI deficiency							
Female	56		110–140	Pupura, epistaxis, postcoital bleeding, postoperative bleeding			Arai et al. (1995)
Female	55	Gray platelet syndrome	18–35	Epistaxis, menorrhagia, postsurgery and gastric bleeding			Nurden et al. (2004)

Female	31		208	Purpura, epistaxis, menorrhagia, postsurgery and posttraumatic bleeding		p.S195N c.142_157del	Hermans et al. (2009)
Female	22		Normal	Purpura		c.711_712insA	Matus et al. (2013)
Female	11		Normal	Purpura		c.711_712insA	Matus et al. (2013)
Male	23		Normal	Purpura		c.711_712insA	Matus et al. (2013)
Male	12		Normal	Purpura		c.711_712insA	Matus et al. (2013)
Female	5		Normal	Asymptomatic		c.711_712insA	Matus et al. (2013)

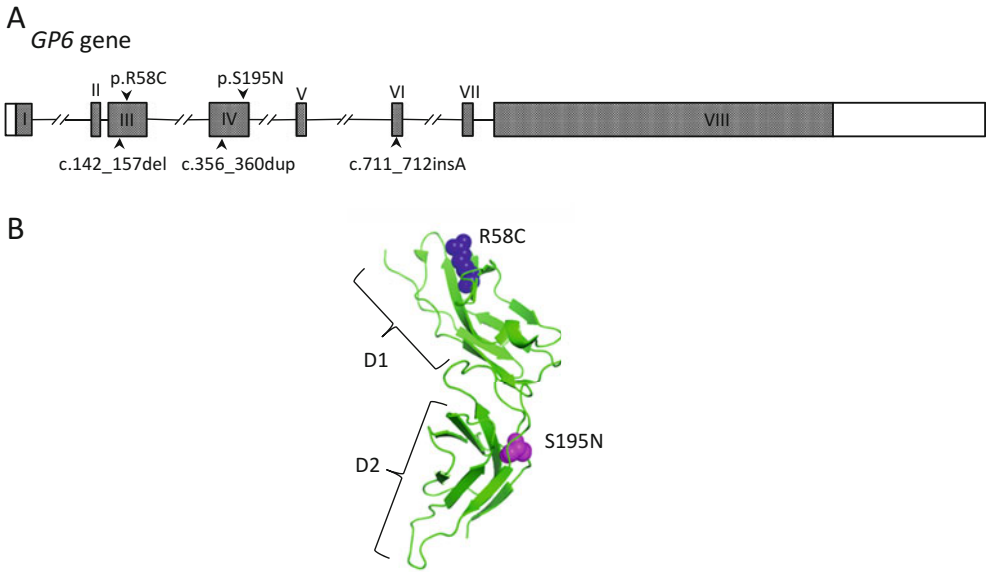

Fig. 5 (**a**) Gene structure and positions of mutations identified in the *GP6* gene. (**b**) Crystal structure of the two immunoglobulin-like domains of GPVI (D1 and D2) and positions of missense mutations. *Magenta* and *blue spheres* indicate lose-of-expression and loss-of-function mutations, respectively

expression of GPVI (Dumont et al. 2009; Hermans et al. 2009) (Fig. 5b). Five GPVI-deficient patients homozygous for an adenine insertion in exon 6 of *GP6* were reported in four unrelated families in Chile (Matus et al. 2013).

Two patients with impaired collagen-induced platelet aggregation caused by α2β1 deficiency have been described (Kehrel et al. 1988; Nieuwenhuis et al. 1985). However, the specific pathology of the reduced expression of α2β1 has not been elucidated.

Take Home Messages

- Bernard–Soulier syndrome and Glanzmann thrombasthenia are the most clinically significant platelet function disorders.
- Recent investigations have provided much information on the structure–function relations of GPIb/IX/V and $\alpha_{IIb}\beta_3$, and insights into the molecular mechanisms of primary hemostasis.
- Novel pathological conditions caused by defects in GPIb/IX/V and $\alpha_{IIb}\beta_3$ have been elucidated.

Defects of Soluble Agonists

Marco Cattaneo

Abstract

Congenital abnormalities of platelet receptors for soluble agonists represent one of the major categories of congenital defects of platelet function. Despite the fact that a selective pathway of platelet activation is abnormal, the most common abnormalities of these receptors involve the two major pathways of amplification of platelet aggregation and secretion: the adenosine diphosphate (ADP) and the thromboxane A2 (TxA2) pathways. For this reason, the abnormalities of platelet function that can be observed using traditional laboratory diagnostic tests are mostly unspecific. In order to raise the correct diagnostic hypothesis, it is important to focus on specific abnormalities: (1) defective platelet aggregation induced by ADP, even at very high concentrations, identifies congenital abnormalities of the platelet $P2Y_{12}$ receptor; (2) abnormal platelet aggregation and secretion induced by a thromboxane A2 mimetic identifies abnormalities of the thromboxane prostanoid (TP) receptor. Confirmation of the diagnostic hypothesis rests on specific tests and the identification of molecular abnormalities of the encoding genes.

Classification of Congenital Disorders of Platelet Function

Congenital disorders of platelet function are generally classified based on the functions or responses that are abnormal. However, since platelet functions are intimately related, a clear distinction between disorders of platelet adhesion, activation, secretion, aggregation, and procoagulant activity is in many instances problematic. For this reason, in 2003 I proposed a classification of congenital disorders of platelet function based on abnormalities of platelet components that share common characteristics (Cattaneo 2003): (1) platelet receptors for adhesive proteins, (2) platelet receptors for soluble agonists, (3) platelet granules, (4) signal transduction pathways, and (5) procoagulant phospholipids. Inherited disorders of platelet function that are less well characterized will be grouped into a sixth category of miscellaneous disorders. This classification approach is summarized in Table 1.

In this chapter, congenital abnormalities of platelet receptors for soluble agonists will be reviewed.

Defects of the Platelet P2 Receptors

Human platelets express at least three distinct receptors stimulated by adenosine nucleotides: $P2Y_1$; $P2Y_{12}$, which bind adenosine diphosphate (ADP); and $P2X_1$, which binds adenosine triphosphate (ATP) (Cattaneo 2011).

ADP plays a key role in platelet function because, when it is secreted from the platelet dense granules where it is stored, it amplifies the platelet responses induced by other platelet agonists (Cattaneo 2011; Packham and Mustard 2005), stabilizes platelet aggregates (Cattaneo et al. 1990; Trumel et al. 1999), and inhibits the antiplatelet effects of prostacyclin (Cattaneo and Lecchi 2007). The interaction of

Table 1 Classification of congenital disorders of platelet function

1. Abnormalities of the platelet receptors for adhesive proteins
• GPIb-IX-V complex: Bernard-Soulier syndrome, platelet-type von Willebrand disease
• GPIIb-IIIa ($\alpha_{IIb}\beta_3$): Glanzmann thrombasthenia
• GPIa-IIa ($\alpha_2\beta_1$)
• GPVI
2. Abnormalities of the platelet receptors for soluble agonists
• $P2Y_{12}$ receptor
• Thromboxane prostanoid receptor
• α_2-Adrenergic receptor
• PAR-1 defect[a]
3. Abnormalities of the platelet granules
• δ-Granules: non-syndromic δ-storage pool deficiency, Hermansky-Pudlak syndrome, Chediak-Higashi syndrome, MRP4 deficiency, thrombocytopenia with absent radius syndrome, Wiskott-Aldrich syndrome
• α-Granules: gray platelet syndrome, Quebec platelet disorder, 11q terminal deletion disorder, white platelet syndrome, Medich platelet disorder, X-linked macrothrombocytopenia with thalassemia, arthrogryposis renal dysfunction and cholestasis (ARC) syndrome
• α- and δ-Granules: α,δ-storage pool deficiency
4. Defects of signal transduction
• Abnormalities of the arachidonic acid/thromboxane A_2 pathway: defects in phospholipase A_2, cyclooxygenase, thromboxane synthetase
• Abnormalities of GTP binding proteins: Gαq deficiency, Gαi1 defect, hyperresponsiveness of platelet Gsα
• Defects in phospholipase C activation: partial selective PLC-β2 isozyme deficiency
• Abnormalities in transcription factors
• Abnormality in GPVI/FcRc signaling leukocyte adhesion deficiency-III (LAD-III)
• CalDAG/GEFI defect
5. Abnormalities of membrane phospholipids
• Scott syndrome
• Stormorken syndrome
6. Miscellaneous abnormalities of platelet function
• Primary secretion defects
• Other (osteogenesis imperfecta, Ehlers-Danlos syndrome, Marfan syndrome, hexokinase deficiency, glucose-6-phosphate deficiency)

[a]Defect of PAR-1 function, associated with a polymorphism of the encoding gene, was identified in a patient, who also displayed an inherited defect of the $P2Y_{12}$ receptor for ADP (Patel et al. 2014), and in patients with the gray platelet syndrome (De Candia et al. 2007; Larocca et al. 2015). The table is an updated version of a previously published one (Cattaneo 2003)

ADP with its G_q-coupled, $P2Y_1$ receptor mediates a transient rise in cytoplasmic Ca^{2+}, platelet shape change, and rapidly reversible aggregation, while its interaction with the G_i-coupled, $P2Y_{12}$ receptor mediates inhibition of adenylyl cyclase, phosphatidylinositol 3-kinase (PI3-K) activation, and the amplification of the platelet aggregation response (Cattaneo 2011; Cattaneo and Gachet 1999; Gachet et al. 1995). About 70 % of the platelet binding sites for ADP are associated with $P2Y_1$, while the remaining 30 % are associated with $P2Y_{12}$ (Cattaneo 2011).Concomitant activation of both the G_q and G_i pathways by ADP is necessary to elicit normal aggregation (Cattaneo 2011; Cattaneo and Gachet 1999; Gachet et al. 1995).

ATP, being an antagonist of both $P2Y_1$ and $P2Y_{12}$, inhibits platelet activation by ADP (Mustard and Packham 1970; MacFarlane and Mills 1975); however, through its interaction with $P2X_1$, it can also activate platelets by inducing a very rapid influx of Ca^{2+} from the extracellular medium, which is associated with a transient platelet shape change (Rolf et al. 2001). Platelet activation by ATP amplifies the platelet responses to other agonists, especially in flow conditions that are characterized by high shear stress (Cattaneo et al. 1994a; 1994b; 2002a, 2003a; Oury et al. 2001, 2004; Hechler et al. 2003).

Although a patient with $P2Y_1$ deficiency was described in abstract form by in 1999 (Oury et al. 1999), no further details of this family have been published in a full article since this 1999 abstract. A $P2Y_1$ gene dimorphism, 1622AG, was associated with a significant effect on platelet ADP response, with a greater response in carriers of the G allele (frequency 0.15). The response to all tested concentrations of ADP in GG homozygotes was higher than in AA homozygotes, but greatest with 0.1 μM ADP (on average, 130 % higher) (Hetherington et al. 2005).

The same authors also described a patient with a severe bleeding diathesis associated with a naturally occurring dominant negative $P2X_1$ mutant, lacking one leucine within a stretch of four leucine residues in the second transmembrane domain (amino acids 351–354) (Oury et al. 2000). However, the patient also displayed a severe defect of

ADP-induced platelet aggregation that cannot be explained by the defect of $P2X_1$ and could by itself account for the bleeding diathesis of the patient. Therefore, the relationship between genotype and phenotype in this patient remains unclear.

Defects of the Platelet ADP Receptor $P2Y_{12}$

$P2Y_{12}$ Deficiency

Congenital $P2Y_{12}$ deficiency is an autosomal recessive disorder. The first patient with severe $P2Y_{12}$ deficiency was described in 1992 (Cattaneo et al. 1992). He had a lifelong history of excessive bleeding, prolonged bleeding time (15–20 min), reversible aggregation in response to weak agonists, and impaired aggregation in response to low concentrations of collagen or thrombin. However, the most typical feature was that ADP, even at very high concentrations (>10 μM), did not induce full and irreversible platelet aggregation. When added to citrate platelet-rich plasma (PRP) of the patient, ADP induced normal platelet shape change followed by normal, brisk increase of light transmission, indicative of platelet aggregation; however, when the extent of platelet aggregation was about 10 % of maximal, platelet aggregates rapidly reversed to baseline. This is a typical feature of congenital $P2Y_{12}$ deficiency, which was observed also in patients who were subsequently described (Cattaneo 2011).

This typical abnormality of ADP-induced aggregation of $P2Y_{12}$-deficient platelets can be explained in light of the recently elucidated regulation of platelet RAP1 activation (Stefanini et al. 2015). RAP1 activation is controlled by the antagonistic balance between the calcium-sensitive RAP guanine nucleotide exchange factor (GEF), CalDAG-GEFI, which stimulates GTP loading on RAP1 (GTP-bound, active form), and the RAP GTPase-activating protein (GAP), RASA3, which catalyzes GTP hydrolysis (ADP-bound, inactive form). Platelet stimulation through ITAM-coupled and G protein-coupled (which include the ADP receptor $P2Y_1$) receptors leads to the activation of phospholipase C (PLC) isoforms, which convert phosphatidylinositol 4,5-bisphosphate to diacylglycerol and inositol 1,4,5-trisphosphate (IP3). IP3 then mediates a rise in the cytosolic Ca^{2+} concentration, which triggers CalDAG-GEFI-dependent RAP1 activation. CalDAG-GEFI signaling eventually subsides and RASA3 inactivates RAP1. In order to maintain RAP1 in the activated, ATP-bound form, RASA3 must be inhibited: this effect depends on phosphoinositide 3-kinase signaling, which in platelets is under the control of Gαi-coupled receptors, such as $P2Y_{12}$ and the α2A receptor for epinephrine (Stefanini et al. 2015). Therefore, deficiency of $P2Y_{12}$ prevents the inactivation of RASA3, thus explaining why ADP/$P2Y_1$-induced platelet aggregates rapidly deaggregate, independently of the concentration of ADP used.

Other abnormalities of platelet function observed in the first patient with congenital $P2Y_{12}$ deficiency, which were confirmed also in most similar patients who had been subsequently described, were (1) no inhibition by ADP of prostaglandin (PG) E_1-stimulated platelet adenylyl cyclase, but normal inhibition by epinephrine; (2) normal shape change and borderline-normal mobilization of cytoplasmic Ca^{2+} induced by ADP; and (3) presence of approximately 30 % of the normal number of binding sites for [^{33}P]2MeSADP on fresh platelets (Cattaneo et al. 1992) or [^{3}H]ADP on formalin-fixed platelets, which are associated with the ADP receptor $P2Y_1$ (Gachet et al. 1995). Five additional patients with severe $P2Y_{12}$ deficiency, belonging to four kindreds, were subsequently described: all of them displayed a platelet phenotype that was similar to that of the first patient (Nurden et al. 1995; Dawood et al. 2009).

The study of the son of a patient with homozygous $P2Y_{12}$ deficiency allowed the characterization of heterozygous $P2Y_{12}$ deficiency (Cattaneo et al. 2000): ADP-induced platelet aggregation was reversible for ADP concentrations ≤10 μM, but was full and irreversible for concentrations of ADP ≥10 μM; the inhibition of PGE_1-induced increase in platelet cyclic AMP was impaired, albeit not completely absent; the number of platelet binding sites for [^{33}P]2MeS-ADP was intermediate between his mother's and normal subjects'; finally, the platelet secretion was impaired. Because the secretion defect in this patient's platelets was not associated with impaired production of TXA_2 or low concentrations of platelet granule contents, it is very similar to that described in patients with an ill-defined and probably heterogeneous group of congenital defect of platelet secretion, sometimes referred to with the general term "primary secretion defect" (Cattaneo 2003; Cattaneo et al. 1997).

Mutation Analysis in $P2Y_{12}$ Deficiency

The $P2Y_{12}$ gene of two patients, including the first described one, displayed homozygous base pair deletions in the open reading frame, resulting in frameshifts and premature truncation of the protein (Table 2) (Dawood et al. 2009; Conley et al. 2001). Molecular analysis of the $P2Y_{12}$ gene of two sisters revealed an identical single bp deletion (378delC) occurring just beyond the coding sequence for the third transmembrane domain in $P2Y_{12}$, resulting in a frame shift (p.Thr126fs) and premature truncation of the protein (Conley et al. 2001). As only alleles encoding the mutated DNA sequence were found by PCR analysis, the patients were considered homozygous for the 378delC mutation. However, a subsequent study revealed that they suffer

Table 2 Characteristics of the patients with congenital $P2Y_{12}$ deficiency

Patient number [reference]	$P2Y_{12}$ mutations	$P2Y_{12}$-associated binding sites	Platelet aggregation induced by high concentrations of ADP	Bleeding time (min)	History of pathological bleeding
1 (Cattaneo et al. 1992)	p.[Gln98fs] +[Gln98fs]	Severely reduced	Reduced and reversible	15; 20	Yes

from $P2Y_{12}$ deficiency owing to haploinsufficiency and to the 378delC mutation in their remaining allele (Table 2) (Fontana et al. 2009). A patient of Japanese origin was homozygous for a single nucleotide substitution in the transduction initiation codon (ATG to AGG) (Table 2) (Shiraga et al. 2005). The molecular defect that is responsible for the severe $P2Y_{12}$ deficiency in another patient (Cattaneo et al. 2000) is less well defined (Hollopeter et al. 2001). One mutant allele contains a deletion of 2 bp within the coding region, at codon 240, resulting in a frameshift and early truncation of the protein. Surprisingly, the other allele did not display any mutation. The findings that the patient's platelets contained $P2Y_{12}$ transcripts derived from the mutant allele only and that his daughter, who had a heterozygous phenotype, inherited the mutant allele from her father and a normal allele from her mother suggest that the propositus has an additional, as yet unknown, mutation that silences the other allele (Table 2).

Congenital Dysfunction of $P2Y_{12}$

One patient with congenital bleeding disorder associated with abnormal $P2Y_{12}$-mediated platelet responses to ADP, whose platelets display normal number of dysfunctional $P2Y_{12}$ receptors, has been described (Cattaneo et al. 2003b). Platelets from this patient displayed reduced and reversible aggregation in response to 4 μM ADP, similar to normal platelets with a blocked $P2Y_{12}$ receptor. However, the response to 20 μM ADP, albeit still decreased and reversible, was more pronounced and was further inhibited by a $P2Y_{12}$ antagonist, indicating residual receptor function. ADP failed to lower adenylyl cyclase activity stimulated by PGE_1 in the patient's platelets. Analysis of the patient's $P2Y_{12}$ gene revealed, in one allele, a G to A transition changing the codon for Arg256 in transmembrane (TM) 6 to Gln and, in the other, a C to T transition changing the codon for Arg265 in extracellular loop (EL) 3 to Trp (Table 3). Neither mutation interfered with receptor surface expression but both altered receptor function, since ADP inhibited the forskolin-induced increase of cyclic AMP markedly less in cells transfected with mutant $P2Y_{12}$ than in wild-type cells (Cattaneo et al. 2003b). These observations, in accordance with previous studies of the $P2Y_1$ receptor (Moro et al. 1998, 1999) and the recent solution of the receptor structure (Zhang et al. 2014a, b), helped to identify regions in TM6 and EL3, whose structural integrity is necessary for normal receptor function. A heterozygous point mutation in the same region of the molecule, which changed codon 258 coding for proline (CCT) to threonine (ACT) (p.Pro258Thr), was described in a patient with mild bleeding disorder and severely impaired ADP-induced platelet aggregation (Table 3) (Remijn et al. 2007). Since the proline to threonine substitution alters the protein hydrophobicity, size, and rotational mobility, it is likely to affect the function of $P2Y_{12}$.

A heterozygous mutation, predicting a lysine to glutamate (p.Lys174Glu) substitution in $P2Y_{12}$, was identified in one patient with mild type 1 von Willebrand disease (VWD) (Daly et al. 2009). Platelets from this patient showed reduced and reversible aggregation in response to ADP, up to 10 μM. The reduced response was associated with an approximate 50 % reduction in binding of [^{3}H]2MeS-ADP. Considering that Lys174 is situated in the second extracellular loop of $P2Y_{12}$, adjacent to Cys175, which may be important for the expression of the ADP binding site receptor, and that a hemagglutinin-tagged p.Lys174Glu $P2Y_{12}$ variant showed surface expression in Chinese hamster ovary cells, it is likely that the Lys174Glu mutation is responsible for disruption of the ADP binding site of the receptor.

Table 3 Characteristics of the patients with congenital dysfunction of $P2Y_{12}$

Patient number [reference]	$P2Y_{12}$ mutations	$P2Y_{12}$-associated binding sites	Platelet aggregation induced by high concentrations of ADP	Bleeding time (min)	History of pathological bleeding
9 (Cattaneo et al. 2003b)	p.[Arg256Gln] +[Arg265Trp]	Normal	Reduced and reversible	19; 20	Yes

Patients 10 and 11 are the son and the daughter of patient 9. The upper normal limit of the bleeding time varies between 8 and 10 min in different laboratories

NA not available

[a]Patient 13 also had type 1 von Willebrand disease

[b]The data refer to the mother of the propositus, who had the same defect of her son, but had normal von Willebrand factor plasma levels. The propositus had type 1 von Willebrand disease, which accounted for a bleeding history of moderate severity

[c]The patients' platelets also displayed reduced platelet response to thrombin and PAR-1, associated with the presence of an intronic polymorphism of F2R gene, encoding for PAR-1, which had been shown to be associated with reduced PAR-1 receptor activity

It is interesting to note that, for reasons that are presently unclear, the two patients with heterozygous dysfunctional $P2Y_{12}$ described above (one with p.Pro258Thr and one with p.Lys174Glu) display a much more severe impairment of ADP-induced platelet aggregation compared to the two patients who are heterozygous for $P2Y_{12}$ deficiency (Remijn et al. 2007; Daly et al. 2009) and to the two children of patient AC, who are heterozygous for the p.Arg265Gln mutation (Cattaneo et al. 2003b) (Table 1).

$P2Y_{12}$ undergoes internalization and subsequent recycling to maintain receptor responsiveness, which is regulated by four amino acids at the extreme C-terminus of this receptor, a putative postsynaptic density 95/disc large/zonula occludens-1 (PDZ)-binding motif (Nisar et al. 2011). A heterozygous mutation in the PDZ-binding sequence of $P2Y_{12}$ (p.Pro341Ala) was detected in a patient with reduced expression of $P2Y_{12}$ on the cell surface, which was associated with significantly compromised $P2Y_{12}$ (Nisar et al. 2011).

A woman with lifelong bleeding history, characterized by both spontaneous and excessive postsurgical and post-traumatic hemorrhages, displayed severely impaired ADP-induced platelet aggregation and inhibition of PGE1-induced VASP phosphorylation, suggesting severely impaired $P2Y_{12}$ receptor function. Binding studies revealed a decreased expression of the receptor and low affinity for 2MeSADP (Patel et al. 2014). Thrombin- or protease receptor-activated peptide-1 (PAR-1)-induced platelet aggregation was impaired, compared to control; the addition of the $P2Y_{12}$ antagonist cangrelor did not reproduce the defect in control platelets, suggesting that it was not attributable to the lack of amplification by released ADP interacting with $P2Y_{12}$. The patient was found to be homozygous for c364C>T transition and p.Arg122Cys mutation. Arg122 is within the highly conserved region DRY motif, occurring at the boundary between transmembrane III and extracellular loop II, which is associated with G protein-coupled receptor activation and/or G protein coupling and plays a role in regulating receptor conformational states (Rovati and Capra 2014). The patient also displayed an intronic polymorphism in the F2R gene, which encodes PAR-1, which had been shown to be associated with reduced PAR-1 receptor activity. Studies in transfected cell lines revealed that the reduced p.Arg122Cys $P2Y_{12}$ expression is a consequence of agonist-independent internalization followed by subsequent receptor trafficking to lysosomes (Patel et al. 2014).Two sisters of the proposita had the same phenotype and genotype, while her two sons had mild bleeding symptoms and were heterozygous for the defect.

More recently, two brothers of Turkish descent, with bleeding disorder and severe defect of $P2Y_{12}$-mediated

platelet responses to ADP, were described (Lecchi et al. 2015), whose platelets displayed normal number of binding sites for the $P2Y_{12}$ antagonist [^{3}H]PSB-0413 (Ohlmann et al. 2013). However, the affinity of [^{3}H]PSB-0413, and that of the agonists ADP and 2MeSADP, was reduced. Patients' DNA showed a homozygous c.847T>A substitution that changed the codon for His-187 to Gln (p.His187Gln). Crystallographic data and molecular modeling studies indicated that His187 in transmembrane (TM)5 is important for agonist and nucleotide antagonist binding and located in a region undergoing conformational changes (Zhang et al. 2014a, b; Lecchi et al. 2015).

Bleeding Diathesis

Patients with defects of $P2Y_{12}$ experience mucocutaneous bleedings and excessive postsurgical or post-traumatic blood loss. The severity of their ISTH bleeding score (Ohlmann et al. 2013) of two sisters with the same molecular defect (Cattaneo et al. 2000) was quite different: 7 (mild bleeding history) and 13 (moderate/severe bleeding history) (unpublished observations). After extensive investigation of hemostasis parameters, which included measurement of the activity of clotting and fibrinolytic factors and the search for known polymorphisms of hemostasis proteins, we found no explanation for the discrepancy in the severity of bleeding manifestations in the two sisters.

The bleeding score of patients with heterozygous defect, son of one of the two sisters mentioned above, was normal; however, it must be noted that this young boy had not yet experienced situations that could challenge the hemostatic system at the time of our investigation. His bleeding time, despite the mild defect of $P2Y_{12}$, was prolonged (13 min).

Diagnosis and Treatment

The diagnosis of a $P2Y_{12}$ defect should be suspected when ADP, even at relatively high concentrations ($\geq$10 μM), is unable to induce full, irreversible platelet aggregation, while inducing normal shape change. Tests that evaluate the degree of inhibition of adenylyl cyclase by ADP, by measuring either the platelet levels of cyclic adenosine monophosphate (cAMP) or the phosphorylation of vasodilator-stimulated phosphoprotein (VASP) (Zighetti et al. 2010) after the exposure of platelets to prostaglandin (PG) E_1, should be used to confirm the diagnosis. Measurement of the number of platelet binding sites for radiolabeled 2-methyl-thyo ADP or of the specific $P2Y_{12}$ antagonist [(3) H]PSB-0413 (Ohlmann et al. 2013) could be used as a further confirmatory tests, which, however, could give normal results in patients with dysfunctional $P2Y_{12}$ (Table 4).

The intravenous infusion of the vasopressin analogue desmopressin (0.3 μg/kg) shortened the prolonged bleeding time of a patient from 20 min to 8.5 min (Cattaneo et al. 1994b). After the infusion of desmopressin, which was repeated twice at 24-h intervals, the patient underwent a surgical intervention for disc hernia repair, which was not complicated by excessive bleeding. Although the efficacy of desmopressin in reducing bleeding complications of patients with defects of primary hemostasis is anecdotal (Cattaneo et al. 2002b), its administration is generally without serious side effects.

Polymorphisms of the $P2Y_{12}$ Gene

Four polymorphisms of the $P2Y_{12}$ gene were identified, which were in total linkage disequilibrium, determining haplotypes H1 and H2, with respective allelic frequencies of 0.86 and 0.14. H2 haplotype is a gain-of-function haplotype, associated with increased ADP-induced platelet aggregation (Fontana et al. 2003a). The H2 haplotype was more frequent among 184 patients with peripheral artery disease than in 330 age-matched control subjects (OR, 2.3; CI, 1.4 to 3.9; $p = 0.002$ after adjustment for diabetes, smoking, hypertension, hypercholesterolemia, and other selected platelet receptor gene polymorphisms) (Fontana et al. 2003b).

Several studies tested the hypothesis that common polymorphisms of the $P2Y_{12}$ gene might interfere with the antiplatelet effects of drugs inhibiting the $P2Y_{12}$ receptor, accounting for the well-known individual variability in the response to these agents (Cattaneo 2004, 2012). The vast majority of these studies, with few exceptions, reported that $P2Y_{12}$ polymorphisms are not associated with altered platelet function inhibition by $P2Y_{12}$ antagonists (von Beckerath et al. 2005; Angiolillo et al. 2005).

Table 4 Diagnosis of defects of the platelet $P2Y_{12}$ receptors

1. Diagnostic suspicion
– Evidence that ADP, even at high concentrations (>10 μM), is unable to induce full and irreversible platelet aggregation (light transmission aggregometry)
2. Confirmatory tests
– Evidence that ADP fails to inhibit the increase in platelet cyclic AMP concentration induced by PGE1 (or other molecules that stimulate adenylyl cyclase)
– Reduced platelet reactivity index at the VASP-phosphorylation assay
3. Supplementary test
– Defective platelet binding of agonists (e.g., radiolabeled 2MeSADP) or antagonists (e.g., radiolabeled PSB-0413) at the $P2Y_{12}$ receptor

Defects of the Platelet Thromboxane Prostanoid Receptors

The thromboxane prostanoid (TP) receptor is a G protein-coupled receptor that is encoded in humans by the TBXA2R gene. Thromboxane A_2 (TXA_2) and its endoperoxide precursors prostaglandin (PG)G_2 and PGH_2 mediate a range of physiological and pathological responses in platelets, monocytes, macrophages, endothelial cells (EC), and smooth muscle cells (SMC), which all express TP receptor (Capra et al. 2014).

Activation of the platelet TP receptor triggers platelet activation, secretion, and aggregation, which play important roles in the formation of both hemostatic plugs and pathological thrombi.

Defects of the platelet TP receptor are associated with mild-moderate impairment of primary hemostasis, which is generally characterized by pathological mucocutaneous bleeding. The phenotype of patients with TP receptor defects is similar to that described in transgenic mice lacking TP receptor (Thomas et al. 1998).

In 1981, three reports of impaired platelet responses to TXA_2 in patients with bleeding disorders were published (Lages et al. 1981; Samama et al. 1981; Wu et al. 1981). The platelets from these patients could synthesize TXA_2 from exogenous arachidonate, but were unable to undergo normal TXA_2-dependent aggregation and secretion in response to a variety of agonists. In one patient, the stable TXA_2 mimetic U46619 was tested and found to be unable to elicit normal platelet responses (Wu et al. 1981), providing convincing evidence that his platelets had a defect at the receptor level.

In 1993, a similar patient with a mild bleeding disorder was described, whose platelets did not undergo shape change, aggregation, and secretion in response to the synthetic TXA_2 mimetic STA_2 (Fuse et al. 1993). Binding studies of radiolabeled TXA_2 agonists and antagonists revealed that the patient platelets had normal number of TXA_2 binding sites and normal equilibrium dissociation rate constants. Despite the normal number of TP receptors, TXA_2-induced inositol 1,4,5-triphosphate formation, Ca^{2+} mobilization, and guanosine-5′-triphosphate (GTP)ase activity were abnormal, suggesting that the abnormality of these platelets was impaired coupling between TP, G protein, and phospholipase C (PLC). The platelet aggregation and secretion responses to several agonists were impaired. A similar patient, who was also affected by polycythemia vera, had previously been described by Ushikubi et al. (1987).

These two last patients were subsequently found to have an Arg60 to Leu mutation in the first cytoplasmic loop of the TxA_2R (Hirata et al. 1994), affecting both isoforms of the receptor (Hirata et al. 1996; Okuma et al. 1996). The mutant receptor expressed in Chinese hamster ovary cells showed decreased agonist-induced second messenger formation despite its normal ligand binding affinities. The mutation was found exclusively in the affected members of the two unrelated families and was inherited as an autosomal dominant trait. Although the heterozygous patients did not differ from the homozygous patients in terms of aggregation and secretion responses of platelets to TXA_2, subsequent studies showed that in heterozygous patients, the mutant TXA_2R suppresses the wild-type receptor-mediated platelet aggregation and secretion by a mechanism independent of inhibition of PLC activation (Fuse et al. 1996; Higuchi et al. 1999).

In the year 2010, a heterozygous Asp304Asn substitution in TXA_2R was described in a 14-year-old boy experiencing severe nose bleeding. Platelet aggregation and ATP secretion induced by U46619 were reduced. The TXA2R antagonist [^{3}H]-SQ29548 showed an approximate 50 % decrease in binding to the patient's platelets, indicating that the mutation is associated with reduced ligand binding (Mumford et al. 2010).

Kamae et al. (2011) described a severe defect of U46619-induced platelet aggregation and secretion in a 7-year-old girl and her father. Immunoblots showed that the TP receptor expression levels in their platelets were approximately 50 % of controls, and nucleotide sequence analysis revealed that they were heterozygous for a novel mutation, c.167dupG in the TP receptor cDNA. Expression studies in CHO cells indicated that the mutation was responsible for the expression defect in the TP receptor. Finally, Mumford et al. (2013) described a patient with reduced platelet aggregation and secretion responses to TP receptor activators, and a heterozygous Trp29 to Cys substitution. Total TP receptor expression in patient's platelets was normal, but there was reduced maximum binding and reduced affinity of binding to the TP receptor antagonist [^{3}H]-SQ29548.

Defects of the α_2-Adrenergic Receptors

In two families whose members had impaired platelet aggregation and secretion in response to epinephrine but normal responses to other agonists, the defect was a decreased number of platelet α_2-adrenergic receptors (Rao 2003; Tamponi et al. 1987). Surprisingly, in one family inhibition of platelet adenylyl cyclase by epinephrine was normal (Rao 2003). Considering that impaired platelet responses to epinephrine are observed in a relatively high percentage of otherwise normal subjects, the relationship between the described defects and bleeding manifestations still needs to be clarified.

Defects of the PAR-1 Receptors

PAR-1, encoded by the F2R gene, is one of the two GPCR for thrombin expressed by human platelets, the second one being PAR-4 (De Candia et al. 2007). Thrombin cleaves the N-terminal extracellular domain of the receptor, which exposes a new N-terminus that, by refolding, acts as ligand to the receptor. A synthetic dodecapeptide simulates the physiological ligand and is available for studies of platelet function involving PAR-1.

Isolated, congenital defects of the PAR-1 receptor for thrombin have not been described yet.

As already mentioned, a polymorphism of the encoding gene, associated with decreased receptor function, has been described in association with dysfunctional $P2Y_{12}$ in a kindred with bleeding diathesis (Patel et al. 2014).

It has been shown that some patients with the gray platelet syndrome display a decreased expression of PAR-1 on the platelet membrane, which may contribute to their platelet function defect and bleeding tendency (De Candia et al. 2007; Larocca et al. 2015).

Take-Home Message

- Abnormalities of the platelet $P2Y_{12}$ receptor for ADP and of the TP receptor for thromboxane A2 are the best characterized disorders of platelet function associated with defects of receptors for soluble agonists.
- In spite of the selective abnormality of the platelet activation pathway, general alterations of platelet aggregation and secretion are observed in affected individuals, because both secreted ADP and thromboxane A_2 play important roles in the amplification of platelet responses to other agonists.
- The inability of ADP, even at very high concentrations, to elicit full, irreversible platelet aggregation should raise the hypothesis of $P2Y_{12}$ defect.
- The inability of thromboxane A_2 analogues to cause platelet shape change and/or aggregation should raise the hypothesis of TP receptor defect.

Defects of Platelet Granules and Secretion

Barbara Zieger

Abstract

Inherited platelet disorders are usually classified according to the defect in the platelets. These comprise defects of platelet receptors, signal transduction, cytoskeleton, and platelet granule secretion. Platelet α-granules, δ-granules, or both may be affected resulting in phenotypical changes. According to the disorder platelet size and morphology can also be altered.

Platelet Granules

Platelets contain three groups of secretory organelles: α-granules, δ-granules ("dense bodies"), and lysosomes. The role played by platelet lysosomes remains unclear.

In unactivated platelets α-granules and δ-granules are distributed throughout the whole platelet. The actin skeleton lies between them acting as a barrier. However, after platelet activation, the actin skeleton facilitates granule secretion by disassembling its network and subsequently participating in new interactions. Platelet activation leads to platelet shape change and to centralization of the granules within the platelets. Granules fuse with other granules and then with the open canalicular system (OCS), so that the granules' contents can be discharged into the extracellular space (Stenberg et al. 1984). Individual granules can, however, fuse with the platelet plasma membrane and thus discharge their contents into the extracellular space (Morgenstern et al. 1987). The fusions between the plasma membrane, granule membrane, and OCS are regulated by so-called SNARE proteins (Feng et al. 2002). These proteins are in turn influenced by other proteins (i.e., NSF or Sec1/Munc) (Lo et al. 2005). Actomyosin contraction supports granule secretion (Suzuki et al. 1999), which then intensifies platelet activation. As the granule membrane fuses with the platelet membrane during secretion, the surface of the platelets increases, as does the number of its receptors, e.g., the expression of P-selectin (α-granules) rises on the platelet surface (Fig. 1).

α-Granules

α-Granules are the most frequently appearing granules in platelets (about 40–80 α-granules per platelet measuring 200–500 nm). Interestingly, megakaryocytes and platelets can, via endocytosis, absorb fibrinogen and factor V from the extracellular space, storing them in α-granules (Bouchard et al. 2008). α-Granules contain membrane-bound proteins that are expressed on the platelet surface after platelet activation (i.e., P-selectin) and as well dissolvable proteins that are released into the extracellular space (e.g., VWF, thrombospondin, FV, fibrinogen).

P-Selectin

P-selectin is a key platelet adhesion receptor. The most important ligand for P-selectin is P-selectin glycoprotein ligand-1 (PSGL-1) which is expressed on almost all leukocytes. P-selectin is a typical membrane protein in the α-granule family and is thus employed as a marker when investigating an α-granule defect via flow cytometry. It is increasingly expressed on the platelet surface after platelet activation and granule secretion.

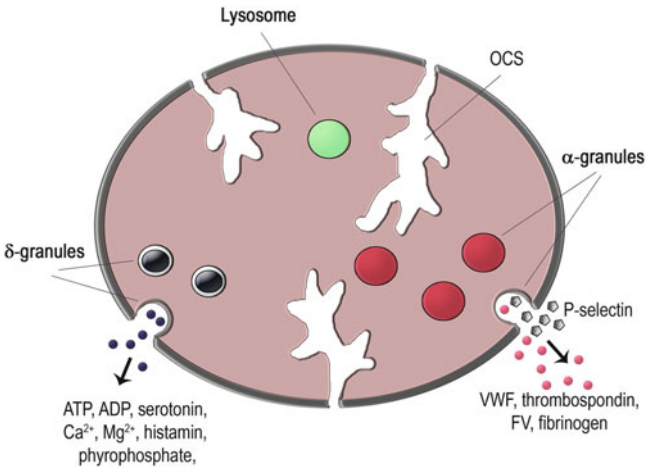

Fig. 1 Platelets contain three groups of secretory organelles: α-granules, dense (δ-) granules, and lysosomes. The contents of these granules can be mobilized for extracellular degranulation

δ-Granules ("Dense Bodies")

δ-Granules are in the family of lysosome-related organelles to which melanosomes, cytotoxic T-cell granules, and basophilic and azurophilic granules also belong. δ-Granules are smaller (approx. 200 nm) and more seldom found in platelets (3–9 δ-granules per platelet) as α-granules (Sixma et al. 1989). δ-Granules contain ATP, ADP, serotonin, histamine, pyrophosphate, and Ca^{2+}- and Mg^{2+}-ions. Serotonin and CD63 function as markers for δ-granules and their secretion. CD63 (granulophysine, LAMP3) is a typical membrane protein in lysosome-related organelles.

Platelet Granule Defects

Platelet granule defects can be detected in isolation or in conjunction with various syndromal disorders. Platelet granule defects are categorized as α-storage pool defects (α-granule secretion is reduced), δ-storage pool defects (δ-granule secretion is inadequate), and α-/δ-storage pool defects (both α- and δ-granule secretion are pathological) (Table 1).

Table 1 Genetic mutations and patterns of inheritance associated with granule defects

	Disease	Gene mutation	Inheritance
α-Granule defects	Gray platelet syndrome	*NBEAL2*	Autosomal recessive
		GFI1B	Autosomal dominant
	Arthrogryposis, renal dysfunction, and cholestasis (ARC) syndrome	*VPS33B*	Autosomal recessive
	Quebec platelet defect	*PLAU*	Autosomal dominant
	X-chromosomally inherited macrothrombocytopenia	*GATA1*	X-linked dominant
	Hermansky-Pudlak syndrome	*HPS1-HPS10*	Autosomal recessive
δ-Granule defects	Chediak-Higashi syndrome	*LYST*	Autosomal recessive
	Griscelli syndrome	*RAB27A*, *MYO5A*, *MLPH*	Autosomal recessive
	TAR (thrombocytopenia with absent radius) syndrome	*RBM8A*	Autosomal recessive/ dominant
	Wiskott-Aldrich syndrome	*WAS*	X-linked recessive
α-/δ-Granule defects	RUNX1 defect	*RUNX1*	Autosomal dominant
	Paris-Trousseau syndrome/Jacobsen syndrome	*FLI1*	

α-Granule Defects

Gray Platelet Syndrome

Gray platelet syndrome (GPS) is characterized by a grayish appearance of the patient's platelets in the peripheral blood smear and the presence of a platelet α-granule defect. The platelets appear grayish due to a severe shortage (or even absence) of α-granules (Raccuglia 1971; White and Brunning 2004). Platelet vacuoles are often visible. These patients usually present with macrothrombocytopenia. The α-granule secretion defect can be diagnosed via flow cytometry analysis (CD62 expression). The severity of bleeding tends to vary enormously from individual to individual. The patients can develop bone marrow fibrosis and splenomegaly. This is an autosomal recessive inherited disease caused by a mutation in the *NBEAL2* (neurobeachin-like 2) gene which codes for neurobeachin-like 2 protein (Kahr et al. 2001; Gunay-Aygun et al. 2011; Albers et al. 2011). NBEAL seems to be involved in granule trafficking and the development of α-granules.

Mutations in the *GFI1B* gene (which encodes for the transcriptional repressor growth factor independent 1B) lead to a truncated protein and are associated with an autosomal dominant form of GPS. In these patients macrothrombocytopenia with dyserythropoiesis and α-granule defect have been described (Hinckley and Di Paola 2014).

Arthrogryposis, Renal Dysfunction, and Cholestasis Syndrome

These patients are characterized by anomalies such as arthrogryposis multiplex congenita, kidney dysfunction,

cholestasis, failure to thrive, and increased bleeding tendency. Usually the patients die during their first year of life. The children present with pale platelets and a pronounced shortage or absence of α-granules (Kim et al. 2010). Aggregation after stimulation with ADP and arachidonic acid is pathological. Arthrogryposis, renal dysfunction, and cholestasis (ARC) syndrome is caused by defects in the VPS33B protein, a Sec1/Munc protein. VPS33B protein is a membrane-associated protein that regulates the SNARE proteins and is involved in biogenesis of granules. This disease is inherited via the autosomal-recessive pathway.

Quebec Platelet Defect

Quebec platelet defect is characterized by the upregulation of urokinase plasminogen activator in platelet α-granules (Kahr et al. 2001), which leads to increased levels of u-plasminogen activator and to exaggerated fibrinolytic activity, that is, the increased depletion of α-granule proteins via plasmin. This defect, which is inherited via the autosomal dominant pathway, is attributable to a duplication in the *PLAU* (urokinase plasminogen activator) gene. Affected patients suffer from severe bleeding that fails to respond adequately to platelet administration; however, they do respond to antifibrinolytics.

X-Chromosomally Inherited Macrothrombocytopenia

Patients with a mutation in GATA1 present with thrombocytopenia, gray platelets, and very reduced or absent α-granules. The hypothesis is that GATA1 is a regulator of several genes lying upstream that are responsible for α-granules biogenesis. As GATA1 is important as a transcription factor for megakaryocytopoesis and erythropoiesis, these patients have anemia as well as thrombocytopenia (Nichols et al. 2000).

Secretion Disorder Affecting δ-Granules

Following platelet activation, the δ-granules release their contents (ADP, ATP, and serotonin) and thus contribute to increased platelet activation. 10–18 % of patients with a congenital platelet functional disorder suffer from a secretion disorder of the δ-granules whose genetic origin is currently unknown. The assumption is that the platelet secretion disorder is caused by various genetic anomalies. δ-Granule secretion defect seems to be inherited either via the autosomal recessive or autosomal dominant pathway. The degree of bleeding tendency varies widely. The diagnosis of this disorder using platelet aggregometry yields highly variable results, which is why it is important to employ flow cytometry analyses to diagnose the secretion disorder (decreased CD63 expression). The platelet concentration of adenin nucleotides and the ADP/ATP quotient are both reduced.

Hermansky-Pudlak Syndrome

Patients with Hermansky-Pudlak syndrome are characterized by tyrosinase-positive oculocutaneous albinism and increased bleeding symptoms which are caused by a δ-granule defect (Gahl et al. 1998). These patients suffer from poor vision and nystagmus. They can also develop inflammatory intestinal diseases and/or interstitial lung fibrosis. Accumulation of ceroid-like material in various tissues has been described and is caused by defect involving the organelles in different cell systems. Platelet δ-granules, melanosomes, and lysosomes are affected. Most patients present prolonged bleeding time (Ivy) and pathological δ-granule secretion. The disease is inherited via the autosomal recessive pathway, triggered by a mutation on one of the ten *HPS* genes. All the HPS proteins are members of the four protein complexes: BLOC-1 (biogenesis of lysosome-related organelle complex-1), BLOC-2, BLOC-3, and adaptor protein complex-3 (AP-3).

HPS type 2 (HPS2) is caused by mutations in the gene encoding the β-subunit of the cytosolic adaptor protein AP-3 (*AP3B1*). The AP-3 complex is important for the formation of vesicles at the early endosomes and is ubiquitously expressed. This complex is responsible to recruit cargo proteins to newly formed vesicles and transport them to late endocytic compartments. The absence of the AP-3 complex leads to missorting of various proteins from specialized intracellular compartments to the general exocytotic pathway. Patients with HPS2 develop an immune deficiency in addition to the other symptoms. Protein missorting leads to several features of the HPS2 phenotype (neutropenia, pigmentation disorder, platelet secretion defect). Patients with HPS2 can be distinguished by platelet flow analysis from the other HPS subtypes. Flow cytometric analysis of the patient's platelets showed already elevated CD63 expression on resting platelets with no further increase after thrombin stimulation. Misrouting of lysosomal proteins such as CD107 or CD63 to the cell membrane has also been found on fibroblasts and CTL clones. So far, one patient with HPS2 who developed hemophagocytic lymphohistiocytosis (HLH) has been described (Enders et al. 2006). In addition, one patient with a HPS10 defect which caused an immune deficiency has been described (Ammann et al. 2016).

Chediak-Higashi Syndrome

Patients with Chediak-Higashi syndrome present with an immune deficiency (lysosomal defect) due to a mutation in the *LYST* (lysosomal traffic regulator) gene, oculocutaneous albinism, neurological anomalies, and mild hemophilia (platelet δ-granule defect). The protein LYST is involved in trafficking processes of lysosomes and δ-granules. The disease is inherited via the autosomal recessive pathway. Patients suffer from recurrent bacterial infections, leukocytopenia, and pathological natural killer (NK) function (Rendu et al. 1983). Thrombocytopenia may be present due to splenomegaly. The blood smear typically reveals peroxidase-positive inclusions in the neutrophils. Most of these patients develop lymphohistiocytosis. The children tend to die before the tenth year of life unless hematopoietic stem cell transplantation (HSCT) has taken place.

Griscelli Syndrome

Patients with Griscelli syndrome (mutation either in the *RAB27A*, *MYO5A*, or *MLPH* gene) present (in addition to the typical hypopigmentation) with frequent bacterial infections, hepatosplenomegaly, neutro- and thrombocytopenia, and immune deficiency. There is no solid evidence thus far of increased bleeding tendency. The disease is inherited via the autosomal recessive pathway. Patients with a RAB27A mutation still express the *RAB27B* gene (which compensates in part for the RAB27A defect), which may be why their bleeding tendency is not very pronounced. In a mouse model (*ashen*) a reduction of δ-granules has been described (Gunay-Aygun et al. 2004; Sandrock and Zieger 2010).

TAR (Thrombocytopenia with Absent Radius) Syndrome

Typically, patients with TAR are missing the bilateral radii, but their thumbs are present. They also show transient thrombocytopenia ($<50 \times 10^9$/L) and may have a reduced number of δ-granules in platelets (Bonsi et al. 2009). Other potential malformations include skeletal anomalies, heart defects, or malformations in the urogenital tract. TAR syndrome is caused by an at least 200 kb-large deletion on chromosome region 1q21.1, and it is inherited either via an autosomal recessive or a dominant pathway. Most of the patients with TAR carry a rare null allele at the *RBM8A* locus (Albers et al. 2012).

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS), an X-chromosomal, recessively inherited disease, is associated with microthrombocytopenia, a severe immune deficiency, eczematous skin disorders, and myeloproliferative disease (immune histiocytosis) (Gulacsy et al. 2011). Patients can display increased bleeding symptoms, and the severity of the bleeding tendency can vary. Typical are thrombocytopenia and a seriously reduced number of platelet δ-granules. This disease is caused by a mutation in the *WAS* gene which codes for WAS protein (WASP). WASP regulates actin filament organization. Hematopoietic stem cell transplantations have successfully performed in these patients.

Secretion Disorder Affecting α- and δ-Granules

Patients with RUNX1 haplodeficiency present with an autosomal dominant thrombocytopenia, abnormal platelet responses, and an increased predisposition to leukemia. The platelet function and biochemical abnormalities reported with RUNX1 mutations comprise decreased aggregation and α- and δ-granule deficiencies (Hinckley and Di Paola 2014; Stockley et al. 2013; Rao 2013).

Paris-Trousseau Syndrome and Jacobsen Syndrome (11q Terminal Deletion Syndrome)

Patients with Paris-Trousseau syndrome or Jacobsen syndrome usually present with mild tendency to bleed and congenital macrothrombocytopenia. α-Granules are present, but α-granule secretion is highly pathological. In addition, Stockley et al. described a few patients with FLI1 defects and reduction in platelet ATP secretion in response to all agonists (Stockley et al. 2013). The cause is a defect in the *FLI1* gene (Hart et al. 2000; Favier et al. 2003). In the case of Jacobsen syndrome, there is a large deletion on chromosome 11, which incorporates the *FLI1* gene. FLI1 is a member of the ETS (E-twenty six) family of transcription factors and is expressed in hematopoietic cells. FLI1 regulates genes expressed in early and late megakaryocytopoiesis. These patients can additionally present a congenital heart defect, facial dysmorphia, and psychomotoric retardation.

Therapy

In case of a bleeding, hemostyptical measures locally are important. Other potential therapies are antifibrinolytics or DDAVP (desmopressin, only in children over 3 years of age) (Hayward et al. 2006). Recombinant FVIIa or platelet concentrate can also be administered. However, after application of platelet concentrates, the patients can develop antibodies against platelets and HLA antigens, respectively. Patients who develop anemia should undergo iron substitution. To achieve normalization of the hematocrit is important as the red blood cells have the ability to force platelets onto the vessel wall so that they adhere to the injured endothelium. These patients had been suffering from very severe, life-threatening bleeding symptoms and therefore, HSCT was performed.

Take Home Message

Patients with thrombocytopenia and/or thrombocytopathia should be further investigated using blood smear, platelet aggregometry (Born), and flow cytometry. It is important to distinguish micro- and macrothrombocytopenia. Analyses of platelet receptors expression and their function can hint to the diagnosis. In addition, P-selectin (CD62) is a marker for α-secretion defect and CD63 is used to identify a δ-granule secretion defect in platelets.

Defects of Platelet Signal Transduction

Binggang Xiang and Zhenyu Li

Abstract

Blood platelets play an essential role in hemostasis. The primary physiological function of platelets is to form hemostatic thrombi that prevent blood loss and maintain vascular integrity, which requires a robust and precise response of platelets to vascular injury. On the other hand, platelet activation must be tightly controlled. Dysregulated thrombus formation (thrombosis) causes blockage of blood vessels, leading to ischemia. Platelets in normal circulation are in a non-adherent "resting" state. Upon vascular injury, platelets are activated following initial adhesion to adhesive proteins like von Willebrand factor (VWF) and collagen or by soluble platelet agonists like ADP, thrombin, and thromboxane A_2 (TXA_2). These adhesive proteins and soluble agonists induce signal transduction via their respective receptors and receptor-specific signaling pathways. The various receptor-specific platelet activation signaling pathways converge into common signaling events, such as activation of PKC and Ca^{2+} mobilization, which stimulate platelet shape change, granule secretion, and ultimately induce the "inside-out" signaling process leading to activation of the ligand binding function of integrin $\alpha_{IIb}\beta_3$. Ligand binding to integrin $\alpha_{IIb}\beta_3$ mediates platelet adhesion and aggregation and triggers "outside-in" signaling, resulting in platelet spreading, granule secretion, stabilization of platelet adhesion and aggregation, and clot retraction. Defects in platelet signal transduction may lead to bleeding disorder. This chapter briefly introduces normal signal transduction of platelet activation followed by detailed description of inherited defects in the signaling molecules in platelets including receptors and kinases, leading to impaired platelet function and bleeding disorders (Table 1).

Defects of Collagen/GPVI/Integrin α2β1 Signaling

Platelets have two major receptors for collagen, integrin $\alpha_2\beta_1$, which is important for platelet adhesion to collagen, and GPVI, which is required for collagen-induced platelet signaling and activation (Clemetson and Clemetson 2001). GPVI is a member of the immunoglobulin superfamily, which is coupled to IgG Fc receptor γ chain (FcRγ) (Tsuji et al. 1997). Upon cross-linking of GPVI by its ligand, the immunoreceptor tyrosine-based activation motif (ITAM), YxxL/I-X_{6-8}-YXXL/I, within FcRγ cytoplasmic domain, is tyrosine phosphorylated by Src family kinases (SFKs) (mainly Lyn and Fyn) bound to the cytoplasmic domain of GPVI (Ezumi et al. 1998; Quek et al. 2000). ITAM phosphorylation leads to binding and activation of the tyrosine kinase Syk, which phosphorylates downstream targets such as the transmembrane adapter linker for activation of T cells (LAT) and the Src homology (SH) 2 domain-containing leukocyte phosphoprotein of 76 kDa (SLP-76). This induces formation of a signaling complex including LAT, SLP-76,

Table 1 Defects of platelet signal transduction and bleeding disorder

1. Defects of collagen/GPVI/integrin $\alpha_2\beta_1$ signaling
(a) Defects in GPVI gene
(b) Defects in integrin $\alpha_2\beta_1$
(c) Defects in Bruton's tyrosine kinase (Btk)
2. Defects of VWF/GPIb-IX-V signaling
(a) Defects in GPIb-IX-V complex (Bernard-Soulier syndrome)
3. Defects in integrin signaling
(a) Defects in $\alpha_{IIb}\beta_3$ (Glanzmann thrombasthenia)
(b) Defects in kindlin 3 (LAD-III)
(c) Defects in ADAP
4. Defects in platelet activation and signaling mediated by G protein-coupled receptors (GPCRs)
(a) Defects in GPCRs
Defects in TXA_2 receptor
Defects in ADP receptors $P2Y_{12}$ and P2Y1
Defects in ATP receptor P2X1
(b) Defects in Gq signaling
(c) Defects in Gi signaling
(d) Defects in Gs signaling
(e) Defects in the regulator of G protein signaling (RGS)
5. Defects in common platelet activation signaling and amplification pathways
(a) Defects in TXA_2 generation
cPLA2 deficiency
COX-1 deficiency
TXA_2 synthase deficiency
(b) Defects in PKA
(c) Defects in phospholipase C signaling
Defects in phospholipase C β2
(d) Defects in calcium signaling
Defects in CalDAG-GEFI
(e) Defects in procoagulant activity
Defects in TMEM16F (Scott syndrome)
Defects in STIM1(Stormorken syndrome)
(f) Defects in cytoskeletal organization
Defects in WASP (Wiskott-Aldrich syndrome)
(g) Defects in secretion signaling
Defects in syntaxin-11 (FHLH type 4)

Btk, Gads, and phospholipase Cγ2 (PLCγ2), which further activates PLCγ2 (Watson et al. 2005; Nieswandt and Watson 2003), leading to TXA_2 synthesis, granule secretion, and integrin activation (Ezumi et al. 1998; Quek et al. 2000). Signal transducer and activator of transcription 3 (STAT3) is a transcription factor activated by cytokine-induced intracellular signals. A recent study reported that a novel nontranscriptional activity of STAT3 enhanced collagen-induced signaling in platelets (Zhou et al. 2013). STAT3 serves as a protein scaffold to facilitate the activation of PLCγ2 by Syk. Maintenance of a pool of active SFKs in platelets appears to be important for GPVI-mediated platelet activation and involves CD148, a receptor-like protein tyrosine phosphatase (PTP), which has been reported to dephosphorylate the C-terminal inhibitory tyrosines of SFKs (Senis et al. 2009). The PH domain of PLCγ2 also interacts with the PI3K product phosphatidylinositol 3,4,5-trisphosphate (PI 3,4,5P3), thereby facilitating PLCγ2 recruitment to the plasma membrane and activation (Pasquet et al. 1999; Watanabe et al. 2003; Gilio et al. 2009). Platelet ITAM signaling appears critical for vascular integrity in inflammation (Boulaftali et al. 2013).

Integrin $\alpha_2\beta_1$ plays a critical role in adhesion of platelets to collagen and the stabilization of platelet-collagen interactions. Although megakaryocyte- and platelet-specific β1 conditional knockout mice have normal aggregation to collagen and tail-bleeding times, suggesting $\alpha_2\beta_1$ is not an essential receptor for collagen (Nieswandt et al. 2001), binding of platelets to collagen is reduced when integrin β1 is deleted or platelets are treated with a blocking antibody against $\alpha_2\beta_1$. $\alpha_2\beta_1$ mediates platelet adhesion and spreading on collagen via a pathway involving multiple signaling events, including Src, Syk, SLP-76, PLCγ2, FAK, plasma membrane calcium ATPase, and Ca^{2+} mobilization (Inoue et al. 2003). Under flow conditions, efficient platelet adhesion on collagen requires both integrin $\alpha_2\beta_1$ and GPVI (Sarratt et al. 2005). SLP-76 but not LAT plays an important role in platelet adhesion on collagen under flow.

Defects in GPVI gene have been reported previously in several unrelated patients (Dumont et al. 2009; Hermans et al. 2009; Matus et al. 2013). A patient with an R38C mutation in exon 3 of one allele and an insertion of five nucleotides in exon 4 of the other allele of the gene coding GPVI had a mild bleeding phenotype (Dumont et al. 2009). Platelets from the patient had no response to collagen stimulation. The expression level of GPVI in platelets was dramatically reduced. In contrast to wild-type recombinant GPVI-Fc, the ability of R38C GPVI-Fc to bind to collagen was diminished. Another patient was compound heterozygous for an out-of-frame 16-bp deletion and a missense mutation S175N (Hermans et al. 2009). The patient had a lifelong history of bleeding problem. Platelets from this patient did not respond to collagen, convulxin, or the collagen-related peptide (CRP). Patients lacking integrin $\alpha_2\beta_1$ showed prolonged bleeding (Nieuwenhuis et al. 1985). Bruton's tyrosine kinase (Btk) plays a crucial role in B-cell development. Lack of Btk expression due to mutations in the gene coding Btk in humans leads to the B-cell deficiency X-linked agammaglobulinemia (XLA). Btk is also expressed in platelets and plays roles in collagen- and VWF-induced platelet activation (Liu et al. 2006; Quek et al. 1998). Platelet aggregation and secretion in response to collagen in the XLA patients were significantly diminished (Quek et al. 1998).

Defects of VWF/GPIb-IX-V Signaling

Under high shear rate flow conditions, initial platelet adhesion requires binding of immobilized VWF to its receptor, GPIb-IX-V complex on platelets (Savage et al. 1996; Lopez and Dong 1997; Du 2007). VWF forms a so-called catch-bond or flex-bond with the ligand binding domain of GPIbα (Yago et al. 2008; Kim et al. 2010), allowing transient platelet adhesion under high shear stress. VWF/GPIb-IX-V interaction induces signaling events, leading to integrin activation and integrin-dependent stable platelet adhesion and aggregation (Du 2007). In addition, GPIb-IX-V binds thrombin and sensitizes platelets to low-dose thrombin (Estevez et al. 2016).

There has been evidence that GPIb-IX-V is associated with the ITAM receptors Fcγ receptor IIA (FcγRIIA) (Sullam et al. 1998) or FcRγ (Wu et al. 2001). Genetic deletion of ITAM signaling molecules, such as FcRγ, LAT, SLP-76, and Btk, abolishes the TXA_2- and secretion-dependent second wave of platelet aggregation induced by VWF/botrocetin in washed mouse platelets (Liu et al. 2005, 2006). However, loss of FcRγ and LAT does not appear to affect GPIb-IX-V-dependent integrin activation (Liu et al. 2005). Similarly, Syk is not required for GPIb-IX-V- and integrin-dependent stable platelet adhesion to VWF under shear stress (Yin et al. 2008b). Considering the importance of the ITAM pathway in granule secretion and integrin outside-in signaling, it likely functions as an important signal amplification mechanism in GPIb-IX-V signaling.

The cytoplasmic domain of the GPIbα chain interacts with SFKs and PI3Ks (Wu et al. 2001; Mu et al. 2010), which are both important for transmitting the "early" activation signals from GPIb-IX-V (Yap et al. 2002; Kasirer-Friede et al. 2004; Mu et al. 2010; Liu et al. 2005; Yin et al. 2008a). The SFK Lyn is required for activation of PI3K and its downstream effector Akt, leading to integrin activation (Liu et al. 2005; Yin et al. 2008a, b). Interestingly, VWF/GPIb-IX-V interaction induces elevation of intracellular cGMP levels (Li et al. 2003b; Riba et al. 2006), which sequentially activate the cGMP-dependent protein kinase (PKG) and the mitogen-activated protein kinases (MAPK) p38 and ERK (Li et al. 2001, 2003b, 2006). GPIb-IX-V-dependent activation of the cGMP pathway is downstream of the Lyn-PI3K-Akt pathway (Yin et al. 2008a, b), which is known to activate nitric oxide (NO) synthase (NOS). VWF-induced cGMP elevation may involve both NO-dependent (Li et al. 2003b; Riba et al. 2006) and NO-independent mechanisms (Gambaryan et al. 2008). It is important to note that the role of NO and cGMP in platelet activation is biphasic (Li et al. 2003b). The low concentrations of NO/cGMP synthesized endogenously during platelet activation are stimulatory, whereas high concentrations of NO and cGMP inhibit platelet activation. The biphasic role of the NO/cGMP pathway may serve to stimulate robust hemostatic thrombus formation at sites of vascular injury while preventing overgrowth of the thrombus.

Defects in the GPIb-IX-V complex result in Bernard-Soulier syndrome (BSS). BSS is characterized by prolonged bleeding time, thrombocytopenia, increased megakaryocytes, and enlarged platelets. The large platelets and low platelet count in BSS are due to the absence of GPIbα and the filamin A binding site that links the GPIb-IX-V complex to the platelet membrane skeleton, because the enlarged platelet abnormality and low platelet count have been reversed in GPIbα knockout mice by the expression of a chimeric GPIbα composed of the extracellular human IL-4 receptor and the cytoplasmic tail of GPIbα (Kanaji et al. 2002). Mutants in the genes coding GPIbα, GPIbβ, or GPIX can cause a lack of expression of the GPIb-IX-V complex or abnormalities of GPIb-IX-V function, resulting in BSS.

Defects in Integrin Signaling

Integrin Signaling

Integrin Inside-Out Signaling

Integrins expressed in platelets include $\alpha_{IIb}\beta_3$ (fibrinogen receptor), $\alpha_v\beta_3$ (vitronectin receptor), $\alpha_2\beta_1$ (collagen receptor), $\alpha_5\beta_1$ (fibronectin receptor), and $\alpha_6\beta_1$ (laminin receptor). $\alpha_{IIb}\beta_3$ is the most abundant integrin in platelets. $\alpha_{IIb}\beta_3$ is normally kept in a "resting" or low-affinity state in circulating platelets, but transforms into a high-affinity "activated" state following platelet activation. Activated $\alpha_{IIb}\beta_3$, by binding to its ligands (fibrinogen, VWF, and many matrix proteins containing RGD-like sequences), mediates stable platelet adhesion, aggregation, and thrombus formation. The integrin-proximal intracellular signaling mechanism that induces changes in the extracellular ligand binding domain of integrins from a "low-affinity" state to the "activated" state is referred to as "inside-out" signaling. Inside-out signaling requires the binding of talin and kindlins to the cytoplasmic domain of β3 (Tadokoro et al. 2003; Moser et al. 2008; Ma et al. 2008). Talin and kindlins bind to different sites in the β_3 cytoplasmic domain. Talin binds to the membrane-proximal region and the membrane-proximal NXXY motif of β_3 (Calderwood et al. 1999; Patil et al. 1999; Wegener et al. 2007), but kindlins bind to the sequences around the C-terminal NXXY motif (Moser et al. 2008; Ma et al. 2008). The possible role of integrin transmembrane domain interactions in this process has also been suggested (Li et al. 2003a). Defects in integrin inside-out signaling result in reduced ligand binding function of integrin and deficient platelet aggregation.

CalDAG-GEF1 and its downstream target, Rap1, play an important role in inside-out signaling (Crittenden et al. 2004; Chrzanowska-Wodnicka et al. 2005). CalDAG-GEF1 converts Rap1, a member of Ras family of small GTPases, from the GDP-bound form to the active GTP-bound form, which interacts with the Rap1-GTP-interating adaptor molecule (RIAM). The role of CalDAG-GEF1/Rap1 in integrin inside-out signaling is consistent with the data that RIAM promotes $\alpha_{IIb}\beta_3$-talin interaction and integrin activation (Lafuente et al. 2004). Rap1b has also been shown to be involved in $\alpha_{IIb}\beta_3$ outside-in signaling (Zhang et al. 2011).

Outside-In Signaling

Ligand binding to integrin $\alpha_{IIb}\beta_3$ mediates platelet adhesion and aggregation and also initiates a series of intracellular signaling events ("outside-in" signaling), leading to platelet spreading, granule secretion, stable adhesion, and clot retraction (Shattil and Newman 2004). Defects in integrin outside-in signaling result in reduced platelet spreading, adhesion, and clot retraction. Following ligand binding, integrins undergo "a ligand-induced conformational change" that can be propagated outside-in to the cytoplasmic domain (Leisner et al. 1999). However, although ligand-induced conformational changes of $\alpha_{IIb}\beta_3$ occur with either the multimeric macromolecular ligands such as fibrinogen or monomeric peptide ligands such as RGDS, significant cellular response only occurs with multimeric macromolecular ligands, suggesting that ligand-induced receptor clustering may be important for transmitting outside-in signals. The most proximal signaling event that occurs following integrin ligation is the binding of the G protein subunit $G\alpha_{13}$ to the cytoplasmic domain of β3 (Gong et al. 2010). $G\alpha_{13}$ and talin bind to mutually exclusive but distinct sites within the integrin β_3 cytoplasmic domain in opposing waves. A recent study reported a novel integrin binding protein, VPS33B, a member of the Sec1/Munc18 (SM) family. VPS33B binds directly to the integrin β subunits and is required specifically for $\alpha_{IIb}\beta_3$ outside-in signaling (Xiang et al. 2015).

Defects in Integrin Signaling

Defects in $\alpha_{IIb}\beta_3$

$\alpha_{IIb}\beta_3$ is coded by two genes *ITGA2B* and *ITGB3*. Defects in either α_{IIb} or β_3 lead to a bleeding disorder called Glanzmann thrombasthenia (GT). Platelets from GT patients fail to aggregate in response to all physiological agonists due to quantitative or qualitative defects in the $\alpha_{IIb}\beta_3$ integrin (Nurden et al. 2011; Nurden and Nurden 2015; Sandrock-Lang et al. 2015). Bleeding tendency in GT patients is variable but may be severe.

Defects in Kindlin 3

Leukocyte adhesion deficiency (LAD) is a rare autosomal recessive disorder characterized by immunodeficiency resulting in recurrent infections. LAD is currently divided into three subtypes, LAD-I, LAD-II, and LAD-III, due to deficiency of β2 integrin, GDP-fucose transporter 1, and kindlin-3, respectively. Because kindlin-3 affects multiple integrin function including $\alpha_{IIb}\beta_3$, LAD-III patients have a Glanzmann thrombasthenia-like bleeding tendency (Malinin et al. 2009; Svensson et al. 2009; Jurk et al. 2010; Meller et al. 2012; Crazzolara et al. 2015).

Defects in ADAP

Adhesion and degranulation promoting adapter protein (ADAP) is an adapter protein that plays a role in inside-out activation of the integrin LFA-1 (αLβ2) in T cells. ADAP is also expressed in platelets and promotes integrin $\alpha_{IIb}\beta_3$ activation through interactions with talin and kindlin-3 (Kasirer-Friede et al. 2014). A homozygous nonsense mutation (c.393G>A) in the ADAP coding gene, FYB, is associated with reduced platelet activation by ADP. The patient lacking ADAP had thrombocytopenia and a significant bleeding tendency (Levin et al. 2015).

Defects in Platelet Activation and Signaling Mediated by G Protein-Coupled Receptors (GPCRs)

Platelet Activation and Signaling Mediated by GPCRs

A variety of soluble platelet agonists are released from damaged cells (e.g., ADP), produced during coagulation (e.g., thrombin) and inflammation [e.g., platelet-activating factor (PAF)], and enriched in atherosclerotic plaques [e.g., lysophosphatidic acid (LPA)]. These agonists play critical roles in platelet activation and thrombus formation (Offermanns 2006). Equally important, soluble platelet agonists, TXA_2, ADP, and serotonin are released from stimulated platelets and serve to amplify platelet activation. All these agonists activate platelets via GPCRs, a family of seven-transmembrane domain receptors that transmit signals through heterotrimeric G proteins (Fig. 1).

The heterotrimeric G proteins consist of three subunits, α, β, and γ, which bind to GPCR in an α/β/γ complex. Upon receptor ligation, the α subunit is converted from a GDP-bound form to the active GTP-bound form. Activated Gα subunits dissociate from the receptor and from the β/γ complex and interact with specific downstream targets to transmit GPCR signals. Based on the similarity of the α subunits, G proteins can be divided into four subfamilies:

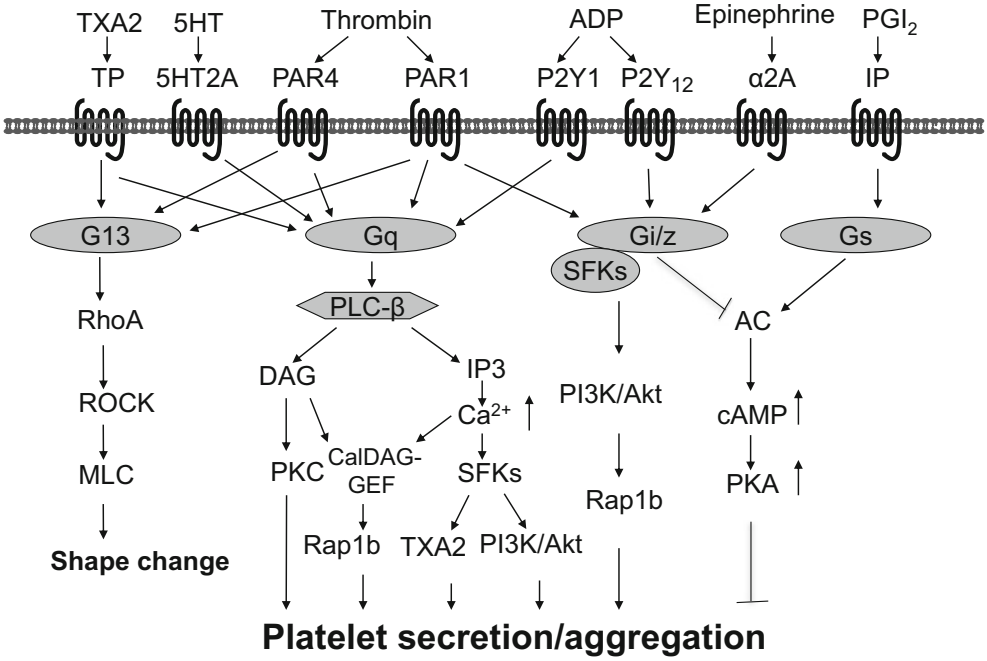

Fig. 1 GPCR signaling in platelets

G_q/G_{11}, G_{12}/G_{13}, $G_i/G_o/G_z$, and G_s, each of which couples to selective receptors and downstream effectors (Fig. 1) (Offermanns 2006). Platelets express G_q, G_{12}/G_{13}, $G_i/_z$, and G_s. G proteins in platelets couple to agonist receptors that stimulate platelet activation, with the exception of G_s. G_s couples to receptors for physiological platelet inhibitors (PGI2 and adenosine) that mediate inhibitory signals by stimulating adenylyl cyclase-dependent cAMP synthesis. Thrombin-induced platelet activation is mediated via a dual system of G protein-coupled protease-activated receptors (PARs): PAR1 and PAR4 in humans (Coughlin 1999) and PAR3 and PAR4 in mice (Kahn et al. 1998). PAR3 appears to sensitize PAR4 to thrombin (Nakanishi-Matsui et al. 2000; Sambrano et al. 2001). PAR1 and PAR4 directly couple to G_q and G12/G13 (Kahn et al. 1998) and probably also G_i (Coughlin 2005). TXA_2 activates platelets via the TXA_2 receptor TP, which couples to G_q and G_{13} (Knezevic et al. 1993; Djellas et al. 1999). ADP induces platelet activation via P2Y1 (G_q-coupled) and $P2Y_{12}$ (G_i-coupled) (Offermanns 2006). Serotonin recognizes the G_q-coupled receptor 5HT2A (Offermanns 2006).

G_q transmits cellular signals mainly through its interaction and stimulation of phospholipase C-β (PLCβ). G_q signaling is important for GPCR-stimulated platelet granule secretion, integrin activation, and consequent platelet aggregation (Offermanns et al. 1997). Deletion of G_q causes defects in platelet secretion and aggregation in response to a variety of agonists including thrombin, ADP, TXA_2 analog U46619, and even collagen (probably due to the dependence of the collagen signaling pathway on TXA_2) (Offermanns et al. 1997). Two alternative signaling pathways, the Ca^{2+}/SFKs/PI3K and PKC, mediate Gq-dependent platelet activation (Xiang et al. 2012).

Cyclic nucleotide cAMP is an important second messenger in platelets and plays a critical role in regulating platelet function. cAMP activates the cAMP-dependent protein kinase (PKA) to inhibit platelet activation. Intracellular cAMP levels in platelets are regulated by G_i and G_s. While platelet agonists such as ADP activate G_i to decrease cAMP levels, prostaglandin E1 (PGE1) and PGI2 inhibit platelet function through elevating intra-platelet cAMP levels via activating their G_s-coupled receptors. Optimal platelet activation also requires G_i signaling, especially in response to weak or low-dose platelet agonists. The G_i-coupled ADP receptor, $P2Y_{12}$ (Hollopeter et al. 2001; Foster et al. 2001), is required for ADP-induced platelet activation and also promotes platelet activation induced by TXA_2 and low-dose thrombin. $P2Y_{12}$ couples to G_{i2} (Ohlmann et al. 1995; Jantzen et al. 2001) and the epinephrine receptor in platelets couples to G_z, another G_i subtype (Yang et al. 2000). The importance of G_i-coupled receptors in promoting platelet activation is consistent with the inhibitory effect of G_i on cAMP synthesis. In addition to the inhibition of cAMP synthesis, G_i also plays a role in the activation of the PI3K/Akt signaling pathway and the small GTPase Rap1b (Fig. 1) (Woulfe et al. 2002; Lova et al. 2003).

G_{13} also plays a role in platelet activation. G_{13} knockout platelets show partial reduction in platelet secretion and unstable platelet aggregation induced by low-dose thrombin and the TXA_2 analog U46619 (Moers et al. 2003). Shape change induced by these agonists is also abolished in G13

knockout platelets. GTP-bound G_{13} interacts with and activates guanine nucleotide exchange factors (GEF) for the small G protein RhoA, such as p115RhoGEF, which subsequently converts RhoA into the active GTP-bound form (Kozasa et al. 1998). RhoA activates Rho kinase, which phosphorylates and inhibits myosin light chain (MLC) phosphatase (Klages et al. 1999), consequently, enhancing MLC phosphorylation and MLC-dependent contraction. Thus, G_{13} stimulates platelet shape change and granule secretion (Klages et al. 1999). However, the relatively mild in vitro aggregation defect in G_{13} knockout platelets is contrasted with the dramatic defects in hemostasis and thrombosis in vivo, suggesting an additional role of G_{13} in platelet-dependent thrombus formation (Moers et al. 2003). Indeed, G_{13} also binds to the cytoplasmic domain of integrin β3 and plays a critical role in integrin outside-in signaling (Gong et al. 2010).

Defects in GPCR Signaling

Defects in GPCRs

Defects in TXA_2 Receptor

Mutations in GPCRs have been identified in patients with bleeding. A single amino acid substitution R60L in the first cytoplasmic loop of the TXA_2 receptor was found in two unrelated families. Although the ligand binding affinity was not affected, R60L substitution in the TXA_2 receptor resulted in impaired PLC activation in response to a TXA_2 analog in recombinant Chinese hamster ovary cells (CHO) (Hirata et al. 1994). Platelets from heterozygous R60L mutation showed impaired platelet response to TXA_2 as well as to ADP or epinephrine, although not as severe as that in the homozygote. D304N mutation in the TXA_2 receptor gene has been reported to cause a mild mucocutaneous bleeding in another patient (Mumford et al. 2010). U46619 did not increase cytosolic free Ca^{2+} concentration in CHO cells expressing the variant D304N TXA_2 receptor (Mumford et al. 2010). D304 is located within a conserved NPXXY motif in transmembrane domain 7 of the TXA_2 receptor. D304N substitution leads to impaired ligand binding, suggesting a role of this domain in the ligand binding function of the receptor. A W29C in the TXA_2 receptor results in reduced ligand binding function of the receptor, and U46619 was less potent at inducing Ca^{2+} mobilization in HEK293 cells expressing the W29C receptor than in WT controls (Mumford et al. 2013). A heterozygous c.167dupG mutation in the TXA_2 receptor leading to frameshift was identified in a family. Patients carrying this mutant had bleeding tendency and impaired platelet aggregation, secretion, and integrin activation in response to U46619 (Kamae et al. 2011). A heterozygous N42S mutation in the TXA_2 receptor resulted in reduced surface expression of the receptor and platelet dysfunction (Nisar et al. 2014). The patient had significant bleeding phenotype.

Defects in ADP Receptors $P2Y_{12}$ and $P2Y_1$

Mutations in the ADP receptor $P2Y_{12}$ can also cause bleeding disorder. Patients with homozygous mutations in $P2Y_{12}$ gene that produce a frameshift and premature truncation of the protein had a bleeding tendency (Cattaneo 2005). Another patient with an allele of a frameshift mutation in the $P2Y_{12}$ gene and a normal allele also had a bleeding tendency (Cattaneo 2005). A patient with a compound heterozygote in the $P2Y_{12}$ gene with one allele containing a G to A transition resulting in R256Q substitution and the other allele containing a C to T transition resulting in an R265W substitution had reduced and reversible aggregation in response to ADP (Cattaneo 2005). ADP failed to inhibit adenylyl cyclase activity stimulated by PGE1. A patient carrying a heterozygous mutation of P341A in the $P2Y_{12}$ gene has a mild bleeding disorder (Cunningham et al. 2013). It is found that P341 is important for $P2Y_{12}$ recycling. Another patient with a homozygous H187Q mutation in the $P2Y_{12}$ had bleeding diathesis (Lecchi et al. 2015). ADP-induced platelet aggregation was markedly reduced and rapidly reversible in this case. A patient with a homozygous R122C mutation in $P2Y_{12}$ plus an intronic polymorphism in the thrombin receptor PAR1 coding gene has been reported recently (Patel et al. 2014). Platelet response to ADP or thrombin was reduced. The patient had a chronic bleeding disorder. Mutations in thrombin receptors can also cause bleeding disorder. A mutation of Y157C in the thrombin receptor PAR4 resulted in reduced thrombin-induced platelet responses (Nurden and Nurden 2015). Platelet aggregation and secretion in response to epinephrine was impaired in family members with deficiency of the epinephrine receptor alpha 2-adrenergic receptor (Rao et al. 1988). The patients had slightly prolonged bleeding times. A patient with a history of bleeding following surgery was associated with reduced platelet $P2Y_1$ mRNA. No mutation was detected in the gene coding $P2Y_1$. ADP-induced platelet aggregation was reduced (Cattaneo 2011).

Defects in ATP Receptor P2X1

P2X1 belongs to the family of purinoceptors for ATP. A patient carrying a mutant in P2X1 that lacks one leucine within a stretch of four leucine residues in its second transmembrane domain (amino acids 351–354) showed a selective impairment of the ADP-induced platelet aggregations (Oury et al. 2000). Voltage-clamped HEK293 cells expressing mutated P2X1 channels failed to develop an ATP- or ADP-induced current. When co-expressed with the wild-type receptor in *Xenopus* oocytes, the mutated protein exhibited a dominant negative effect on the normal

ATP- or ADP-induced P2X1 channel activity. The patient had severe bleeding disorder.

Defects in Gq Signaling

Gabbeta et al. reported a patient with deficiency of Gq in platelets (Gabbeta et al. 1997). Platelet aggregation and secretion in response to multiple agonists were defective in this patient. Agonist-induced release of arachidonic acid from phospholipids and calcium mobilization are impaired upon platelet activation. The amount of dense granule contents was normal. Although no mutations are detected in the G_q cDNA, mRNA and protein levels are decreased more than 50 % compared to normal subjects, suggesting that impaired platelet activation and bleeding phenotype of this patient are due to the quantitative abnormality of G_q.

Defects in Gi Signaling

Patel et al. reported that a patient with a chronic bleeding disorder was due to deficiency of G_{i1} in platelets (Patel et al. 2003). Although no mutation was identified in the G_{i1} gene, the expression level of G_{i1} in platelets from the patient was reduced to 25 %, compared to that in normal platelets. The expression levels of G_{i2}, G_{i3}, G_z, and G_q in the patient platelets were normal. Platelet aggregation stimulated by weak agonists such as ADP and adrenaline was severely impaired. Forskolin-stimulated rise in cyclic AMP (cAMP) was impaired. These data suggest that impaired platelet activation and bleeding phenotype of this patient are due to the quantitative abnormality of G_{i1}.

Defects in Gs Signaling

Hyperfunction of G_s has been described in several patients with bleeding disorder. The α subunit of the G protein Gs is encoded by a complex imprinted gene cluster called GNAS1, which is located in the chromosome 20q13 region. This gene has four alternative first exons including an extra-large (XL)-exon1 that correspond to different promoters (Hayward et al. 1998). The four different exons splice to the common exons 2–13 of the classical $G_{s\alpha}$ gene. In three patients, a 36 bp insertion and two base pair substitutions flanking this insertion were found in the paternally inherited XL-GNAS1 exon 1. Platelets from those patients display G_s hyperfunction as evidenced by enhanced cAMP generation upon stimulation of G_s-coupled receptors. All the patients had enhanced trauma-related bleeding tendency (Freson et al. 2001).

Defects in the Regulator of G Protein Signaling

Regulator of G protein signaling 2 (RGS2) negatively regulates Gs signaling by inhibiting the activation of adenylyl cyclase (Roy et al. 2006; Sinnarajah et al. 2001). Noe et al. reported a G23D heterozygous RGS2 mutation in three related patients, leading to Gs hypofunction in their platelets (Noe et al. 2010). cAMP production after stimulation of the G_s-coupled receptors was reduced. Platelet shape change was reduced in the patients. However, platelet aggregation was normal and no bleeding phenotype was observed in the patients.

Defects in Common Platelet Activation Signaling and Amplification Pathways

The initial signaling upon stimulation of various platelet receptors ultimately converges into common intracellular signaling events. In particular, almost all agonists induce activation of PLC (Varga-Szabo et al. 2009). PLC catalyzes the hydrolysis of phosphatidylinositol bisphosphate (PIP2) to release inositol trisphosphate (IP3) and diacylglycerol (DAG), which activate calcium mobilization and PKC, respectively. All platelet agonists can induce platelet secretion and synthesis of TXA_2, two major amplification mechanism of platelet activation.

The critical role of cytosolic calcium elevation in platelet activation and function has been known for many years. Agonist-induced calcium elevation is mainly induced by IP3 receptor-mediated release of calcium from intracellular stores and store-operated calcium entry from outside of platelets (Hassock et al. 2002; Bergmeier and Stefanini 2009). A role for the store-independent calcium entry has also been shown (Hassock et al. 2002). Certain canonical transient potential channels (TRPC) and calcium release-activated channel (CRAC) (Orai1) have been shown to mediate calcium entry (Hassock et al. 2002; Bergmeier and Stefanini 2009). Elevation of calcium levels activates multiple signaling events and molecules including actin-myosin interaction, protein kinase C (PKC), calmodulin, nitric oxide synthases (NOS), and calcium-dependent proteases. Calcium elevation also positively regulates SFKs and the PI3K/Akt signaling pathway (Xiang et al. 2010, 2012).

Platelets express several members of the PKC family, including the classical (or conventional) PKC, α, β, and γ (calcium and DAG dependent); the novel PKC, δ, θ, and η (DAG dependent, calcium independent); and an atypical PKC ζ (calcium and DAG independent) (Murugappan et al. 2004; Konopatskaya et al. 2009; Nagy et al. 2009; Chari et al. 2009; Pula et al. 2006). Classical PKCs, particularly PKC α, play a critical and general role in platelet granule secretion and secretion-dependent aggregation. PKC α has also been shown to regulate Rap1 and integrin signaling in a reconstituted CHO cell model (Han et al. 2006). PKC δ and θ promote dense granule secretion in response to thrombin receptor agonists (Murugappan et al. 2004; Chari et al. 2009; Nagy et al. 2009). Pleckstrin is a major PKC substrate and may possibly be involved in cytoskeleton regulation

(Lian et al. 2009). Although no bleeding disorder has been reported to be due to defects in the genes coding PKCs, a patient with thrombocytopenia and impaired receptor-mediated aggregation was reported to be caused by a defect in a transcription factor called core-binding factor A2 (CBFA2) with reduced PKCθ mRNA levels in platelets and impaired agonist-induced pleckstrin phosphorylation (Sun et al. 2004).

A common platelet response to all agonists is the secretion of granule contents, which further amplifies platelet activation (Reed et al. 2000; Ren et al. 2008). Besides its role in hemostasis, granule secretion plays important roles in inflammation, atherosclerosis, host defense, wound healing, angiogenesis, and malignancy (Blair and Flaumenhaft 2009). Platelet secretion is mediated by soluble NSF attachment protein receptor (SNARE) proteins from granule and plasma membranes. Platelets contain three major types of granules, α-granules, dense granules, and lysosomes (Ren et al. 2008). The SNAREs form transmembrane complexes that mediate membrane fusion and granule cargo release. It has been known that both VAMP-8 (v-SNARE) and SNAP-23 (a t-SNARE class) are important for platelet secretion (Ren et al. 2008). The interaction between SNARE proteins is regulated by their phosphorylation and involves small GTPases such as Rab27.

Defects in TXA_2 Generation

The thromboxane A_2 (TXA_2) is one of the major contributors to the amplification of the initial platelet activation process. The TXA_2 pathway has been a major target in the treatment of cardiovascular disease. The COX1 inhibitor, aspirin, has been widely used as an antithrombotic drug. On the other hand, defects in TXA_2 synthesis result in bleeding disorder. TXA_2 is synthesized from phospholipids through a series of enzyme-dependent metabolic reaction. It has been reported that defects in cPLA2, COX1, or thromboxane synthase lead to a lack of TXA_2, low platelet activation, and bleeding disorder.

cPLA2 Deficiency

Cytosolic phospholipase A2 (cPLA2) hydrolyzes cellular membrane phospholipids to release arachidonic acid, which is the substrate for the synthesis of eicosanoids, including prostaglandins and leukotrienes. A patient with defects in the gene coding cPLA2 had bleeding disorder (Adler et al. 2008). This patient had two heterozygous single base pair mutations and a known SNP in the coding regions of the patient's cPLA2 gene (S111P+R485H; K651R). The expression of cPLA2 and the total PLA2 activity in platelets were diminished. The urinary metabolites of prostacyclin, prostaglandin E2, prostaglandin D2, and thromboxane A_2 were also reduced. Platelet aggregation and secretion induced by ADP or collagen were diminished in this patient but were normal in response to arachidonic acid. The patient had repeated gastrointestinal bleeding.

COX-1 Deficiency

Defects in the gene coding cyclooxygenase 1 (COX-1) (also known as prostaglandin H synthase 1, PGHS-1) can also lead to bleeding disorder. It has been reported that three female patients had a mild bleeding disorder due to defective COX1 activity (Matijevic-Aleksic et al. 1996). Platelet aggregation in response to ADP, collagen, and epinephrine was impaired. Platelet aggregation induced by arachidonic acid was defective, whereas PGH2-induced aggregation was normal. Platelet TXA_2 production in response to arachidonic acid was reduced, whereas they were normal in response to exogenous PGH2. In two of the three patients, the COX-1 protein was undetectable. The amount of the TXA_2 synthase in platelets was normal in all three patients.

TXA_2 Synthase Deficiency

Defryn et al. reported a bleeding disorder due to thromboxane synthase deficiency (Defreyn et al. 1981). Three family members from three successive generations had a moderate bleeding tendency and a functional platelet defect. All three patients had absent aggregation in response to arachidonic acid. ADP-induced platelet aggregation was reversible. They had a prolonged bleeding time. Serum thromboxane B_2 concentrations were significantly reduced.

Defects in PKA

cAMP-dependent protein kinase (PKA) is an important modulator of platelet function. Many substrates of PKA have been identified in platelets, including Rap1B, GPIbβ, VASP, and filamin A. Manchev et al. recently reported a homozygous mutation I74M in PKA leads to macrothrombocytopenia associated with a thrombocytopathy (Manchev et al. 2014). The patients had a bleeding tendency. Platelet activation as evidenced by P-selectin expression and Ca^{2+} mobilization upon stimulation with the PAR4-activating peptide or thrombin was impaired in these homozygous patients. I74IM substitution in PKA was associated with a marked defect in proplatelet formation and a low level in filamin A in megakaryocytes. Overexpression of wild-type PKA in the patient megakaryocytes in vitro rescued the defect in proplatelet formation.

Defects in Phospholipase C Signaling

Activation of phospholipase C is a key signaling event downstream of Gq. Lee et al. reported a patient with a mild inherited bleeding disorder and abnormal platelet activation due to deficiency of phospholipase C β2 isoform (Lee et al. 1996; Mao et al. 2002). Although no mutation was identified in the gene coding phospholipase C β2, the expression level of phospholipase C β2 decreased by two-third, compared to normal subjects. Generation of inositol 1,4,5-trisphosphate, mobilization of intracellular Ca^{2+}, and phosphorylation of pleckstrin in response to several G protein-mediated agonists were reduced in the patient. Agonist-induced platelet aggregation and secretion were defective.

Defects in Calcium Signaling

CalDAG-GEFI has been shown to mediate several important Ca^{2+} responses, including Rap1 activation, ERK activation, TXA_2 synthesis, and granule secretion (Bergmeier and Stefanini 2009). Importantly, a patient carrying a homozygous G248W mutation in CalDAG-GEFI showed severe bleeding phenotype (Canault et al. 2014). Platelets from the patient presented a reduced ability to activate Rap1 and impaired platelet aggregation in response to agonists. Expression of CalDAG-GEFI mutant in HEK293T cells abolished Rap1 activation. Thrombus formation under flow and platelet spreading on immobilized fibrinogen were defective in the patient. Platelets from the patient exhibited a reduced number of filopodia and failed to form lamellipodia on fibrinogen. Platelet adhesion under flow and spreading on fibrinogen were also impaired in the heterozygotes who had normal platelet aggregation and did not suffer from bleeding. Three other unrelated families with mutations in the CalDAG-GEFI coding gene RASGRP2 have since been identified by exome sequencing, including patients carrying a homozygous RASGRP2 c.1490delT giving a frameshift and a stop codon (p.Phe497 fs*22) (Nurden and Nurden 2015). These patients had severe bleeding phenotype and their platelets failed to aggregate.

Defects in Procoagulant Activity

Platelet phosphatidylserine (PS) exposure is critical to trigger coagulation cascade. Agonist-induced platelet PS exposure involves multiple signaling pathways (Lhermusier et al. 2011; Delaney et al. 2014) and requires a transmembrane domain protein, the calcium-dependent lipid scramblase TMEM16F (Suzuki et al. 2010; Yang et al. 2012; Fujii et al. 2015; Brooks et al. 2015). Deficiency of TMEM16F in patients leads to a rare bleeding disorder Scott syndrome, which was first described in 1979 by Weiss et al. (Weiss et al. 1979; Rosing et al. 1985). Patients with Scott syndrome have normal platelet count and structure and normal platelet secretion, aggregation, metabolism, granule content, and adhesion (Satta et al. 1997; Zwaal et al. 2004). However, platelets from patients with Scott syndrome fail to promote fibrin formation in the presence of coagulation factors. In a Scott syndrome patient, a G-to-T homozygous mutation at the splice-acceptor site in intron 12 of the TMEM16F gene was identified, which causes exon 13 skipping, frameshift, and premature termination of translation (Suzuki et al. 2010). Two different mutations were identified in another Scott syndrome patient: a G-to-A mutation at the first nucleotide of intron 6, disrupting the donor splice site consensus sequence of intron 6, and a single-nucleotide insertion in exon 11 (c.1219insT, cDNA numbering from the ATG), resulting in a frameshift and premature termination of translation at codon 411 (Castoldi et al. 2011).

In contrast to Scott syndrome, patients with Stormorken syndrome have spontaneous PS exposure on platelets. Ca^{2+} release-activated Ca^{2+} channels, which are composed of Orai1 proteins located in the plasma membrane, mediate a specific form of Ca^{2+} influx called store-operated Ca^{2+} entry that contributes to the function of many cell types. Orai1 channels are activated by stromal interaction molecule (STIM) 1 and 2 located in the endoplasmic reticulum (Lacruz and Feske 2015). Gain-of-function gene mutations in ORAI1 and STIM1 lead to Stormorken syndrome. Stormorken syndrome is a rare autosomal-dominant disease with mild bleeding tendency. A heterozygous missense mutation in STIM1 exon 7 (R304W) was found in several Stormorken syndrome patients (Morin et al. 2014; Misceo et al. 2014; Nesin et al. 2014). Platelets from the Stormorken syndrome patients had high basal P-selectin expression and high exposure of phospholipids on the outer surface of the plasma membrane. Store-operated Ca^{2+} entry was markedly attenuated in platelets though resting Ca^{2+} levels were elevated. Agonist-induced platelet aggregation and integrin activation as evident by PAC-1 binding were defective in the Stormorken syndrome patients.

Defects in Cytoskeletal Organization

Wiskott-Aldrich syndrome (WAS), an X-linked immunodeficiency disorder, is caused by mutations in the *WAS* gene coding the WAS protein (WASP) (Derry et al. 1994). WASP is a key regulator of actin polymerization in hematopoietic cells (Thrasher 2002). Wiskott-Aldrich syndrome is characterized by recurrent infections, thrombocytopenia, eczema, autoimmunity, and an increased risk of lymphoma (Notarangelo et al. 2008; Puck and Candotti 2006). Patients with Wiskott-Aldrich syndrome are thrombocytopenic and platelet size is smaller than normal. Severe Wiskott-Aldrich syndrome leads to early death because of infections,

hemorrhage, or malignancy. Defects in myosin heavy chain, filamin, tubulin beta 1, or actin 1 genes/proteins can also lead to defective cytoskeletal organization (Freson et al. 2014).

Defects in Secretion Signaling

Except for SNAP proteins, platelets also express another t-SNARE class, syntaxins, including syntaxin-2, 4, 7, and 11. Syntaxin-11 appears to be the most abundant syntaxin in both human and murine platelets. Syntaxin-11 can form SNARE complexes with both VAMP-8 and SNAP-23. Abnormalities in syntaxin-11 are responsible for familial hemophagocytic lymphohistiocytosis (FHLH) type 4, a rare primary immunodeficiency (zur Stadt et al. 2005). A homozygous D58R mutation in syntaxin-11 had a robust defect in agonist-induced secretion. The patient had normal platelet morphology, activation, and cargo levels (Ye et al. 2012). Platelet secretion was normal in the syntaxin-2 and syntaxin-4 single- or double-knockout mice (Ye et al. 2012). These results indicate that syntaxin-11, but not syntaxin-2 or syntaxin-4, is required for platelet exocytosis.

Take Home Message

- Activation of integrin $\alpha_{IIb}\beta_3$ is essential for hemostasis. Defects in either integrin $\alpha_{IIb}\beta_3$ function or proteins that regulate $\alpha_{IIb}\beta_3$ activation (such as kindling 3 or ADAP) result in severe bleeding disorder.
- Defects in collagen receptor signaling (GPVI and integrin $\alpha_2\beta_1$) or in VWF receptor GPIb-IX-V signaling result in bleeding disorder.
- Defects in GPCRs, the TXA2 receptor, ADP receptors $P2Y_1$ or $P2Y_{12}$, ATP receptor $P2X_1$ or defects in the downstream signaling events of GPCRs, including Gq, Gi, Gs, and the regulators of G protein signaling, result in bleeding disorder.
- Defects in common platelet activation signaling and amplification pathways, such as TXA_2 generation, calcium signaling, phospholipase C signaling, platelet procoagulant activity, cytoskeletal organization, or secretion signaling, result in bleeding disorder.

Alterations of the Platelet Procoagulant or Fibrinolytic Functions

Bernard Payrastre, Marie-Christine Alessi, and Pierre Sié

Abstract

Discovered in the 1980s, the procoagulant function of platelets is due to their inherent ability to provide, following activation, a critical platform at their plasma membrane surface for the activation of blood clotting enzyme complexes to generate thrombin. Upon platelet activation, the asymmetric orientation of membrane phospholipids rapidly collapses resulting in a calcium-dependent exposure of the anionic phospholipid, phosphatidylserine (PS), at the outer platelet surface. Binding of blood clotting enzyme complexes to this procoagulant membrane surface allows a dramatic increase in the rate of conversion of zymogens to active serine proteases and in turn the production of a burst of thrombin leading to fibrin clot formation and to further platelet activation. The energy-independent, calcium-dependent, platelet scramblase activity, which governs the bidirectional exchange of phospholipids between the two leaflets of the bilayer, is essential for PS exposure during platelet activation. The platelet scramblase protein has remained elusive for years until a significant advance was recently made with the identification of TMEM16F, a membrane protein essential for calcium-dependent PS exposure with loss-of-function mutations in Scott syndrome, a bleeding disorder due to an impaired platelet procoagulant activity.

Platelets also have the capacity to interfere with the fibrinolytic system in several ways, and so doing they can modulate the outcome of thrombolytic therapy by delaying reperfusion and mediating reocclusion but also by promoting bleeding complications. Remarkably, a rare autosomal dominant bleeding disorder, the Quebec platelet disorder, is a unique gain-of-function defect in fibrinolysis.

The most clinically relevant aspects of these two platelet functions will be discussed in this chapter.

Platelet Procoagulant Functions

Disruption of Plasma Membrane Phospholipid Asymmetry Following Platelet Activation

In eukaryotic cells, phospholipids are asymmetrically distributed across the bilayer of the plasma membranes. As a general rule, the amine-containing phospholipids, together with phosphoinositides, are enriched on the cytoplasmic surface of the plasma membrane (inner leaflet), while the choline-containing phospholipids and sphingomyelin are

enriched on the outer leaflet. Maintenance of transbilayer lipid asymmetry, due to specific protein activity, is essential for normal membrane function. Transbilayer phospholipid exchanges via ATP-requiring translocase activities (flippases and floppases) control unidirectional phospholipid transports against a concentration gradient between the two leaflets of the plasma membrane (Daleke 2003; Zwaal et al. 2005). Moreover, an energy-independent, calcium-dependent, scramblase activity governs the bidirectional exchange of phospholipids between the two leaflets of the bilayer (Kodigepalli et al. 2014). This scramblase activity is critical for the activation of the procoagulant function of blood platelets via the so-called platelet factor-3 (Lhermusier et al. 2011). In 1977, Zwaal et al. (1977) noticed that resting intact platelets offer an inert surface to the plasma coagulation system, owing to the virtual absence, on the cell exterior, of the most procoagulant lipid phosphatidylserine (PS). Conversely, they observed that activated platelets disrupt membrane phospholipid asymmetry to allow PS translocation through the plasma membrane, providing a catalytic lipid surface for interacting coagulation factors. Using both purified coagulation factors and external phospholipases, Bevers et al. (1982, 1983) investigated the mechanisms by which platelets activated with thrombin *plus* collagen are able to expose, on their surface, the procoagulant phospholipid PS. This active process occurred in the absence of cell lysis and corresponded to a transfer of the aminophospholipids, PS, and phosphatidylethanolamine (PE), from the inner to the outer leaflet of the plasma membrane. It was also shown that PS exposure required a large increase in cytoplasmic free calcium concentration, as achieved by calcium ionophores or, more physiologically, by the combination of thrombin *plus* collagen (Bevers and Williamson 2010). Upon cytosolic Ca^{2+} increase, the ATP-dependent flippase activity, able to transfer aminophospholipids, mainly PS, from the outer to the inner leaflet is inhibited. However, this is not sufficient to provide a rapid PS exposure, and the activation of phospholipid scrambling is mandatory. This set of data is at the basis of the biochemical characterization of the platelet scramblase activity (Fig. 1). Importantly, this Ca^{2+}-dependent scramblase activity turned out to be deficient in Scott syndrome patients, a rare inherited bleeding disorder with deficiency in platelet procoagulant activity (Rosing et al. 1985a). This observation strongly stimulated the search of the gene encoding the hypothetical scramblase, but, despite considerable efforts, the platelet scramblase remained elusive for years. A major advance has been made recently with the identification of TMEM16F, also called anoctamin 6 (ANO6), a membrane protein essential for Ca^{2+}-dependent PS exposure that carries loss-of-function mutations in Scott syndrome (Suzuki et al. 2010).

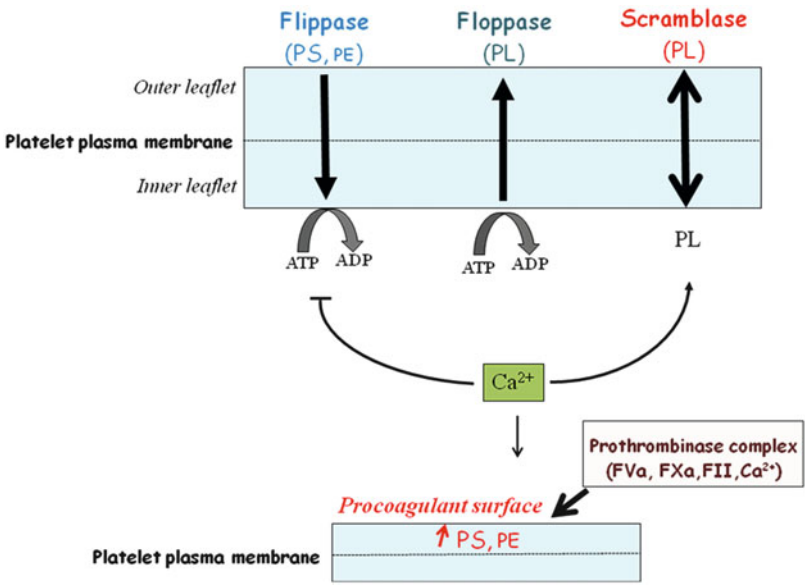

Fig. 1 Phospholipid transport proteins in the platelet membrane and formation of a procoagulant surface. In unstimulated platelets, phospholipid transverse asymmetry is maintained through the action of the two ATP-dependent translocases (flippase and floppase). The external membrane surface consisting almost exclusively of sphingolipids and phosphatidylcholine exerts no procoagulant activity. In contrast, PS, PE, and phosphoinositides are confined to the inner leaflet of the membrane. In the presence of μM Ca^{2+} concentrations (for instance, following thrombin + collagen stimulation), the scramblase catalyzes the bidirectional transfer of phospholipids, while inhibition of flippase contributes to PS exposure on the external surface. This leads to the appearance of a procoagulant surface made of aminophospholipids, mainly PS and PE on the external surface of the plasma membrane. This procoagulant lipid surface interacts with and activates the prothrombinase complex and also the tenase complex (not shown)

PS Exposure as a Critical Event for the Procoagulant Activity of Platelets

As proposed in the 1980s, activated platelets have the capacity to provide at their plasma membrane surface a platform for the activation of blood clotting enzyme complexes to generate thrombin (Tracy et al. 1985; Monroe et al. 2002; Heemskerk et al. 2002; Weiss 2009). Thrombin is a key protease as it cleaves fibrinogen to produce the insoluble fibrin clot and also potently activates platelets, proving an amplification loop of the reaction. Thus, the ability of aminophospholipids, chiefly PS but also PE, to interact with clotting factors at the surface of activated platelets and microparticles amplifies and focuses the clotting reaction at the site of vascular injury, making PS exposure by platelets a critical step in hemostasis.

Following potent activation by soluble agonists, by molecules of the subendothelial matrix, or, more efficiently, by a combination of collagen *plus* thrombin, platelets lose their plasma membrane phospholipid asymmetry leading to PS exposure. Concomitantly, they produce platelet-derived microparticles that also expose PS and PE on their surface (Bevers et al. 1983; Morel et al. 2006). At a physiological pH, the surface exposure of PS provides a negatively charged membrane platform appropriate for the interaction of the nonenzymatic plasma protein factor Va and two other components of the so-called prothrombinase complex, the serine protease factor Xa and the proenzyme factor II (prothrombin). It is thought that the negatively charged membrane binds factor Va in the presence of calcium ions, inducing a conformational change generating a high affinity binding site for factor Xa (Rosing et al. 1980; Bevers et al. 1985). On the other hand, factor Xa and factor II, in the presence of calcium, bind to negatively charged phospholipids by their gamma-carboxylated tail, a product of posttranslational modification dependent on vitamin K in hepatocytes. Assembly of the prothrombinase complex leads to a local propagation of blood coagulation with a rapid and efficient conversion of prothrombin (factor II) to thrombin (factor IIa) through cleavage of two peptide bonds (Husten et al. 1987; Krishnaswamy et al. 1987; Nesheim and Mann 1983; Boskovic et al. 2001). Activated platelets express specific and saturable binding sites for both factors Va and Xa (Rosing et al. 1985b; Bouchard et al. 1997). Compared to factor Xa alone, addition of factor Va into the prothrombinase complex increases the rate of prothrombin cleavage by 5–10 orders of magnitude (Rosing et al. 1985b; Nesheim et al. 1979). Besides providing the membrane surface for assembly of prothrombinase, activated platelets secrete a pool of factor Va which is stored in α-granules of platelets. They also shed microparticles that support prothrombinase complex formation at the vicinity of activated platelets (Sims et al. 1988, 1989; Freyssinet and Toti 2010).

Besides the prothrombinase complex, the tenase complex (VIIIa/IXa), also called "factor Xa-generating complex," interacts with the aminophospholipid surface in a Ca^{2+}-dependent manner which enhances enzymatic activity (Tavoosi et al. 2011; Lentz 2003; Falls et al. 2000). In addition to PS, the role of PE in the assembly and activity of the tenase complex has been documented (Falls et al. 2000). On this phospholipid procoagulant surface, factor IXa and its nonenzymatic cofactor, factor VIIIa, form a complex due to multiple inter-protein contacts (Autin et al. 2005) that converts factor X into factor Xa. Recent data suggest that the interaction with aminophospholipids is not exclusive as factor VIIIa can bind to fibrin on the platelet surface (Gilbert et al. 2015).

Interestingly, aminophospholipids with particular fatty acyl chain composition have been shown to be preferentially externalized suggesting that specific molecular species of PS and PE may preferentially modulate coagulation efficiency (Clark et al. 2013). PE are thought to enhance the rate of interaction of the γ-carboxylated glutamic acids (Gla domains) of vitamin K-dependent coagulation factors with the head group of PS. The fatty acid chain length appears to regulate the ability of PE to favor coagulation, with platelet-specific PE species showing optimum activity.

Regulation of PS Exposure in Platelets

Scrambling activity is not energy-dependent but requires a sustained cytosolic Ca^{2+} increase which acts as a switch for the scrambling machinery (Bevers and Williamson 2010; Williamson et al. 1995). Most platelet agonists induce phospholipase C activation and inositol trisphosphate (IP3) production leading to Ca^{2+} mobilization. This is important but not sufficient to switch on the scrambling process since an influx of Ca^{2+}, via store-operated Ca^{2+} entry (SOCE), appears essential (Kunzelmann-Marche et al. 2001). Recent reports implicate the SOCE machinery, including the Orai 1 channel and the STIM1 Ca^{2+} sensors, in PS exposure following collagen activation of mouse platelets (Bergmeier et al. 2009; Gilio et al. 2010). However, using STIM1- and Orai 1-deficient platelets, Gilio et al. (2010) found that another still uncharacterized mechanism of Ca^{2+} entry initiated by thrombin receptors also contributes to PS exposure.

The interactions between membrane glycoproteins and the cytoskeleton can also impact on the process of PS exposure. For instance, glycoprotein Ib-V-IX complex, the receptor for von Willebrand factor on platelets in flowing blood, modulates platelet procoagulant activity through the intracellular cytoskeleton-anchoring portions of GPIb (Ravanat et al. 2010). The calcium-dependent protease calpain, known to hydrolyze filamin A and spectrin, contributes to platelet

PS exposure (Comfurius et al. 1985; Fox et al. 1990). Of note, the physiological shear stress found in arteries significantly enhances agonist-induced platelet PS exposure in a small GTPase Rac1-dependent manner (Delaney et al. 2014). The lateral organization of plasma membrane and the dynamics of cholesterol and sphingolipid rich-microdomains also appear to be important for phospholipid scrambling (Kunzelmann-Marche et al. 2002).

PS exposure, resulting from inhibition of phospholipid translocase and activation of scramblase, is also a hallmark of apoptotic cells and a signal to eliminate these cells via phosphatidylserine receptors of professional phagocytes. Besides PS exposure, other features of strong platelet activation required for procoagulant activity resemble those occurring in apoptotic cells, including membrane blebbing and microparticle production. Platelets express many apoptotic regulators such as members of the Bcl-2 protein family, caspases, and antiapoptotic proteins such as BcL-x_L which maintain platelet viability (see Leytin (2012) for a review). It is proposed that two distinct molecular mechanisms, yet incompletely characterized, regulate platelet PS exposure induced either by apoptosis or by agonist-mediated platelet procoagulant function (Schoenwaelder et al. 2009). These data are consistent with a previous study demonstrating that, in Scott syndrome, PS exposure in apoptotic lymphocytes is normal, whereas calcium-induced PS exposure is absent in these cells (Bevers et al. 1992). Whether the role of PS exposure at the surface of apoptotic platelets can impact on thrombin generation in vivo or is exclusively a signal to eliminate these platelets remains to be established.

The Scott Syndrome

Scott syndrome is a rare inherited autosomal recessive bleeding disorder due to a defect in platelet procoagulant activity (Toti et al. 1996; Zwaal and Schroit 1997; Zwaal et al. 2004). It was first described by Weiss et al. (1979) in a patient with a history of bleeding episodes due to an impaired platelet procoagulant activity (Mrs M.A. Scott, 1939–1996). In the mid-1980s, Scott syndrome was recognized as a very rare, moderately severe bleeding disorder characterized by a defect of membrane phospholipid scrambling in activated platelets (Rosing et al. 1985b). The phospholipid composition of the outer plasma membrane leaflet of Scott syndrome platelets remains unchanged after activation by a mixture of thrombin *plus* collagen (Rosing et al. 1985b). Although the scrambling defect was also observed in red cells and lymphocytes (Bevers et al. 1992; Williamson et al. 2001), most patients do not experience clinical symptoms other than bleeding. The platelet count and structure are normal in Scott syndrome. Moreover, no significant defect of platelet secretion, aggregation, metabolism, granule content, platelet adhesion to subendothelium, or coagulation factor levels could be observed (Satta et al. 1997; Zwaal et al. 2004). The apparently unique defect of Scott syndrome platelets is the failure to promote fibrin formation in the presence of coagulation factors. Prothrombin consumption during clotting of whole blood is impaired and not restored by addition of normal plasma. Thus, measurement of residual prothrombin in serum is a simple laboratory screening test for the diagnosis of this syndrome. Diagnosis will be confirmed by flow cytometry, with annexin V binding on platelets (annexin V binds to PS in the presence of Ca^{2+}) indicating the lack of PS exposure following Scott syndrome platelet activation (Toti et al. 1996). A similar defect was also observed in a canine model presenting a deficiency in platelet procoagulant activity (Brooks et al. 2002, 2010).

Identification of TMEM16F as an Essential Component of the Calcium-Dependent Scramblase Activity Deficient in Scott Syndrome

The identity of the scramblase remained elusive until recently when Suzuki et al. identified the protein TMEM16F, also called anoctamin 6 (Ano6), a member of a family of Ca^{2+}-gated channel (Galietta 2009) as an essential component of the Ca^{2+}-dependent PS exposure (Suzuki et al. 2010). This discovery started with the isolation of a Ba/F3 cell subline exhibiting strong PS exposure in the absence of Ca^{2+} ionophore. This cell subline allowed identification of a cDNA encoding a constitutively active mutant of TMEM16F that was responsible for this effect. TMEM16F is a protein of predicted molecular mass of 106 kDa located on the plasma membrane with eight transmembrane domains. The TMEM16F expressed in the cell subline expressing PS constitutively exhibited a point mutation replacing the aspartate 409 by a glycine (D409G). Importantly, a sequence analysis indicated that the cDNA from a patient with Scott syndrome lacked the 226-bp sequence corresponding to exon 13 of the gene encoding TMEM16F. Direct sequencing of the chromosomal DNA showed that the TMEM16F gene of the patient carried a homozygous G-to-T mutation in the splice acceptor site in intron 12 causing exon 13 to be skipped. The resulting frameshift led to a premature termination of the protein at the third transmembrane domain of TMEM16F. Two novel mutations in the TMEM16F gene have been described in another patient with Scott syndrome (Castoldi et al. 2011) with previously characterized scramblase defect of his platelets (Munnix et al. 2003). The mutations were identified in intron 6 (G-to-A) disrupting the donor splice site consensus sequence and in exon 11 as a single-nucleotide insertion

predicting a frameshift and a premature termination of translation at codon 411. The first mutation is predicting the in-frame deletion of 38 amino acids in the N-terminal cytoplasmic tail of TMEM16F, and the second mutation is predicting the truncation of the protein between the second and the third transmembrane domains. Importantly, TMEM16F knockout mice recapitulate the platelet procoagulant defects that characterize Scott syndrome patients (Yang et al. 2012).

Following this breakthrough, a critical question remains: is TMEM16F a phospholipid scramblase itself? The literature provides very strong arguments that TMEM16F is a critical regulator of the Ca^{2+}-induced lipid scrambling processes, but, based on structural and biophysical data, it is difficult to conclude that this protein is indeed the scramblase itself (Lhermusier et al. 2011; Picollo et al. 2015). So far, a model explaining how TMEM16F could catalyze lipid movements by positioning adequately water molecules, lipid head groups, and the fatty acid chains is lacking. Thus, it is still controversial whether it is a channel, a scramblase, or both. Yang et al. showed that TMEM16F is a Ca^{2+}-activated channel permeable to Ca^{2+} and critical for the platelet scramblase activity (Yang et al. 2012). These authors propose that TMEM16F is essential but not sufficient for the Ca^{2+}-dependent scramblase activity that may be due to another protein. There are also contrasting results concerning the ion channel activity of TMEM16F (Suzuki et al. 2013). However, recent studies brought evidence that TMEM6F is both a Ca^{2+}-gated channel and a Ca^{2+}-dependent scramblase. Malvezzi et al. have shown that the ancestral TMEM16 homologue from *Aspergillus fumigatus* has the dual activity (Malvezzi et al. 2013). Moreover, by comparing the characteristics of TMEM16F variants generated by alternative splicing, Scuderi et al. also published data that bolster the idea that TMEM16F is directly involved in ion conduction and phospholipid scrambling (Scudieri et al. 2015). Some results argue with the fact that the two activities are not mutually exclusive (Malvezzi et al. 2013; Kmit et al. 2013; Yu et al. 2015). The recently published crystal structure of a TMEM16 family member (Brunner et al. 2014) provides further insight into the potential coexistence of the two activities: ion channels and phospholipid scramblase in the TMEM16 family. Based on these important but somehow conflicting results, three possibilities remain valid: (1) TMEM16F is a Ca^{2+}-dependent scramblase with no ion channel activity, (2) TMEM16F is a Ca^{2+}-dependent ion channel, and (3) TMEM16F possesses both intrinsic ion channel and scramblase activities.

Further studies are required to unambiguously characterize the intrinsic function of TMEM16F. The molecular interplay between lipid scrambling and ion channels remains to be fully elucidated, leaving still open the long lasting and fascinating story of scramblase identification in platelets.

Platelet Procoagulant Function in Pathology

Besides the very rare inherited Scott syndrome, due to a primary defect in platelet procoagulant activity, abnormal ability of platelets to express negatively charged phospholipids upon activation with physiological agonists seems to be relatively frequent. In vitro, strong stimulation of platelets with a combination of thrombin and collagen has led to the characterization of a fraction of platelets exposing on their surface, not only PS but also various proteins secreted from α-granules (Dale 2005). They have been named "coated platelets" because their surface is coated with adhesive and procoagulant proteins. They are also called "superactivated" platelets (Mazepa et al. 2013) because they exhibit a stronger ability to promote thrombin generation. They can be detected by flow cytometry measurement of Annexin-V binding and co-staining of factor V/Va. Confocal microscopy analysis has revealed that the secreted α-granule protein coat organizes into a cap resembling a small ball-like structure polarized to a distinct zone (Abaeva et al. 2013). Coated platelets are virtually absent in unstimulated platelets (<2 % of the platelet population), but this proportion rises to about 30 % after stimulation (Alberio et al. 2000) with a large variability (15–50 %) between healthy subjects (Dale 2005). What explains such platelet heterogeneity, besides their younger age in circulation, and why such variability in response between subjects, remain largely unknown. In a recent study (Daskalakis et al. 2014), isolated impairment of the ability to generate coated platelets in vitro (<20 % of cells converted into coated platelets) was identified in a significant number of patients with mild bleeding diathesis and non-diagnostic laboratory work-up. Of note, these patients had a normal expression of negatively charged phospholipids in response to the calcium ionophore A23187. The correlation between the ability to form coated platelets following stimulation and the patient symptoms has been studied. The results indicate lower levels of coated platelet formation in hemorrhagic conditions. Conversely, higher levels were found in ischemic strokes and related diseases, suggesting a contribution of coated platelets to thrombosis in the arterial and microcirculation (Daskalakis et al. 2014).

Moreover, in patients with primary platelet disorders and impaired aggregation response to various agonists, the administration of desmopressin (DDAVP) enhanced the ability to form coated platelets and subsequent thrombin generation, in parallel with sustained free cytosolic Ca^{2+} increase in platelets. This observation provides a possible mechanism of desmopressin action, independent from its effect on von Willebrand factor and factor VIII release (Colucci et al. 2014).

Taken together, these results suggest that the platelet procoagulant activity elicited by physiological agonists is

supported, at least in vitro, by a subset of circulating platelets. The ability to produce such "super-platelets" (Pecci and Balduini 2014) is variable between subjects, but so far only limited data suggest their role as potential clinical or pharmacological target.

Platelet Fibrinolytic Functions

Fibrinolysis and Platelet Interplay

The main function of fibrinolysis is the dissolution of fibrin clots in blood vessels. The fibrinolytic system comprises a proenzyme, plasminogen, which can be converted into the active serine protease plasmin by two main plasminogen activators: the tissue-type plasminogen activator (t-PA) and the urokinase-type plasminogen activator (u-PA). Inhibition of fibrinolysis occurs at the level of these activators by plasminogen activator inhibitors (PAIs) or at the level of plasmin, mainly by the alpha 2-antiplasmin (α2AP). Proteolytic cleavage of fibrin by plasmin generates C-terminal lysine residues capable of binding both plasminogen and t-PA, thereby propagating fibrinolysis. This positive feedback mechanism is negatively regulated by activated thrombin-activatable fibrinolysis inhibitor (TAFI), which cleaves C-terminal lysine residues from the fibrin surface. Currently, administered thrombolytic drugs consist of recombinant PAs that rapidly lyse thrombi by catalyzing the formation of plasmin (Longstaff and Kolev 2015).

Platelets and the fibrinolytic system interact in several ways (Fig. 2). We will discuss here some clinically relevant aspects of these complex interrelations. It is now clear that platelets can modulate endogenous fibrinolysis and also the outcome of thrombolytic therapy by delaying reperfusion and mediating reocclusion and also by promoting bleeding complications (Coller 1990; Pasche and Loscalzo 1991). Therefore, it is worthwhile to understand the different facets of the relationship between platelets and fibrinolysis. Moreover, it is noteworthy that a rare platelet pathology, the Quebec platelet disorder, is a unique gain-of-function defect in platelet fibrinolysis due to an increase in u-PA production by megakaryocytes and storage in platelet granules (Blavignac et al. 2011).

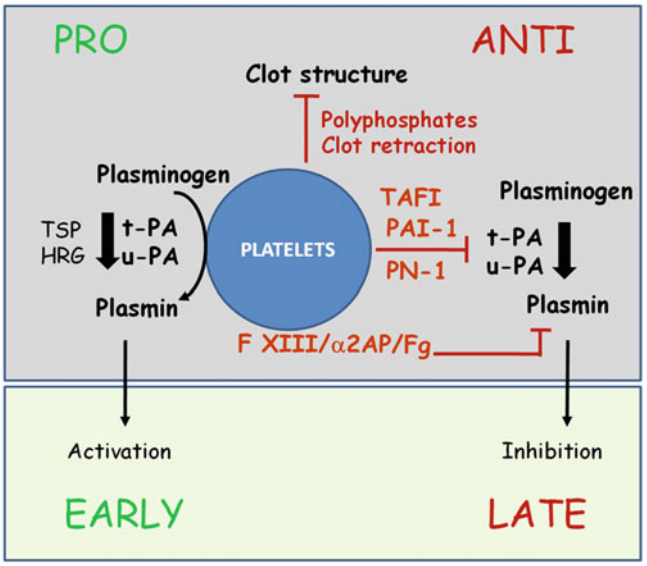

Fig. 2 Platelets and fibrinolysis: a schematic representation of the interplay between platelets and fibrinolysis. *Upper panel*: Profibrinolytic activity (PRO) involved the binding of plasminogen and u-PA at the cell surface and the release of α-granule proteins [thrombospondin (TSP), histidine-rich glycoprotein (HRG)]. Antifibrinolytic properties involved the release of fibrinolysis inhibitors (TAFI, PAI-1, PN-1). Polyphosphates and clot retraction impair fibrinolysis through modification of clot structure. Platelet factor XIII (FXIII) participates to the fibrinolysis inhibition by mediating cross-linking between platelet α2AP and platelet fibrin(ogen) (Fg). *Lower panel*: During the early phase of thrombolysis, the platelets become transiently activated and, consequently, delay the lytic process. In the late phase, however, platelets become progressively inhibited

Platelets in Fibrinolysis Resistance

Studies mimicking the physiopathological conditions have consistently reported that platelets play a pivotal role in fibrinolysis resistance (Jang et al. 1989; Fay et al. 1994) and that antiplatelet agents enhance the efficacy of thrombolytic treatment (Collet et al. 2001; Yasuda et al. 1990, 1991; Fitzgerald and Fitzgerald 1989; Lam et al. 1991; Ohman et al. 1997). Both in vitro and in vivo data point to different mechanisms of platelet-mediated fibrinolysis resistance.

Cellular factor XIII (XIIIa) is abundant in platelets and is thought to play a major role in lysis resistance. Analysis of plasma clot structure by polyacrylamide gel electrophoresis and immunoblotting revealed accelerated α2AP-fibrin cross-linking in platelet-rich compared with platelet-depleted plasma clots (Reed et al. 1991). In washed platelets aggregated by thrombin, a platelet factor XIII-mediated cross-linking between platelet α2AP and platelet fibrin(ogen) has been observed. Using the Chandler model, it has been shown that thrombi formed from factor XIII-depleted plasma are stabilized by platelets in a factor XIII-dependent manner (Mitchell et al. 2014). Incorporating a neutralizing antibody to α2AP into factor XIII-depleted thrombi revealed that the stabilizing effect of platelet factor XIIIa on lysis was dependent on α2AP. Fluorescence confocal microscopy and flow cytometry studies have unveiled the exposure of factor XIIIa on activated platelet membranes, with maximal signal detected with thrombin and collagen stimulation, which is also known to induce coated-platelets formation. Factor XIIIa was evident in protruding caps on the surface of PS-positive platelets.

This indicates that the subpopulation of coated platelets (see Kasirer-Friede and Shattil 2017) displays both procoagulant and antifibrinolytic properties.

Release of fibrinolysis inhibitors by activated platelets also makes clots resistant to fibrinolysis. PAI-1 is present in platelet α-granules. A large fraction (92 %) of PAI-1 antigen is released from platelets, whereas only 8 % is found in the corresponding platelet-poor plasma. The bulk of PAI-1 released from platelets is inactive, but it is unclear whether this inactive material is already present in platelets or whether platelet PAI-1 is inactivated during release (Declerck et al. 1988). Several studies are in favor of a functional role of platelet PAI-1 and underline its contribution in fibrinolysis resistance. When washed human platelets are added to a t-PA-dependent lysis system, the clot lysis becomes highly sensitive to the addition of thrombin. De Fouw et al. (1987) reported a more than threefold increase in the time necessary to reach half maximal lysis when the thrombin concentration was raised from 0.5 to 12.2 nM in the presence of 0.2×10^9 platelets/mL. The explanation given for this platelet-dependent inhibition of clot lysis is that thrombin-activated platelets release PAI-1 which in turn neutralizes a part or possibly all t-PA present in the system. Keijer et al. (1991) further demonstrated that addition of a monoclonal antibody against PAI-1, which inhibits t-PA neutralization, completely quenches the inhibitory effect of platelets on t-PA-dependent clot lysis in a system of purified components. Together these experiments indicate that, locally, the time course of thrombin formation and the availability of platelets are important parameters in determining the lysability of thrombi. These in vitro results were confirmed by the studies performed by other groups (Braaten et al. 1993; Booth et al. 1992; Stringer et al. 1994). Experiments conducted in vivo showed that platelet-dependent resistance could be completely neutralized by anti PAI-1 molecules (Levi et al. 1992; Rupin et al. 2001). The effect of platelet PAI-1 on fibrinolysis in humans is supported by the severe autosomal recessive bleeding disorder described in patients with complete loss of PAI-1 in plasma and platelets (Fay et al. 1992).

Thrombin activatable fibrinolysis inhibitor (TAFI) is a fibrinolysis inhibitor that provides a balance between coagulation and fibrinolysis. TAFI is activated by thrombin to yield an active carboxypeptidase, TAFIa. TAFIa regulates fibrinolysis by removing carboxyterminal lysine residues from fibrin. These lysine residues are exposed during plasmin degradation of fibrin and are important for the binding of plasminogen and t-PA and fibrinolysis amplification. Removal of these sites by TAFIa prolongs the rate of lysis. The presence of TAFI in platelet granules has been established in 2003 (Mosnier et al. 2003). It was first observed that TAFI from platelets contributes less than PAI-1 to fibrinolysis resistance of platelet-rich clots (Mutch et al. 2007). However, using thromboelastography, Carrieri et al. (2011) have shown that neutralization of TAFI, but not of PAI-1, shortened the lysis time suggesting that TAFI activation is a major mechanism whereby platelets make clots resistant to fibrinolysis.

Protease nexin-1 (PN-1) is a serpin that inhibits plasminogen activators, plasmin and thrombin, and is present within the α-granules of platelets but barely detected in plasma. PN-1 deficiency within platelets results in increased clot lysis. Vascular recanalization is significantly increased in PN-1-deficient mice suggesting that PN-1 inhibition promotes endogenous and exogenous t-PA-mediated fibrinolysis (Boulaftali et al. 2011).

It is noteworthy that in addition to favoring the release of fibrinolysis inhibitors from platelets, clot retraction has been demonstrated to affect clot structure and t-PA binding and diffusion (Kunitada et al. 1992; Collet et al. 2001, 2002; Katori et al. 2005; Weisel and Litvinov 2008) contributing to fibrinolysis resistance. Moreover, platelets are a source of polyphosphate, which is released from activated platelets and supports localized changes in fibrin structure. Polyphosphates of sufficient length have been shown to result in thicker fibrin strands that are more resistant to fibrinolysis (Mutch et al. 2010).

Contribution of Platelets to Fibrinolysis

Besides being implicated in fibrinolysis resistance, platelets have also been shown to promote fibrinolysis. On their membrane, platelets can bind plasminogen (Miles and Plow 1985) and express urokinase receptors (Wohn et al. 1997; Jiang et al. 1996). Remarkably, plasminogen binds platelets by two distinct mechanisms: (1) a direct binding and (2) a fibrin(ogen)-dependent binding on PS-exposing platelets (Whyte et al. 2015). This relatively late mechanism suggests that the subpopulation of procoagulant coated platelets retain on their cap not only procoagulant and antifibrinolytic but also profibrinolytic factors. Platelets, like many cells, provide a surface for enhanced plasminogen activation by promoting the interaction between t-PA and plasminogen (Deguchi et al. 1985; Ouimet et al. 1994) and by enhancing clot lysis mediated by single chain u-PA (Baeten et al. 2010; Loza et al. 1994; Lenich et al. 1997).

In addition, secreted α-granule proteins may contribute to fibrinolysis. Significant amounts of plasmin can be generated from the trimolecular complex formed between the granular protein thrombospondin, histidine-rich glycoprotein, and plasminogen (Silverstein et al. 1985).

These data indicate that platelets exhibit pro- and antifibrinolytic effects (Fig. 2). This balance may be regulated by the level of platelet activation and secretion and may be different at the cell surface and in the platelet environment.

Impact of Fibrinolysis/Thrombolysis on Platelet Function

The success of PAs in recanalizing occluded coronary arteries may be influenced by their effect on blood platelets. Upon exposure to a fibrinolytic milieu, platelets become transiently activated and, consequently, delay the progression of the lytic process. However, following continued exposure to a fibrinolytic milieu, platelets become progressively inhibited, and, as a result, bleeding times prolong and hemorrhagic risk increases. As described below, the molecular events leading to these changes in platelet function during thrombolysis are complex. Increased plasmin and plasminogen activator levels during thrombolysis can cause platelet activation and aggregation. When added to platelets, plasmin can induce aggregation (Puri et al. 1992) and a prompt, concentration-dependent $[Ca^{2+}]i$ increase and 5-HT release (Penny and Ware 1992). Plasminogen activators can increase platelet surface P-selectin expression in a concentration-dependent manner (Kawano et al. 1998). These platelet effects occur at clinically achievable concentrations and may affect the success of therapy with thrombolytic agents. Such activation is followed by subsequent inhibition of cellular activation by a second agonist; this inhibitory effect being in proportion to the degree of initial activation and ADP is an important cofactor in both processes (Penny and Ware 1992). This second wave of platelet inhibition has been mainly attributed to GPIb and GPIIbIIIa degradation (Stricker et al. 1986; de Haan and van Oeveren 1998; Kamat et al. 1995). A study in patients treated with 150 mg of rt-PA given over 6 hours has suggested a redistribution of GPIb induced by plasmin with an increased circulating level of glycocalicin, a proteolytic fragment of GPIbα, and a concomitant decrease in whole platelet GPIb content but without change in GPIb surface expression (Michelson et al. 1990). Moreover, administration of the nonspecific protease inhibitor with antifibrinolytic activity, aprotinin, increases the number of surface GPIb platelet receptors in patients who bled in excess during cardiac surgery (Kallis et al. 1994). Also, the antifibrinolytic tranexamic acid shortens the bleeding time and improves platelet aggregation and secretion in patients with chronic renal failure (Mezzano et al. 1999).

Overall, the strong interplay evidenced between platelets and fibrinolysis may contribute to the control of the bleeding/thrombosis balance during thrombolysis and in a large set of clinical conditions associated with fibrinolysis activation.

Quebec Platelet Disorder

Quebec platelet disorder (QPD) is a very rare autosomal dominant bleeding disorder associated with a unique gain-of-function defect in platelet fibrinolysis (see Hayward and Rivard (2011) for a comprehensive review). It was initially reported in a family of patients with delayed, moderate to severe bleeding, responsive to fibrinolytic inhibitors, and first attributed to a deficiency in platelet factor V, hence called factor V Quebec in 1984 (Tracy et al. 1984). The name was changed to Quebec platelet disorder with the description of α-granule protein proteolysis, abnormal aggregation response to various agonists, and moderately reduced platelet count (Hayward et al. 1996, 1997).

The biochemical defect of QPD and the pathogenesis were elucidated 15 years after the first report, as being a massive increase in the α-granule stores of u-PA. This increase in u-PA triggers the intra-platelet generation of plasmin from the plasminogen endocytosed into α-granules in circulating platelets and the degradation of stored proteins (Sheth et al. 2003; Kahr et al. 2001). As developed in Colucci et al. (2017), when activated, normal platelets display a subtle profibrinolytic activity as a secondary process to their procoagulant activity (Kim 2015), tightly controlled by the natural inhibitors (PAI-1, α2-antiplasmin, TAFI) released from the α-granules. The degradation of these regulators and the release of large amounts of u-PA and plasmin in the growing thrombus explain the instability and premature lysis of the clot and thereby the bleeding phenotype and its exquisite sensitivity to fibrinolytic inhibitors.

The molecular origin of QPD was demonstrated to be a massively increased expression of the u-PA gene (*PLAU*) in differentiated megakaryocytes (Diamandis et al. 2009; Veljkovic et al. 2009), without change in the expression of the other platelet proteins. The unique QPD mutation, described in all unrelated families so far, is a direct tandem duplication of a large 77 kb region on chromosome 10 that includes *PLAU* and its regulatory elements, in addition to the gene of unknown function, *c10orf55* (antisense to *PLAU*) (Paterson et al. 2010). To date, QPD is the only inherited bleeding disorder known to be caused by a *PLAU* mutation and the only one attributed to a gene duplication mutation. How only one extra copy of *PLAU* can cause more than 100-fold increase in u-PA production by megakaryocytes is unknown. Why this mutation does not result in the overproduction of u-PA in other tissues, since plasma and urinary u-PA levels are normal in QPD (Diamandis et al. 2008), remains also unexplained.

The clinical features of QPD consist in delayed bleeding (1–3 days) following hemostatic challenges, easy bruising, prolonged bleeding after deep cuts, muscle and joint bleeds, hematuria, long menses, and postpartum hemorrhages (McKay et al. 2004; Blavignac et al. 2011). The bleeding scores of affected patients are easily distinguished from those of their unaffected relatives (McKay et al. 2004).

Apart from bleeding symptoms, there are no other known clinical manifestations of QPD (Tracy et al. 1984; McKay et al. 2004). There are no reproductive disorders and, strikingly, QPD does not preclude thromboembolic events. Most laboratory findings of current practice, such as moderate thrombocytopenia with normal platelet and megakaryocyte morphology, low factor V, and reduced aggregation response to epinephrine, ADP, or collagen, are nonspecific of QPD. A simple screening test is the measurement of D-dimer levels, unusually high in the serum from clots prepared from whole blood compared to platelet-poor plasma (Diamandis et al. 2006). The confirmatory test consists in the detection of increased u-PA and degraded forms of α-granule proteins in QPD platelets by Western blot assays and antigen assays to quantify u-PA. Finally, the method of choice for the diagnosis of QPD is the detection by PCR assay of the *PLAU* gene duplication mutation (Paterson et al. 2010). Although a founder effect is likely from the epidemiology and genetics of QPD, it cannot be formally excluded that QPD-like disorders can be caused by other *PLAU* mutations.

The treatment of QPD is fibrinolytic inhibitor therapy at standard doses. Desmopressin and platelet transfusions are ineffective (Hayward et al. 2006).

Conclusion

Activated platelets are considered the prominent cell membrane surface required for the assembly of coagulation factor complexes and the formation of the fibrin network. In addition, they also contribute to modulate fibrinolysis. However, much of our current understanding of the platelets' contribution to coagulation and fibrinolysis derives from in vitro/ex vivo studies that may not reliably reflect hemostatic events under the influence of the native environment. Therefore, many important questions remain open such as:

1. How is the spatiotemporal regulation of platelet coagulant and fibrinolytic responses organized?
2. What is the in vivo implication and functions of the coated platelets?
3. What is the relative contribution of platelets and fibrin surfaces to fibrinolysis?
4. How is the distribution of procoagulant or fibrinolytic platelet surfaces altered in pathological conditions resulting either in hemorrhage or thrombosis?

The remarkable advances in intravital imaging techniques in the last decade should make it possible to answer these questions in the near future.

Take Home Messages

- Platelet procoagulant activity is triggered by a calcium-dependent scramblase activity, allowing exposure of the anionic phospholipid, phosphatidylserine, at the plasma membrane surface.
- TMEM16F is a membrane protein essential for calcium-dependent phosphatidylserine exposure with loss of function mutations in Scott syndrome.
- Platelets have the capacity to interfere with the fibrinolytic system in several ways and by doing so they can modulate the outcome of thrombolytic therapy.
- The Quebec platelet disorder is a rare autosomal dominant bleeding disorder characterized by a unique gain-of-function defect in fibrinolysis.

Disclosure of Conflict of Interests The authors state that they have no conflict of interest.

Acquired Disorders of Platelet Function

Rüdiger E. Scharf

Abstract

Platelet function can be abnormally *increased*, as in association with vascular events, or *defective*, as in a variety of clinical settings, or display converse phenotypes with *increased* and *decreased* platelet responsiveness, as in myeloproliferative neoplasms. Drugs represent the most common cause of platelet dysfunction in our overmedicated society. While aspirin, clopidogrel, prasugrel (or more recently also ticagrelor), and integrin $\alpha_{IIb}\beta_3$ receptor antagonists (abciximab, eptifibatide, and tirofiban) are well-known prototypes of antiplatelet drugs, other widely used agents (e.g., nonsteroidal anti-inflammatory drugs, antibiotics, serotonin reuptake inhibitors, and volume expanders) and supplements can also impair platelet function and thus cause or aggravate hemorrhages. Apart from pharmacological agents, certain clinical conditions are often associated with qualitative platelet disorders and a bleeding diathesis. Consequently, in contrast to inherited platelet disorders, acquired platelet function defects are much more frequent in clinical practice and therefore deserve special attention. Their pathogenesis is widespread and heterogeneous with various, sometimes overlapping abnormalities in the same clinical setting. Moreover, acquired platelet dysfunction may occur at any age, and platelet defects can range in severity from mild to life-threatening hemorrhages. Diagnostic work-up of platelet disorders requires meticulous evaluation of medical history, specifically of any drugs interfering with platelet function, careful clinical examination, and a staged laboratory protocol to assess the underlying platelet defect(s). Interpretation of laboratory findings may sometimes be difficult, as reduced platelet responsiveness obtained by in vitro settings may result from "exhausted" platelets due to increased activation in vivo. To identify hyperactive platelets ex vivo, costly procedures are required using flow cytometry in combination with specific monoclonal antibodies. Currently, this approach can be recommended for research purposes only. Platelet dysfunction, sometimes in association with quantitative abnormalities, is present in uremia, liver disease, hematologic disorders, cardiac valvular disease, and extracorporeal settings. Due to their heterogeneity, acquired platelet function disorders will be discussed according to the underlying clinical condition.

Introduction

Platelets contribute essentially to survey the integrity of the vascular system. They respond immediately to vascular lesions by becoming adherent within milliseconds and by forming aggregates at sites of injured endothelial cells or exposed subendothelial matrix structures. Following activation,

platelets provide a highly effective catalytic membrane surface for the generation of thrombin that in turn accelerates the recruitment of circulating platelets and the formation of fibrin necessary to stabilize thrombi and to prevent their detachment by flowing blood (Ruggeri 2009). Once stimulated, platelets respond uniformly and do not distinguish between traumatic injury and atherosclerotic or inflammatory damage of the vessel wall (Ruggeri and Mendolicchio 2007, 2015). While their physiological function is to support arrest of bleeding, to contribute to host defense and wound healing, and to restore vessel wall integrity, platelets can form occlusive thrombi as a consequence of vascular diseases, such as atherosclerosis. Thus, under pathological conditions, platelet responses may result in acute ischemic syndromes of the heart, brain, and other organ systems.

Antiplatelet agents are therefore being widely used to prevent and treat thromboembolic events in patients with arterial disease (Aguilar and Hart 2005; Antithrombotic Trialists' Collaboration 2002, 2009). Overall, it has been documented that the risk of severe bleeding increases, when more intense antithrombotic regimens are administered (Eikelboom and Hirsh 2007; May et al. 2008). This is especially true in comorbid patients with preexisting hemostatic defects of any kind. Such disorders may remain compensated, unless platelet function is not inhibited pharmacologically (Scharf 2009) (Box 1). Apart from well-known prototypes of antiplatelet agents such as acetylsalicylic acid, thienopyridines, and integrin $\alpha_{IIb}\beta_3$ receptor antagonists, other widely used agents and supplements can impair platelet function (Scharf 2012) and, consequently, cause or aggravate hemorrhages in certain conditions (Scharf 2009).

This chapter will consider both features of platelet abnormalities, namely, platelet hyperreactivity (associated with a prothrombotic state) and, conversely, defective platelet function that occurs in a variety of clinical settings or is due to pharmacological inhibition, or both. Relevant developments are reviewed, and recent insights into pathomechanisms will be discussed.

Increased Platelet Function

Platelet Hyperreactivity and Prothrombotic State(s)

Numerous experimental and clinical studies have documented that vascular events cause platelet activation and formation of platelet thrombi, which in turn can lead to acute coronary syndromes, myocardial infarction, or stroke (Fitzgerald et al. 1986; Scharf 1986a, b; Fuster et al. 1992). Thus, platelet activation occurs at the site of a fissured coronary atherosclerotic plaque with exposure of highly thrombogenic substances (Fuster et al. 1992; Ruggeri and Mendolicchio 2015).

For example, the effect of angioplasty-injured coronary arteries on platelet activation has been studied (Scharf et al. 1992). Using flow cytometry in combination with specific monoclonal antibodies, activated platelets were demonstrated in patients undergoing percutaneous transluminal coronary angioplasty (Fig. 1). By contrast to these conditions, in which platelet activation and thrombus formation emerge in response to the exposure of subendothelial extracellular matrix proteins, less well documented, and perhaps less frequent, are several clinical settings, in which an acute vascular event appears to result from intrinsic platelet activation. Patients with transient neurological deficits in migraine accompagnée provide a striking example of this assumption (Scharf et al. 1982, 1983a). In this setting, platelet activation markers can correlate inversely with the interval between the time of a migraine attack and blood collection (Fig. 2), suggesting a direct association of increased platelet secretion with clinical symptoms. This observation is in accord with findings from others, who reported on an augmented rate of circulating platelet aggregates in patients with migraine accompagnée at the time of migraine attacks (Hannington et al. 1981).

Along with suchlike findings, it has been postulated clinically that hyperactive platelets exist (Davies and McNicol 1981; Yee et al. 2005). From a laboratory point of view, this condition has been termed platelet hyperaggregability, defined as a feature, in which the threshold concentration for aggregating agents, including ADP, epinephrine, and collagen, is lowered in patients (Trip et al. 1990; Yee et al. 2005)

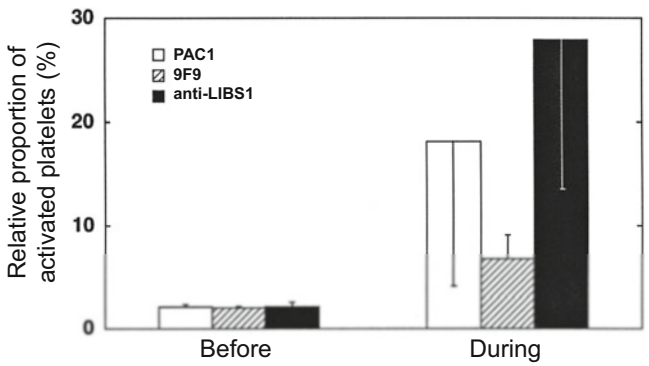

Fig. 1 Flow cytometric detection of circulating activated platelets in patients undergoing percutaneous transluminal coronary angioplasty (PTCA). Blood was sampled continuously via a heparin-coated catheter placed in the coronary sinus before vascular intervention and remained in situ 30 min after termination of PTCA to allow further collection of blood samples. Binding of fluoresceinated monoclonal antibodies specific for activation-dependent platelet epitopes, including activated $\alpha_{IIb}\beta_3$ (PAC-1), fibrinogen bound to $\alpha_{IIb}\beta_3$ (9F9), ligand-induced binding sites on β3 (anti-LIBS1), and P-selectin (S12), was evaluated by flow cytometry. A 2 % platelet subpopulation with the brightest membrane fluorescence intensity at baseline was analyzed separately and quantified for relative increase in platelet number during PTCA. Bars represent mean ± SD. *P*-values for increased binding of PAC-1, anti-LIBS1, and 9F9 were <0.01, <0.01, and 0.03, respectively. Adapted from Scharf et al. (1992) and reprinted with permission of the publisher

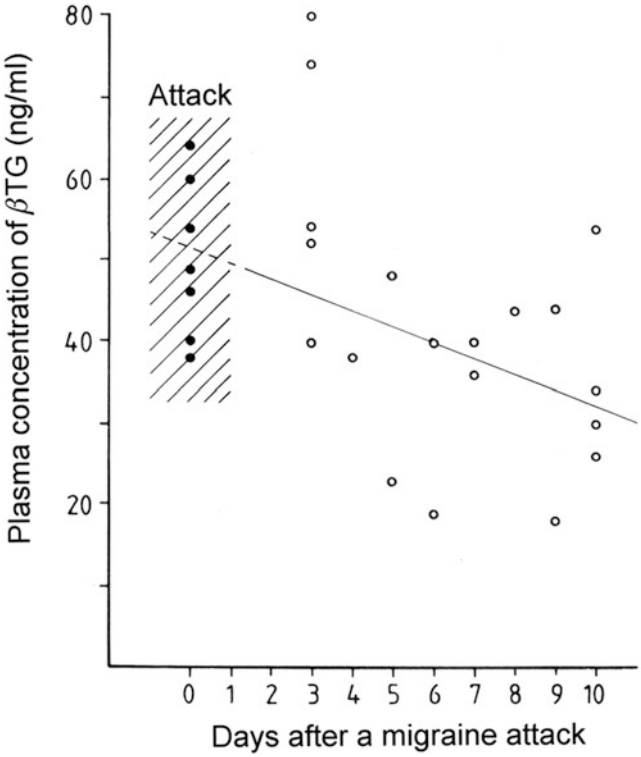

Fig. 2 Platelet secretion in patients with migraine acompagnée. Blood was collected at the time of a migraine attack (*hatched area*) in seven patients (*solid circles*) and at various days after a migraine attack in 19 patients (*open circles*). β-thromboglobulin (βTG) was determined in platelet-free plasma as a marker of platelet secretion in vivo. Note the inverse relationship of the individual plasma levels of βTG and the interval between time of migraine attacks and blood collection ($r = -0.7211$, $p < 005$). Adapted from Scharf (1986a) and reprinted with permission of the publisher

and also in healthy individuals (Yee et al. 2005). This phenomenon should be carefully distinguished from the "sticky platelet syndrome," an autosomal dominant hereditary disorder (Mammen 1999). In a more general way, the term "prothrombotic state" has been introduced. It is postulated for a condition, which precedes clinically overt thrombosis during which hemostasis is altered in a way that promotes formation or deposition of platelet thrombi and generation of fibrin (Davies and McNicol 1981). This definition has raised several questions, including suitable biomarkers of a prothrombotic state and its molecular nature. In this context, distinct polymorphisms of platelet membrane glycoprotein receptors have come into the focus of interest.

Polymorphisms of Platelet Membrane Glycoproteins (GP)

Platelet membrane GP are highly polymorphic and can be recognized as self-antigens or alloantigens. Incompatibility of distinct epitopes, also known as human platelet antigens (HPA), on various platelet receptors is responsible for alloimmune thrombocytopenias and refractory platelet transfusions.

HPA-1 Polymorphism of $\alpha_{IIb}\beta_3$ Platelet integrin $\alpha_{IIb}\beta_3$ (GPIIb-IIIa) carries HPA-1 and other diallelic alloantigen systems (Kunicki and Newman 1992). The HPA-1 polymorphism arises from a single T→C nucleotide substitution at position 1565 in the β3 gene, which in turn leads to an amino acid change at position 33 in the β3 subunit (GPIIIa) with leucine in HPA-1a (Leu33) and proline in HPA-1b (Pro33) (Newman et al. 1989). Importantly, the HPA-1b allele is not rare; approximately 25 % of Caucasians have at least one allele (Kunicki and Newman 1992).

Polymorphisms of $\alpha_2\beta_1$ Platelets contain several receptors for collagen, including GPVI and integrin $\alpha_2\beta_1$ (GPIa-IIa), both of which are important for platelet adhesion. $\alpha_2\beta_1$ exhibits at least three alleles of the α2 gene, which are defined by eight nucleotide polymorphisms (Kunicki et al. 1997). This integrin is expressed at low density on the platelet surface (1000–3000 receptor copies per platelet). Interestingly, there is an approximately tenfold variation among normal individuals that can modulate platelet responses to collagen (Kritzik et al. 1998). Allele 1 (807T/837T/873A/1648G), also referred to as $\alpha_2$807T, is associated with increased surface expression of $\alpha_2\beta_1$ (high-density variant), while alleles 2 (807C/837T/873G/1648G) and 3 (807C/837C/873G/1648A), also designated $\alpha_2$807C, are associated with low surface expression of the receptor (Kritzik et al. 1998). Indeed, in whole blood, the rate of platelet adhesion onto type I collagen under high-shear conditions is proportional to the density of $\alpha_2\beta_1$ receptor copies on the platelet surface (Kritzik et al. 1998). The frequency of allele 1 and 2 is 39 % and 53 %, respectively, and that of allele 3 is 7 % (Kunicki et al. 1997).

Prothrombotic Platelet Receptor Variants

Clinical Association Studies Weiss et al. (1996) first reported on an association between HPA-1b and myocardial infarction (MI). The prevalence of HPA-1b was higher in MI patients than in those without coronary artery disease (CAD) (39.4 % vs. 19.1 %, odds ratio 2.8, $p = 0.01$). In patients, whose MI occurred prior to the age of 60 years, an even greater difference between cases and controls (50 % vs. 13.9 %, odds ratio 6.2, $p = 0.002$) was observed. By contrast, no such difference in the prevalence of HPA-1b was documented in the Physicians' Health Study, prospectively comparing MI patients and matched individuals without cardiovascular events (25.2 % vs. 26.4 %, $p = 0.4$)

(Ridker et al. 1997). These two studies are representative for discrepant results published subsequently (Bray 2000).

Since then, the conflicting findings have been a matter of debate. The same is true for the α_2C807T polymorphism of integrin $\alpha_2\beta_1$. Moshfegh et al. (1999) found a higher prevalence of the $\alpha_2$807TT genotype in patients with MI as compared to healthy controls (16.4 % vs. 2.6 %, $p = 0.022$). By contrast, no significant association of the $\alpha_2\beta_1$ receptor variant and MI was observed by Santoso et al. (1999). However, in the same study, subgroups of younger patients (<62 or <49 years) revealed an increased risk in carriers of the T-allele (odds ratio 1.57, $p = 0.004$, or 2.61, $p = 0.009$, respectively).

In a retrospective study on patients with MI, those with CAD but no history of MI, and control patients, who all had undergone coronary angiography, Zotz et al. (1998) found no difference in the overall prevalence of HPA-1b among case patients with MI (23 %) and control patients (25 %, $p = 0.75$), confirming the results of the Physicians' Health Study (Ridker et al. 1997). However, a post hoc analysis revealed that the prevalence of HPA-1b was related to the patients' age and time after MI with highest values in MI patients <60 years of age and those with recent-onset (<1 year) MI (45 % vs. 23 % in controls, odds ratio 2.0, $p = 0.007$), thereby confirming the observations by Weiss et al. (1996). Moreover, patients with CAD, who are carriers of the HPA-1b allele, experienced a MI earlier in life than HPA-1b-negative patients (Zotz et al. 1998). The authors concluded that the HPA-1b allele of $\alpha_{IIb}\beta_3$ is not a risk factor for atherosclerosis but a risk factor for arterial thrombosis. Moreover, Zotz et al. (1998) hypothesized that HPA-1b is a prothrombotic risk determinant that requires the presence of an atherosclerotic lesion to become effective. Thus, unlike conventional risk factors, HPA-1b is not a risk factor for CAD as such but appears to be associated with increased platelet thrombogenicity. This contention provides an explanation for conflicting results of association studies on the role of the HPA-1 polymorphism of $\alpha_{IIb}\beta_3$ in CAD. Along with this hypothesis, it can be anticipated that, even in prospective studies, the effect of a polymorphism coupled to the presence of CAD will provide no difference in the prevalence of HPA-1b between MI patients and controls, since the receptor variant is not associated with an increased rate of MI but a *premature* onset of MI.

This hypothesis was tested in a cohort of 3250 carefully characterized patients, including survivors of MI, patients with CAD but no history of MI, and control patients (no angiographically detectable CAD) in comparison to healthy volunteers (Zotz et al. 2005). In a *case-control* design, the prevalence of HPA-1b and $\alpha_2$807TT genotypes did not differ between patients with CAD or MI and patient controls or healthy volunteers. By contrast, using a multivariate *case-only* design, the median age at onset of MI was 5.2 years earlier ($p = 0.006$) in carriers of the HPA-1b allele and 6.3 years earlier ($p = 0.006$) in carriers of the $\alpha_2$807TT genotype in 264 survivors of recent-onset MI (Fig. 3).

A prospective study on patients undergoing saphenous-vein coronary artery bypass grafting documented that the prevalence of HPA-1b was higher among those with bypass occlusion, MI, or death >30 days after surgery as compared to those without postoperative complications (60 % vs. 24 %, odds ratio 4.7, $p < 0.05$). Using a stepwise logistic regression analysis with the variables HPA-1b, age, sex, BMI, smoking, hypertension, diabetes, and hyperlipidemia, only HPA-1b had an association with bypass occlusion, MI, or death after bypass surgery (odds ratio 4.7, $p = 0.019$) (Zotz et al. 2000).

The results suggest that distinct integrin genotypes may modulate platelet function and lead to increased platelet thrombogenicity. As the effects of the critical receptor variants are coupled to the presence of CAD, it is likely that an atherosclerotic lesion (e.g., plaque instability) becomes a decisive trigger. The remarkable similarity, in which the genetically unlinked markers behave, supports the contention that HPA-1b (Pro33) of $\alpha_{IIb}\beta_3$ and $\alpha_2$807TT of $\alpha_2\beta_1$ are prothrombotic (Box 2).

Functional Properties of Platelet Integrin Variants Under Arterial Flow Conditions To define the genotype-phenotype relation of critical $\alpha_{IIb}\beta_3$ and $\alpha_2\beta_1$ variants, HPA-1b (Pro33) or $\alpha_2$807TT platelets were studied in an established model, simulating arterial flow conditions in combination with digital imaging. This model permits the analysis of shear-induced platelet adhesion and thrombus formation onto thrombogenic surfaces (Ruggeri 2009). Using these techniques, it was demonstrated that the HPA-1b variant of $\alpha_{IIb}\beta_3$ and the $\alpha_2$807TT genotype of $\alpha_2\beta_1$ have indeed prothrombotic properties. Major characteristics of their phenotype are increased adhesion activity (Loncar et al. 2007), increased thrombus formation (Scharf et al. 2009), and increased outside-in signaling (Scharf et al. 2009; Gyenes et al. 2011). These findings were confirmed with transfected cell lines expressing $\alpha_{IIb}\beta_3$ of either isoform, HPA-1a or HPA-1b. Upon exposure of adherent cells to increasing shear rates (up to 1600 s^{-1}), HPA-1b (Pro33) cells were more resistant than HPA-1a (Leu33) cells (El Khattouti et al. 2011). Along with these findings, it was concluded that the increased thrombogenicity of the Pro33 variant of $\alpha_{IIb}\beta_3$ is due to elevated thrombus stability resulting from a polymorphism-mediated modulation in mechanotransduction. Thus, thrombus formation and thrombus stability would be driven, at least in vitro, by the biophysical transmission of receptor-ligand interactions to the platelet cytoskeleton. In vivo, the prothrombotic character of HPA-1b (Pro33) platelets

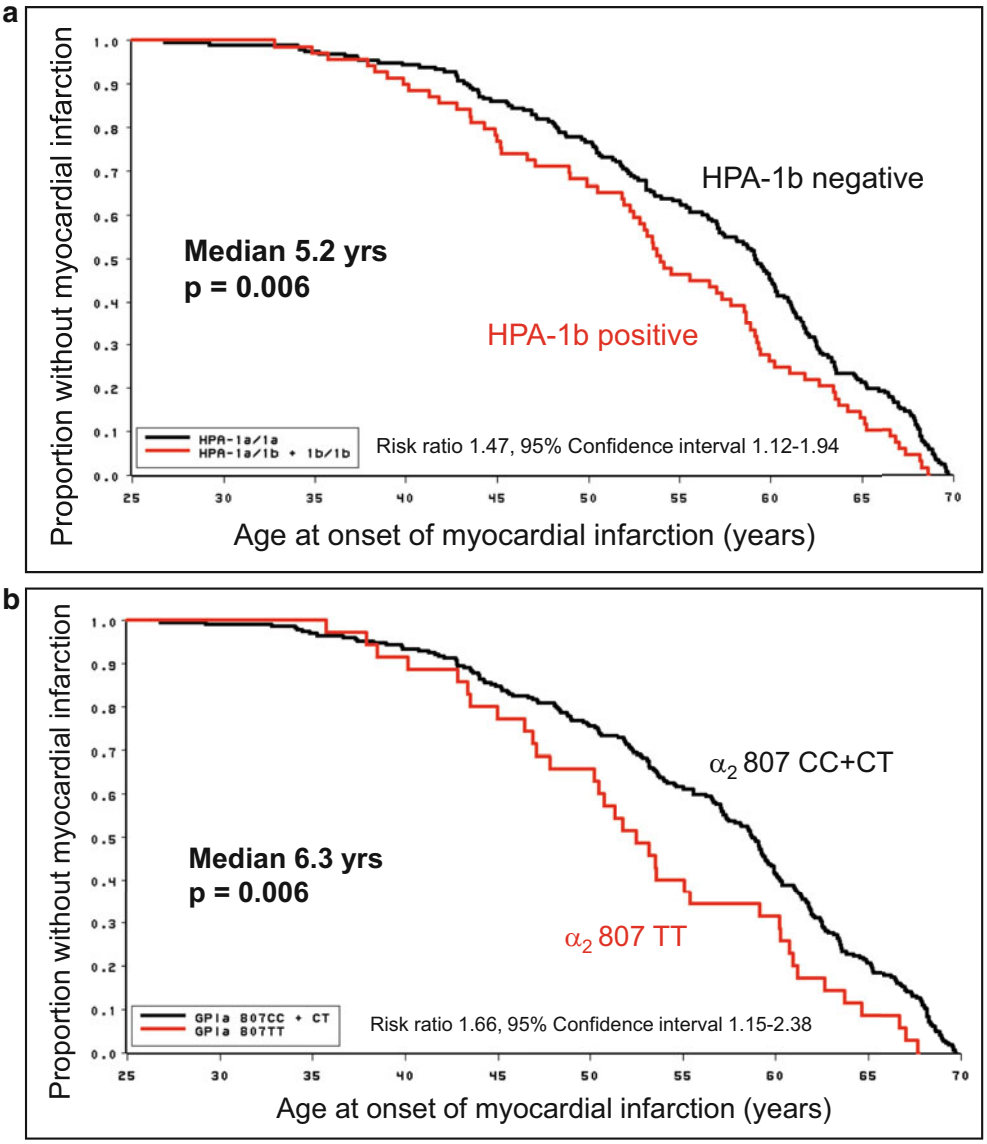

Fig. 3 Distribution of age at onset of myocardial infarction in relation to the HPA-1 (β3 C1565T) and α_2C807T polymorphisms of $\alpha_{IIb}\beta_3$ and $\alpha_2\beta_1$. The plots display the proportion of patients without myocardial infarction (MI) in the subgroup of patients with one- and two-vessel disease and recent-onset myocardial infarction recent (<1 year). The ages at onset of MI are referred to as event times, (**a**) in relation to HPA-1and (**b**) in relation to α_2C807T. The median age at onset of MI was 54.0 years in HPA-1b-positive patients and 59.2 years in the HPA-1b-negative patients ($p < 0.006$ by log-rank test). The median age at onset of MI was 52.5 in carriers of the $\alpha_2$807TT genotype and 58.8 years in carriers of the $\alpha_2$807CC or $\alpha_2$807CT genotype ($p < 0.006$ by log-rank test). Adapted from Zotz et al. (2005) and reprinted with permission of the publisher

is linked to the presence of arteriosclerotic vascular lesions (Zotz et al. 2005; Scharf and Zotz 2006).

Further aspects of platelet hyperreactivity in cardiovascular disorders are reviewed in Chap. 3.2.7. Increased platelet function associated with clonal hematopoietic proliferation will be discussed in the section on myeloproliferative neoplasms (Alimam & Harrison (2017) in this volume).

Decreased or Defective Platelet Function

Frequency of Acquired Platelet Disorders and Screening for Defects in Primary Hemostasis

Data on the rate of defects in primary hemostasis are available from a prospective analysis by Koscielny et al. (2004), who studied 5649 consecutive patients (age ranging from 17 to 87 years) prior to elective surgery. Aside from history and physical examination, the investigators used a bleeding questionnaire and a standardized test panel for hemostatic screening, including in vitro bleeding time determined by platelet function analyzer (PFA-100). Patients with preexisting hemostatic disorders or anticoagulation therapy were primarily excluded from the analysis. Of the 5649 patients, bleeding history was negative in 5021 (88.8 %); in the remaining group (11.2 %) with a bleeding history, screening for hemostatic defects was positive in 256 of the 628 patients (40.8 %). Diagnostic work-up of the 256 patients revealed platelet function defects in 73 %, coagulation disorders in 0.8 %, and combined hemostatic defects in 26.2 % (including a predominant proportion of patients with von Willebrand disease). Among the 187 individuals with defects in primary hemostasis, acquired platelet dysfunction was drug-induced in 162 patients (63.3 %); among them, 147 were taking aspirin, ticlopidine,

clopidogrel, or other nonsteroidal anti-inflammatory agents, while in 10 patients (6.2 %) antibiotic treatment appeared to be the cause of platelet dysfunction. It is conceivable that this rate of antibiotic-induced bleeding diathesis may be even higher in other patient groups. Indeed, as reported on a smaller cohort of hospitalized patients with prolonged Ivy bleeding time, 54 % were receiving large doses of antibiotics and 10 % were taking aspirin or other nonsteroidal anti-inflammatory agents (Wisloff and Godal 1981). The data by Koscielny et al. (2004) illustrate several important issues summarized in Box 3.

Drugs That Inhibit or Impair Platelet Function (See also other Chapters "Aspirin" Patrono (2017), "Inhibitors of $P2Y_{12}$" (Gross et al. 2017), "Glycoprotein IIb/IIIa Antagonists" (Shanmugasundaram and Moliterno 2017), "Dipyridamole and the PDE Inhibitors" (Gresele et al. 2017), "PAR-Antagonists" (Guimarães and Tricoci 2017) and "Inhibitors of Platelet Adhesion to VWF and Collagen" (Tersteeg et al. 2017)

Prototypes of antiplatelet agents and their mode of action are displayed in (Fig. 4). Acetylsalicylic acid (aspirin) and nonsteroidal anti-inflammatory agents, thienopyridines (clopidogrel, prasugrel, or ticagrelor), and integrin $\alpha_{IIb}\beta_3$ receptor antagonists (abciximab, eptifibatide, and tirofiban) are the most prominent causes of acquired platelet function disorders and, thus, of potential bleeding risk. Moreover, agents that increase intraplatelet cAMP, either by stimulation of its synthesis (prostaglandin E_1, prostacyclin) or by phosphodiesterase inhibition (dipyridamole, theophylline, caffeine), may also impair platelet function. Nitric oxide donors can increase the bleeding time and may contribute to hemorrhage, specifically in uremic patients. Antibiotics, particularly those of the β-lactam type such as penicillins and cephalosporins, may cause prolongation of the bleeding time even in normal volunteers. The mechanism, whereby these antibiotics impair platelet function, is currently not known, although it has been proposed that they bind to the platelet membrane and inhibit the interaction of agonists and von Willebrand factor (VWF) or modify platelet receptors chemically (George and Shattil 1991). Differences in antiplatelet effects (e.g., inhibition of aggregation) of carbenicillin, penicillin G, ticarcillin, ampicillin, nafcillin, azlocillin, piperacillin, alpacillin, or mezlocillin probably relate to differences in blood levels and drug potency. Adsorption and nonspecific binding to platelet membrane constituents are also discussed as mechanism, by which volume expanders can impair platelet aggregation; however, interference of dextran or hydroxyethyl starch with $\alpha_{IIb}\beta_3$ and its plasma ligands may be clinically relevant only in patients with a preexisting hemostatic defect.

Among psychotropic drugs, selective serotonin reuptake inhibitors (SSRIs) that are widely used for the treatment of anxious disorders and depression can cause abnormal bleeding (Halperin and Reber 2007). Specifically, agents with the highest degree of serotonin reuptake inhibition such as fluoxetine, paroxetine, and sertraline are associated more frequently with hemorrhagic events (Serebruany 2006). Various adverse effects implicating drug-induced platelet dysfunction have been reported upon the use of SSRIs. Abnormal bleeding time (Ivy) and prolongation of closure times (PFA-100) are frequent abnormalities upon screening together with platelet aggregation and secretion defects upon stimulation with ADP, collagen, epinephrine, or thrombin (Halperin and Reber 2007). The spectrum of antiplatelet effects induced by SSRIs is broad, including reduced platelet responsiveness, blockade of intraplatelet calcium mobilization, and lowered surface expression of GPIb-IX-V, integrin $\alpha_{IIb}\beta_3$, P-selectin, VLA-2, and PECAM-1 (Halperin and Reber 2007; Serebruany 2006).

In general, acquired platelet function defects secondary to drugs are mild and ubiquitous, considering, for example, the large number of individuals, who take aspirin regularly and therefore have impaired platelet function due to irreversible inhibition of cyclooxygenase-1 (COX-1)-dependent thromboxane A_2 (TXA_2) formation. The effect of aspirin ingestion on the hemostatic competency of normal volunteers has been debated but appears to be of minor relevance. Nevertheless, individuals taking aspirin chronically report a significant increase in bruising, epistaxis, and gastrointestinal blood loss. More importantly, there was a slight but statistically insignificant increase in hemorrhagic strokes in a group of otherwise healthy physicians who took aspirin chronically as primary prophylaxis against MI (Steering Committee of the Physicians' Health Study 1989). Besides aspirin, more than 250 pharmacological agents, foods (fish oils) or diets (eicosapentaenoic acid), spices (onion, garlic), and vitamins have been reported to impair platelet function (for review: Scharf 2012) (Box 4).

Taken together, for almost all agents interfering with platelet reactivity or inhibiting platelet function, data are limited to abnormal platelet aggregation studies in vitro or prolonged bleeding time, which do not necessarily reflect the true bleeding risk and, therefore, may have minor or questionable clinical importance. By contrast, treatment with antiplatelet agents can cause or aggravate severe hemorrhage in patients with preexisting hemostatic defects of any kind. This is particularly true for certain clinical settings (sepsis, disseminated intravascular coagulation), or conditions (cardiopulmonary bypass surgery, liver transplantation), and systemic or hematologic diseases that affect platelet function and can be associated with bleeding disorders (renal failure, liver cirrhosis, myeloproliferative

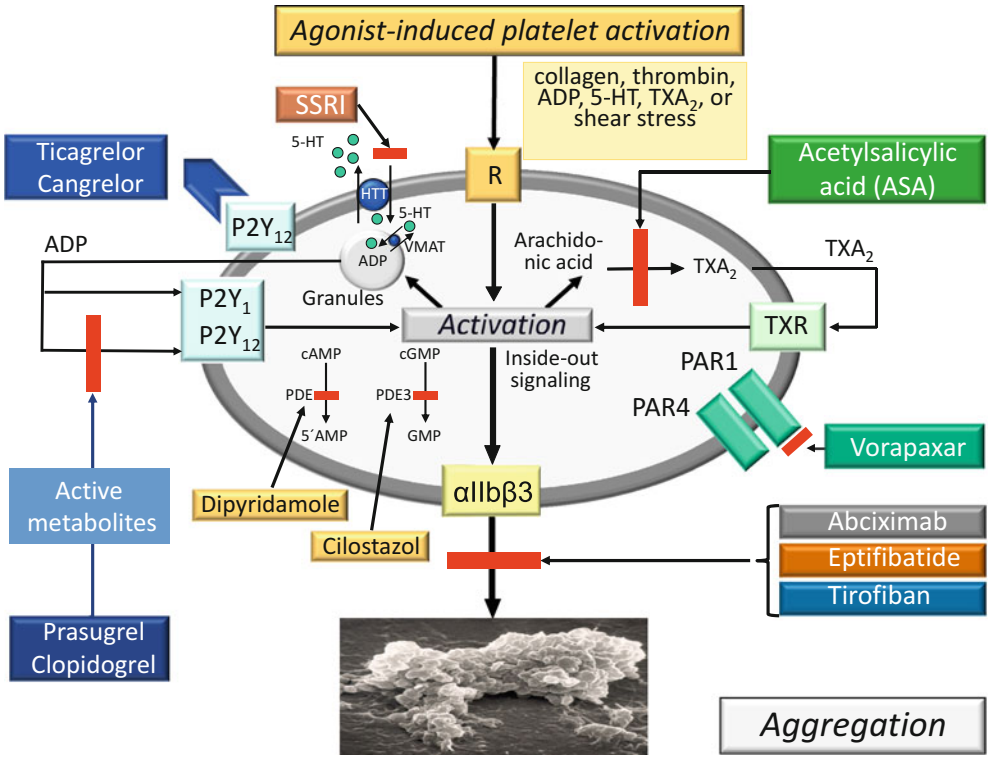

Fig. 4 Antiplatelet agents and their mode of action. Stimulation of circulating platelets with agonists such as collagen, thrombin, ADP, 5-HT, TXA_2, or by biomechanical forces such as shear stress results in platelet activation via inside-out signaling with conformational changes of integrin $\alpha_{IIb}\beta_3$ and subsequent platelet aggregation. Inhibition of TXA_2 formation or antagonism of the ADP receptor $P2Y_{12}$ interrupts positive feedback loops necessary for sustained platelet activation. Note that thienopyridines (clopidogrel and prasugrel) are prodrugs, which require conversion to their active metabolites, while the two newly designed direct and reversible platelet $P2Y_{12}$ antagonists, cangrelor and ticagrelor, are immediately active. Direct pharmacological blockade of $\alpha_{IIb}\beta_3$ by specific antibodies or receptor antagonists inhibits platelet aggregation. At approximately 15,000–20,000 intact residual $\alpha_{IIb}\beta_3$ receptor copies, antagonism is sufficient to suppress occlusive platelet thrombus formation in acute coronary interventions without inducing major bleeding. Abbreviations: ADP, adenosine diphosphate; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; 5-HT, 5-hydroxytryptamine (serotonin); HTT, serotonin transporter; PAR, protease-activated receptor; PDE, phosphodiesterase; R, agonist receptor; SSRI, selective serotonin reuptake inhibitor; TXA_2, thromboxane A_2; TXR, thromboxane receptor; VMAT, vesicular monoamine transporter. Updated modification adapted from Scharf (2009) and reprinted with permission of the publisher

neoplasms, acute leukemias, myelodysplastic syndromes, and myeloma).

End-Stage Renal Disease (See also Lutz and Jurk 2017)

Bleeding may be a serious complication in patients with acute and chronic renal failure and is observed in up to one-third of uremic patients. Hemorrhages are also a concern in renal biopsy.

The pathogenesis of uremic bleeding is multifactorial (Table 1). It should be stressed that bleeding due to platelet abnormalities and other alterations involved in hemorrhagic complications is by far not the only hemostatic disorder in chronic renal failure. Thus, thrombosis of vascular access is common in patients undergoing hemodialysis. Moreover, uremic patients are highly susceptible to the development of atherosclerosis and its thrombotic complications (Boccardo et al. 2004).

Various platelet abnormalities, with partially conflicting results, have been reported in end-stage renal disease, including defects in platelet adhesion, aggregation, secretion, signal transduction, and metabolism of arachidonic acid and nitric oxide (Boccardo et al. 2004; Gawaz et al. 1994; Lutz et al. 2014; Oudemans-van Straaten 2015). More recently, it has also been shown that uremia can alter the platelet transcriptome (mRNA), thereby leading to an abnormal protein expression profile of platelets in patients with chronic kidney disease (Plé et al. 2012). The most consistent finding in end-stage renal disease is prolongation of the bleeding time, which may be abnormal in about 75 % of uremic patients. However, its value in predicting the risk of hemorrhage in uremia has never been

Table 1 Abnormalities and other determinants involved in the pathogenesis of bleeding associated with chronic renal failure. Data from Scharf and Schneider (1985), Scharf (1990), Gawaz et al. (1994), Boccardo et al. (2004), Plé et al. (2012)

Qualitative platelet abnormalities
– Reduced δ-granule content (ADP, serotonin)
– Reduced α-granule content (platelet factor 4, β-thromboglobulin) with
– Impaired secretion of α-granule constituents
– Elevated intracellular cAMP
– Abnormal mobilization of platelet Ca^{2+}
– Increased generation of nitric oxide by uremic platelets
– Defective cyclooxygenase activity
– Abnormal platelet arachidonic acid metabolism
– Abnormal platelet aggregation ex vivo in response to different stimuli
– Activation and ligand binding defects of $\alpha_{IIb}\beta_3$
– Altered platelet transcriptome (mRNA) with abnormal protein expression profile
– Uremic toxins, including urea, creatinine, phenol, phenolic acid, guanidine, guanidinosuccinic acid and parathyroid hormone
Quantitative platelet abnormalities
– Mild to moderate thrombocytopenia (due to inadequate production and/or consumption)
Abnormal platelet-vessel wall interactions
– Abnormal platelet adhesion
– Increased formation of vascular prostacyclin
– Abnormal production of nitric oxide
– Quantitative and/or qualitative alterations in plasma von Willebrand factor
Anemia
– Altered blood rheology
– Erythropoietin deficiency
Drugs[a]
– Antiplatelet agents
– Nonsteroidal anti-inflammatory drugs such as indomethacin, ibuprofen, and naproxen
– β-Lactam antibiotics
– Third-generation cephalosporins
– Selective serotonin reuptake inhibitors (SSRI) such as sertraline, paroxetine, and fluoxetine
– Heparin (during hemodialysis)

[a]Additional information can be obtained from Scharf (2012)

defined. Thus, numerous studies have failed to determine a consistent defect of platelet function or a clearly characterized abnormality in plasma VWF, both of which can be causally linked (Box 5).

Commonly, uremic patients with bleeding improve upon hemodialysis and transfusion of red blood cells. Nowadays, with appropriate continuous renal replacement therapy (CRRT) and the use of erythropoietin, the frequency and extent of bleeding episodes in renal disease have decreased (Oudemans-van Straaten 2015). In fact, reducing serum levels of uremic toxins that may cause or attribute to platelet dysfunction (Table 1), and increasing the hematocrit, thereby improving blood rheology, does correct several conditions, which otherwise contribute to defective hemostasis. Indeed, anemia is the main determinant of the prolonged bleeding time in uremic patients, as also demonstrated by an inverse relationship of increasing the hematocrit and concomitantly decreasing the bleeding time upon treatment with recombinant erythropoietin (Boccardo et al. 2004). However, the early termination of the Normal Hematocrit Cardiac Trial (Besarab et al. 1998), in which cardiac patients, who had been randomly assigned to the normal hematocrit group, presented with a higher mortality and a higher incidence of nonfatal MI, raised questions about the safety of the long-term maintenance of a normal hematocrit (Boccardo et al. 2004).

While it is generally assumed that hemodialysis corrects platelet abnormalities and reduces bleeding, it does not eliminate the hemorrhagic risk. Thus, platelet aggregation can be improved but also transiently impaired by CRRT, indicating that dialysis does not only remove inhibitors of platelet function but also causes activation and granular secretion upon platelet interaction with dialysis membranes (Scharf and Schneider 1985; Boccardo et al. 2004). For example, it has been demonstrated that hemodialysis induces a transient α-granule storage pool defect, leading to "exhausted" platelets that continue to circulate and exhibit defective TXA_2 formation (Stockschlader and Scharf 1989; Scharf 1990). This condition favors bleeding in uremic patients. Other platelet defects in patients with chronic renal failure are related to dysfunctional $\alpha_{IIb}\beta_3$ and defective interaction with fibrinogen or VWF (Escolar et al. 1990; Benigni et al. 1993; Gawaz et al. 1994). By contrast, binding of VWF to GPIbα and expression of GPIb-IX-V on platelets appear to be normal (Benigni et al. 1993). However, quantitative changes such as a decrease in total platelet GPIb content associated with an increase in soluble glycocalicin, a proteolytic GPIb fragment, have also been reported (Sloand et al. 1991).

Thrombocytopenia due to inadequate platelet production and/or consumption during regularly performed hemodialysis is also a common finding. However, platelet counts are rarely <80,000/μL and thus sufficient for primary hemostasis, presupposing intact platelet function. Other mechanisms that may cause a decrease in platelet counts are related to side effects of the anticoagulation regimen used for hemodialysis, in particular, to heparin-induced thrombocytopenia (Oudemans-van Straaten 2015).

Liver Disease (See also Lisman 2017)

Complex disorders of the hemostatic apparatus are present in acute and chronic liver disease, involving combined abnormalities of the megakaryocyte-platelet system, coagulation, and fibrinolysis. Apart from coagulation defects (INR >1.5) due to reduced hepatocellular synthetic capacity, thrombocytopenia of variable extent is a frequent feature both in acute and chronic liver disease. An analysis by the Acute Liver Failure Study Group, enrolling 1600 patients,

documented that the median platelet count on admission was approximately 130,000/μL; 60 % of patients had platelets counts <150,000/μL, 35 % <100,000/μL, and 10 % <50,000/μL (US Acute Liver Failure Study Group). In patients with advanced fibrosis or liver cirrhosis, the prevalence of thrombocytopenia ranges between 15 and 75 % (Giannini and Savarino 2008). The degree of thrombocytopenia appears to be proportionally related to the severity of liver disease but not associated with spontaneous bleeding, unless platelets counts decrease <50,000–60,000/μL (Scharf 1986a; Tripodi et al. 2006; Tripodi and Mannucci 2011).

Thrombocytopenia in liver disease results from increased lineal sequestration due to portal hypertension and subsequent hypersplenism (Scharf et al. 1983b; Scharf 1986a; Bashour et al. 2000), decreased thrombopoietin (TPO) production (Peck-Radosavljevic et al. 2000), and/or from toxic or virus-induced suppression of megakaryocytopoiesis (Scharf and Aul 1988; Bordin et al. 1995). In the past, low platelet counts in liver disease were mainly attributed to splenic pooling and/or consumption. More recently, the association between hepatic synthesis of TPO and residual hepatic function allowed a more specific insight into the pathophysiology of thrombocytopenia in liver disease. In fact, TPO levels are near-normal or even increased in acute hepatic failure (Schiodt et al. 2003). This is in contrast to patients with chronic liver disease, in whom TPO serum levels are significantly decreased and therefore thought to contribute to thrombocytopenia in cirrhosis (Giannini and Peck-Radosavljevic 2015). Treatment with TPO receptor agonists (e.g., eltrombopag) appears to be a promising therapeutic option to increase low platelet counts in patients with cirrhosis associated with hepatitis C (McHutchison et al. 2007). However, a double-blinded, randomized, placebo-controlled, phase 3 trial using eltrombopag prior to invasive procedures in patients with cirrhosis and thrombocytopenia was prematurely terminated because of an increased rate of thrombotic events (Afdhal et al. 2012).

Despite the multifaceted hemostatic defects, hemostasis-related bleeding episodes are relatively infrequent in patients with in liver disease. Based on clinical and systematic laboratory findings, we hypothesized as early as the mid-1980s that a balanced *low-level* hemostatic equilibrium due a *concordant* reduction in pro- and antihemostatic components is present in stable liver cirrhosis (Scharf et al. 1983b; Scharf 1986a). However, this balance is extremely labile and thus can be easily destabilized by various triggers (e.g., infection, variceal bleeding, decompensated liver cirrhosis, invasive procedures, or inadequate hemotherapy with prothrombotic components such fresh-frozen plasma, activated prothrombin complex concentrates, or recombinant factor VIIa). Recent studies have confirmed our contention of a *rebalanced* hemostasis resulting from a commensurate decline in pro- and antihemostatic factors both in patients with acute and chronic liver disease (Tripodi 2015; Lisman and Stravitz 2015). Moreover, despite decreased procoagulant coagulation factors, thrombocytopenia, and suspected platelet dysfunction, patients with acute or chronic liver disease can display hypercoagulable features, which may explain, at least in part, that thrombotic complications are more common than spontaneous bleeding complications (Tripodi 2015; Lisman and Stravitz 2015) (Box 6). For example, apart from normal or even enhanced thrombin generation in liver cirrhosis (Tripodi et al. 2005, 2011; Tripodi and Mannucci 2011), recent studies have shown increased levels of highly procoagulant platelet-derived microparticles (Stravitz et al. 2013). In addition, elevated plasma levels of VWF, typically observed in chronic liver disease, can compensate for the low numbers of circulating platelets (Lisman et al. 2006) and may restore primary hemostasis (Tripodi and Mannucci 2011; Tripodi 2015; Lisman and Stravitz 2015). However, these compensatory mechanisms fail to operate in patients with end-stage liver disease, in whom prominent bleeding complications remain a serious concern (Tripodi and Mannucci 2011).

Concomitant platelet function defects, as suggested in chronic liver disease, are less well defined. Generally, it has been assumed that platelet function deteriorates with the severity of liver failure. Older studies have described in vitro aggregation abnormalities in response to several agonists (Rubin et al. 1977; Weston et al. 1977). Some of the platelet aggregation defects were attributed to elevated levels of fibrinogen/fibrin degradation products or dysfibrinogenemia, both of which are rather common in chronic hepatitis and cirrhosis. Toxic effects of ethanol may also contribute to platelet dysfunction (Scharf and Aul 1988). Other possible mechanisms include defects in GPIb (Sanchez-Roig et al. 1994), decreased availability of arachidonic acid and consequently reduced TXA_2 formation (Laffi et al. 1988), increased cholesterol content of the platelet plasma membrane, impaired transmembrane signaling (Laffi et al. 1988), elevated sialic acid concentration of circulating platelets, and hypersialylated fibrinogen (Scharf 1986a). By contrast, antiplatelet antibodies, although rather frequently found in patients with acute or chronic viral liver disease, appear to be of minor relevance of qualitative or quantitative platelet disorders in this setting (Giannini and Savarino 2008). The diagnosis of impending DIC in patients with liver disease is often difficult to ascertain because of the multiple hemostatic alterations.

Disseminated Intravascular Coagulation (DIC)

Progressive thrombocytopenia and complex coagulation abnormalities are leading laboratory features in patients with DIC caused by a broad variety of conditions, including viral or bacterial infections and sepsis. Apart from pathogen-

induced thrombocytopenia, resulting from decreased platelet production, enhanced platelet consumption and clearance, or a combination of both, concomitant dysfunction of the circulating platelet population may aggravate bleeding at different stages of DIC. Some of the defects in primary hemostasis are attributed to "exhausted" platelets, an acquired storage pool deficiency that is believed to result from repetitive platelet stimulation in DIC (Pareti et al 1980; Scharf 1986a, b). Indeed, exhausted platelets continue to circulate (O'Brien 1978; Scharf 1990).

Generally, platelet dysfunction in DIC is not well characterized. For example, it has been suggested that elevated fibrin(ogen) degradation products, typically present in patients with DIC, are responsible for impaired platelet aggregation in vitro; however, the concentrations required to cause aggregation defects are unlikely to be found in vivo. The same is true for low fibrinogen levels (<100 mg/dL), which, except in cases with extreme hypofibrinogenemia, can rarely cause platelet aggregation defects, as platelet receptors are saturated at a fibrinogen concentration of only 10 mg/dL (Marguerie et al. 1984). More recently, sepsis-related alterations in platelet function have been studied in critically ill patients with and without DIC. Yaguchi et al. (2004) observed reduced in vitro platelet aggregability in septic patients, whereby the severity of sepsis was related to platelet aggregation defects. This observation can be interpreted in two ways: it may be that sepsis induces indeed a decreased platelet function, or, what is more likely that increased platelet aggregability is present in patients with sepsis that in turn will lead to circulating activated platelets, which will not respond properly in an ex vivo setting (Levi 2004). Likewise, Gawaz et al. (1997) found increased platelet surface expression of thrombospondin and platelet-neutrophil adhesion in septic patients. Overall, it appears likely that platelets become activated and hyperadhesive to neutrophils and endothelial cell in sepsis with and without DIC and that this mechanism promotes platelet sequestration, microcirculatory arrest, and in turn multiple organ failure.

Cardiopulmonary Bypass, Valvular Heart Disease, and Ventricular Assist Devices

Open-heart surgery using cardiopulmonary bypass (CPB) is accompanied by significant alterations, including "whole-body inflammatory response," reduction in coagulation factors, activation of fibrinolysis, and quantitative and qualitative platelet changes. Among these alterations, triggered by the contact between flowing blood and synthetic surfaces of the extracorporeal circuit, platelet dysfunction represents the major insult to hemostasis in this setting.

Thrombocytopenia secondary to CPB is caused by hemodilution and consumption due to adherence of platelets on the bypass circuit. CPB also results in shear stress-induced platelet activation, adherence onto immobilized adhesive plasma proteins, formation of platelet aggregates, secretion of granular constituents, platelet fragmentation, and generation of platelet-derived microparticles. Typically, CPB causes prolonged bleeding times, reduced platelet aggregation responses to several agonists in vitro, and acquired platelet storage pool deficiency, involving selective α-granule secretion or depletion of both α- and δ-granules (Bick 1985; Harker et al. 1980; Harker 1986; Kestin et al. 1993). Circulating degranulated ("exhausted") platelets due to activation induced by the interaction between blood and artificial surfaces were also identified in patients with chronic renal failure upon hemodialysis (Scharf and Schneider 1985; Scharf 1986a, b). Attempts have been made to prevent platelet activation during bypass and hemodialysis by infusion of prostaglandin E_1 or prostacyclin.

Highly abnormal rheologic conditions with excessive shear stress can also result in hemostatic defects with manifest bleeding. Acquired von Willebrand syndrome (aVWS) due to reduction or loss in large VWF multimers appears to be the underlying mechanism in suchlike settings. This has been convincingly shown in patients with severe aortic-valve stenosis (Vincentelli et al. 2003; Sadler 2003; Sucker et al. 2003) and subsequently also in patients with mitral regurgitation (Blackshear et al. 2014), in whom hemorrhagic complications due to aVWS resolved upon valve replacement. Interestingly, in aortic stenosis, the proportion of high-molecular-weight VWF multimers was inversely correlated with the mean transvalvular gradient (Vincentelli et al. 2003).

Acquired platelet dysfunction and qualitative and quantitative abnormalities in VWF are also frequently observed in patients with left ventricular assist devices (LVAD) and may cause otherwise unexplained bleeding complications (Steinlechner et al. 2009; Meyer et al. 2010; Baghai et al. 2015). The defects are attributed to abnormally high-shear conditions and the contact of circulating blood with artificial surfaces. Again, loss of high-molecular-weight VWF multimers appears to be the predominant pathomechanism in this setting; removal of the device is associated with complete restoration of the VWF monomer and multimer pattern (Meyer et al. 2010). Relevant pathologies of symptomatic defects in VWF are discussed in the Section on acquired von Willebrand syndrome.

Antiplatelet Antibodies

The overall impact of platelet-antibody interaction may be thrombocytopenia and platelet function abnormalities, as noted in the wide range of autoimmune disorders, including

idiopathic thrombocytopenic purpura (ITP), also designated immune thrombocytopenic purpura or immune thrombocytopenia (Ruggeri et al. 2008), or secondary causes such as systemic lupus erythematosus, rheumatoid arthritis, antiphospholipid syndrome, viral infections (with cytomegalovirus, hepatitis C virus, human immunodeficiency virus, or varizella zoster virus), or side effects upon vaccination or administration of certain drugs (Neunert et al. 2011). Autoantibodies can induce platelet dysfunction by multiple mechanisms. In some patients, antibodies are directed against distinct platelet surface glycoproteins, including GPIa, GPIIa, GPIb, GPIIb, GPIIIa, GPIV, and GPVI.

In a traditional view, ITP was considered as being caused predominantly by antibody-mediated platelet destruction in the circulation at a rate that is not compensated by enhanced platelet production in the bone marrow. However, it has become evident that both megakaryocyte production and maturation and in turn thrombocytopoiesis can be also compromised by antiplatelet antibodies (McMillan and Nugent 2005; Bussel et al. 2006; Bromberg 2006; Nugent et al. 2009). Specifically, it was shown that TPO levels are inappropriately low for the degree of thrombocytopenia in the majority of patients with chronic ITP (Kuter and Gernsheimer 2009; Kuter 2009). This observation has provided a rationale for treatment with TPO mimetics in patients suffering from chronic refractory ITP (Bussel et al. 2006; Bromberg 2006; Kuter and Gernsheimer 2009; Kuter 2009; Neunert et al. 2011; Liebman and Pullarkat 2011). Two TPO receptor agonists, romiplostim and eltrombopag, have been approved for refractory postsplenectomy ITP patients. Currently, the use of these agents earlier in the disease course is debated but remains controversial (Liebman and Pullarkat 2011).

In the 1980s, two useful antigen-specific assays, the immunobead assay and the monoclonal antibody-specific immobilization of platelet antigens (MAIPA) assay, were reported (McMillan et al. 1987; Kiefel et al. 1987). Applying these assays (specificities 78–93 %; sensitivities 49–66 %) (McMillan 2005), specific antiplatelet autoantibodies can be detected in 40–80 % of patients with clinical ITP (Liebman and Pullarkat 2011; McMillan 2009). Studying selected patients with chronic ITP, in about 60–70 % of cases, platelet-bound autoantibodies are directed against distinct epitopes on integrin $\alpha_{IIb}\beta_3$, while components of the (non-integrin) GPIb-IX-V complex are the antigenic target in approximately 5–20 % of cases (Liebman and Pullarkat 2011; McMillan 2009). In a subset of ITP patients, platelet-bound autoantibodies are directed concomitantly against $\alpha_{IIb}\beta_3$ and GPIb-IX-V or other platelet antigens. Less frequently, serum autoantibodies against platelets are also detected by either assay. More importantly, the absence of detectable antiplatelet autoantibodies (in about 20–30 % of patients) does not rule out the diagnosis of ITP. The reason for antibody-negative testing is unknown but may relate to heterogeneity of antigenic targets or methodological problems (Brighton et al. 1996).

Several patients have been described with autoantibodies directed against $\alpha_{IIb}\beta_3$ or GIb-IX-V, blocking the receptor-ligand interaction, thereby producing acquired Glanzmann thrombasthenia or acquired Bernard-Soulier syndrome (DiMinno et al. 1986; Niessner et al. 1986; Varon et al. 1992; Scharf 1996, 2003; Morath et al. 2005; Nurden and Nurden 2008). Inhibitory autoantibodies to GPIa and GPVI have also been found. Moreover, an ITP patient was identified, in whom binding of the anti-GPVI autoantibody resulted in the loss of GPVI from platelets (Boylan et al. 2004). Alloantibodies from Glanzmann thrombasthenia individuals with a history of frequent platelet transfusions can have the same thrombasthenia-like effect on transfused platelets (Coller et al. 1986).

Paraproteinemia and Amyloidosis

Qualitative platelet defects along with bleeding and symptomatic hyperviscosity are observed in approximately 30 % of patients with IgA myeloma or Waldenström macroglobulinemia (IgM), 15 % of patients with IgG myeloma, and occasionally in patients with monoclonal gammopathy of undetermined significance (Mehta and Singhal 2003). In the majority of cases with systemic amyloidosis, bleeding and platelet dysfunction appear to correlate closely with the plasma paraprotein concentration.

It has been suggested that some monoclonal immunoglobulins interact with the platelet surface and interfere nonspecifically with platelet adhesion or stimulus-response coupling. This contention has been supported by several observations summarized in Box 7.

Anecdotic cases of IgG myeloma have been described, where the paraprotein interacted with $\alpha_{IIb}\beta_3$ and blocked binding of fibrinogen, thus inducing a platelet defect of the Glanzmann thrombasthenia-like phenotype (DiMinno et al. 1986). In addition to platelet dysfunction and hyperviscosity syndrome, other causes of bleeding must be considered in myeloma patients, including thrombocytopenia, coagulation factor deficiencies by inhibitory paraproteins, impaired fibrin polymerization, and acquired von Willebrand syndrome (Bovill et al. 1986). Prolonged bleeding time and defective platelet adhesion due to interference of paraproteins with plasma VWF and the VWF-GPIb interaction have also been reported (Bovill et al. 1986; Mohri et al. 1987).

Similar hemostatic alterations are observed in amyloidosis (Sucker et al. 2006; Zangari et al. 2007). Prolongation of thrombin time, reptilase time, Russell viper venom time, prothrombin time, and activated partial thromboplastin time are found in most cases. Despite these frequent

abnormalities, major bleeding is present only in a minority of patients, who display associated hemostatic defects, including dysfunctional platelet aggregation, decreased coagulation factors (preferentially reduced factor X activity), abnormal fibrin polymerization, hyperfibrinolysis, and perivascular amyloid deposition (Sucker et al. 2006). Moreover, circulating paraproteins with associated amyloid and inhibitory effects on factor VIII and/or VWF have been reported (Zangari et al. 2007).

Acute Leukemias and Myelodysplastic Syndromes (MDS)

The most common cause of hemorrhages in these disorders is thrombocytopenia. In addition, acquired abnormalities of platelet function associated with clinical bleeding can be also present in acute myelogenous leukemia (AML) and, less frequently, in MDS. In the AML and MDS setting, qualitative and quantitative platelet changes result from abnormal megakaryo- and thrombocytopoiesis. Indicative of platelet dysfunction is a disproportionally prolonged bleeding time, or manifest bleeding, particularly from mucosal sites, at platelets counts >50,000/μL, which usually do not cause hemorrhages. Platelet abnormalities in AML and MDS include defective aggregation, storage pool deficiency, and reduced TXA_2 synthesis. Recently, it was reported in MDS patients that platelet aggregation defects result from dysfunctional $\alpha_{IIb}\beta_3$ and reduced expression of talin-1 (Fröbel et al. 2013).

Myeloproliferative Neoplasms (MNN)

Numerous structural, biochemical, and functional platelet changes have been described in patients with MPN (Table 2) (Schafer 1984, 2004; Wehmeier et al. 1989, 1990; Elliott and Tefferi 2004, 2005; Papadakis et al. 2010; Falanga and Marchetti 2014). Most likely, these heterogeneous alterations are the result of abnormal platelet populations derived from a malignant hematopoietic clone, but some of the abnormalities may be secondary due to enhanced platelet activation in vivo. The clinical impact of qualitative platelet defects observed in vitro is often unclear with widely divergent findings in different studies (Wehmeier et al. 1989, 1990, 1991a; Elliott and Tefferi 2005; Papadakis et al. 2010; Falanga and Marchetti 2014). Thus, platelet aggregation responses are highly variable and may vary in the same individual over time (Wehmeier et al. 1990). Likewise, platelet defects are demonstrable even in asymptomatic patients. Impaired responsiveness to epinephrine is a relatively frequent finding in MPN (>50 % of patients). The abnormality has been attributed to a decrease in the number of platelet α_2-adrenergic receptors (Schafer 1984).

Among the changes summarized in Table 2, functional defects of $\alpha_{IIb}\beta_3$ have been identified resembling Glanzmann variants. Thus, in flow cytometric studies, platelet aggregation abnormalities in MPN can be phenotypically characterized as (1) defects in $\alpha_{IIb}\beta_3$ activation, (2) defects in ligand binding, or (3) defects in postoccupancy events (Fig. 5). Other platelet alterations reported in MPN include abnormal arachidonic acid metabolism, defective signaling through the TXA_2 receptor, and impaired protein phosphorylation (Schafer 1984). Abnormalities in plasma VWF documented in patients with MPN are secondary and related to the degree of thrombocytosis, as discussed below.

Another unique feature of MPN is that thrombohemorrhagic events may occur concurrently, reflecting the complexity of pathomechanisms involved and also the difficulty of interpreting laboratory findings (Wehmeier et al. 1990; Schafer 2004; Elliott and Tefferi 2005; Papadakis et al. 2010).

Relevant Disease-Specific Somatic Mutations Significant advances in the molecular pathogenesis of MPN have improved our understanding of essential thrombocythemia (ET), primary myelofibrosis (PMF), and polycythemia vera (PV) and may explain some of the overlapping clinical features in these settings. The abnormalities identified include somatic mutations in the tyrosine kinase Janus 2 gene *(JAK2)* and the thrombopoietin receptor gene *(MPL)*. The *JAK2* mutation results from a valine-to-phenylalanine (V617F) exchange and represents a gain-of-function variant, inducing increased phosphorylation of JAK2 substrates and increased responsiveness of myeloid cells (James et al. 2005). Approximately 50–60 % of patients with ET or PMF carry the *JAK2* V617F mutation that is also present in 95 % of patients with PV (Baxter et al. 2005). Activating mutations of the *MPL* gene are identified in about 5–10 % of patients with ET and PMF, who display nonmutated *JAK2* (Rumi et al. 2013). Subsequently, recurrent mutations in the gene encoding calreticulin (*CALR*) were detected in patients with ET or PMF but nonmutated *JAK2* or *MPL* (Klampfl et al. 2013; Nangalia et al. 2013). These molecular markers can fill the diagnostic gap that had existed in about 30–45 % of patients with ET or PMF so far. Very recently, novel noncanonical mutations (i.e., not V617F in *JAK2*) were reported in the minority of ET and PMF patients *without* established mutations in *JAK2*, *MPL*, or *CALR* genes ("triple-negative" MPN) (Milosevic Feenstra et al. 2016; Cabagnols et al. 2016). Interestingly, the presence of *CALR* mutations in ET appears to be associated with a better prognosis and a lower risk of thrombosis than in patients with the *JAK2* V617F mutation (Klampfl et al. 2013; Rotunno et al. 2014).

JAK2 V617F Mutation and Increased Platelet Function Several studies have explored the impact of disease-specific mutations on platelet function in MPN. When comparing platelets from *JAK2* V617F-positive with

Table 2 Morphologic, metabolic, and functional abnormalities in myeloproliferative neoplasms (MPN). Data from Wehmeier et al. (1990), Scharf et al. (1993)

Abnormalities	Specific findings
Heterogeneity in platelet size	
Morphologic abnormalities	Reduction in α- and δ-granules Alterations in the open canalicular and dense tubular systems Reduction in number and size of mitochondria
Acquired storage pool deficiencies	Decreased content of δ-granule constituents (ADP, ATP, serotonin)
Aggregation abnormalities	Highly variable; enhanced responses to agonists or even spontaneous platelet aggregation in some patients; diminished aggregation responses upon stimulation by ADP (40%), collagen (35%), or epinephrine (50–60%)[a]
Secretion	Highly variable; elevated plasma concentrations of α-granular constituents such as platelet factor 4 and β-thromboglobulin ex vivo, indicative of platelet activation; decreased secretion of δ-granule content (ADP, ATP, serotonin) caused by platelet storage pool deficiency
Platelet plasma membrane abnormalities	
– Glycoprotein receptor defects	Decreased expression of $\alpha_{IIb}\beta_3$, GPIb-IX-V, or $\alpha_2\beta_1$, increased expression of GPIV; dysfunctional $\alpha_{IIb}\beta_3$ with defective binding of soluble fibrinogen[b]; activation defects or other ligand binding defects of $\alpha_{IIb}\beta_3$; dysfunctional $\alpha_2\beta_1$
– Agonist receptor defects	Decreased number of α_2-adrenergic receptors; reduced responsiveness to TXA_2
– Alterations of Fc receptors	Increased binding of IgG
– PGD_2 receptors	Decreased number of PGD_2 binding sites
– Defective release of arachidonic acid	Reduced conversion of arachidonic acid to prostaglandin endoperoxides (TXA_2) or 12-lipoxygenase products (see metabolic abnormalities)
Metabolic abnormalities	
– Arachidonic acid metabolism	Enhanced synthesis of metabolites of the cyclooxygenase pathway (e.g., TXA_2); defective 12-lipoxygenase pathway with decreased formation of 12-hydroperoxyeicosatetraenoic acid (12-HPETE) and 12-hydroxyeicosatetraenoic acid (12-HETE)
– cAMP and cGMP metabolism	Deficiency in cyclic adenylate cyclase and cyclic guanosine monophosphate (cGMP)-dependent protein kinase
Defective signaling	Abnormalities in calcium mobilization; reduced Ca^{2+} fluxes across platelet membranes; impaired protein phosphorylation (see cGMP metabolism)

[a]Rates in brackets indicate percentage of patients with defective aggregation responses (Schafer 1984)
[b]Enhanced binding of thrombospondin to the platelet surface of MPN patients has been observed in some but not in other studies (Wehmeier et al. 1991b)

JAK2 V617F-negative patients, an association between the *JAK2* V617F allele burden and increased platelet-mediated thrombin generation was documented (Panova-Noeva et al. 2011a). Other phenotypic features, as reported by Panova-Noeva et al. (2011b), are summarized in Box 8. Hobbs et al. (2013) studied a conditional *JAK2* V617F knock-in mouse model of ET, in which all megakaryocytes and platelets express *JAK2* V617F at a level, equivalent to that present in human ET patients. In this murine model, *JAK2* V617F-positive megakaryocytes displayed increased differentiation, higher proplatelet formation, and greater migratory ability. Concomitantly, platelet reactivity to different agonists was enhanced, as shown by a variety of assays (platelet aggregation and thrombus formation at arterial shear rates, spreading on fibrinogen, outside-in signaling, and platelet surface expression of activation markers). The increased platelet responses in vitro translated into increased hemostasis in vivo with markedly reduced duration of bleeding independently of the elevated platelet counts (Hobbs et al. 2013). These findings further suggest that *JAK2* V617F can induce intrinsic changes in both megakaryocyte and platelet biology beyond the effect on an increase in cell number.

Antiplatelet Therapy in MPN Aspirin is being widely administered for primary prophylaxis of vascular events in patients with ET and PV. However, the use of low-dose aspirin remains controversial in ET (Alberio 2016; Scharf 2016b). Several investigators recommend aspirin for *all* ET patients unless contraindicated (e.g., platelet count $>$ 1 mio/μL) (Beer et al. 2011; Cervantes 2011). Others restrict aspirin to high-risk patients (age $>$ 60 years, cardiovascular risk factors, previous thrombosis, *JAK2* V617F mutation), as assessed by risk scores (e.g., IPSET-thrombosis) (Barbui et al. 2012a; Passamonti et al. 2012), or to those with symptomatic microcirculatory disturbances (Schafer 2004; Harrison and Garcia 2014). Indeed, due to effective inhibition of enhanced platelet TXA_2 production, low-dose aspirin remains the treatment of choice in ET patients with erythromelalgia or transient neurological deficits.

While a significant benefit of low-dose aspirin has been convincingly documented for PV in the ECLAP study (Landolfi et al. 2004), no such prospective, double-blinded, placebo-controlled, randomized trial on aspirin exists in ET. Thus, the rationale for using aspirin in ET is not evidence-based but rather guided by analogies. Currently

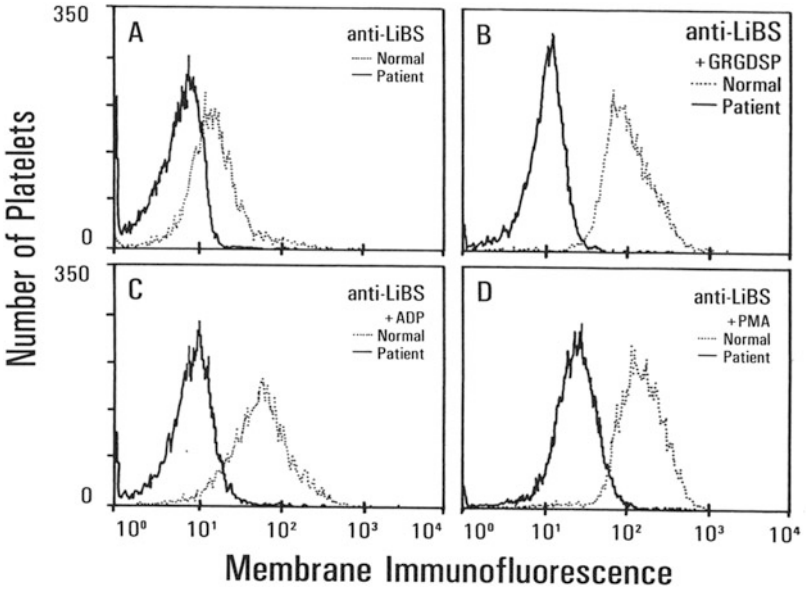

Fig. 5 Phenotypic characterization of dysfunctional integrin $\alpha_{IIb}\beta_3$ in myeloproliferative neoplasms associated with platelet aggregation defects. Depicted are flow cytometric histograms obtained from a patient with essential thrombocythemia (*solid line*) as compared with a normal subject (*dashed line*). Citrated whole blood was incubated with anti-LIBS-1, a conformation-specific monoclonal antibody that can distinguish between the resting, activated, and ligand-occupied state of $\alpha_{IIb}\beta_3$ in the absence (panel **a**) or presence (panels **b** through **d**) of other agents such as GRGDSP, adenosine diphosphate (ADP), or phorbol myristate acetate (PMA), an intracellular signal mimetic, which circumvents normal agonist receptor-mediated pathways by directly activating protein C kinase. Anti-LIBS-1 selectively reacts with a ligand-induced binding site on β3. This epitope is expressed upon receptor occupancy by fibrinogen (a process that requires platelet activation) or by fibrinogen-mimetic RGD-containing peptides (which bind to $\alpha_{IIb}\beta_3$ in an activation-*independent* manner). Immunolabeling of platelets with fluoresceinated anti-LIBS-1 in the presence of GRGDSP (panel **b**) or upon stimulation with ADP (panel **c**) resulted only in a minor increase of specific membrane immunofluorescence in the patient's platelets. Upon platelet activation with PMA (panel **d**), binding of anti-LIBS-1 increased but still differed significantly from that in a normal volunteer. These findings are indicative of a combined defect in activation and ligand binding of $\alpha_{IIb}\beta_3$ in the patient. The conclusion is supported by results obtained with PAC-1, a monoclonal antibody that specifically recognizes activated $\alpha_{IIb}\beta_3$ (data not shown). This diagnostic approach permits classification of platelet aggregation abnormalities as *(i)* defects of agonist-induced *activation* (no PAC-1 binding upon platelet stimulation by physiological agonists), *(ii)* defects of *ligand binding* (no LIBS expression and, consequently, no anti-LIBS-1 binding in the presence of fibrinogen-mimetic peptides), and *(iii)* defects of *postoccupancy processes*. The dysfunctional postoccupancy phenotype is characterized by defective platelet aggregation despite intact binding of PAC-1 and anti-LIBS-1 in response to platelet stimulation. Adapted from Scharf et al. (1993) and reprinted with permission of the publisher

available data in ET are limited and controversial. For example, in "low-risk" ET, an observational *case-control* study showed no difference in the incidence of thrombosis between untreated patients and healthy volunteers (Ruggeri et al. 1998), while a retrospective analysis suggested variable benefits for antiplatelet treatment (Alvarez-Larrán et al. 2010). Moreover, some studies included aspirin for all "high-risk" ET patients (Harrison et al. 2005), whereas other more recent studies did not (Gisslinger et al. 2013). These basic differences reflect a "dichotomy of opinion" in the field (Harrison and Garcia 2014). Essential concerns related to the use of antiplatelet agents in ET include drug-induced bleeding, specifically in ET patients with very high platelet counts, and "overtreatment" in patients whose disease is otherwise well controlled.

Another facet of thromboprophylaxis with aspirin is that its pharmacological inhibition of platelet COX-1 can be ineffective, in particular in high-risk ET patients, when low-dose aspirin (100 mg) is administered once daily. In fact, incomplete or absent suppression of TXA_2 production despite administration of aspirin results from accelerated renewal of platelet COX-1 due to enhanced clonal thrombocytopoiesis in ET (Pascale et al. 2012). Aspirin-insensitive TXA_2 biosynthesis can be reverted by modulating the aspirin-dosing interval (i.e., 100 mg twice daily) (Pascale et al. 2012).

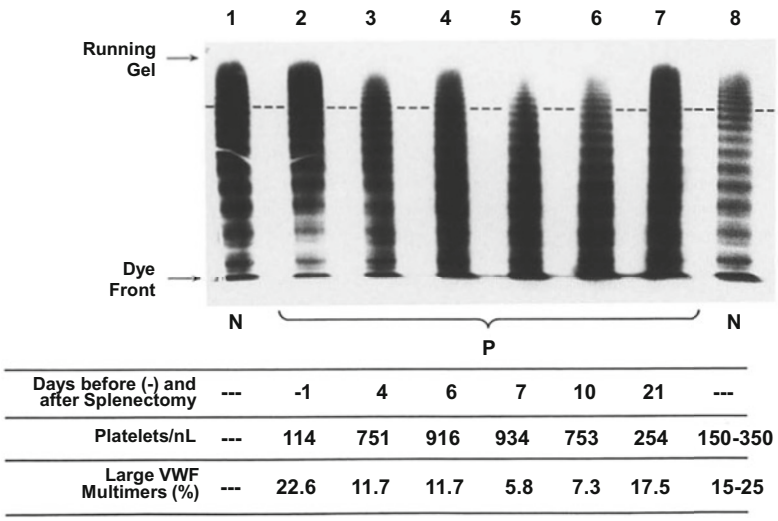
Altogether, the significance of antiplatelet treatment in ET using low-dose aspirin remains to be proven. Although aspirin appears to have more antithrombotic benefit than prohemorrhagic risk in this setting, drug-induced major bleeding remains a serious concern. Concomitantly, hemorrhagic complications in ET have been presumed to be due to acquired abnormalities in VWF. However, the proof of this association has not been demonstrated (Harrison and Garcia 2014). By contrast, it is evident that the abnormalities in VWF correlate with the degree of thrombocytosis, as discussed below.

Acquired Von Willebrand Syndrome (aVWS)

Bleeding events of the platelet-like phenotype can be caused by aVWS in a variety of conditions. A relevant pathomechanism of aVWS is increased proteolysis of intact VWF, which normally circulates as very large, homologous multimers composed of 250 kDa subunits (Sadler 2003). Upon exposure of VWF to high-fluid shear stress, present in valvular heart disease such as aortic-valve stenosis (Vincentelli et al. 2003; Sadler 2003; Sucker et al. 2003) and mitral regurgitation (Blackshear et al. 2014), or in cardiovascular assist devices (Steinlechner et al. 2009; Meyer et al. 2010; Baghai et al. 2015), circulating VWF multimers become most susceptible to cleavage by ADAMTS13, a plasma metalloproteinase that can be induced by high-shear conditions (Sadler 2003). Ultimately, its action leads to a deficit in large VWF multimers, which are particularly effective in hemostasis. Thus, shear stress-induced aVWS phenotypically resembles that of inherited mutations in VWF, which also increase its susceptibility to ADAMTS13 and cause von congenital Willebrand disease (VWD) type 2A. In both settings, a discrepancy between VWF: activity (ristocetin cofactor, RCo) and VWF: antigen (Ag) with discordantly lowered RCo can be present, resulting in an abnormally reduced VWF ratio (VWF: RCo: VWF: Ag, <0.7), indicative of a deficiency (or defect) in high-molecular-weight VWF species. However, this laboratory finding is only suggestive for VWD or aVWS and requires confirmation by multimeric analysis (Fig. 6).

The pathogenesis of aVWS can also result from decreased synthesis of VWF, as documented in association with hypothyroidism (Michiels et al. 2001), or from increased immune clearance of plasma VWF, as occasionally reported in patients with autoimmune, neoplastic, or lymphoproliferative disorders (Tefferi and Nichols 1997; Michiels et al. 2001). Various mechanisms may be involved, including inhibitory antibodies to VWF, formation of immune complexes between VWF and specific antibodies, and absorption of plasma VWF onto tumor cells (e.g., nephroblastoma), or abnormal lymphoid cells (e.g., in non-Hodgkin's lymphomas) (Michiels et al. 2001; van Genderen et al. 1994).

Myeloproliferative neoplasms, specifically ET at platelet counts exceeding 1 mln/μL, are rather frequently associated with aVWS. Affected patients have a decreased VWF: activity (RCo)/VWF: antigen ratio due to a decrease or absence of the largest plasma VWF multimers (Budde et al. 1984, 1986, 1993). A similar phenomenon is observed in patients with reactive thrombocytosis at excessive platelet counts, e.g., after splenectomy (Fig. 6). In clonal and reactive thrombocytosis, the underlying mechanisms appear to be the same: high-molecular-weight plasma VWF multimers are transiently bound to the increased mass of circulating platelets and preferentially degraded by ADAMTS13 (Shim



Days before (-) and after Splenectomy	---	-1	4	6	7	10	21	---
Platelets/nL	---	114	751	916	934	753	254	150-350
Large VWF Multimers (%)	---	22.6	11.7	11.7	5.8	7.3	17.5	15-25

Fig. 6 Multimeric structure of plasma VWF in a patient undergoing splenectomy because of chronic ITP. Blood samples were obtained before (lane 2) and after splenectomy (lanes 3 through 7), as indicated. VWF was identified with an anti-VWF antibody followed by immunoperoxidase staining. VWF multimers were detected by luminography and analyzed; their relative concentration was determined densitometrically. The high-molecular-weight VWF multimers are displayed at the top of the gel. The dotted line indicates the position of the tenth band resolved as an individual species; lager multimers were arbitrarily defined as those above the tenth band. N denotes normal control plasma (lanes 1 and 8). Note the normal distribution of multimers at a platelet count of 114,000/μL prior to splenectomy (lane 2); the progressive disappearance of the larger ones, as platelet counts increased following splenectomy (lanes 3 through 6); and the restoration of multimeric distribution upon normalization of the platelet count (lane 7). Taken from Budde et al. (1993) and reprinted with permission of The American Society of Hematology

et al. 2008). Thus, in both conditions, aVWS may explain the apparent paradox, why thrombocytosis can be associated with bleeding. Drug-induced aVWS has been described upon intake of pesticides or the use of valproic acid, certain antibiotics (ciprofloxacin, tetracycline) and mycotoxins (e.g., griseofulvin), thrombolytic agents, and hydroxyethyl starch (Michiels et al. 2001).

Conclusions and Future Directions

Acquired platelet disorders can be caused by a variety of clinical conditions and induce *increased* or *defective* platelet function. Precise identification of either phenotype, diagnosis of the underlying disease and knowledge of pathomechanism(s) resulting in abnormal platelet function, and appropriate translation into decision-making remain crucial in clinical practice (Box 9).

Acute vascular insults in arterial disease require primary intervention and secondary prophylaxis with antithrombotic, specifically antiplatelet agents. However, the expanding use of such agents has resulted in an increased proportion of the population being at risk for abnormal bleeding due to drug-induced platelet inhibition. This is especially true for elderly, comorbid patients. Hence, drugs represent the most common cause of platelet dysfunction in our overmedicated society. This also applies to a variety of pharmacological compounds, which by no means are aimed at interfering with platelet function (e.g., SSRIs for treatment of depression).

Regarding prevention and treatment of thromboembolic complications in patients with arterial disease, using antiplatelet agents (with or without combination of anticoagulants), we are currently facing two unresolved problems: firstly, the more intense antithrombotic therapy is, the more frequently major bleeding occurs; secondly, the agents used should be anti*thrombotic* but not anti*hemostatic*. In other words, we need effective drugs capable of preventing thrombus formation but not at the price of a concomitant risk of increased bleeding. This demand requires highly selective pharmacological strategies. Several innovative concepts have been designed and examined in animal models. For example, extensive efforts are being made to develop antiplatelet compounds that specifically block thrombotic effects without compromising primary hemostasis (Scharf 2016a). However, it remains to be seen whether these strategies can be really translated from mice to men. Thus, the novel agents under study warrant testing in preclinical and clinical trials.

Over the last decade, significant progress has been made to explore the nature of acquired hemostatic dysfunction in certain diseases. This applies primarily to hematologic disorders that can lead to *increased* or *decreased* platelet function and, along with these converse phenotypes, be associated with thrombotic or hemorrhagic complications. For example, characterization of malignant clones in MPN, specifically genotyping for mutations in genes encoding *JAK2*, *MPL*, and *CALR* in ET, PMF, or PV, is now being used in clinical risk scores to improve patient stratification and decision-making for or against antiplatelet treatment (Passamonti et al. 2012; Barbui et al. 2012a, b; Scharf 2016b). Moreover, recent insights into the kinetics of clonal thrombocytopoiesis in ET with enhanced platelet production that can circumvent COX-1 inhibition by low-dose aspirin, when administered once daily, have elucidated the phenomenon of incomplete or absent inhibition of platelet TXA_2 production (Pascale et al. 2012). Thus, it has been documented convincingly that the aspirin insensitivity in ET is due to accelerated renewal of platelet COX-1, the drug target, and that impaired platelet inhibition can be rescued by modulating the aspirin-dosing interval (i.e., 100 mg twice daily) rather than the dose (Pascale et al. 2012).

Hemostatic function and dysfunction in acute and chronic liver disease is another example for the significant progress that has been made in recent years. According to traditional paradigms, liver cirrhosis was considered as the epitome of an acquired coagulopathy that in combination with thrombocytopenia and/or thrombopathy causes hemorrhagic complications. Based on recent findings, this contention has been revised fundamentally in several aspects. Firstly, patients with liver failure are also prone to thrombotic events, which may be even more common than bleeding complications, except for end-stage liver disease. Secondly, the commensurate decrease in pro- and antihemostatic components can lead to a *rebalanced low-level* hemostatic equilibrium. The rebalanced hemostatic system is, however, labile and can be destabilized by various triggers, which in turn may explain the occurrence of both bleeding and thrombotic complications. Thirdly, thrombocytopenia in liver cirrhosis results from multifaceted causes; apart from lienal pooling, decreased production of TPO plays a major role, as shown by the correlation between TPO levels and residual hepatic function. Fourthly, defective platelet function as a concomitant cause of bleeding events in hepatic failure has been overestimated in the past. Fifthly, high levels of plasma VWF can restore platelet-vessel wall interaction and thus rebalance primary hemostasis that may be compromised otherwise in chronic hepatic disease. Sixthly, rebalanced hemostasis and, all the more, hypercoagulable features in liver disease have a major impact on the prevention and management of both bleeding and thrombosis. Thus, by contrast to common practice, a restrictive transfusion regimen is required in patients with liver disease to avoid prohemostatic hemotherapy and treatment-induced thrombotic complications. However, limitations of the progress made in this setting have also become evident in the meantime. For example, as a clinical consequence, eltrombopag, a TPO receptor agonists, was used in patients with cirrhosis and thrombocytopenia in order to increase platelet counts prior to elective invasive

procedures. Indeed, eltrombopag reduced the need for platelet transfusions but was associated with an increased incidence of thrombotic events (Afdhal et al. 2012). Consequently, early termination of the trial was mandatory.

Take-Home Messages

Box 1: Drugs represent the most common cause of acquired platelet dysfunction

Box 2: Platelet Receptor Polymorphisms

- Genetically determined integrin variants can modulate receptor expression and platelet function.
- Distinct integrin variants such as HPA-1b (Pro33) of $\alpha_{IIb}\beta_3$ and $\alpha_2$807TT of $\alpha_2\beta_1$ are associated with *premature* manifestation of myocardial infarction in patients with coronary artery disease.
- HPA-1b (Pro33) of $\alpha_{IIb}\beta_3$ is not a pro-atherogenic risk factor but a prothrombotic risk determinant that requires the presence of an atherosclerotic lesion to become effective, leading to increased platelet thrombogenicity.
- Indeed, HPA-1b (Pro33) of $\alpha_{IIb}\beta_3$ and $\alpha_2$807TT of $\alpha_2\beta_1$ have a prothrombotic phenotype in vitro.

Box 3: Frequency of Acquired Platelet Disorders and Screening for Defects in Primary Hemostasis

- Acquired platelet function defects are more frequent in clinical practice than generally believed.
- In the majority of cases, platelet dysfunction is drug-induced.
- Despite the broad use of antiplatelet agents, inhibitory effects of antibiotics should not be underestimated.
- Screening for defects in primary hemostasis requires appropriate laboratory techniques (e.g., PFA testing).
- Albeit trivial, the widespread practice of platelet counting and coagulation screening (APTT, prothrombin time) is inappropriate to identify individuals with platelet dysfunction.
- Pure coagulation defects occur less frequently than generally assumed in clinical practice.

Box 4: Drug-Induced and Disease-Associated Platelet Function Defects

- Acquired platelet dysfunction secondary to drugs is usually mild. By contrast:
- Treatment with antiplatelet drugs can aggravate hemorrhage in patients with preexisting hemostatic defects.
- Certain settings, conditions, and systemic or hematologic disorders may affect platelet function and cause bleeding:
  - Sepsis and disseminated intravascular coagulation.
  - Cardiopulmonary bypass surgery.
  - Liver cirrhosis and liver transplantation.
  - Renal failure and hemodialysis.
  - Myeloproliferative neoplasms, acute leukemias, myelodysplastic syndromes, and myeloma.

Box 5: Screening for Platelet Dysfunction in Renal Disease

- Prolongation of the bleeding time (BT) is a frequent finding in uremic patients.
- But BT is not a valid parameter in predicting the individual hemorrhagic risk in end-stage renal disease.

Box 6: Hemostatic Disorders in Liver Disease

- Coagulation defects (INR >1.5) in liver disease are not equivalent to pharmacological anticoagulation. By contrast:
- Patients with hepatic failure can display hypercoagulable features and are also prone to thrombotic events.

Box 7: Platelet Function Defects in Paraproteinemia and Amyloidosis

- Platelet dysfunction is more common at high paraprotein concentrations.
- Platelet aggregation, secretion, clot retraction, and platelet procoagulant activity may all be affected.
- Normal platelets acquire these defects upon incubation with patient plasma or purified paraprotein.

(continued)

Box 8: JAK2 V617F Mutation and Increased Platelet Function in MPN (Panova-Noeva et al. 2011a, b)

- Increase in platelet-mediated thrombin generation.
- Increase in immature platelets (which are hemostatically more active than mature platelets) in ET and PV.
- Linkage between amount of immature platelets and *JAK2* V617F mutation.
- Immature platelets in MPN are more susceptible to myelosuppressive treatment with hydroxyurea.

Box 9: Identification of Individual Patients with Preexisting Hemostatic Defects Remains Crucial

- To prevent otherwise unexpected bleeding complications
- To manage hemorrhagic symptoms adequately
- To minimize the risk from invasive procedures
- To avoid unnecessary exposure to blood products (including recombinant coagulation factor concentrates with adverse prothrombotic side effects)

Disclosures The author states that he has no conflict of interest.

Acknowledgment The author's work was supported by grants from the Deutsche Forschungsgemeinschaft (Scha 358/3-1 and Sonderforschungsbereich 612, Project B2). Additional support was provided by the Society of Thrombosis and Haemostasis Research, the Biological Medical Research Center, Heinrich Heine University, Düsseldorf, Germany, and the NRW Research School BioStruct "Biological Structures in Molecular Medicine and Biotechnology."

Pathology: Thrombotic Disorders

Platelets in Arterial Thrombosis

Christian Schulz and Steffen Massberg

Abstract

Platelets play a key role in arterial thrombosis, a frequent and life-threatening condition. Upon vascular injury, platelets are rapidly recruited to the site of endothelial disruption, where they become activated and critically contribute to the formation of an occlusive clot. To treat or prevent arterial thrombosis, various antiplatelet therapies have been developed. However, many pathways targeted are also involved in hemostasis. Their inhibition therefore poses an increased risk of bleeding. To date it remains an eminent task to identify thrombosis-specific pathways in arterial thrombosis. Platelet receptors and intracellular molecules, whose absence does not cause overt bleeding in humans, may open up new therapeutic avenues. We here recapitulate the pathophysiology of arterial thrombosis and present newly identified pathways, which may serve as drug targets in the future. Finally, we will discuss the reciprocal interactions of platelets and innate immune cells and their potential role in arterial thrombosis. A detailed understanding of the mechanisms underlying this life-threatening condition is crucial for future research and the development of novel therapies.

Introduction

Arterial thrombosis is a major cause of mortality and morbidity worldwide. According to the recent Global Burden of Diseases Study 2013, ischemic heart diseases accounted for 7.0 million deaths worldwide (Collaborators 2015). Thus, there is an unmet clinical need to further improve patient treatment. While this requires a multimodal approach, antiplatelet therapies represent an important cornerstone of current treatment regimes. However, standard antithrombotic drugs that efficiently target thrombosis also affect hemostasis, which may offset the treatment benefit at the expense of bleeding. A deeper understanding of the processes underlying arterial thrombosis is therefore warranted to identify novel targets in thrombosis-specific pathways.

Platelet Tethering and Firm Adhesion

The primary trigger for arterial thrombosis is the rupture of an atherosclerotic plaque. Under physiological conditions, platelets circulate in the bloodstream without significant binding to the vascular endothelium. Adhesion is prevented by endothelial nucleotide-hydrolyzing enzymes and mediators such as nitric oxide (NO) and prostaglandins, which reduce platelet activation and allow for an unperturbed blood flow (Marcus et al. 1997; Persson et al. 1990). Injury of the vessel wall exposes the thrombogenic subendothelial matrix (ECM) and initiates rapid platelet recruitment. The von Willebrand factor (vWF) receptor GPIb-V-IX axis plays a pivotal role in establishing platelet tethering to the vessel wall at arterial shear rates (Sakariassen et al. 1979; Savage et al. 1996) (Fig. 1). vWF derives mainly from the

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_65

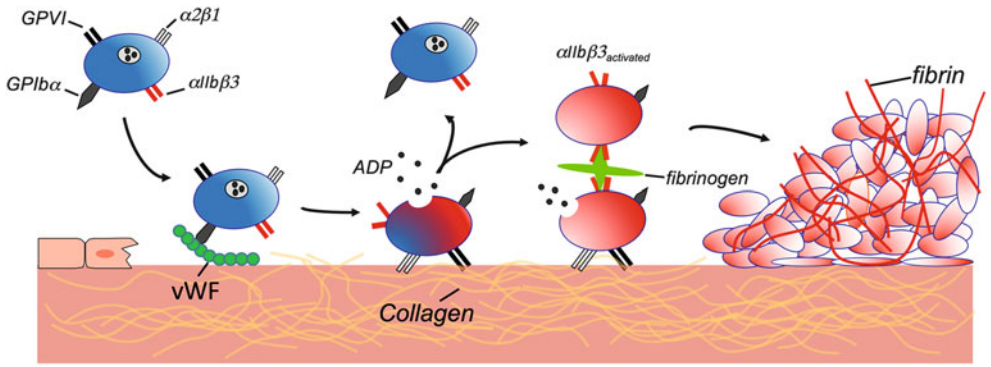

Fig. 1 Platelet adhesion in arterial thrombosis. The simplified schematic illustrates the principal steps of platelet recruitment and activation at the site of vascular injury. Initial tethering is mediated by GPIba interactions with surface-bound vWF resulting in slow surface translocation. The collagen receptors GPVI and integrin $\alpha_2\beta_1$ then mediate firm adhesion to fibrillar collagen exposed within the subendothelial matrix. Platelet activation leads to release of secondary mediators (e.g., ADP, TxA2) and $\alpha_{IIb}\beta_3$ activation, which culminates in platelet aggregation and clot formation (modified from Schulz and Massberg, Handb Exp Pharmacol 2012)

endothelium and is released upon injury toward both the luminal side and the subendothelial matrix. It is also synthesized by megakaryocytes and contained in platelets, which represent approximately 15 % of the circulating protein in blood (Howard et al. 1974). vWF immobilizes via its A3 domain to collagen fibrils (type I, III, and VI) within the ECM. Once exposed to high shear rates, conformational changes of vWF multimers allow the binding of its A1 domain to multiple platelet GPIbα receptors (Celikel et al. 2000). Platelet tethering via GPIbα-vWF interactions is characterized by rapid on-rates underscoring its importance at high shear rates which prevail in stenosed arteries. At very high shear stress, probably exceeding 400 dyn/cm^2, thrombus development is mediated solely by the interaction of GPIb with vWF and becomes independent of platelet activation (Ruggeri et al. 2006). Genetic ablation or antibody blockade of GPIbα abrogates arterial thrombosis (Bergmeier et al. 2006). However, the GPIb-V-IX receptor is also important for hemostasis. Consequently, patients with Bernard-Soulier syndrome as well as GPIbα-deficient mice develop a strong bleeding diathesis (Caen et al. 1976; Ware et al. 2000). Thus, complete ablation of GPIbα function does not represent a reasonable approach to treat or prevent arterial thrombosis. An alternative therapeutic strategy, which is currently under clinical investigation, is provided by specific inhibition of the GPIb-binding site on vWF (A1 domain). Because interactions of GPIbα and vWF become increasingly important at high shear stress, such approach may provide a more selective (shear-dependent) inhibition of platelet adhesion (Ulrichts et al. 2011). This concept is underscored by experimental models of thrombotic occlusion, in which increasing shear stress drives platelet binding to vWF-A1. This is specifically the case in boundary areas of newly formed thrombi that have not yet stabilized. In this setting, pharmacological blockade of GPIbα-vWF interactions has even been shown to disaggregate adherent platelets and restore patency of newly obstructed arteries (Le Behot et al. 2014; Momi et al. 2013). In contrast, stabilized fibrin-rich layers, which constitute inner parts of the thrombus, remain unchanged upon vWF-A1 antibody application. Thus, antithrombotic strategies targeting platelet-vessel wall interactions that occur predominantly at elevated shear rates might be promising to reduce platelet adhesion at specific pathologic conditions while having less impact on hemostatic plug formation.

While GPIbα is absolutely required for platelet adhesion at high shear rates, thrombus formation is reduced but not absent in vWF-null mice (Bergmeier et al. 2006). Thus, additional ligands exist which contribute to GPIbα-dependent platelet adhesion. Platelet-released thrombospondin-1 (TSP1) has recently been identified as an alternative adhesive ligand for GPIbα. It contributes to platelet adhesion at arterial shear stress (Jurk et al. 2003; Prakash et al. 2015) but also protects vWF from degradation by the cleaving protease ADAMTS13 and thereby fosters thrombus formation (Bonnefoy et al. 2006). While GPIbα is of paramount importance for initial binding to the injured vessel wall, the rapid off-rates of these bonds do not allow stable adhesion in the absence of other ligand-receptor interactions (Savage et al. 1998). Thus, GPIbα binding only reduces the velocity of tethered platelets thereby enabling interactions required for irreversible adhesion (Savage et al. 1996). Firm adhesive bonds are then formed by other platelet receptors, namely, integrins, which have relatively slow on-rates.

Integrins are heterodimeric proteins that consist of α- and β-subunits. Platelets express the β3-integrins $\alpha_{IIb}\beta_3$ (fibrinogen receptor) and αvβ3 (vitronectin receptor) and the β1-integrins $\alpha_2\beta_1$ (collagen receptor), α5β1 (fibronectin receptor) and α6β1 (laminin receptor). In nonactivated platelets, integrins are surface expressed in a resting conformation, which is shifted to a state of high affinity following

activation (inside-out signaling). For example, clustering of GPIbα during the initial adhesion step and consequent slow surface translocation represents an important activator of platelet integrins (Kasirer-Friede et al. 2002). Further, platelet-released factors, most prominently adenosine diphosphate (ADP) and thromboxane A2 (TxA2), induce and amplify platelet activation (Fig. 1). Likewise, ligation of platelet collagen receptors increases integrin affinity through inside-out signaling. This is noteworthy, because collagen represents the strongest activator of platelet integrins within the subendothelial matrix. Once activated, $\alpha_{IIb}\beta_3$ integrin binds to soluble fibrinogen resulting in firm platelet adhesion and aggregation (Shattil and Newman 2004). Exposure of the subendothelial matrix also allows binding of $\alpha_{IIb}\beta_3$ to collagen utilizing vWF as bridging molecule. Ligand binding to $\alpha_{IIb}\beta_3$ in turn triggers outside-in signaling, which activates various signaling complexes and maximizes platelet activation. Not surprisingly, genetic absence of the integrin domains α_{IIb} or β_3, the latter causing defects of both $\alpha_{IIb}\beta_3$ and αVβ3 integrins, abrogates arterial thrombosis in mice (Massberg et al. 2005; Smyth et al. 2001). Thus, $\alpha_{IIb}\beta_3$ inhibition is highly effective in arterial thrombosis and therapeutic antibodies for usage in human patients have consequently been developed (Gold et al. 1997). However, genetic absence of $\alpha_{IIb}\beta_3$ in humans causes Glanzmann thrombasthenia, which is characterized by significant bleeding diathesis, indicating that chronic inhibition of this integrin cannot represent an adequate strategy for continuous treatment or prevention of arterial thrombosis (Glanzmann 1951). And in the era of new $P2Y_{12}$ antagonists, even short-term inhibition of $\alpha_{IIb}\beta_3$ during coronary intervention is nowadays mostly restricted to usage as a bail-out strategy (Kastrati et al. 2004; Roffi et al. 2016). Specific targeting of activated platelets using conformation-specific antibodies could represent an alternative strategy to lower the bleeding risk of $\alpha_{IIb}\beta_3$ blockade (Schwarz et al. 2006). Novel approaches have focused on $\alpha_{IIb}\beta_3$-associated intracellular signaling pathways. Integrin-induced outside-in signaling depends on the G-protein-coupled receptor Gα13, which binds to its cytoplasmatic domain. Crosstalk of $\alpha_{IIb}\beta_3$ and Gα13 then promotes platelet spreading and clot retraction (Gong et al. 2010). These findings are in line with earlier observations that presence of Gα13 is critical for platelet thrombus formation and deficiency in Gα13 protects against arterial thrombosis in mice (Moers et al. 2003). However, primary hemostasis is also severely affected in these animals. In order to reduce negative effects caused by absence of Gα13, distinct signaling pathways have been addressed. Importantly, selective inhibition of the ExE binding motif of Gα13 blocks interactions with integrin β3 and selectively reduces outside-in signaling and platelet spreading, which is sufficient to abrogate arterial thrombosis. Because integrin ligation is not affected by the antibody, primary hemostasis is not altered (Shen et al. 2013). Thus, targeting of specific integrin-related pathways yields interesting therapeutic options in arterial thrombosis without causing a bleeding diathesis (Table 1).

In contrast to β3 integrins, platelet β1 can bind directly to collagen and other matrix molecules within the ECM. β1 integrins, however, seem dispensable for hemostasis. Even low levels (≥3 %) allow triggering of platelet signals required for normal hemostasis and bleeding time is not prolonged in β1 hypomorphic mice (Petzold et al. 2013). Nevertheless, near absence of β1 integrins significantly reduces arterial thrombosis in mice and therefore represents a potential therapeutic target for the treatment of arterial thrombosis without increasing the risk of bleeding (Petzold et al. 2013). A systematic comparison of platelet adhesive proteins recently indicated an important role of α6β1 in arterial thrombosis (de Witt et al. 2014). These findings have been corroborated in mice deficient in α6β1 integrin. Platelets from these animals are unable to adhere to the laminin isoforms composing blood vessels and consequently arterial thrombosis is markedly reduced (Schaff et al. 2013). Most importantly, hemostasis remains unaltered in this model, which suggests α6β1 as a suitable target for the treatment of arterial thrombosis (Table 1).

Platelet-Collagen Interactions

GPVI is the most prominent collagen receptor and plays a pivotal role in arterial thrombosis (Massberg et al. 2003; Nieswandt et al. 2001b). It represents a type I transmembrane glycoprotein and belongs to the immunoglobulin superfamily (Jandrot-Perrus et al. 2000). GPVI acts in concert with GPIbα to mediate platelet tethering at the site of vascular injury (Fig. 1); however firm adhesion can be achieved by direct binding of GPVI to the subendothelial collagen matrix (Nieswandt et al. 2001b). Not surprisingly, GPVI plays a pivotal role in arterial thrombosis following rupture of atherosclerotic plaque (Jamasbi et al. 2015). In line with the experimental observations in rodents described above, studies in human patients indicate that polymorphic variation at the GPVI locus is associated with an increased risk of myocardial infarction (Croft et al. 2001). Thus, GPVI could represent a potential target in arterial thrombosis.

Fibrillar collagen is the most prominent ligand of GPVI. Interestingly, various non-collagenous ligands have recently been identified suggesting that the role of GPVI in arterial thrombosis is not limited to its interactions with collagen. They include adiponectin (Riba et al. 2008), fibronectin (Bultmann et al. 2010; Maurer et al. 2015), and laminins (Inoue et al. 2006; Schaff et al. 2013), which can mediate platelet adhesion and activation via GPVI. Surprisingly, GPVI also binds to fibrin. This interaction amplifies platelet

PDI	PF4-dependent gene deletion	Laser injury of cremaster arterioles	Reduced thrombosis, normal hemostasis	Kim et al. (2013)

activation and procoagulant activity fostering thrombin formation and promoting platelet recruitment into the thrombus. In mouse arterial thrombosis models, GPVI-dependent binding to fibrin enhances thrombus growth and stabilization (Alshehri et al. 2015; Mammadova-Bach et al. 2015). Further, GPVI-activated platelets provide procoagulant activity by various means. For example, GPVI ligation induces phosphatidylserine exposure, which provides a platform for the binding of coagulation factors and thereby promotes thrombin and factor Xa formation (Munnix et al. 2005; van der Meijden et al. 2009). Further, GPVI-stimulated platelets release thiol isomerases, which directly activate $\alpha_{IIb}\beta_3$ integrin to foster platelet recruitment but also increase the activity of tissue factor, an important initiator of blood coagulation (Schulz et al. 2010; Wang et al. 2013). Because it has been unclear until recently how absence of GPVI not only protects from arterial thrombosis but directly reduces thrombus growth and stability (Bender et al. 2011), these findings close an important knowledge gap and link the function of GPVI in platelet activation and adhesion with a role in blood coagulation.

Importantly, absence of GPVI in humans and mice confers only a mild bleeding phenotype (Moroi et al. 1989; Nieswandt et al. 2000), supporting the suitability of GPVI as a therapeutic target in arterial thrombosis (Table 1). In addition to antibody blockade, GPVI function can also be inhibited by application of a soluble GPVI-FC dimer. In animal models of arterial thrombosis, GPVI-FC reduces thrombus formation and organ ischemia (Goebel et al. 2013; Massberg et al. 2004). The agent is currently undergoing clinical evaluation (ClinicalTrials.gov Identifier: NCT01645306) (Ungerer et al. 2011). Interestingly, chronic inhibition of GPVI not only inhibits platelet adhesion and protects from arterial thrombosis but also reduces atherosclerotic lesion formation in mice (Schulz et al. 2008). This is most likely due to inhibition of platelet activation and adhesion to collagenous structures within microerosions, which are eventually exposed at the atherosclerotic arterial wall. Further, collagen-GPVI interactions may induce platelet secretion (Ollivier et al. 2014), a process well known to be critical for the initiation of atherosclerotic lesion formation (Huo et al. 2003; Massberg et al. 2002). Thus, blockade of GPVI may not only prevent arterial thrombosis but could also impact on chronic inflammatory processes associated with atherogenesis and other conditions (Boilard et al. 2010).

The receptors involved in platelet adhesion and activation in arterial thrombosis depend on various factors, such as the prevailing shear stress as well as rheological conditions. It also depends on the composition of the subendothelial matrix. Collagen fibers and proteoglycans are main components of the ECM. They are embedded in elastin lamellae and together with smooth muscle cells form the tunica media (Wagenseil and Mecham 2009). Collagen types I and III represent the major component of the vascular matrix (Plenz et al. 2003) and account for up to 90 % of total collagenous protein in atherosclerotic lesions (Katsuda and Kaji 2003). In addition, also non-collagenic adhesion proteins such as fibronectin, vitronectin, and laminin are expressed (Watson 2009). However, the regional distribution of collagenous proteins varies strongly. Collagen type I accumulates preferably within the fibrous cap, whereas collagen type III is mostly found in the atheromatous core. Because platelets can adhere directly to collagen fibers via their collagen receptors, ECM composition is another factor determining the type of platelet receptors involved in adhesion. Indeed, $\alpha_2\beta_1$ integrin mediates adhesion preferably to collagen type III and thereby promotes shape change of aggregating platelets (Penz et al. 2005; Schulz et al. 2008). However, GPVI is significantly more important than $\alpha_2\beta_1$ integrin in platelet adhesion and aggregation induced by atheromatous plaque and represents the predominant collagen receptor in arterial thrombosis (de Witt et al. 2014; Nieswandt and Watson 2003).

In addition to sensing the composition of the adhesive matrix, e.g., by tethering to collagen fibers or surface-bound vWF, platelets seem to respond also to the matrix geometry. In fact, platelets are able to identify spatially restricted matrix cues during adhesion, which results in the directed release of their granule content toward this region. Platelet-derived matrix proteins (e.g., fibrinogen, fibronectin) and other molecules (e.g., P-selectin) then bind to the

subendothelial matrix (SEM) and extend the area available for platelet tethering and spreading (Kita et al. 2011; Sakurai et al. 2015). Whether this mechanism has a role in arterial thrombosis remains to be determined. However, it likely contributes to platelet adhesion at sites of minor vascular injury, such as plaque microerosions, and facilitates the recruitment of platelets to exposed SEM.

Platelet Activation and Intracellular Signaling

The detailed mechanisms of platelet activation and the underlying intracellular signaling cascades are described elsewhere in this book. However, recent findings have established a role of distinct signaling molecules in arterial thrombosis. We will therefore briefly highlight some of these pathways in the following paragraph.

Platelet function is controlled by intracellular calcium (Ca^{2+}) levels (Fig. 2). Thus, inhibition of signaling pathways responsible for changes in Ca^{2+} during platelet activation is likely to affect thrombus formation. Stimulation with various agonists culminates in activation of phospholipase C and production of diacylglycerol (DAG) and triphosphoinositol, which mediates rapid release of Ca^{2+} from the sarcoplasmic reticulum (SR). Depletion of internal stores then triggers sustained Ca^{2+} influx through store-operated calcium entry (SOCE) channels located in the plasma membrane (Prakriya and Lewis 2015). In recent years the identity of some platelet Ca^{2+} channel regulators and their role in thrombosis have been revealed. Stromal interaction molecule 1 (STIM1) has been identified as an important Ca^{2+} sensor in the SR that controls Ca^{2+} release-activated channels (Luik et al. 2008; Park et al. 2009). Consequently, in STIM1-deficient mice, SOCE is absent and sustained Ca^{2+} influx is abrogated. This results in incomplete clot formation and protection of STIM1-knockout mice from arterial thrombosis and organ ischemia (Varga-Szabo et al. 2008). Hemostasis is only mildly affected probably because the rapid calcium burst from internal stores is sufficient in this context. Mechanistically, STIM1 oligomerizes and redistributes to the plasma membrane, where it associates with Orai1, the pore-forming subunit of Ca^{2+} release-activated channels, to trigger SOCE. Absence of Orai1 impairs Ca^{2+} entry, platelet secretion, and aggregation (Bergmeier et al. 2009; Braun et al. 2009). Together, STIM1 and Orai1 provide a crucial Ca^{2+} entry mechanism triggering platelet secretion and procoagulant activity. This pathway is mainly important for GPVI-mediated thrombus formation, while platelet activation through G-protein-coupled receptors (e.g., thrombin) is not altered (Gilio et al. 2010). In contrast to SOCE, receptor-operated calcium entry (ROCE) is mediated by ligand binding (e.g., ATP) to G-coupled receptors such as the cation channel P2X1. Transient Ca^{2+} influx via P2X1 receptors contributes to platelet activation and shape change (Rolf

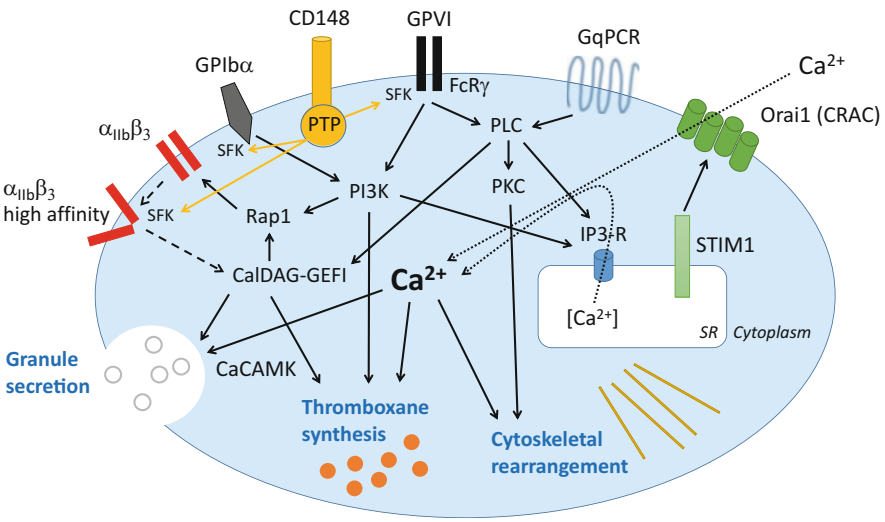

Fig. 2 Signaling cascades involved in platelet activation. The simplified model illustrates signaling molecules important in platelet biology. This includes the key stimulatory mediators PI3K, PKC, and PLC and the second messenger Ca(2+). They are critical for platelet activation, shape change, spreading, secretion, and integrin activation. Ca(2+) flux controls the activity of CalDAG-GEFI, which regulates platelet responses via Rap1 (modified from Bergmeier et al. Channels. 2013). The receptor-like PTP CD148 maintains Src family kinases (SFK) in an activated state which contributes to platelet activation downstream of various surface receptors. aIIbb3 integrin, fibrinogen receptor; GPIba, glycoprotein Ib-V-IX (vWF receptor); GPVI, glycoprotein VI (collagen receptor); GqPCR, Gaq protein-coupled receptor (e.g., thrombin receptor); Orai1, ORAI calcium release-activated calcium modulator 1; CRAC, Ca(2+) release-activated calcium channel; SFK, Src family kinases; PTP, protein tyrosine phosphatase; FcRg, Fc receptor common g chain; Rap1, small GTPase; PI3K, phosphoinositide 3-kinase; PLC, phospholipase C; PKC, protein kinase C; CalDAG-GEFI, Ca(2+) and DAG-regulated guanine nucleotide exchange factor I; IP3-R, inositol trisphosphate receptor; STIM1, stromal interaction molecule 1; CaCAMK, Ca(2+)-calmodulin kinase; SR, sarcoplasmic reticulum

and Mahaut-Smith 2002). Interestingly, activation of P2X1 also amplifies Ca^{2+} signaling through P2Y1 and other Gq-coupled receptors (Jones et al. 2014). In the absence of P2X1, platelet aggregation and secretion in response to agonists are decreased, and in mice thrombus formation in arterioles and small arteries is inhibited (Hechler et al. 2003). However, the role of P2X1 in arterial thrombosis occurring in larger vessels remains elusive. In summary, calcium channels play a critical role in mediating platelet activation downstream of various agonists. Specifically, proteins regulating SOCE could represent interesting targets because of their imminent role in arterial thrombosis while causing only mild changes in the hemostatic response. However, due to their broad expression, genetic deficiency and gain-of-function mutations of the above-described proteins result in severe adverse effects on immune responses and tissue function (Lacruz and Feske 2015). Thus, further research is required to identify platelet-specific approaches for the inhibition of calcium channel regulators to reduce platelet activation in arterial thrombosis.

Small GTPases are cytosolic G-proteins, which regulate signal transduction processes involved in platelet granule secretion and integrin activation (Fig. 2). They are among the most abundant proteins in platelets (Burkhart et al. 2014). The guanine nucleotide exchange factor (GEF) calcium- and DAG-regulated GEF 1 (CalDAG-GEFI) is a critical regulator of small GTPases. It activates small GTPases, such as Rap1 and Rac1, and thereby activates β1 and β3 integrins in platelets (Bernardi et al. 2006; Crittenden et al. 2004). Absence of the CalDAG-GEFI encoding *RASGRP2* gene in humans causes a significant bleeding diathesis (Canault et al. 2014). However, presence of a single normal allele in heterozygous patients is sufficient to prevent bleeding while platelet adhesion and spreading on collagen remains absent. Thus, partial inhibition of CalDAG-GEFI may represent a safe therapeutic strategy in arterial thrombosis. In fact, in mice targeting of the regulatory C1 domain within CalDAG-GEFI reduces (but does not abrogate) its function and consequently decreases $\alpha_{IIb}\beta_3$ activation. Importantly, CalDAG-GEFI deficiency has only minor impact on hemostasis, less than inhibition of $P2Y_{12}$ (another pathway signaling through Rap1 activation) or genetic absence of Rap1 (Andre et al. 2003; Chrzanowska-Wodnicka et al. 2005). Thus, CalDAG-GEFI signaling represents a molecular pathway pivotal for platelet adhesion and thrombus formation, particularly under arterial shear conditions. However, its (partial) absence does allow the formation of hemostatic plugs, and therefore specific targeting of CalDAG-GEFI represents an interesting therapeutic strategy for the treatment of arterial thrombosis (Bergmeier et al. 2007; Stolla et al. 2011).

Finally, the signaling cascades induced by platelet-activating receptors, which mainly involve nonreceptor tyrosine kinases (NRTK) or G-protein-coupled receptors, may represent an interesting target for the inhibition of thrombosis. GPVI and the C-type lectin-like receptor 2 (CLEC-2) have been identified as major NRTK-coupled platelet-activating receptors both signaling through Src family kinases (SFK) and Syk (Lorenz et al. 2015; Severin et al. 2011). CLEC-2 deficiency abrogates platelet aggregation and arterial thrombosis in mice but also diminishes the hemostatic response (Bender et al. 2013; May et al. 2009). The pivotal role of tyrosine phosphorylation in the regulation of platelet function has been further corroborated by genetic deletion of regulatory molecules involved in downstream signaling pathways. For example, absence of the receptor-like protein tyrosine phosphatase CD148, a global activator of SFK signaling, abrogates thrombus formation and disrupts hemostasis (Fig. 2) (Mori et al. 2012; Senis et al. 2009). Syk tyrosine phosphorylation downstream of both CLEC-2 and GPVI signaling pathways is positively regulated by the dual-specificity phosphatase 3 (DUSP3). In mutant mice lacking DUSP3, platelet activation and arterial thrombosis are reduced (Musumeci et al. 2015). However, DUSP3 is dispensable for GPIbα binding and integrin $\alpha_{IIb}\beta_3$ outside-in signaling (mediating fibrin clot retraction) explaining why primary hemostasis is not affected in these animals. These findings nicely illustrate that selective inhibition of signaling pathways (e.g., downstream of GPVI/CLEC-2) yields interesting therapeutic options in arterial thrombosis, while ablation of regulatory molecules involved in a broad range of platelet functions is more likely to cause aberrant hemostasis.

Platelet-Released Molecules Modulating Arterial Thrombosis

Platelets contain a large repertoire of molecules, which are released upon activation and exert various functions in thrombosis and inflammatory conditions (Semple et al. 2011). Most of these molecules are actually platelet derived; however some factors are primarily circulating in blood, become internalized in platelets, and accumulate in their granule stores. ADP and TxA2 belong to the most established platelet mediators. They are released from activated platelets and act as secondary agonists to induce platelet integrin activation and aggregation (Offermanns 2006). However, recent studies have identified various other platelet-released mediators, which influence pathways involved in both platelet activation as well as blood coagulation and thereby impact on arterial thrombosis.

One example is plasma fibronectin (pFn). As outlined above, fibronectin is an important component of the ECM and represents a ligand for various platelet receptors, including $\alpha_{IIb}\beta_3$ integrin and GPVI. In contrast to cellular

fibronectin, which is generated and deposited locally, pFn is produced in the liver and circulates in blood. Interestingly, platelets internalize and accumulate pFn in larger amounts in a process involving $\alpha_{IIb}\beta_3$ (Ni et al. 2003a). In case of endothelial injury, pFn is readily deposited at the arterial wall and incorporated into the fibrin network, which is thereby strengthened. pFn promotes platelet aggregation and plays a role already in the initial phase of hemostasis (Wang et al. 2014). Consequently, depletion of pFN results in decreased thrombus formation and stability (Ni et al. 2003b), however, only in the presence of fibrin (Reheman et al. 2009). In the absence of fibrin, pFn inhibits platelet aggregation and thrombus formation (Wang et al. 2014). This mechanism seems to play a role in limiting platelet aggregation in the growing thrombus, particularly at border zones to the blood stream where fibrin is low or absent. By these means, pFn regulates thrombus growth and fine tunes the hemostatic response. However, in more severe vessel injuries, in which larger amounts of fibrin are generated (e.g., following plaque rupture), pFn switches its function to promote thrombus formation. Thus, pFn could represent a therapeutic target in arterial thrombosis, while its inhibition in the physiological process of hemostasis, in which it negatively regulates thrombus formation, probably is counterproductive.

In addition to proteins that interact with matrix components (e.g., fibrin) of a growing thrombus or the injured vessel wall, platelets also host molecules that directly promote fibrin formation and blood coagulation, i.e., proteins of the thioredoxin superfamily. They are generally contained in the endoplasmic reticulum (ER) of mammalian cells and play a central role in protein folding and processing of secretory proteins by enzymatic (e.g., disulfide bond formation) and nonenzymatic functions (Gething and Sambrook 1992). Interestingly, a growing body of work indicates a role in arterial thrombosis. Various thiol isomerases have been identified in platelets including ERp5, ERp57, and protein disulfide isomerase (PDI). Upon activation, they are mobilized to the cell surface and secreted; however, they can also bind to $\alpha_{IIb}\beta_3$ and thereby remain surface bound (Holbrook et al. 2010; Schulz et al. 2010; Wang et al. 2013). In fact, $\alpha_{IIb}\beta_3$ is a major target of these proteins, and direct interaction with the β3 integrin during its activation is required for incorporation of platelets into a growing thrombus (Cho et al. 2012; Passam et al. 2015; Wang et al. 2013). Besides inducing platelet activation and aggregation, thiol isomerases are also critical effectors of blood coagulation. PDI and ERp57 have been shown to trigger conversion of tissue factor (TF) from the functionally inactive to the active form (Reinhardt et al. 2008; Schulz et al. 2010). This process is referred to as TF decryption and represents an initial step in coagulation activation. Thus, platelet-released thiol isomerases support TF-dependent blood coagulation at sites of vessel damage in mice (Kim et al. 2013; Reinhardt et al. 2008). Notably, the endothelium represents another source of these proteins, and the precise contribution of endothelium versus platelet derived thiol isomerases in arterial thrombosis is subject to ongoing investigations. It not only seems to vary for the individual proteins but also depend on the mouse injury model analyzed (Jasuja et al. 2010; Passam et al. 2015). Further, thioredoxin family members are close structural homologues and recognize common substrates; however they may also bind to distinct domains and have specialized functions (Maattanen et al. 2006). This observation has been corroborated in the context of platelet biology. For example, the absence of platelet ERp57 prolongs tail bleeding times, whereas hemostasis is not altered in mice with PDI-deficient platelets (Kim et al. 2013; Wang et al. 2013) (Table 1). In line with this, combined antibody blockade of ERp5 and PDI has additive but not synergistic effects on platelet aggregation (Jordan et al. 2005). Thus, the precise role of individual thiol isomerases in arterial thrombosis awaits further experimental data. Nonetheless, genetic deficiency as well as antibody blockade of either ERp5, ERp57, or PDI reduces platelet aggregation and thrombus formation in mice in vivo (Kim et al. 2013; Passam et al. 2015; Reinhardt et al. 2008; Wu et al. 2012; Zhou et al. 2014). Thus, inhibition of these proteins represents a potential strategy in arterial thrombosis. Particularly PDI, whose absence is not associated with overt bleeding in animal models, seems to be a promising drug target (Jasuja et al. 2012). A first clinical trial addressing PDI inhibition in patients with cancer-associated thrombosis is currently under way (ClinicalTrials.gov Identifier: NCT02195232).

Various other proteins exist in platelets of which we have only begun to understand their functions and potential implications in arterial thrombosis. They include Gas6, a protein encoded by the growth arrest-specific 6 gene, which has previously been shown to play a role in inflammatory processes involving leukocytes and endothelial cells. Platelets are an important source of Gas6 but also contain receptor tyrosine kinases on their surface that bind Gas6 as a ligand. Gas6 binding then induces platelet secretion, $\alpha_{IIb}\beta_3$-dependent outside-in signaling, and aggregation (Angelillo-Scherrer et al. 2005; Gould et al. 2005). Importantly, the absence of Gas6 is associated with thrombus instability and protects mice from arterial thrombosis. Similar results have been observed in the absence of either of the three known platelet Gas6 receptors (Angelillo-Scherrer et al. 2001, 2005; Cosemans et al. 2010; Gould et al. 2005). Future studies will have to define in more detail the suitability of Gas6 as a therapeutic target in arterial thrombosis.

Matrix metalloproteinases (MMPs) play an important role in tissue remodeling and contribute to vascular inflammation. Their identification in platelets has opened another chapter in platelet activation and thrombosis. Platelets

contain MMP-1 (not in *Mus musculus*), MMP-2, MMP-3, and MMP-14 (also known as membrane type 1 [MT1]-MMP), all of which can be secreted upon activation (Kazes et al. 2000; Sawicki et al. 1997). MMP-1 and MMP-2 have been shown to promote platelet activation and aggregation in vitro (Fernandez-Patron et al. 1999; Galt et al. 2002), and MMP-2 enhances arterial thrombosis in mice in vivo (Momi et al. 2009). MMPs also modify the extracellular matrix by exerting lytic activity and degrading collagen fibers. This potentially limits thrombus formation at later stages of arterial thrombosis when platelet MMP activity and secretion reaches a maximum (Mastenbroek et al. 2015). Thus, platelet-released MMPs can be considered a potential therapeutic target in arterial thrombosis (Table 1). This is specifically interesting as conventional antiplatelet agents, namely, acetylsalicylic acid, do not prevent the release of MMP-2 from activated platelets (Falcinelli et al. 2007).

Because platelets host numerous proteins with agonistic and pro-inflammatory functions (Semple et al. 2011), it is interesting to note that some molecules act as negative regulators of platelet activation. They include carcinoembryonic antigen cell adhesion molecule-1 (CEACAM1), endothelial cell-specific adhesion molecule (ESAM), junctional adhesion molecule-A (JAM-A), and platelet endothelial cell adhesion molecule-1 (PECAM-1). Consequently, absence of these molecules results in gain of platelet function and susceptibility to thrombosis. The mechanisms by which these mediators inhibit platelet activation are incompletely understood. CEACAM1 and PECAM-1 seem to act predominantly through reducing collagen-dependent platelet activation (Falati et al. 2006; Jones et al. 2001; Wong et al. 2009), while JAM-A acts as an endogenous inhibitor of integrin outside-in signaling (Naik et al. 2014, 2012). The precise function of ESAM remains to be explored. The protein has been shown to cluster in areas of homotypic platelet interactions and might therefore interfere with contact-dependent platelet activation. Absence of ESAM in mice confers increased platelet integrin activation and arterial thrombosis (Stalker et al. 2009). Together, regulatory proteins that inhibit platelet functions may deem useful in arterial thrombosis. It should be noted, however, that platelets are not the only source of these molecules and that endothelium and other blood cells may also produce and secrete them.

In summary, platelet-derived molecules may affect arterial thrombosis in multiple ways. They may interact with fibrin and matrix proteins at the vessel wall (e.g., pFn), promote blood coagulation (e.g., TF activation by thiol isomerases), and directly promote (e.g., ADP, Gas6, TxA2) or inhibit (e.g., CEACAM1, ESAM, JAM-A) platelet activation. The plethora of molecules that is potentially released from activated platelets and modulates their function is intriguing. Future research will have to define in more detail the specific pathological conditions, in which certain factors are of critical importance, their mechanisms of action, and whether they can be harnessed for the development of novel therapeutic approaches.

Platelet Interactions with Innate Immune Cells

Circulating innate immune cells act as a central line of defense against invading pathogens. Besides providing an array of bactericidal mechanisms, they promote pro-coagulatory pathways to initiate thrombus formation within the microvasculature, which contributes to the containment and elimination of pathogens. Thus, thrombosis represents an important mechanism of intravascular immunity (Engelmann and Massberg 2013). Interestingly, innate immune cells also represent a common cellular substrate in human arterial thrombus specimen (Mangold et al. 2015; Riegger et al. 2016) (Fig. 3a, b). The pathophysiology and clinical consequences are incompletely understood; however, reciprocal activation of platelets and immune cells likely contributes to arterial thrombosis. Platelets can directly recruit leukocytes to sites of injury, and in the absence of circulating platelets, recruitment of myeloid cells is strongly reduced (Schulz et al. 2011). Activated platelets express a broad spectrum of adhesion molecules on their surface, which allows interactions not only with the vessel wall but also with circulating blood cells (Fig. 3a). The most prominent ligand is P-selectin, which is expressed on activated platelets and mediates aggregate formation with various leukocyte subsets, mostly monocytes and polymorphonuclear neutrophils (PMN). In patients with acute coronary syndrome, platelet-leukocyte-aggregate (PLA) formation is increased and coincides with the early phase of arterial thrombosis (Furman et al. 2001; Sarma et al. 2002). Platelets also form aggregates with lymphoid cells under flow; however, the pathophysiological relevance of this interaction remains to be elucidated (Diacovo et al. 1998; Marquardt et al. 2009). Aggregation of platelets and myeloid cells is mostly established via binding of P-selectin to P-selectin glycoprotein ligand-1 (PSGL-1) (Yokoyama et al. 2005). However, blockade of P-selectin on activated platelets only partly reduces leukocyte adhesion under arterial flow conditions, clearly indicating the involvement of additional ligand-receptor pairs. Alternatively, interactions of the membrane proteins CD154 (CD40 ligand) and CD40 mediate PLA formation. Further, platelet GPIbα and αbβ3 integrins bind to leukocyte β2-integrins (CD11b, MAC-1) and cellular adhesion molecules (e.g., ICAM-1), respectively, whereas platelet GPVI has been shown to bind CD147 on myeloid cells (Diacovo et al. 1996; Schulz et al. 2011; Seizer et al. 2009).

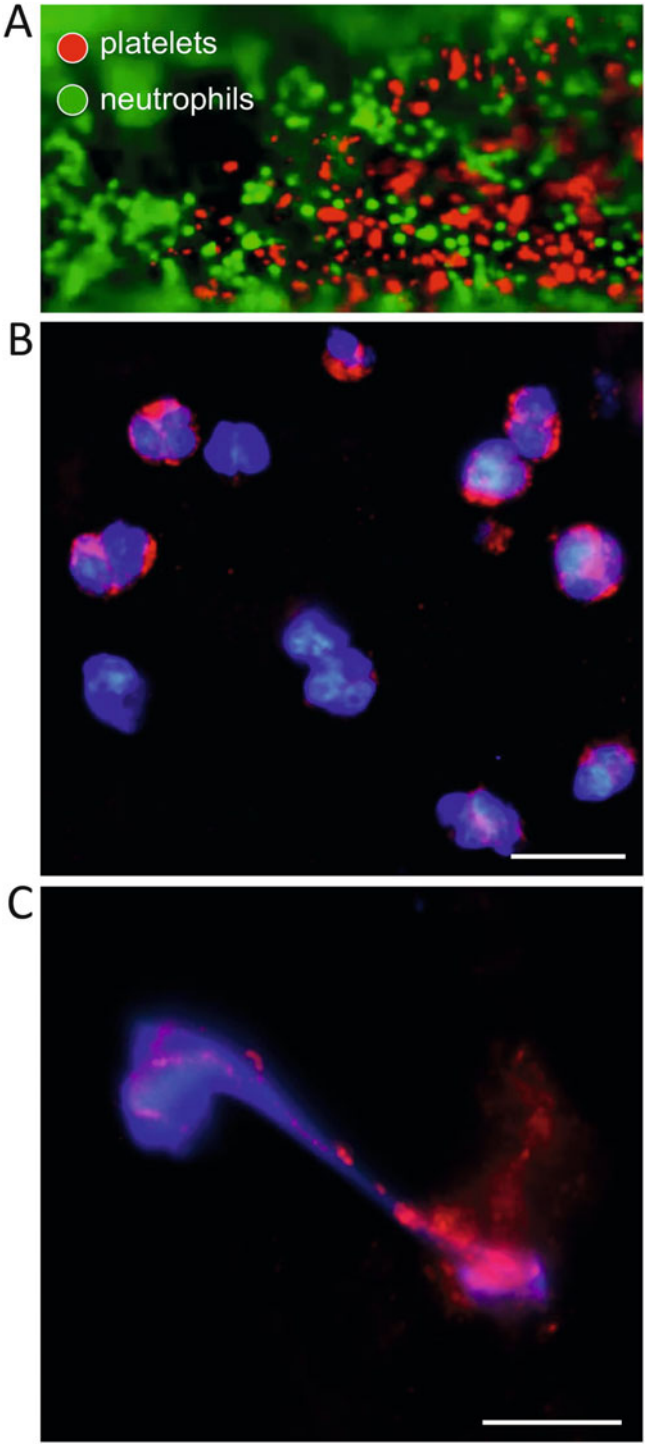

Fig. 3 Immune cells in arterial thrombosis. (**a**) Intravital microscopy of arterial thrombosis in a mouse carotid artery injury model. Platelets (*red*) and neutrophils (*green*) closely interact during thrombus formation at the injured vessel wall. (**b** and **c**) Leukocyte accumulation in thrombus specimens retrieved from coronary arteries of patients with myocardial infarction (Riegger et al. 2016). (**b**) Immunofluorescence staining of a coronary thrombus identifies neutrophils (*red*, neutrophil elastase (NE) staining) and nuclei (*blue*, Hoechst). Bar, 10 mm. (**c**) Activated neutrophils release prothrombotic nucleosomes (*blue*) in a process termed NETosis. Bar, 5 mm

Activated platelets foster prothrombotic pathways in myeloid cells (Celi et al. 1994; Lindmark et al. 2000; Sako et al. 1993). Among others, this leads to formation of TF by monocytes, which culminates in fibrin deposition and thrombus stabilization (Palabrica et al. 1992). In PMN, platelet-secreted molecules such as P-selectin and high-mobility group box 1 induce neutrophil activation and NET formation (Etulain et al. 2015; Maugeri et al. 2014). NETs are scaffolds of extracellular nucleic acids that act as strong procoagulant surfaces and propagate local coagulation (Engelmann and Massberg 2013; Martinod and Wagner 2014) (Fig. 3c). They can bind to and activate platelets and other procoagulant effectors such as factor XII (Brinkmann et al. 2004; Fuchs et al. 2010; von Bruhl et al. 2012). NETs also bind to TF, which is activated and then triggers the extrinsic pathway of blood coagulation (Reinhardt et al. 2008). Thus, NETs provide several mechanisms to foster fibrin formation and potentiate thrombus stability but also directly induce platelet activation and aggregation, suggesting that inhibition of NET formation represents an interesting therapeutic strategy in arterial thrombosis. This is corroborated by recent data in patients with myocardial infarction showing that the number of NETs in coronary thrombi correlates positively with infarct size (Mangold et al. 2015). Together, reciprocal activation of platelets and myeloid cells, together with fibrin formation and the induction of pro-coagulative pathways, plays a decisive role in arterial thrombosis. Thus, the inhibition of immune cell activation and recruitment may open up new therapeutic avenues for the treatment and prevention of this condition. Further, effective platelet inhibition is likely to reduce the number of leukocytes recruited into the growing thrombus and may also abrogate their sequelae (e.g., NET formation).

As a side note, platelets not only directly recruit leukocytes to sites of injury (via ligand-receptor interactions) but also indirectly through release of soluble factors. These include chemotactic mediators, such as CCL5 (regulated on activation normal T cell expressed and secreted, RANTES), CXCL4 (platelet factor 4, PF4), or stromal cell-derived factor 1α (SDF-1α), which are abundant in platelets. Once released upon activation, they recruit and bind leukocytes and hematopoietic progenitor cells at the site of injury. However, instead of acute thrombosis, this mechanism is probably more important in chronic pathologies such as atherogenesis or post-injury remodeling (Massberg et al. 2006; Schober et al. 2002).

In summary, inhibition of platelet-immune cell interactions as well as their bidirectional activation paths is likely to represent a novel therapeutic option in arterial thrombosis. Specifically P-selectin represents an interesting target because of its leading role in PLA formation (Michelson et al. 2001). Consequently, antibodies for in human use

have been developed. In a first placebo-controlled randomized trial in patients with acute coronary syndrome, P-selectin blockade abrogated PLA formation and neutrophil activation. The antibody-treated group also showed a trend toward reduced myocardial injury (Tardif et al. 2013). Further studies will have to decipher the consequences and benefit of P-selectin blockade in humans.

Outlook

Arterial thrombosis is an acute and life-threatening condition with severe impact on morbidity and mortality worldwide. Despite improvements in antithrombotic therapies, there is an unmet clinical need in strategies protecting from thrombosis while leaving physiological hemostasis unaffected. Ongoing and future research will have to unravel the mechanisms and molecular cues specific for thrombosis-related pathways. GPVI and integrin α6β1 represent examples of platelet receptors, whose absence does not cause overt bleeding. Likewise, interference with crucial signaling pathways by targeting distinct binding motifs (e.g., Gα13-EXE, vWF A1, or CalDAG-GEFI C1 domain) or tyrosine phosphatases (e.g., DUSP3) may yield protection from atherothrombotic complications. Other potential targets include molecules such as PDI, which function at the intersection of blood coagulation and platelet activation. Carefully performed clinical trials are then required to validate these targets in larger patient cohorts. Finally, the immune component in arterial thrombosis warrants further characterization. Activated monocytes and neutrophils not only participate in a mutual interplay with platelets, which potentially results in reciprocal activation, but also have direct impact on thrombus formation. These recent findings open up new therapeutic avenues in research and contribute to the development of safer strategies in arterial thrombosis.

Take Home Messages

- Platelets are key players in arterial thrombosis.
- Inhibition of platelet function reduces thrombus formation but is associated with an increased risk of bleeding.
- Antiplatelet strategies targeting thrombotic functions, but leaving hemostasis unaffected, are warranted.
- Novel platelet signaling pathways and surface receptors more specifically modulating thrombotic processes have been identified, which could lead to new therapies.
- Innate immune cells contribute to arterial thrombosis, opening up additional avenues of research.

Platelets in Atherosclerosis

Madhumita Chatterjee and Meinrad Gawaz

Abstract

Platelets play a critical role in haemostasis and thrombosis. Recent discoveries provide evidence that platelets promote atherogenesis and augment vascular inflammation and remodelling of the arterial wall, resulting in formation of atherosclerotic plaques. Upon activation, platelets adhere to the endothelial monolayer and release a variety of inflammatory mediators. Platelet-derived inflammatory mediators promote activation of the endothelial monolayer and recruitment of circulating blood cells, including monocytes and endothelial progenitor cells (EPCs). Further, platelets stimulate differentiation of monocyte and endothelial progenitor cells into macrophages and foam cells. Thus, at the site of platelet accumulation on the arterial wall, platelets form an inflammatory 'hot spot' that constitutes an early trigger for atherosclerotic lesions. On the other hand, platelets also control healing of vascular lesions by recruitment and differentiation of circulating endothelial progenitor cells to promote repair of the endothelial monolayer. Thus, platelets ensure both repair of vascular lesions ('healing') and foster lesion formation and progression, depending on atherosclerotic cofactors such as oxidized LDL (oxLDL). The diverse mechanisms by which platelets accomplish a balance between vascular injury and repair encompass a variety of inflammatory mediators and receptors. Recent clinical studies provide evidence that an intensified and prolonged antiplatelet therapy improves clinical prognosis of patients with atherosclerotic disease. This chapter highlights the recent developments concerning platelets in the context of atherosclerosis and highlights the novel therapeutic strategies.

Introduction

The pathogenesis of atherosclerosis encompasses a strong inflammatory component that involves various cell types including platelets and inflammatory mediators (Lusis 2000; Libby et al. 2011). Not long ago the pathophysiological contribution of platelets to atherosclerosis was contemplated mainly in the context of the coagulation cascade, participating in the final step of atherosclerosis, and eventual thrombus build up following plaque rupture causing thrombotic narrowing or occlusion of a vessel. However, abundant experimental evidences have changed this point of view and established platelets as early responders seeding atheroprogression. Platelets are the prime responders to vascular injury and ensure haemostasis and vascular integrity to prevent extravasal blood loss (Ruggeri 2002, 2009). Platelets rapidly adhere to vascular lesions via adhesion receptors (e.g. GPIb, GPVI), aggregate via the fibrinogen receptors $\alpha_{IIb}\beta_3$ and become activated during the adhesion process. Usually, the intact endothelial monolayer prevents platelet attachment and accumulation at the vessel wall. However, inflamed endothelial cells (ECs) develop properties that render them adhesive for platelets. In accordance with the 'response-to-

injury' hypothesis of atherogenesis, atherosclerotic lesions result in an orchestrated response to a localized injury to the vascular endothelium, which subsequently triggers platelet adhesion, aggregation and release of pro-inflammatory mediators like regulated upon activation normal T-cell expressed and secreted (RANTES), epithelial neutrophil-activating peptide (ENA-78), IL-1β, chemotactic (e.g. stromal-derived factor-1, SDF-1) and growth factors (e.g. platelet-derived growth factor, PDGF) from activated platelets. Upon activation platelets also release substantial amounts of alarmin or danger signals which function as inflammatory mediators and *damage-associated molecular pattern* proteins (DAMPs) (Gleissner et al. 2008; Gawaz et al. 2005; Karshovska et al. 2013; Gawaz and Vogel 2013). Activated platelets recruit circulating blood cells (e.g. monocytes and endothelial progenitor cells) at the site of vascular lesions and interact with resident vascular cells such as endothelial and smooth muscle cells (Langer and Gawaz 2008). Under physiological conditions all these mechanisms contribute to vascular repair and preservation of vessel integrity.

Platelets adhere under pathophysiological conditions to endothelial cells via multiple adhesion receptors including selectins, integrins and immunoglobulin-type receptors (Gawaz 2004). During the adhesion process, platelets become activated and release an arsenal of potent inflammatory and mitogenic substances into the local microenvironment, thereby alter the characteristics of the endothelial monolayer into a proatherogenic substrate (Gleissner et al. 2008; Karshovska et al. 2013). Platelet-derived chemokines and DAMPs attract circulating monocytes and endothelial progenitor cells towards the inflamed endothelium, which is a critical step in atherosclerotic lesion formation (Karshovska et al. 2013; von Hundelshausen and Schmitt 2014; Chatterjee and Gawaz 2013). Once circulating blood cells are recruited towards the atherogenic *hot spot*, platelets induce differentiation of recruited bone-marrow-derived cells into macrophages/foam cells (Massberg et al. 2006; Stellos and Gawaz 2007a, b; Langer et al. 2007; Stellos et al. 2008, 2010; Daub et al. 2006). A key mechanism in this differentiation process is the generation and uptake of oxidized low-density lipoprotein (oxLDL). OxLDL is bound to the surface and phagocytosed by platelets by means of scavenger receptors like CD36, LOX-1 and CXCL16/PS-OX, making platelets a major vehicle for oxLDL (Fig. 1)

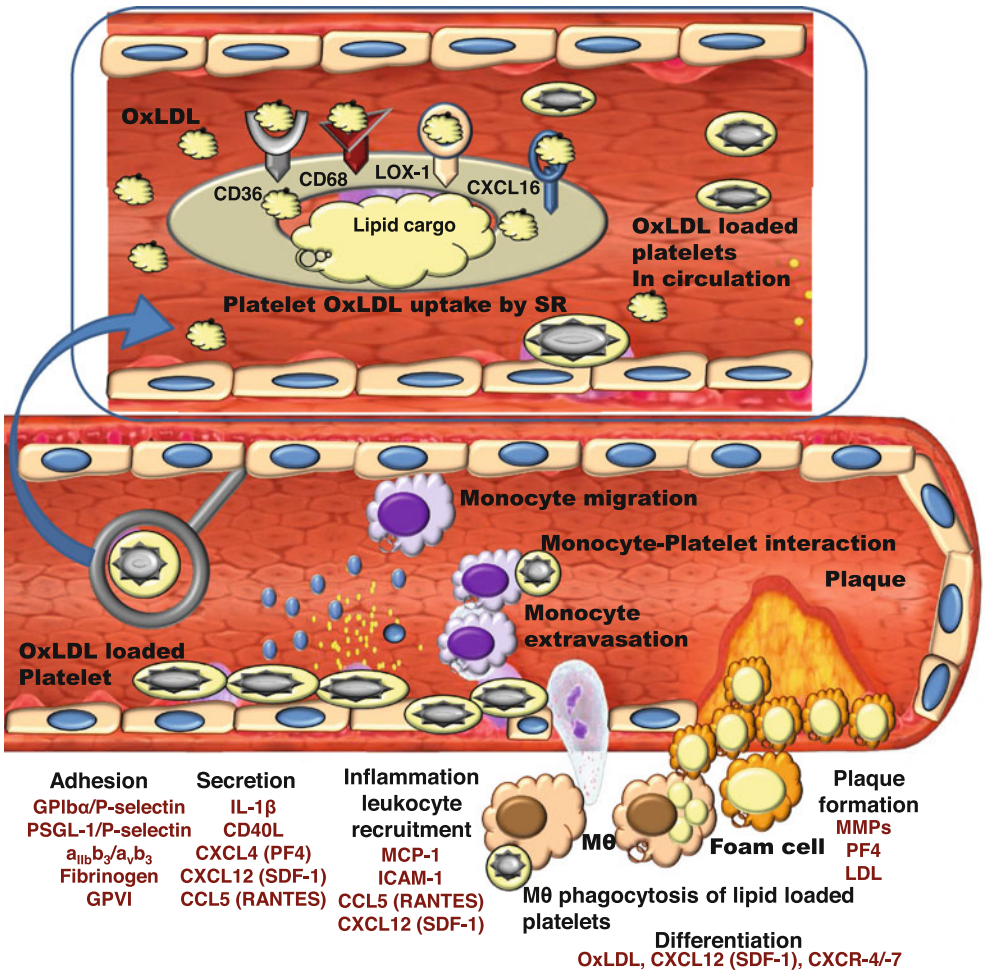

Fig. 1 Platelets orchestrate atherogenesis. Above: Platelets interact with circulatory lipoproteins. Platelets can take up oxLDL by scavenger receptors like CD68, CD36, LOX-1 and CXCL16/PS-OX. Therefore platelets serve as lipid vehicles in circulation. Below: Activated lipid-laden platelets in circulation interact with the vascular endothelium, release pro-inflammatory factors and also induce a proatherogenic phenotype of ECs. Subsequently, adherent platelets recruit circulating monocytes, bind them and inflame them by receptor interactions and paracrine pathways, thereby initiate monocyte transmigration, their phagoctytic uptake of lipid-loaded apoptotic platelets and differentiation into macrophages and foam cells. Thus, platelets provide the inflammatory basis for plaque formation before physically occluding the vessel by thrombosis upon plaque rupture

(Siegel-Axel et al. 2008; Magwenzi et al. 2015; Badrnya et al. 2014). OxLDL-rich platelets are rapidly taken up by monocytes and stimulate transformation into macrophages and foam cells (Stellos et al. 2010; Daub et al. 2006, 2007; Chatterjee et al. 2015a, b; Nurden 2011). Thus, platelet adhesion, release of inflammatory mediators, recruitment of monocytes, uptake of lipid-laden platelets by monocytes and their differentiation into foam cells represent a critical step in early lesion formation of atherosclerotic plaques (Fig. 1). On the other hand, platelet interaction and phagocytosis by endothelial progenitor cells can induce differentiation into an endothelial phenotype that favours vascular repair and regeneration and may limit atherosclerotic lesion progression (Massberg et al. 2006; Stellos and Gawaz 2007a, b; Langer et al. 2007; Stellos et al. 2008, 2010; Daub et al. 2006) (Fig. 2). The key mechanisms that flip the switch between regeneration versus disease progression remain unknown. Thus, understanding the mechanistic basis that modulates platelet-dependent vascular inflammation and formation of atherosclerotic lesions is an attractive strategy to prevent or to control the consequences of atherosclerosis such as myocardial infarction or stroke.

Platelet Adhesion to the Endothelium

Under pathophysiological circumstances platelets adhere even to the intact endothelial monolayer especially at the lesion-prone sites of vessel bifurcation governed by altered shear stress. Normal 'resting' endothelium represents a nonadhesive and non-thrombogenic surface that prevents extravasation of circulating blood cells. In contrast, activated endothelial cells are pro-adhesive and promote the adhesion of circulating blood platelets (May et al. 2008; Gawaz et al. 1991, 1996, 1998). Adhesion of platelets to the intact but activated endothelium in the absence of previous endothelial denudation involves a surface receptor-dependent process that allows *capturing* or tethering of circulating platelets towards the vessel wall even under high shear stress, followed by rolling and subsequent firm adhesion. Platelets are well equipped to adhere to endothelial cells in vitro and in vivo. Platelet interaction with intact endothelium is a well-orchestrated procedure (Fig. 3). These processes are dependent on receptor interactions via selectins, integrins and immunoglobulin-like receptors, which induce receptor-specific activation signals in both platelets and the interacting cell partner involved in adhesion, for instance, endothelial cells. Initially, platelets roll loosely on the endothelial layer. Rolling is often dependent on endothelial activation induced by inflammatory assaults inflicted by infection, mechanic erosion or ischaemia and reperfusion. High levels of C-reactive proteins are associated with high rate of vascular events and promote platelet adhesion to endothelial cells. Platelets get activated during rolling interaction with the endothelium and subsequently adhere more and more tightly. Endothelial cells in turn get activated, too, and both cells express or secrete chemokines to perpetuate vascular inflammation. Activated endothelial cells surface-express ICAM-1, vascular cell adhesion molecule-1, E-selectin and P-selectin and release the chemokines MCP-1, SDF-1 and interleukin-8. Both activated platelets and endothelial cells can actively release pro-inflammatory interleukin-1β and CD40L. Platelet-specific release is chiefly characterized as RANTES and ENA-78. This vast array of secretory products, besides mediating interaction with leukocytes and endothelium, acts as inflammatory cues for the recruitment of immune or inflammatory cells, e.g. monocytes, also prompt their differentiation into macrophages to seed the process of plaque formation and atherosclerosis. Rolling is followed by firm adhesion that is mediated by integrin binding. Firm platelet adhesion triggers maximal platelet activation, instigating shape change, cytoskeletal rearrangement and release of potent inflammatory and mitogenic mediators into the local microenvironment. GPIIb-IIIa ($\alpha_{IIb}\beta_3$) is the major integrin on platelets and plays a key role in platelet accumulation on the activated endothelium. Among the integrins expressed on the luminal side of endothelial cells, the vitronectin receptor ($\alpha_v\beta_3$) plays a crucial role in promoting platelet adhesion. Another adhesion molecule for the contact of platelets with the vascular wall is GPIb-IX. Taken together platelet–endothelial cell interactions involving selectins, integrins and immunoglobulin-like adhesion receptors perpetuate transcellular communications leading to a pro-inflammatory status of both endothelial cells and inflammatory cells recruited to the site of action, thus contribute to vascular inflammation and atherosclerosis.

The Role of Selectins The initial loose contact between circulating platelets and the vascular endothelium ('platelet rolling') is mediated by selectins, present on both endothelial cells and platelets (Frenette et al. 1995, 1998a, b; Massberg et al. 1998; Subramaniam et al. 1996). P-selectin (CD62P) is rapidly expressed on the endothelial surface in response to inflammatory stimuli. In addition, P-selectin is stored in platelet α-granules and can rapidly translocate to the platelet surface upon activation. Endothelial P-selectin has been demonstrated to mediate platelet rolling in both arterioles and venules in acute inflammatory processes, such as ischaemia/reperfusion. Further, P-selectin glycoprotein ligand 1 (PSGL-1) is expressed on platelets and can mediate platelet–endothelial interaction in vivo (Lam et al. 2011; Frenette et al. 2000). E-selectin, which is also expressed on inflamed endothelial cells, allows a loose contact between platelets and the endothelium in vivo (Frenette et al. 1998a, b). In line with the concept of endothelial inflammation as a trigger for platelet accumulation, the process of platelet rolling does not require previous platelet activation, since platelets from mice lacking P- and/or E-selectin roll as efficiently as wild-type platelets (Frenette et al. 1995).

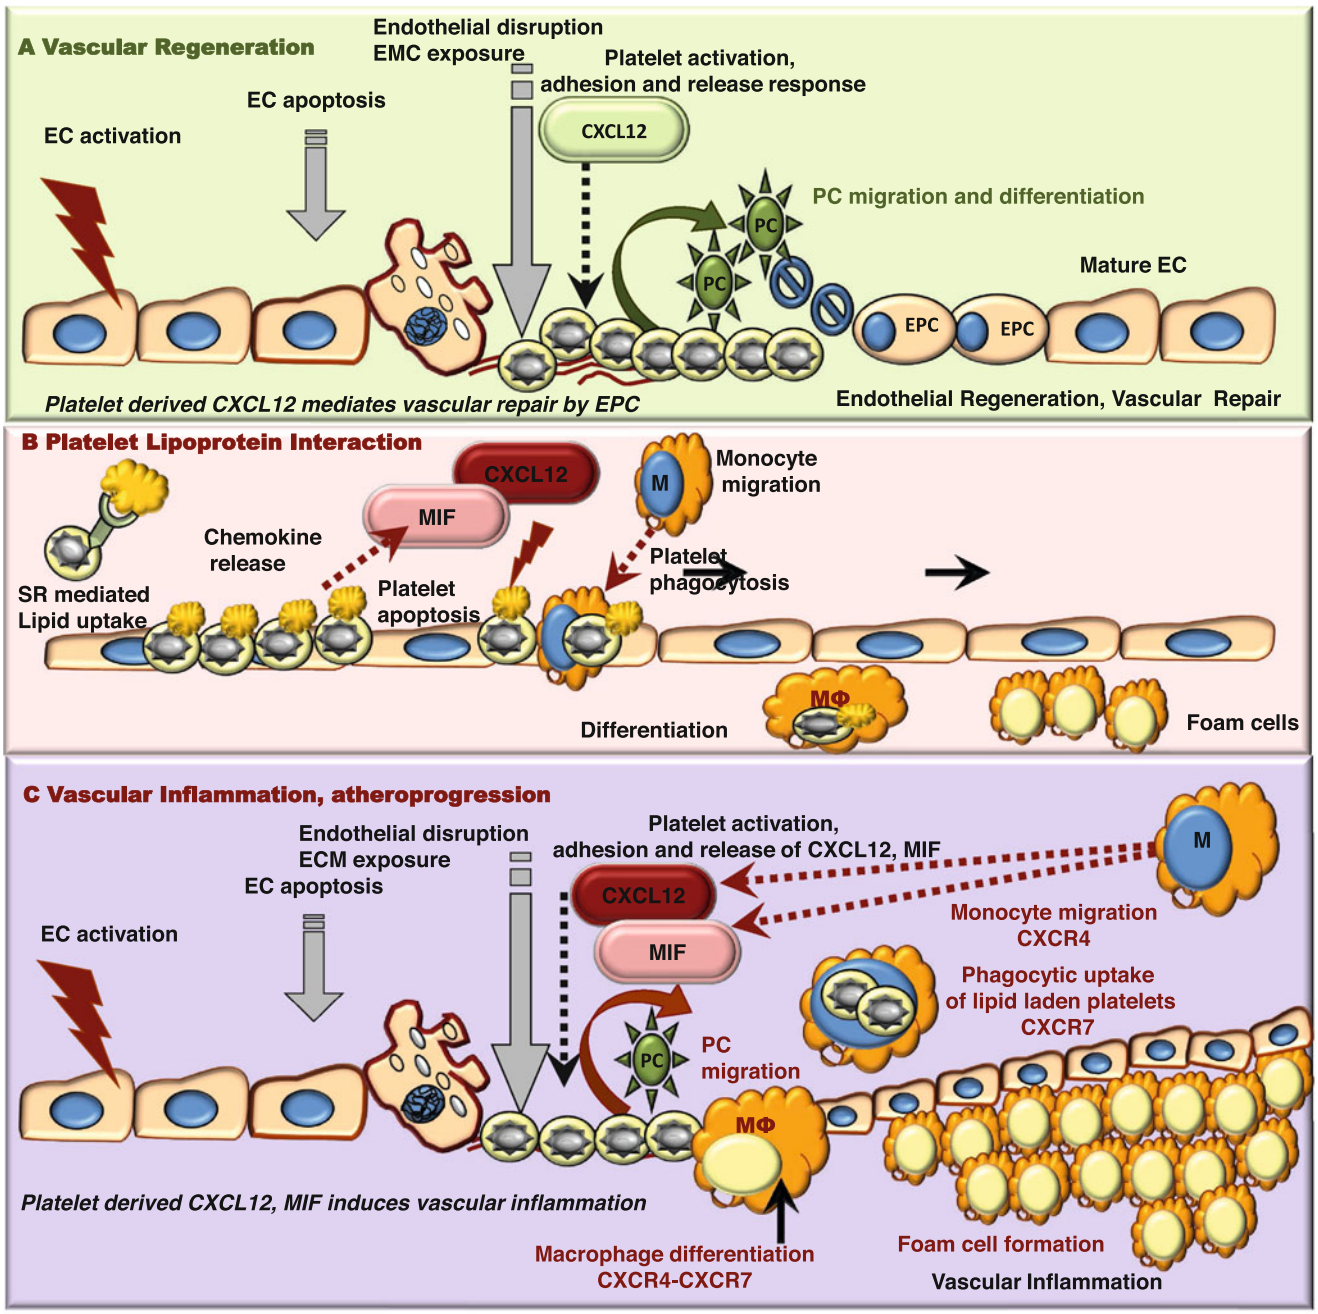

Fig. 2 Platelet chemokines in balancing atheroprogression and vascular regeneration. Platelets adhere to and interact with the injured or inflamed endothelium (EC, endothelial cell) or exposed sub-endothelial matrix components (EMC) and secrete CXCL12 and MIF upon activation. Platelet-derived CXCL12 mediates the migration and differentiation of progenitor cells (PC) into an endothelial phenotype (endothelial progenitor cell, EPC) to promote vascular repair or regeneration (**a**) and also supports the migration of inflammatory monocytic cells (M). Monocytes phagocytose activated platelets and CXCL12 present in the immediate microenvironment supports their differentiation into foam cells. This contributes to vascular inflammation and injury (**c**). Platelets bind lipids like LDL and OxLDL in circulation through scavenger receptors. Lipid-loaded activated platelets adhere to the endothelium and release chemotactic factors like CXCL12 and MIF. Monocytes migrate towards CXCL12 and MIF. These infiltrated monocytes phagocytose lipid-laden apoptotic platelets and subsequently migrate into the intima of the vessel wall where they differentiate into macrophages and foam cells (**b**). Thus platelet–lipoprotein interaction (**b**) and platelet-derived factors can decide the balance of vascular regeneration (**a**) versus vascular inflammation and atheroprogression (**b–c**)

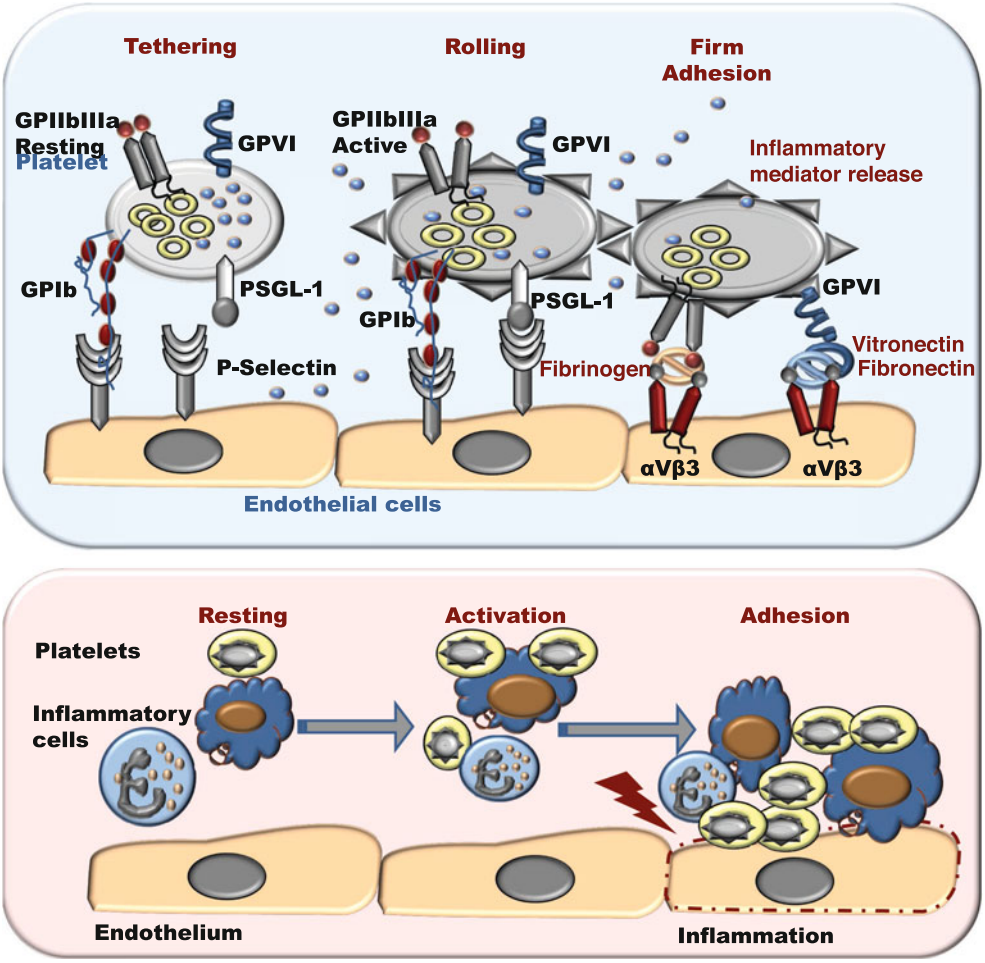

Fig. 3 Platelet interaction with the vascular endothelium. Above: Platelet–endothelium adhesion is a multistep process involving several adhesion receptors. Activated endothelium surface expresses P-selectin. Platelet surface receptors GPIbα and PSGL-1 interact with endothelial P-selectin and mediate platelet rolling. Subsequent firm adhesion is mediated through β3 integrins. Below: Platelets recruit inflammatory cells like monocytes and neutrophils. Activated platelets in circulation form co-aggregates with inflammatory cells and foster their subsequent interaction with intact or inflamed endothelial cells and inflame monocytes. Thus, platelet–monocyte interaction provides an atherogenic milieu at the vascular wall that supports plaque formation

The Role of GPIb-IX-V Glycoprotein Ib (GPb) mediates platelet–endothelium adhesion (von Hundelshausen and Weber 2007). Glycoprotein Ib has been identified as counter-receptor for P-selectin (Etingin et al. 1993; Theilmeier et al. 2002). Platelet rolling on the activated endothelium can be inhibited by antibodies against both P-selectin and GPIbα (Frenette et al. 1995, 1998a, b; Massberg et al. 1998). Interactions of selectins with their counter-receptors are characterized by high on- and off-rates, enabling platelets to rapidly attach to the endothelial monolayer with high resistance to shear stress. However, due to their biophysical characteristics, selectin–ligand interactions are not sufficient to promote firm adhesion of platelets in the bloodstream. This implicates that these tighter interactions between platelets and the vascular wall involve the interplay of platelets and endothelial integrins as well as immunoglobulin-like adhesion molecules.

The Role of Integrins In the presence of soluble fibrinogen, $\alpha_{IIb}\beta_3$ mediates heterotypic cell adhesion to $\alpha_v\beta_3$-expressing cells including endothelial cells (Gawaz et al. 1991, 1996, 1997; Bombeli et al. 1998). Moreover, platelets firmly adhere to activated endothelial cells via $\alpha_{IIb}\beta_3$, a mechanism that can be blocked by antagonists of β3-integrins (Gawaz et al. 1997). In vivo, firm platelet adhesion to the endothelium can be inhibited by anti-$\alpha_{IIb}\beta_3$ mAb, and platelets defective in $\alpha_{IIb}\beta_3$ do not firmly adhere to activated endothelial cells (Gawaz et al. 1997).

The Role of Immunoglobulin-Type Receptors The intercellular adhesion molecule-1 (ICAM-1) is surface expressed on the inflamed endothelium and acts as an endothelial fibrinogen receptor, promoting fibrinogen deposition at the inflamed endothelium (Springer 1994). ICAM-1-fibrinogen interactions have been demonstrated to promote cell adhesion to activated endothelial cells (Bombeli et al. 1998). Another immunoglobulin-type platelet receptor GPVI mediates platelet adhesion to immobilized collagen, fibronectin and vitronectin, the matrix proteins which are exposed upon erosion of the inflamed endothelium (Bültmann et al. 2010; Schönberger et al. 2012).

The Role of Platelet Adhesion Receptors in Atheroprogression With the help of appropriate atherosclerotic animal models, it has become evident that platelets

adhere to the arterial wall early in the process of atherosclerosis before atherosclerotic plaques are morphologically detectable (Massberg et al. 2002, 2005; Huo et al. 2003). Bone marrow transplantation experiments demonstrated that mice receiving P-selectin-deficient platelets develop smaller lesions (Burger and Wagner 2003). Even more drastic findings were obtained in a model of wire-induced arterial injury in *P-selectin*$^{-/-}$*Apoe*$^{-/-}$ double knockout mice (Manka et al. 2004). The most striking effects in inhibiting atherosclerosis could be achieved with a combined deficiency of E-selectins and P-selectins, showing 80 % and 40 % protection in the early and advanced stages of the disease (Dong et al. 1998). Another critical adhesion molecule mediating platelet contact with the vascular wall is GPIb-IX, the significance of which is exemplified by the fact that prolonged antibody blockade of platelet GPIbα profoundly reduced leukocyte accumulation in the arterial intima and attenuated atherosclerotic lesion formation (Massberg et al. 2002). The contribution of platelet GPIIb (α_{IIb}) was also validated in atherosclerotic lesion formation in the carotid artery and aortic arch among *GPIIb*$^{+/+}$*Apoe*$^{-/-}$ and *GPIIb*$^{-/-}$*Apoe*$^{-/-}$ mice where the absence of GPIIb attenuated lesion formation at both vascular locations (Massberg et al. 2005). Further, administration of activated platelets and platelet–leukocyte/monocyte aggregates in *Apoe*$^{-/-}$ mice promote formation of atherosclerotic lesions (Huo et al. 2003). In *Apoe*$^{-/-}$ mice, platelet adhesion to atherosclerotic arteries was significantly inhibited by i.v. injection of soluble GPVI-Fc (Schulz et al. 2008; Schonberger et al. 2008; Ungerer et al. 2013). Long-term administration of an anti-GPVI antibody attenuates atherosclerosis in *Apoe*$^{-/-}$ mice (Schulz et al. 2008). Further, gene transfer of GPVI-Fc to the carotid vascular wall significantly attenuates atheroprogression and endothelial dysfunction in atherosclerotic rabbits in vivo (Bültmann et al. 2010). Inhibition of GPVI both via GPVI-Fc and anti-GPVI antibodies results in protection against atherosclerosis in both cholesterol-fed rabbits and *Apoe*$^{-/-}$ mice (Bültmann et al. 2010).

Platelet Interaction with Leukocytes

Activated platelets promote leukocyte arrest on the vascular endothelium, which is a key process of vascular inflammation during the progression of atherosclerosis (Lusis 2000; Libby et al. 2011). The interaction of platelets with leukocytes has been extensively described (Zarbock et al. 2007). Briefly, platelets physically interact with leukocytes (Rinder et al. 1991; Gawaz et al. 1994; Ott et al. 1996; May et al. 1997) and EPCs (Stellos et al. 2013). Platelet–leukocyte coaggregation can foster adhesion to the intact arterial wall. This interaction can occur in variable sequences: first, platelets can coaggregate with leukocytes in circulation and thereby support leukocyte recruitment to the endothelium by activating leukocyte adhesion receptors or by directly serving as bridging cells. For example, platelet–monocyte co-aggregates can attach to the vascular endothelium by both platelet and endothelium or by monocyte–endothelium contacts. Second, when adhered to the endothelium, platelets can chemoattract leukocytes and then provide a surface for their adhesion to the vascular wall. During these interactions involving platelets, leukocytes and the endothelium, all cell types involved become activated in a cascade-like manner (Fig. 3). Upon adhesion, platelets rapidly translocate P-selectin from α-granules to the plasma membrane. This allows leukocytes to tether to platelets via PSGL-1/P-selectin interaction. Subsequently, monocytes or polymorphonuclear cells firmly adhere to platelets in a Mac-1-dependent (CD11b/CD18, αMβ2) manner (Chavakis et al. 2003). On platelets, various counter-receptors of Mac-1 have been identified: GPIbα (Simon et al. 2000), junctional adhesion molecule-C (JAM-C, JAM-3) (Santoso et al. 2002), CD40L (Zirlik et al. 2007), ICAM-2 (Diacovo et al. 1994) as well as bridging proteins, such as fibrinogen (bound to $\alpha_{IIb}\beta_3$) (Altieri et al. 1988) or high-molecular-weight kininogen (Chavakis et al. 2003). However, the exact contribution of each receptor system awaits clarification. During this adhesive process, receptor engagement of PSGL-1 and Mac-1, together with platelet-derived inflammatory mediators, induces complex activation cascades in monocytes (Neumann et al. 1997; McEver and Cummings 1997; Weyrich et al. 1996) including NFkB activation and thereby promotes monocyte or neutrophil adhesion (by upregulation and activation of Mac-1 and VLA-4), thrombosis (mediated through monocyte secretion of tissue factor), monocytic chemokine and cytokine release (IL-1β, IL-8, MCP-1, TNF-α) (Neumann et al. 1997; McEver and Cummings 1997; Weyrich et al. 1996; Celi et al. 1994) or the oxidative burst of neutrophils (Zarbock et al. 2007). In addition, engagement of PSGL-1 by P-selectin also drives translationally regulated expression of proteins, such as the urokinase receptor (uPAR), a critical surface protease receptor and regulator of integrin-mediated leukocyte adhesion (May et al. 1998) in vivo. Additional adhesion receptor pairs also appear to be involved to induce vascular inflammation. For example, we have recently identified the extracellular matrix metalloproteinase (MMP) inducer (EMMPRIN, CD147) as a monocyte receptor that induces MMP-9 synthesis and secretion on cellular interactions (Schmidt et al. 2006; Lindemann et al. 2007). Thus multifaceted heterotypic platelet–endothelial cell, platelet inflammatory cell or progenitor cell interactions allow transcellular communication via soluble mediators inflicting pro-inflammatory damage to the vascular endothelium and subsequently recruit inflammatory cells to the site of atheroprogression (Fig. 4).

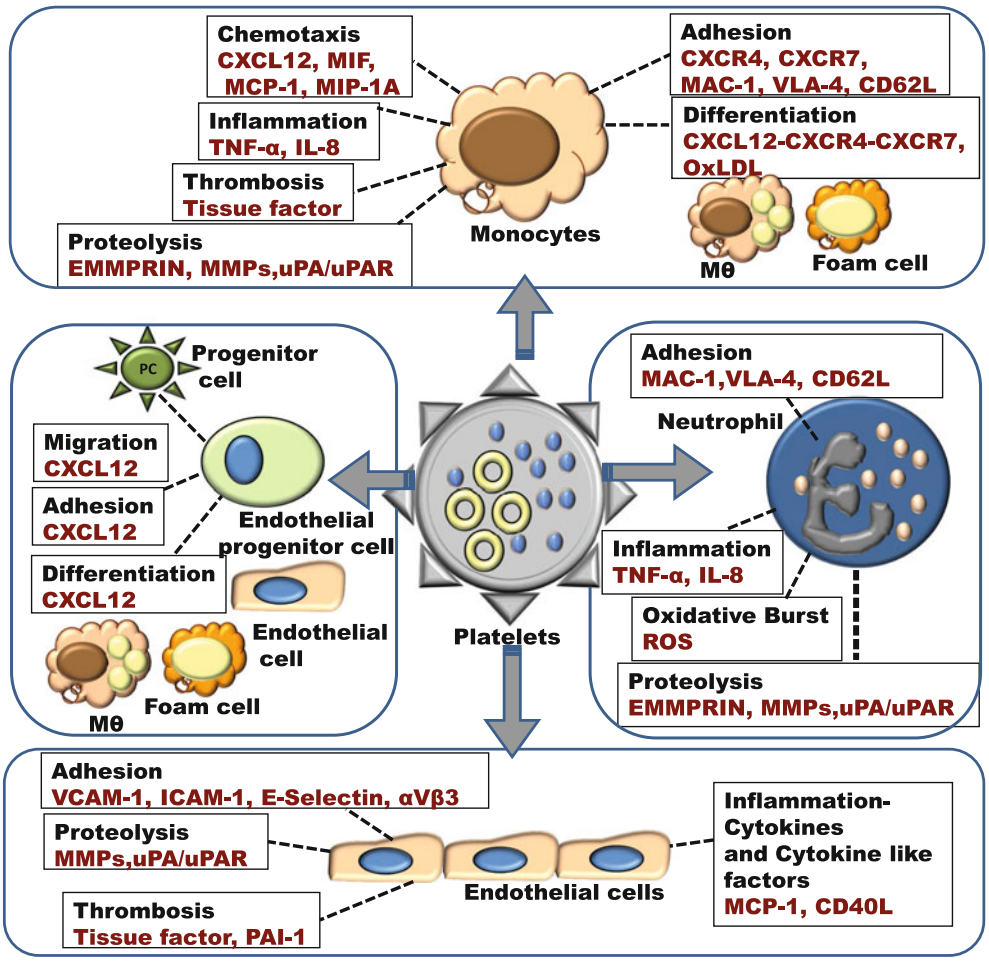

Fig. 4 Platelets have the ability to modulate atherothrombosis via interaction with other vascular cells. Adherent platelets inflame ECs. By adhesion to endothelial cells, platelets induce release of chemoattractants, upregulation of endothelial adhesion molecules and secretion of metalloproteinases. This is mediated by interference with the IκB and NF-κB pathway in ECs. Distinct receptor–ligand pairs mediate the interaction of platelets with endothelial cells involving $\alpha_{IIb}\beta_3$ induces platelet surface exposure of P-selectin (CD62P) and release of CD40L and IL-1β, which stimulate ECs to provide an inflammatory milieu that supports proatherogenic alterations of the endothelium. Platelet adhesion thereby contributes to atheroprogression, a process that involves complex and interacting steps, diverse cell types and mediators. Adherent platelets recruit and inflame monocytes. Adherent and/or activated platelets mainly interact with monocytic PSGL-1 via P-selectin and with monocytic Mac-1 (αMβ2) via $\alpha_{IIb}\beta_3$ (and fibrinogen bridging) or GPIbα. Thereby, platelets initiate monocyte secretion of chemokines, cytokines and procoagulatory tissue factor, upregulate and activate adhesion receptors and proteases and induce monocyte differentiation into macrophages. Thus, platelet–monocyte interaction provides an atherogenic milieu at the vascular wall that supports plaque formation. On the other hand, platelets serve as a bridging mechanism for circulating endothelial progenitor cells and can contribute to atheroprogression and vascular regeneration. Platelet derived inflammatory substances like CXCL12 along with potent adhesion molecules for circulating cells; platelets are capable of recruiting circulating endothelial progenitor cells (EPCs). Depending on the surrounding microenvironment, pro-atherogenic (for instance, the development of foam cells) or vascular reparatory mechanisms (differentiation of progenitor cells towards mature endothelial cells) can be promoted by interaction of platelets with progenitor cells

Platelet-Derived Inflammatory Mediators

Platelet–endothelium interaction occurs in the macro- and microcirculation of inflamed tissue and during reperfusion of ischaemic organs. Platelets adhere to the intact or inflamed endothelium or exposed sub-endothelial matrix components and release pro-inflammatory and mitogenic mediators including cytokines, chemokines and DAMPs that alter physiological characteristics of the vascular endothelium and either prompt tissue (Stellos and Gawaz 2007a, b) restoration or inflict vascular injury (Gawaz and Vogel 2013; Lindemann et al. 2007; Langer et al. 2007) (Fig. 2). Proteomic analysis of platelets has identified more than 300 inflammatory mediators including growth factors, chemokines, cytokines and angiogenic compounds that are released into the microenvironment of accumulating platelets (Maynard et al. 2007). Most of these inflammatory

mediators have been evaluated for paracrine cell function and are potent chemotactic compounds for monocytes. Some of the platelet-derived inflammatory mediators have been also shown to promote and modulate platelet function (*autocrine loop*) (Fig. 5). Atherosclerotic plaques are rich in chemokines including RANTES (Gear et al. 2001). Platelet-derived PF4 and RANTES immobilized on endothelial cells induce monocyte arrest on the activated microvascular or aortic endothelium (von Hundelshausen et al. 2005), promote survival of emigrated monocytes and their differentiation into macrophages (Scheuerer et al. 2000). Atherosclerotic plaque is enriched with CXCL12 deposited from adherent platelets, and a counter-regulation between CXCL12-driven domiciliation of endothelial progenitors (Massberg et al. 2006; Stellos et al. 2008) and PF4–RANTES-triggered recruitment of monocytes (Scheuerer et al. 2000) might influence the outcome of vascular regeneration as opposed to atheroprogression. Other CXC chemokines like fractalkine (Schäfer et al. 2004) and CXCL16 (Borst et al. 2012; Seizer et al. 2011) can heighten atherothrombosis by prompting platelet activation, degranulation and adhesion at sites of atherosclerotic developments. Evidently, fractalkine and CXCL12 are upregulated in neointimal SMCs, which become luminally exposed after arterial denudation (Scheuerer et al. 2000), whereby platelet activation under the pro-inflammatory influence of SMCs might inflict further vascular damage. This part of the chapter summarizes the celebrated platelet-derived accomplices in atheroprogression and particularly highlights the recently unravelled contribution of MIF, CXCL12, CXCL16, HMGB1 and CyPA which have emerged as new molecular targets.

Cytokines Platelet activation results in the release of interleukin-1 (IL-1β) and CD40 ligand (CD40L) (Gawaz et al. 2000; Henn et al. 1998). Activated platelets rapidly synthesize IL-1β via an extranuclear polysomal translation mechanism (Lindemann et al. 2001). Platelet–IL1β induces activation of human endothelial cells and smooth muscle cells and augments neutrophil adhesion (Gawaz et al. 2002; Massberg et al. 2003). CD40L, which belongs to the TNF family is cleaved and released from activated platelets (Henn et al. 1998). Platelet–CD40L induces synthesis and secretion of chemokines, adhesion molecules and metalloproteinases in endothelial cells and promotes neutrophil adhesion. Engagement of $\alpha_{IIb}\beta_3$ on platelets upregulates CD40L and triggers CD40L-dependent matrix degradation by endothelial cells (May et al. 2002). Administration of activated wild-type platelets but not CD40L-deficient platelets stimulates atherosclerotic lesion formation (Lievens et al. 2010).

Macrophage Migration Inhibitory Factor (MIF) MIF is an inflammatory cytokine with chemokine-like functions that plays a role in atherosclerosis (Morand et al. 2006; Bernhagen et al. 2007; Strüßmann et al. 2013). Expression of the pleiotropic inflammatory mediator is enhanced and intricately

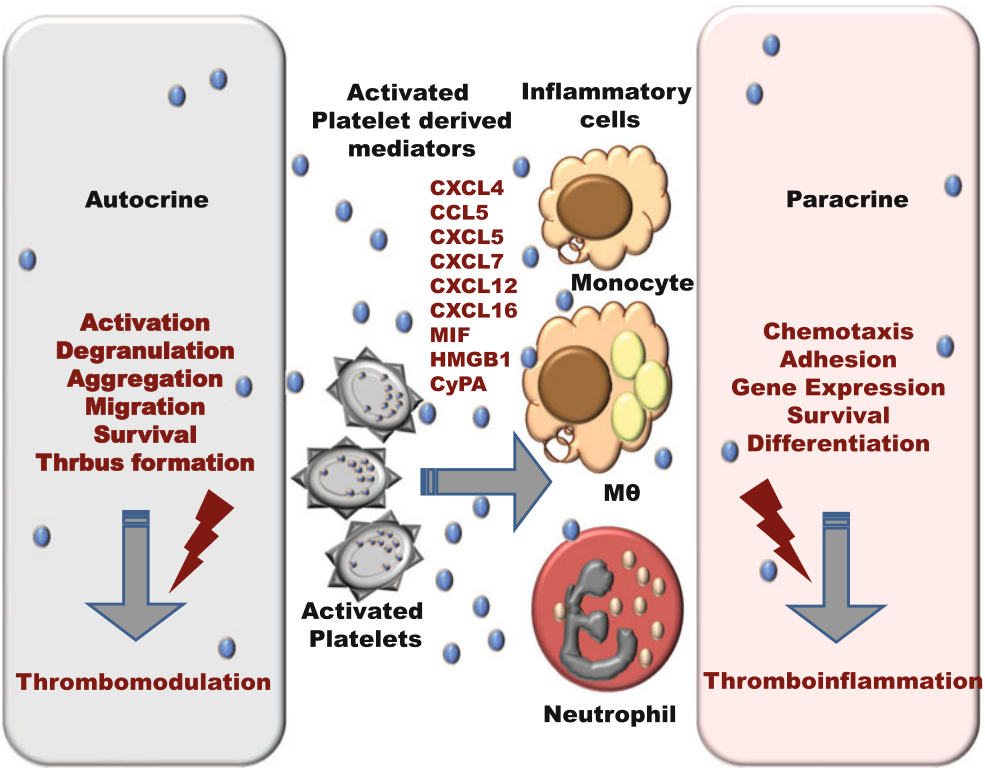

Fig. 5 Autocrine and paracrine effects of platelet-derived factors influence thrombomodulation and thromboinflammation. Platelet-derived inflammatory mediators play a critical role for thromboinflammation (paracrine) and thrombomodulation (autocrine), important mechanisms involved in vascular inflammation and atherosclerosis. Autocrine effects of platelet-derived CCL5, CXCL4, CXCL7, CXCL12, CXCL16, MIF, HMGB1 and extracellular CyPA modulate platelet activation, aggregation and thrombotic events, whereas in a paracrine mode of action, they influence chemotactic migration, adhesion, survival, differentiation and other pro-inflammatory attributes of inflammatory leukocytes by regulating expression of pro-inflammatory genes

associated with course of atherosclerotic progression. The therapeutic impact of MIF in atherosclerosis is exemplified by the fact that peripheral MIF depletion in *Apoe*$^{-/-}$ mice reduces atheroprogression (Bernhagen et al. 2007). MIF is a major platelet-derived chemotactic factor with a retarded release kinetics secreted by the nonclassical secretory pathway independent of ER–Golgi network, however results from degranulation of 60 % of total MIF reserve (Strüßmann et al. 2013; Wirtz et al. 2015) following thrombin and GPVI stimulation. MIF shows a diffused granular pattern of intracellular distribution but does not share co-localization with other α-granule constituents like PF4 and VEGF (Strüßmann et al. 2013). The chemotactic capacity of stimulated platelet supernatants is substantiated by MIF, suggesting a role for atherogenic cell recruitment (Strüßmann et al. 2013; Wirtz et al. 2015). The presence of neutralizing anti-MIF antibody significantly reduces the chemotactic potential of thrombin-activated platelet supernatant, whereas chemotactic potential of activated platelet supernatant derived from *mif*$^{-/-}$ mice is drastically reduced (Wirtz et al. 2015). Moreover, endothelial monolayers incubated with supernatants from MIF-enriched thrombin-stimulated platelets show significantly enhanced monocyte adhesion, supporting its potential as a platelet-derived pro-inflammatory mediator (Wirtz et al. 2015). MIF binds to several chemokine receptors including CXCR-2, CXCR-4 and CXCR-7 (Strüßmann et al. 2013; Wirtz et al. 2015; Chatterjee et al. 2014a, b; Alampour-Rajabi et al. 2015). Plasma levels of MIF are enhanced in acute coronary syndrome and associated with the inflammatory response (Müller et al. 2012, 2013, 2014). MIF binds to the DAN–protein gremlin-1, and a complex formation of MIF with gremlin-1 inhibits its chemotactic activity and reduces atheroprogression in *Apoe*$^{-/-}$ mice (Müller et al. 2013). Plasma levels of MIF and gremlin-1 are associated with acuity of coronary artery disease, and the MIF/gremlin-1 ratio might determine the grade of plaque stability in humans (Müller et al. 2014).

Chemokines The CC and CXC chemokines such as CCL5 (RANTES), CXCL4 (PF4), CXCL5 (ENA-78), CXCL7 (β-TG), CXCL12 (SDF-1) and CXCL16 are the most intensively studied platelet-derived chemokines in the context of atherosclerosis. *CCL5 (RANTES)* is highly expressed and stored in platelets (Karshovska et al. 2013). Platelet–CCL5 is deposited on the endothelial monolayer and favours monocyte activation and adhesion (von Hundelshausen et al. 2001). CCL5 forms heteromers with *CXCL4 (PF4)*, and this complex synergistically supports monocyte/endothelium adhesion (Koenen et al. 2009). Administration of activated platelets in *Apoe*$^{-/-}$ mice enhances CCL5/CXCL4 deposition on the arterial wall and promotes atheroprogression via P-selectin (Huo et al. 2003). Plasma levels of CXCL5 and CXCL7 are increased in *Apoe*$^{-/-}$ mice (Rousselle et al. 2013). *CXCL5* enhances cholesterol efflux in macrophages and seems to be atheroprotective (Rousselle et al. 2013). *CXCL7* cleavage results in formation of platelet basic protein (PBP), beta-thromboglobulin (β-TG) and CTAPIII; all of these cleaved proteins are not chemotactic. After release those proteins are further activated by N-terminal shortening and promote migration of neutrophils and endothelial progenitor cells. *CXCL12 (SDF-1)* is stored in α-granules (Chatterjee et al. 2011) and gets surface expressed and released upon activation (Massberg et al. 2006; Stellos et al. 2008). Platelet–CXCL12 expression is increased in patients with myocardial infarction and correlates with circulating progenitor cells (Stellos et al. 2009). Platelet–CXCL12 and platelet surface expression of CXCR4–CXCR7 is associated with prognosis and recovery of myocardial function in patients with acute coronary syndromes (Geisler et al. 2012; Wurster et al. 2013; Rath et al. 2014, 2015). CXCL12 is a key mediator of regenerative mechanisms and regulates homing and trafficking of EPCs towards vascular and tissue lesions. Platelet–CXCL12 enhances neovascularization by mobilization of CXCR4^{+} cells in the mice hind limp ischaemia model (Jin et al. 2006) indicating recruitment of bone marrow-derived progenitors to support vascular repair. Platelet–CXCL12 interacts with CXCR4-positive EPCs and stimulates adhesion and endothelial differentiation. Systemic application of CXCL12 promotes mobilization of smooth muscle progenitor cells and accumulation in vascular lesions resulting in a stable plaque phenotype in *Apoe*$^{-/-}$ mice (Akhtar et al. 2013). Further, recombinant SDF1–GPVI triggers chemotaxis of CXCR4+ cells, preserves cell survival, enhances endothelial differentiation of BMCs in vitro and reveals proangiogenic effects. In a mouse model of myocardial infarction, administration of the bifunctional recombinant protein SDF1–GPVI leads to enhanced recruitment of BMCs, increases capillary density, reduces infarct size and preserves cardiac function (Ziegler et al. 2012). Thus, platelet–CXCL12 may be an atheroprotective chemokine which needs to be further explored. **CXCL16** is a multifaceted chemokine. Membrane-associated CXCL16/PS-OX is an OxLDL scavenger receptor which facilitates OxLDL binding to activated platelets, in its solubilized form exerts a stimulatory effect on their haemostatic and thrombotic attributes and also mediates inflammatory associations with the endothelium and eryptotic erythrocytes to corroborate atheroprogressive complications. Platelet–CXCL16 surface expression is further enhanced upon activation, and in ACS patients as compared to SAP, shows positive correlation with plasma C-reactive protein and markers of myocardial necrosis (Borst et al. 2012; Seizer et al. 2011). Recent results of a population-based HUNT2 cohort in Norway indicate that high levels of soluble CXCL16 is associated with risk of MI in healthy subjects (Laugsand et al. 2015). CXCL16 is detected in the human carotid atherosclerotic lesions from complex carotid endarterectomy specimens, sequesters circulating platelets through CXCR6 engagement and supports vWF-mediated platelet associations (Meyer Dos Santos et al. 2015). Moreover, high CXCL16 expression is

observed in the endothelium in close proximity to mural thrombus enriched in vWF and platelet GPIbα (Meyer Dos Santos et al. 2015). CXCL16 supplementation also supports platelet adhesion to the injured carotid artery in vivo (Borst et al. 2012). Platelets also release CXCL16 following PAR-1 activation by TRAP and therefore could contribute to CXCL16 plasma levels (Seizer et al. 2011). Moreover, since activated platelets release CXCL16 (Seizer et al. 2011), they might be an enriched source of circulatory CXCL16 levels among ACS patients, which serves as a peripheral biomarker and is associated with long-term motility. *CXCL16*$^{-/-}$ mice show decreased cholesterol efflux and attenuated atheroprogression. The role of platelet–CXCL16 however remains unclear and megakaryocyte–platelet-lineage-specific *CXCL16*$^{-/-}$ needs to be developed.

DAMPs Damage-associated molecular pattern molecules (DAMPs) are a heterogeneous group of nuclear or cytosolic host proteins that can initiate and perpetuate a noninfectious inflammatory response. DAMPs are released or exposed on the cell surface following tissue injury. Recently, two DAMPs have been recognized in platelets which contribute to regulation of thromboinflammatory events, namely, cyclophilin A (CypA) (Coppinger et al. 2004; Seizer et al. 2014, 2015; Elvers et al. 2012) and high-mobility group box 1 (HMGB1) (Rouhiainen et al. 2000; Ahrens et al. 2015; Vogel et al. 2014, 2015a, b). Platelet-bound CypA is enhanced in stable CAD patients, and its surface expression is associated with hypertension and hypercholesterolemia (Seizer et al. 2015). In patients with acute myocardial infarction (AMI), platelet-bound CyPA is significantly decreased (Seizer et al. 2015). CyPA stimulates vascular smooth muscle cell migration and proliferation, endothelial cell adhesion molecule expression and inflammatory cell chemotaxis (Seizer et al. 2015). *Apoe*$^{-/-}$ mice develop more severe atherosclerosis compared with *Apoe*$^{-/-}$/*CypA*$^{-/-}$ mice (Nigro et al. 2011). Platelets are a recently recognized source of high-mobility group box 1 (HMGB1) (Rouhiainen et al. 2000; Ahrens et al. 2015; Vogel et al. 2014, 2015a, b), the circulatory levels of which are elevated in multiple inflammatory diseases (de Souza et al. 2012). Platelets express HMGB1, which is translocated towards surface following activation and subsequently released (Rouhiainen et al. 2000; Ahrens et al. 2015; Vogel et al. 2014, 2015a, b). HMGB1 expression is increased in macrophages and SMCs at atherosclerotic lesions and is implicated in the progression of plaque (de Souza et al. 2012). The contribution of platelet-derived HMGB1 to influence infiltration of inflammatory cells during atheroprogression remains to be seen. Activated platelets interfere with recruitment of mesenchymal stem cells to apoptotic cardiac cells via HMGB1/TLR-4-mediated downregulation of hepatocyte growth factor receptor MET (Vogel et al. 2014). Recently, using a platelet-specific *Pf4-cre-HMGB1*$^{-/-}$ transgenic mice, we have identified platelet-derived HMGB1 as a critical mediator of thrombosis and inflammation in vivo (Vogel et al. 2015a, b). HMGB1 regulates microvascular endothelial inflammation (Fiuza et al. 2003) and leukocyte recruitment (Venereau et al. 2013); platelet-derived HMGB1 instigates neutrophil extracellular trap (NET) formation (Maugeri et al. 2014) and thrombosis (Vogel et al. 2015a, b) suggesting probable inflammatory potential of platelet-derived HMGB1 in linking atheroprogression and atherothrombosis. These evidences encourage further investigations to validate the potential of platelet-derived HMGB1 in influencing the cellular composition of atherosclerotic plaque and thereby its immunogenicity and vulnerability. HMGB1 is highly expressed in platelet-rich human coronary artery thrombi (Ahrens et al. 2015) pointing towards a central role for HMGB1 in atherothrombosis, also suggesting the therapeutic potential of platelet-targeted anti-inflammatory therapeutic strategies for CAD patients.

Platelet-derived HMGB1 might confer heterotypic plaque cellularity rendering them vulnerable, which combined with a pro-thrombotic disposition is an active accomplice in atherothrombosis and subsequent ischaemic events.

Regulation of Platelet Function and Thrombosis by Platelet-Derived Inflammatory Mediators

Upon release platelet-derived compounds can mediate both paracrine and autocrine effects (Fig. 5). Whereas the role of platelet-derived inflammatory mediators for paracrine actions and tissue inflammation has been extensively investigated, the autocrine effects of these molecules on platelet function are far less understood. Platelets express several chemokine receptors like CXCR-4, CXCR-6, CXCR-7 which render them susceptible to autocrine modulation imposed by factors such as CXCL12, CXCL16 and MIF (Chatterjee et al. 2015a, b). Further, platelets express receptors for CypA and HMGB1 (e.g. EMMPRIN, RAGE, TLR4) that significantly modulate platelet functions (Fig. 6). **CXCL12** substantiates platelet aggregation and thrombosis (Abi-Younes et al. 2000; Walsh et al. 2014; Kowalska et al. 2000; Gear et al. 2001; Shenkman et al. 2004). CXCL12 enhances platelet activation through Gαi-coupled CXCR4 (Abi-Younes et al. 2000; Walsh et al. 2014; Kowalska et al. 2000; Gear et al. 2001; Shenkman et al. 2004), antagonizes adenylate cyclase activity and counteracts PGI_2 analogue-induced cAMP levels (Walsh et al. 2014) and further substantiates granular release, PLC activation triggering aggregation. CXCL12–CXCR4-induced primary phase of aggregation occurs through PI3K, whereas the secondary wave involves engagement of downstream tyrosine kinases

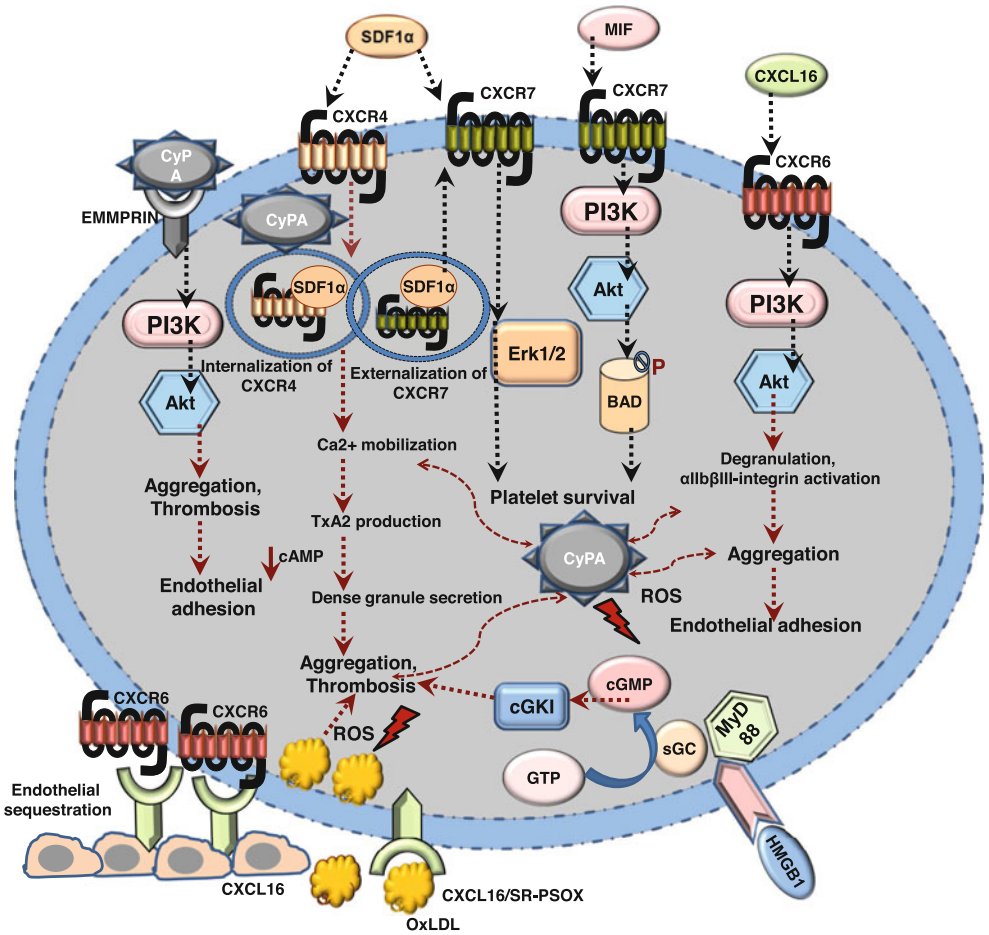

Fig. 6 New platelet-derived mediators in the context of atherothrombosis and atherosclerosis. CXCL12 through CXCR4 ligation substantiates platelet activation, aggregation and thrombotic potential. MIF exerts a prosurvival effect through CXCR7 and downstream activation of the PI3K–Akt pathway culminating in phosphorylation-mediated inactivation of pro-apoptotic protein BAD. The membrane-associated form of CXCL16/SR-PS-OX functions as a scavenger receptor facilitates OxLDL binding and sequesters CXCR6+ platelets from circulation to CXCL16-expressing endothelial cells at atherosclerotic sites. Soluble CXCL16 acts through CXCR6–PI3K–Akt pathway to promote degranulation, cytoskeletal reorganization and shape change, $\alpha_{IIb}\beta_{III}$-integrin activation and adhesion to endothelial layer. Intracellular cyclophilin A (CyPA) is involved in bidirectional trafficking of CXCR4–CXCR7 and extracellular CyPA acting through EMMPRIN engagement regulates aggregation, thrombotic potential of platelets. HMGB1 enhances platelet activation, dense and α-granule secretion, aggregatory response to GPVI stimulation and thrombus formation. HMGB1 exerts its effects through TLR4, myeloid differentiation factor 88-dependent (MyD88), recruitment of guanylyl cyclase (GC) towards platelet membrane and subsequent activation of cGMP-dependent protein kinase I (cGKI) in platelets

and prostanoids to achieve maximal irreversible aggregation and degranulation. CXCL12 co-stimulates aggregation induced by sub-threshold concentrations of agonists under arterial and lower shear conditions (Abi-Younes et al. 2000; Walsh et al. 2014; Kowalska et al. 2000; Gear et al. 2001; Shenkman et al. 2004) and exhibits selective synergistic aggregatory response with serotonin (5HT) but not epinephrine (Abi-Younes et al. 2000; Walsh et al. 2014; Kowalska et al. 2000; Gear et al. 2001; Shenkman et al. 2004). Chemokines are capable of heterophilic interactions exerting synergistic or antagonizing effects. RANTES noncompetitively reduces the stimulatory effect of CXCL12 on aggregation and adhesion to endothelial monolayers under venous flow conditions (Shenkman et al. 2004). Mature platelets also exhibit transmigration through endothelial layer towards CXCL12, mediated through CXCR4–Gαi–PI3K pathway which triggers platelet activation (Kraemer et al. 2010, 2011). Platelets preferentially accumulate at areas with high CXCL12 under flow conditions and exhibit flow-directed migration (Kraemer et al. 2010, 2011).

The receptors of CXCL12, CXCR4 and CXCR7 are constitutively expressed in platelets at transcript and protein levels. The relative surface expression of CXCR4 appears to be much higher than that of CXCR7 at resting state (Chatterjee et al. 2014b). Surface expression of CXCR4–CXCR7 exhibits a unique dynamism in the presence of their ligands, CXCL12 (Chatterjee et al. 2014b) and MIF (Chatterjee et al. 2014a) which influences their relative abundance on platelet surface,

thereby their frequency of participation in effector functions. CXCR4 is internalized by CXCL12 and MIF, while CXCR7 is preferentially externalized in response to CXCL12 but not MIF (Chatterjee et al. 2014b). CXCL12 induced bidirectional trafficking of CXCR4, and CXCR7 is a coupled process executed through the downstream signalling intermediates like Erk1/2 and the PPIase activity of intracellular molecular chaperone CyPA culminating in ubiquitination-driven externalization of CXCR7 (Chatterjee et al. 2014b). However, chemokine-induced receptor trafficking in platelets is a comparatively new idea and warrants further investigations in targeted pathophysiologies where platelet responsiveness and their inflammatory potential are altered. Moreover, CXCL12-executed effects on receptor trafficking can be influenced by the presence of other factors in the immediate microenvironment having differential binding affinities towards their cognate receptors (Chatterjee et al. 2014b). CXCL12 binds to CXCR4 on platelet surface with approximately 2000 sites/platelet and an affinity of 24 nmol/L but shares CXCR4 with MIF. Once released MIF can engage CXCR4 and CXCR7, while CXCR2 surface expression is relatively low and CD74 is absent on platelets. MIF ligates but does not influence CXCR7 availability on platelets. This discrepancy with CXCL12 is attributed to the absence of CD74 (which acts as a co-receptor for MIF–CXCR4 axis) and, therefore, lack of Erk1/2 activation downstream of CXCR4–MIF ligation, which is essential for CXCR7 externalization (Chatterjee et al. 2014a). At CXCL12/MIF-enriched atherosclerotic plaques, this dynamic receptor trafficking could influence relative CXCR4–CXCR7 availability with major functional implications. Both CXCL12 and MIF are ligands for the chemokine receptors CXCR4 and CXCR7 (Chatterjee et al. 2014a, b; Alampour-Rajabi et al. 2015). Unlike CXCL12, MIF does not seem to modulate platelet activation, degranulation or prompt release of chemokines (CXCL4, CXCL12) either alone or in combination with other agonists (Strüßmann et al. 2013; Wirtz et al. 2015). MIF does not amend aggregation by itself or that elicited by ADP and TxA2 analogue or influence integrin activation and spreading over fibrinogen (Strüßmann et al. 2013; Wirtz et al. 2015). MIF, unlike CXCL12, is unable to mobilize intracellular calcium pools in TxA2 receptor presensitized platelets; however, both CXCL12 and MIF significantly block/desensitize increases in calcium transient in response to ADP (Strüßmann et al. 2013; Wirtz et al. 2015). Thus, CXCL12 and MIF although sharing receptors show distinct effects on platelet functionality, possibly executed through distinct intracellular signalling cascades. However, MIF, like CXCL12, as a survival factor, rescues platelets from activation and BH3-mimetic induced apoptosis through CXCR7 engagement (Chatterjee et al. 2014a). The MIF–CXCR7-triggered anti-apoptotic effect is mediated through the PI3K–Akt pathway which culminates in phosphorylation-induced inactivation of pro-apoptotic effector BAD. CXCL12-induced surface availability of CXCR7 can mediate subsequent prosurvival benefits of both CXCR12 and MIF (Chatterjee et al. 2014a). Unlike CXCL12, as a prosurvival agent, MIF attenuates pro-thrombotic phosphatidylserine exposure on platelet surface, whereby MIF–CXCR7 also exerts an antithrombotic effect (Chatterjee et al. 2014a). Thus, current experimental evidence points towards a functional preference in executing haemostatic and thrombotic functions through CXCR4 (by CXCL12), while supports platelet survival through CXCR7 (by CXCL12 and MIF).

CXCL16/SR-PS-OX is a transmembrane chemokine which is cleaved and shedded from the plasma membrane via ADAM10 (Seizer et al. 2011). Soluble CXCL16 chiefly functions as a chemokine for inflammatory cells through CXCR6/BONZO (Borst et al. 2012). CXCL16 can induce platelet degranulation, $\alpha_{IIb}\beta_{III}$-integrin activation, cytoskeletal reorganization and shape change and adhesion to the endothelium under arterial flow conditions in vitro. CXCL16 enhances aggregatory response to sub-threshold ADP concentrations and fibrinogen (Borst et al. 2012). CXCL16 effects mediated through CXCR6 lead to downstream activation of PI3K–Akt pathway and are therefore significantly abrogated in $CXCR6^{-/-}$ and $Akt^{-/-}$ mice (Borst et al. 2012) and following pharmacological inhibition of the PI3K–Akt pathway. Moreover, CXCL16-triggered platelet activation is diminished in the presence of apyrase and purinergic P_2Y_1 and P_2Y_{12} receptor antagonists suggesting a feedback loop mediated through ADP (Borst et al. 2012). Immobilized or microsphere-bound CXCL16, resembling membrane-tethered version of the chemokine, enhances intracellular calcium mobilization and integrin activation, degranulation and aggregation responses to ADP (Borst et al. 2012; Meyer Dos Santos et al. 2015). Therefore, CXCL16 both as a soluble mediator and membrane-associated form can modulate activation and haemostatic functions of platelets.

The DAMP protein CyPA is an abundantly expressed intracellular protein which executes a variety of functions due to its PPIase activity. Intracellular CyPA participates in the bidirectional CXCR4–CXCR7 trafficking (Chatterjee et al. 2014b), whereas extracellular CyPA functions as a redox–stress-sensitive pro-inflammatory cytokine that contributes to atherosclerosis, cardiac hypertrophy myocardial infarction and myocarditis (Seizer et al. 2014). Intracellular CyPA also influences thrombotic and haemostatic functions (Elvers et al. 2012). $Cypa^{-/-}$ mice have prolonged bleeding time; exhibit impaired platelet degranulation, spreading, cytoskeleton reorganization, shape change and aggregation; and show attenuated thrombus formation despite comparable platelet counts and lack of severe haematologic abnormalities (Elvers et al. 2012). Therefore CyPA exerts dual effects in regulating platelet

function: it regulates Ca^{2+} signalling, and when released into the extracellular space, CyPA binds to its extracellular receptor CD147 (EMMPRIN) and thereby initiates a cascade of inflammatory processes. CyPA has been identified in the proteomic analysis of activated platelet releasate as one of >300 proteins, also detected at atherosclerotic plaques where platelets accumulate (Coppinger et al. 2004). Extracellular CyPA activates platelets via CD147/EMMPRIN-mediated PI3K–Akt, leading to enhanced platelet adhesion and thrombus formation in vitro even among *Cypa*$^{-/-}$ mice, independent of intracellular CyPA (Seizer et al. 2015). Thus platelet-derived CyPA is a potential therapeutic target in inflammatory cardiovascular ailments.

Another platelet–DAMP protein is HMGB1. Extracellular HMGB1 enhances platelet activation, dense and α-granule secretion, aggregatory response to GPVI stimulation, adhesion and spreading (Vogel et al. 2015a, b). Collectively, these functional modulations drive a pro-thrombotic disposition. HMGB1 exerts its effects through TLR4, myeloid differentiation factor 88-dependent (MyD88) recruitment of guanylyl cyclase (GC) towards platelet membrane and subsequent activation of cGMP-dependent protein kinase I (cGKI) in platelets. With platelets and pro-thrombotic aspects of HMGB1 come to light, the pathophysiological implication of platelet-derived HMGB1 needs to be evaluated in atherosclerosis (Vogel et al. 2015a, b).

In summary, platelet-derived inflammatory mediators play a critical role for thromboinflammation (paracrine) and thrombomodulation (autocrine), important mechanisms involved in vascular inflammation and atherosclerosis.

Effect of Low-Density Lipoproteins on Platelet Function

Lipoproteins are fundamental 'players' in atherogenesis since they change the properties of different cells involved in atherosclerosis and thrombosis. Low-density lipoproteins (LDL) and its oxidized form bind to the platelet surface via scavenger receptors SR-B, CD36, LOX-1 or CXCL16 (Siegel-Axel et al. 2008). Both oxLDL and LDL activate platelets and induce thrombus formation (Siegel-Axel et al. 2008). Platelets uptake and store both oxLDL and LDL in significant amounts in dense granules (Daub et al. 2007). Lipid-laden platelets are phagocytosed by macrophages (Daub et al. 2006) and induce foam cell development from monocytes and $CD34^+$ progenitor cells (Daub et al. 2006). The soluble scavenger receptor CD68 inhibits platelet-dependent foam cell generation in vitro (Daub et al. 2010) and atheroprogression in *Apoe*$^{-/-}$ mice (Zeibig et al. 2011). Further, oxLDL-laden platelets activate the endothelium, and the number of $CD34^+$ progenitor cells (colony-forming units), which would otherwise transform into endothelial cells, is significantly reduced in the presence of oxLDL loaded–platelets (Daub et al. 2007; Lindemann et al. 2007). Patients with ACS show significantly enhanced oxLDL binding on platelets as compared to patients with stable coronary CAD. Platelet-bound oxLDL positively correlates with the degree of platelet activation and plasma oxLDL levels. Preincubation of isolated platelets with OxLDL, but not with native LDL, results in enhanced platelet adhesion to collagen and activated endothelial cells under high shear stress in vitro, as well as after carotid ligation in *Apoe*$^{-/-}$ and wild-type mice (Stellos et al. 2012). Recently we found that oxLDL uptake by platelets induces platelet apoptosis, like other platelet agonists like thrombin and collagen-related peptide (CRP). CXCL12 facilitates phagocytosis of lipid-laden platelets by monocytes and M1–M2 macrophages and also promotes their differentiation into foam cells via CXCR4 and CXCR7 (Chatterjee et al. 2015a, b). Stimulation of platelets with oxLDL results in the formation of platelet–monocyte aggregates (PMA) and phagocytosis of platelets thereby increases oxLDL uptake by monocytes, dependent on platelet CD36 and CXCL4 release (Badrnya et al. 2014). Thus, platelets have the capacity to store and to transfer significant amounts of oxLDL to sites of atherosclerotic lesions as vehicles, which strengthens the significance of platelets in atherogenesis.

Platelet-Based Theranostics in Atherosclerosis

Apart from inflammatory mediators as highlighted in this chapter and summarized in Table 1, glycoprotein receptors like GPVI offer a platform to regulate platelet responsiveness, thrombotic propensity, inflammatory disposition and immune reactivity particularly in atheroprogression (Fig. 7). Platelet GPVI surface expression is enhanced following acute ischaemic events like myocardial infarction and cerebral stroke, thereby it serves as a biomarker and is associated with poor prognosis (Gawaz et al. 2014). Platelet adhesion to atherosclerotic lesions or ruptured plaques is primarily mediated through GPVI which favours atherothrombosis (Gawaz et al. 2014). Several diagnostic biomarkers have been developed in recent years for evaluation of thromboischaemic coronary and cerebrovascular diseases. These have significantly improved diagnosis and patient care and facilitated individualized risk assessment. A non-invasive platelet-based diagnostic and therapeutic strategy has emerged, which utilizes GPVI for lesion-directed antithrombotic therapy or to counteract atherosclerotic disposition. The objective of this approach is to ameliorate care of patients particularly in the context of cardiocerebrovascular medicine (Gawaz et al. 2014). Conventional imaging modalities to define atherosclerotic vessel disease and luminal stenosis have poor prognostic impact in

Table 1 Platelet-derived mediators contributing to atherosclerosis and atherothrombosis

Platelet-derived inflammatory mediator	Mediator	Receptor	Mechanisms effecting platelet biology	Refs.
Cytokines	Interleukin-1β	IL-1R	Induces activation of human endothelial cells and smooth muscle cells and augments neutrophil adhesion	Gawaz et al. (2000, 2002, 2005), Henn et al. (1998), Koenen et al. (2009), Lievens et al. (2010), Lusis (2000), Magwenzi et al. (2015), Maugeri et al. (2014)

[a]Autocrine effects on platelet functions are defined

predicting subsequent thromboischaemic complications since they are caused by rupture-prone vulnerable plaques (Naghavi et al. 2003) and luminal collagen exposure towards the direction of circulation that are hardly detectable by conventional imaging tools (Langer et al. 2008). The soluble dimeric form of GPVI (GPVI-Fc) exhibits high affinity to collagen (Massberg et al. 2004), competes with platelet GPVI for binding collagen and thereby prevents platelet adhesion onto collagen in vitro and in vivo (Massberg et al. 2004; Schulz et al. 2008; Schonberger et al. 2008). GPVI-Fc binds to collagenous components at the core of human atheromatous plaque (Gawaz et al. 2014; Naghavi et al. 2003; Langer et al. 2008; Massberg et al. 2004; Schulz et al. 2008; Schonberger et al. 2008) and to vascular lesions in mice. Therefore, thrombogenecity of atherosclerotic plaques may be detected by using labelled GPVI. Utilizing ^{124}I-GPVI-Fc and in vivo scintigraphy, a sensitive, non-invasive imaging method to detect thrombogenicity of vascular lesions has been developed (Schonberger et al. 2008; Bigalke et al. 2013). PET imaging reveals an increased uptake of ^{124}I-GPVI-Fc at atherosclerotic lesions in the aortic arch of high-fat diet-fed *Apoe*$^{-/-}$ mice (Bigalke et al. 2013). To allow for clinical translation, ^{64}Cu may be preferred to ^{124}I due to its improved spatial resolution and adequate half-life time for delayed PET studies (Gawaz et al. 2014). Similarly, after systemic administration of GPVI-Fc-FITC, increased signals were recovered from the sites of the injured carotid artery in *Apoe*$^{-/-}$ mice (Wadas et al. 2010; Bigalke et al. 2011). Targeted contrast-enhanced ultrasound (CEU) using target molecules that are conjugated to the surface of microbubble (MB) agents has evolved as a non-invasive imaging technique to evaluate atheroprogression, a method which provides high prospective for early risk stratification. Recently an ultrasound-guided molecular imaging with GPVI-targeted MB (MB_{GPVI}) has been utilized to detect atherosclerotic lesions in mice at the aortic arch and truncus brachiocephalicus (Metzger et al. 2015) following systemic administration of MB_{GPVI}.

GPVI critically influences atherothrombosis. It ensues thrombus growth and stability in a coordinated action with thrombin. Targeting the GPVI axis does not compromise physiological haemostasis, which is mainly ensured by the GPIb–vWF axis (Gawaz et al. 2014). GPVI-Fc owing to its preferential deposition at sites of injured vessels therapeutically blocks GPVI-binding sites on exposed collagen (Fig. 7) at atherosclerotic lesions (Gawaz et al. 2014; 143–145, 149)

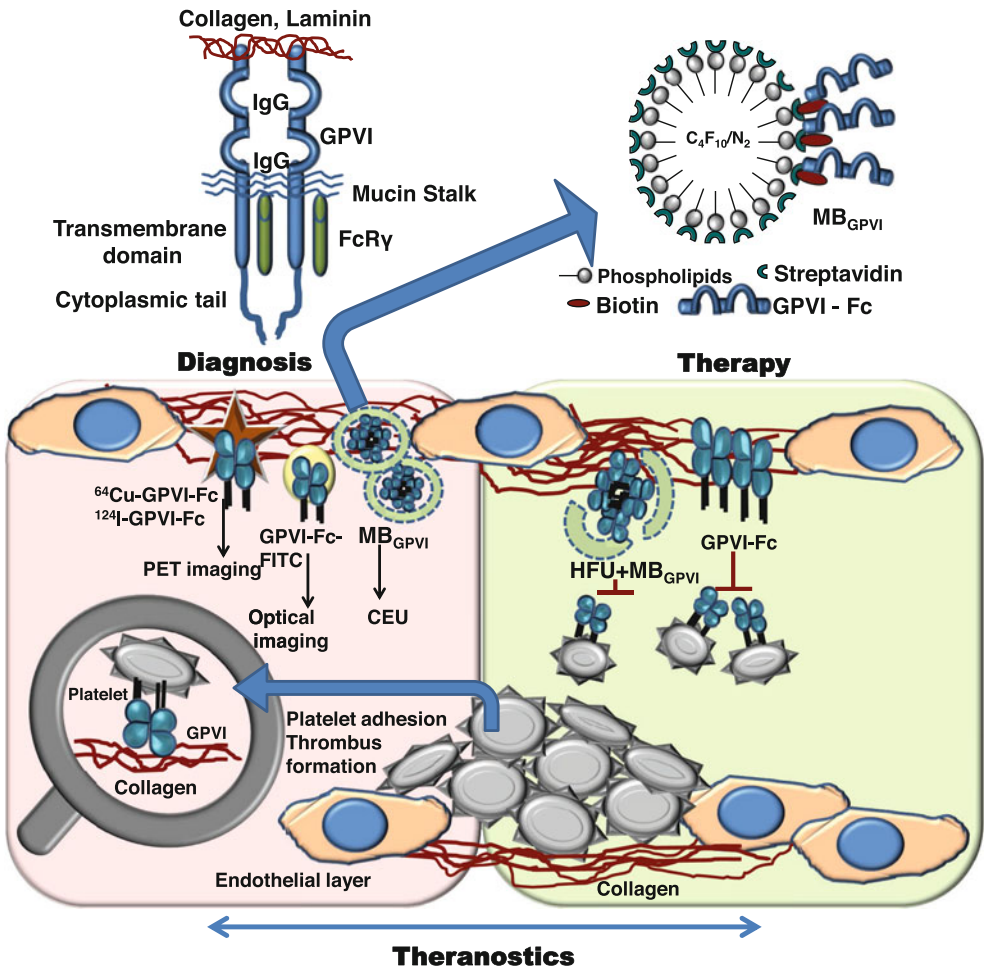

Fig. 7 Platelet theranostics to diagnose and combat atherosclerosis. GPVI is an ~62 kDa protein belonging to the immunoglobulin superfamily. The diagnostic and therapeutic potential of GPVI-based molecules combines to generate GPVI theranostics. Soluble dimeric GPVI-Fc can bind to extracellular matrix collagen in atheromatous plaque. Thrombogenecity of atherosclerotic plaques or non-invasive detection of vascular lesions at risk might be executed by using variously labelled GPVI derivatives like ^{124}I-GPVI-Fc, ^{64}Cu-GPVI-Fc, GPVI-Fc-FITC, GPVI-targeted microbubble agent (MB_{GPVI}) and their subsequent monitoring by PET imaging, optical imaging and contrast-enhanced ultrasound (CEU). Schematic representation of MB_{GPVI} is elaborated in the figure. MB_{GPVI} competes with platelet surface GPVI for binding collagen and attenuates platelet adhesion to immobilized collagen. High-frequency ultrasound (HFU)-guided disruption of MB_{GPVI} enables localized drug delivery at target site, significantly checks atherosclerotic development

and thereby counteracts stable arrest and aggregation of platelets without affecting bleeding times. Further, prolonged administration of GPVI-Fc attenuates atheroprogression (Gawaz et al. 2014) and arterial remodelling after mechanical injury in *Apoe*$^{-/-}$ mice. High-frequency ultrasound (HFU)-guided disruption of MB_{GPVI} injected in *Apoe*$^{-/-}$ mice by rapid ultrasonic 'burst' enhances GPVI accumulation at atherosclerotic lesions, covers the collagen-enriched surface therein, interferes with accumulation of GPIbα-positive platelets, checks lipid-rich plaque formation and exhibits noticeable reduction in plaque area limiting atherosclerotic development (Metzger et al. 2015). Therefore, GPVI-Fc, which ensures targeted delivery appears to be a promising diagnostic and therapeutic agent to combat atherothrombotic and inflammation involving platelet vascular interactions mediated through collagen and GPVI.

Does Uncontrolled Platelet Activation Promote Atherosclerosis in Humans?

There is convincing experimental evidence that platelets are a major driver of atherosclerosis. There are several supportive arguments that platelets initiate atherosclerotic lesions, foster atheroprogression and are critical in development of atherothrombosis leading to acute coronary or cerebrovascular events. Much clinical data has been published that link increased systemic platelet activation and hyperreactivity with poor clinical prognosis and clinical progression of coronary artery disease. Platelet reactivity is influenced by various clinical risk factors including diabetes mellitus, increased body mass index, left ventricular ejection fraction, renal failure, acute coronary syndrome, advanced age and

congestive heart failure (Geisler et al. 2008). Previously, a simple clinical risk score, *R*esidual *P*latelet Aggr*e*gation after *D*eployment of *I*ntra*c*oronary Sten*t* (PREDICT), was developed to identify patients with coronary artery disease at risk for increased platelet reactivity (Geisler et al. 2008; Droppa et al. 2015). The score encompasses different variables including acute coronary syndrome, older age, diabetes mellitus and renal and left ventricular function impairment. After weighing these variables according to their effects size in multivariate analysis, the score ranged from 0 to 9 with higher score levels being significantly associated with both platelet reactivity and cardiovascular outcome. Thus, comorbidity has a major impact on individual responsiveness to antiplatelet drugs. Clinical studies have shown that an increase in activation of circulating platelets is associated with the severity of coronary artery disease and progression of atherosclerosis (Gawaz et al. 2005). Platelet reactivity correlates with coronary plaque burden and calcification as assessed by cardiac computed tomography (Burgstahler et al. 2009). Further, systemic platelet activation is associated with progression of carotid artery disease in patients with diabetes (Fateh-Moghadam et al. 2005) and cardiac transplant vasculopathy (Fateh-Moghadam et al. 2000) within 1 year. Recently, the ADAPT-DES study showed that platelet reactivity is associated with atherosclerotic plaque burden and unstable plaque morphology in patients with coronary artery disease (Wang et al. 2016). In a clinical study, Trip and coworkers showed that spontaneous platelet aggregation in vitro is a useful biologic marker for the prediction of coronary events and mortality in survivors of a myocardial infarction (Trip et al. 1990). A recent systematic review and meta-analysis of individual patient data on major adverse cardiac events (MACE) outcomes (ACS, ischaemic strokes and vascular deaths) in relation to platelet reactivity and its interaction with cardiovascular risk levels were reported (Reny et al. 2015). 6478 patients, out of which 421 who experienced MACE (6.5 %) during a median follow-up of 12 months, were studied. The strength of the association between the risk of MACE and platelet reactivity increased significantly with the number of risk factors present (age $\geq$ 75 years, ACS at inclusion, diabetes and hypertension). Thus, it seems that the level of cardiovascular risk factors determines platelet reactivity and occurrence of MACE.

Currently, targeting cholesterol plasma levels in cardiovascular patients is the cornerstone in secondary prevention of atherosclerosis. To date statins and newly introduced PCSK9 inhibitors are established therapies for clinical progression of atherosclerosis. Besides lipid-lowering strategies, an intensified antiplatelet therapy is critical in treatment of patients with advanced atherosclerosis. Several oral antiplatelet drugs such as aspirin, $P2Y_{12}$ inhibitors (clopidogrel, prasugrel, ticagrelor) or PAR-1 antagonists (vorapaxar) as mono- or combination therapy are established treatment options for secondary prevention in patients with CAD. Since antiplatelet therapy not only reduces the thromboischaemic risk but also decreases ongoing platelet-driven systemic inflammation, possibly it also influences atheroprogression and occurrence of vulnerable plaques. Recent large clinical studies (PEGASUS, TRA2P, DAPT, OPTIDUAL) suggest that a prolonged and intensified antiplatelet therapy reduces progression of CAD as evidenced by reduction of ischaemic events, however, at the cost of higher bleeding event rates. Thus, targeting molecular mechanisms of thromboinflammation may turn out as innovative strategy for disease control among cardiovascular patients in the future.

Take-Home Message

Platelets accumulated at the site of vascular lesion or lesion-prone areas form a regulatory 'hot spot' that determines trigger for atherosclerotic lesions, plaque instability and subsequent atherothrombotic vessel occlusion.

Platelet–endothelial and inflammatory cell interactions mediated through ever-expanding array of adhesion molecules, pro-inflammatory, mitogenic factors and DAMPs promote atherogenesis and vascular remodelling.

Platelets recruit progenitor cells to the injured endothelium and platelet-derived mediators determine the balance between vascular inflammation and regeneration.

Intensified and prolonged antiplatelet therapy improves clinical prognosis of patients with atherosclerotic disease.

Advanced diagnostic and therapeutic strategies target platelet inflammatory biomarkers and mediators to diagnose atherosclerotic predisposition and prevent subsequent thromboischaemic complications.

Platelets in Acute Coronary Syndromes

Mark R. Thomas and Robert F. Storey

Abstract

It has long been recognised that platelets play a key role in the formation of a thrombus after atherosclerotic plaque rupture. If the thrombus becomes occlusive, this may lead to impairment of the blood supply to the heart and an acute coronary syndrome.

Exposure of platelets to subendothelial components initiates platelet adhesion, mediated by the interaction of VWF with platelet GPIb-V-IX. The collagen receptors $\alpha_2\beta_1$ and GPVI then facilitate adhesion and mediate firm adhesion to collagen, respectively. Soluble agonists that are released also activate platelets, triggering specific intracellular signalling pathways and resulting in calcium mobilisation, shape change and increased expression and activation of the integrin $\alpha_{IIb}\beta_3$. This results in fibrinogen cross-linking activated $\alpha_{IIb}\beta_3$ on adjacent platelets, which mediates platelet aggregation.

Inhibition of specific platelet receptors has proved to be an exceptionally successful approach in the treatment of acute coronary syndromes. Although a number of receptor antagonists have been investigated, many receptors have still not been targeted in patients. This book chapter discusses the role of platelets in acute coronary syndromes, but in particular focuses on these potentially exciting, but as yet unexploited mechanisms.

Introduction

Acute coronary syndrome (ACS) refers to a group of conditions that arise when there is acute obstruction to blood flow in the coronary arteries, leading to an impairment of the blood supply to the myocardium of the heart. ACS is subdivided on the basis of electrical abnormalities detected on the electrocardiogram and detection of myocardial proteins that are indicative of myocardial infarction (Roffi et al. 2016). Partial obstruction often leads to unstable angina or non-ST-elevation MI (NSTEMI), whereas total obstruction of the larger coronary arteries normally leads to ST-elevation myocardial infarction (STEMI).

The recognition of the importance of platelets in ACS has led to some of the most successful pharmacological therapies in cardiovascular medicine. Coronary artery disease may not cause symptoms for decades, and the formation of an intracoronary thrombus by platelets is the pivotal moment that initiates ACS, which can be fatal (Falk et al. 2013). Platelets are involved in advanced atherosclerosis and their role intensifies following atherosclerotic plaque rupture or erosion. This exposes platelets to multiple thrombogenic substrates, such as collagen, von Willebrand factor (VWF) and fibronectin, to which platelets adhere, mediated by glycoprotein (GP) Ib-V-X, $\alpha_2\beta_1$ and GPVI. This initiates platelet activation and cross-linking of fibrinogen between platelet $\alpha_{IIb}\beta_3$ receptors, which causes platelet aggregation. Platelet activation is amplified by platelet release of dense granules and interactions with the coagulation cascade and leukocytes. Of these responses, platelet release of adenosine diphosphate (ADP) from dense granules and subsequent activation of platelet $P2Y_{12}$ receptors has a particularly

important role in amplifying the response of platelets to other agonists.

Aspirin was the first medication to demonstrate the dramatic benefits of antiplatelet therapy in patients with ACS, which has led to the now routine strategy of dual antiplatelet therapy (Grove et al. 2015). However, patients with ACS continue to have increased risk of mortality, highlighting the need for further refinement of treatment strategies (Thomas and Storey 2015a). This chapter therefore discusses the major roles of platelets in acute coronary syndromes, with a particular focus on mechanisms that are potentially appealing novel pharmacological targets.

Platelets and the Pathogenesis of Acute Coronary Syndromes

Platelets appear to have a limited role in early atherogenesis (West et al. 2014), but play an increasingly important role during the lead up to atherosclerotic plaque rupture (Li et al. 2012) (Fig. 1). The development of an advanced atherosclerotic plaque is characterised by chronic inflammation, driven primarily by macrophages and T cells (Falk et al. 2013). There is increasing evidence that rupture and erosion of advanced plaques are relatively frequent and do not result in ACS unless other thrombogenic factors are present (Arbab-Zadeh et al. 2012). Multiple asymptomatic plaque ruptures and erosions appear to lead to an increase in plaque volume and the development of high-grade coronary arterial stenosis, however (Arbab-Zadeh et al. 2012). Throughout these processes, platelets promote the underlying inflammatory processes by direct interactions with the cells involved or by releasing pro-inflammatory cytokines (Thomas and Storey 2015b).

Platelets Interact with Activated Endothelium, Promoting Monocyte Recruitment

Although platelets do not normally adhere to endothelium that is intact, they are capable of adhering to activated endothelium (Massberg et al. 2002). Many conditions related to atherosclerosis, such as hypercholesterolaemia, smoking and oxidative stress, induce endothelial dysfunction and activation, resulting in expression of adhesion molecules, such as vascular cell adhesion molecule (VCAM)-1, intercellular adhesion molecule (ICAM)-1 and E-selectin (Liao 2013). Additionally, atherosclerosis increases endothelial VWF, further promoting platelet adhesion and activation (De Meyer et al. 1999). Adhesion of platelets to these adhesion molecules and the endothelium is mediated by a variety of corresponding platelet adhesion molecules and receptors, including P-selectin, GPIbα, GPVI and $\alpha_{IIb}\beta_3$ (Massberg et al. 2002; Huo et al. 2003; Bültmann

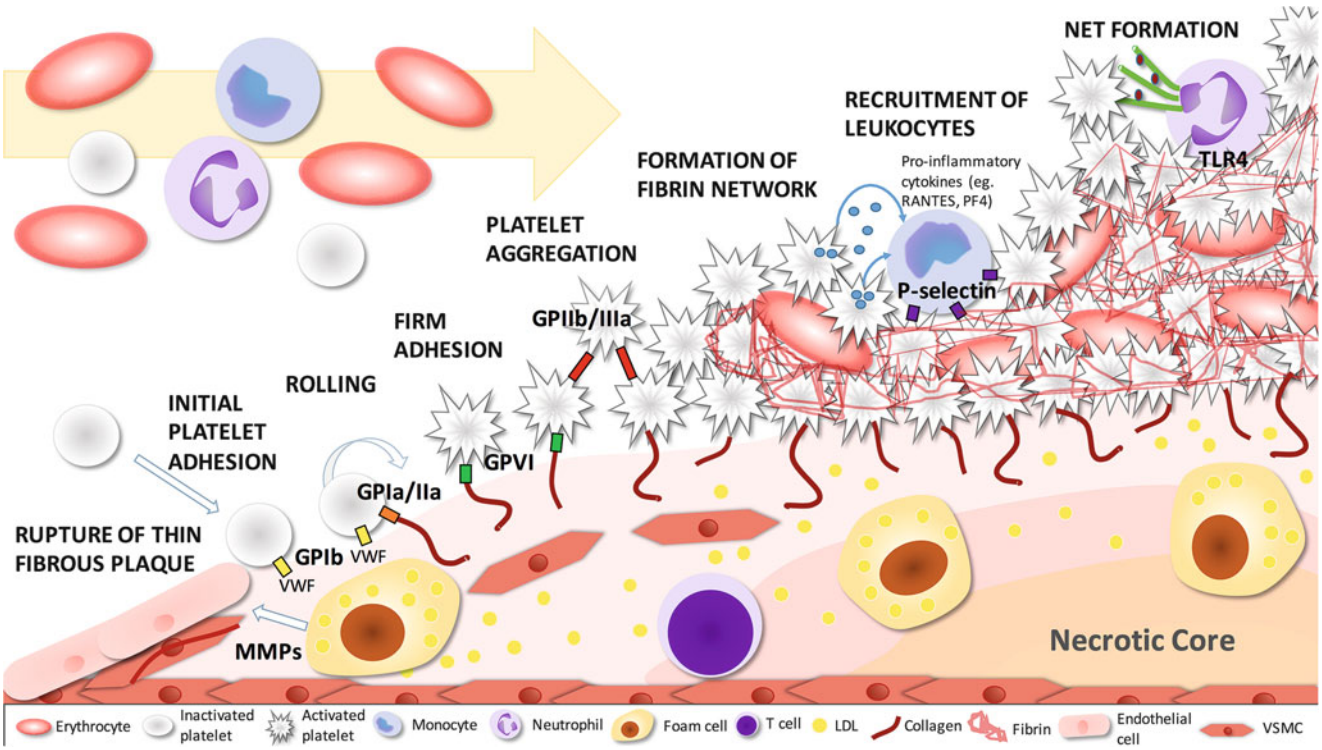

Fig. 1 The role of platelets in forming a thrombus following atherosclerotic plaque rupture

et al. 2010). Depletion of these adhesion receptors reduces leukocyte accumulation within the arterial vessel wall and reduces plaque formation in animal models (Massberg et al. 2002; Huo et al. 2003; Bültmann et al. 2010), demonstrating an important role of platelet adhesion in the pathophysiology of advanced atherosclerotic plaques.

Adherent platelets form bridges between the endothelium and leukocytes (Thomas and Storey 2015b), which facilitates the recruitment of monocytes to the atherosclerotic plaque where they take up cholesterol and become a type of macrophage known as a foam cell (Randolph 2014). Activated platelets release cytokines (Table 1), including platelet factor (PF) 4 and regulated on activation, normal T cell expressed and secreted (RANTES), which are released from α-granules and also act synergistically to promote recruitment of monocytes to the endothelium (Hundelshausen et al. 2005). Platelets are a major source of both PF4 and RANTES, and mice that are deficient in either PF4 or RANTES demonstrate attenuated development of atherosclerosis and reduced macrophage infiltration into atherosclerotic plaques (Koenen et al. 2009). Activated platelets also promote leukocyte recruitment by upregulating endothelial expression of ICAM-1 and release of monocyte chemotactic protein (MCP)-1 (Thomas and Storey 2015b). In addition, platelets facilitate T cell adhesion to the endothelium, and $CD4^+$ T cells actually appear to be incapable of sustaining adhesion with the endothelium under arterial flow conditions in the absence of platelets (Solpov et al. 2006). This enhancement of lymphocyte adhesion by platelets is mediated by P-selectin, $\alpha_{IIb}\beta_3$ and CD40L (Spectre et al. 2012). Platelets interact directly with monocytes and macrophages that are present in the atherosclerotic plaque to alter their phenotype and function. Platelet-derived PF4 prevents monocyte apoptosis and induces a phenotype in macrophages that is functionally distinct to both M1 and M2 macrophages and displays altered matrix metalloproteinase (MMP) gene expression (Gawaz et al. 2000). Platelets are activated by OxLDL, mediated by CD36 and NOX2 (Magwenzi et al. 2015). This induces the formation of platelet-monocyte aggregates, which in turn induces phenotypic changes in monocytes, promoting monocyte extravasation and enhancing foam cell formation (Badrnya et al. 2014).

Platelets Are the Central Mediators of the Progression from Ruptured Atherosclerotic Plaque to Subsequent Thrombus Formation

ACS is largely a stochastic event, and it is therefore particularly difficult to make physiological assessments immediately prior to the onset of ACS to determine possible triggers. However, various different triggers have been described, such as physical activity, emotional stress and infections. It has been suggested that the underlying mechanisms of these triggers may include autonomic activation, vasoconstriction and systemic inflammation, which are all mediated by platelets and point to possible triggers of platelet activation (Boyle et al. 2003). Vulnerable plaques that are prone to rupture are associated with a thin fibrous cap, high leukocyte content and a large necrotic core (Silvestre-Roig et al. 2014). Apoptosis of vascular smooth muscle cells (VSMCs) in the fibrous cap destabilises the plaque and is promoted by macrophage release of tumour necrosis factor (TNF)-α (Boyle et al. 2003) and MMP-mediated degradation of collagen within the fibrous cap (Silvestre-Roig et al. 2014). In addition, CD40L, which is derived from T cells and platelets, also promotes macrophage production of collagen-degrading MMPs (Libby 2013). Although platelets may play a role in these processes (Seizer and May 2013; Libby 2013; Thomas and Storey 2015b), direct evidence for a role of platelets in plaque

Table 1 Summary of major platelet-derived mediators of inflammation (adapted from Thomas and Storey 2015b)

Mediator	Class	Source	Interactions	Major role
P-selectin (CD62P)	Adhesion molecule	Surface expressed Released from α-granules	PSGL-1 on leukocytes	Mediates formation of platelet-leukocyte aggregates Cross-links leukocytes, platelets and endothelium
CD40L	Member of TNF family	Surface expressed Released from α-granules	CD40 on T cells, B cells, monocytes and dendritic cells	Promotes leukocyte adhesion to the endothelium Links innate and adaptive immune responses
Platelet factor 4 (CXCL4)	CXC chemokine	Released from α-granules	CXCR3 on leukocytes	Induces leukocyte pro-inflammatory functions, such as cytokine release, production of reactive oxygen species, phagocytosis and chemotaxis
RANTES (CCL5)	CC chemokine	Released from α-granules	CCR1, CCR3 and CCR5 on monocytes, macrophages and T cells	Promotes monocyte, macrophage and T cell chemotaxis and endothelial recruitment
IL-1	Cytokine	Released from α-granules	Multiple effects on leukocytes and endothelium	Central mediator of pro-inflammatory vascular responses and initiator of the cytokine cascade

rupture is limited. However, it is clear that platelets have a central role in mediating a prothrombotic state, which appears to be the key requirement for progression of plaque rupture or erosion towards thrombus formation and subsequent ACS.

Summary of Platelets in the Pathogenesis of Acute Coronary Syndromes

Platelet adhesion to activated endothelium and release of PF4 and RANTES promotes monocyte recruitment to atherosclerotic plaques. Following plaque rupture or erosion, platelets are activated in response to subendothelial components and play a central role in developing a thrombus within the coronary artery.

Platelet Adhesion in Acute Coronary Syndromes

Following atherosclerotic plaque rupture or erosion, circulating blood is exposed to the highly prothrombotic necrotic core of the plaque and subendothelial components, such as VWF, collagen, fibronectin and laminin (Falk et al. 2013). Exposed macrophages express tissue factor, which is a potent stimulus for thrombin generation and activation of the extrinsic coagulation cascade. Platelet interactions with mononuclear phagocytes further upregulates tissue factor expression (Lindmark et al. 2000), thus increasing thrombin generation. Atherosclerotic plaques also narrow the arterial lumen, thereby inducing haemodynamic disturbances and increasing shear stress (Crea and Liuzzo 2013). Under these conditions, platelet adhesion to exposed subendothelial components is critically dependent upon adhesion to VWF and collagen.

Initial Adhesion to the Vessel Wall Is Mediated by the GPIb-V-IX Complex

The initial adhesion of platelets to exposed subendothelial components is primarily mediated by the platelet GPIb-V-IX complex, which binds to exposed and immobilised VWF (Delaney et al. 2012). Downstream signalling, mediated by Src family kinases (Fig. 3), results in activation of $\alpha_{IIb}\beta_3$, which causes platelet aggregation (Delaney et al. 2012). VWF-mediated pulling of the GPIb unit induces the unfolding of a mechanosensitive domain, which induces platelet activation in response to high levels of sheer stress (Zhang et al. 2015). Platelet GPIb also adheres to VWF that has bound to immobilised collagen or fibrinogen, which allows platelets to bind to collagen and fibrinogen under high shear stress (Crúz et al. 2013). In addition, GPIb-V-IX signalling can be initiated by a direct action of thrombin on the GPIb-V-IX complex, which is synergistic with thrombin's activation of protease-activated receptor (PAR) 1 (Estevez et al. 2014).

A novel GPIb antagonist, anfibatide, has been shown to inhibit platelet aggregation related to VWF in a phase I study, without affecting ADP-, thrombin receptor-activated peptide (TRAP)- or collagen-mediated aggregation (Lei et al. 2014). This potently inhibited platelet adhesion, aggregation and thrombus formation ex vivo under both low and high shear stress (Lei et al. 2014). In addition, anfibatide inhibited thrombus formation in animal models of arterial injury without any apparent adverse effects on haemostasis (Lei et al. 2014). This therefore demonstrates an important role of GPIb in arterial thrombosis and shows therapeutic potential for GPIb inhibitors in ACS. Interestingly, in contradiction to the majority of other platelet mechanisms, GPIb appears to negatively regulate leukocyte trafficking and activation (Kaplan et al. 2015). Correspondingly, absence of GPIb-V-IX augments systemic inflammation in animal models (Corken et al. 2014), which may be an important consideration for clinical applications of GPIb inhibitors.

α2β1 Mediates Early Adhesion to Collagen

The integrin $\alpha_2\beta_1$ is present in a low-affinity state on resting platelets. Following initial adhesion, interaction of platelet GPIb with VWF mediates activation of $\alpha_2\beta_1$ (Crúz et al. 2005), which facilitates platelet adhesion and initiates rolling. Even in its inactive form, $\alpha_2\beta_1$ contributes towards adhesion by binding to collagen, although inside-out signalling changes its conformational shape, thereby increasing its affinity for collagen (Wang et al. 2003; Lecut et al. 2004). $\alpha_2\beta_1$ then acts synergistically with GPVI to reinforce collagen-mediated platelet activation (Jarvis et al. 2002; Kuijpers et al. 2003). $\alpha_2\beta_1$ deficiency in mice does not affect the bleeding time, and $\alpha_2\beta_1$-deficient platelets can still aggregate and adhere, although this is delayed, demonstrating that $\alpha_2\beta_1$ is not essential in the adhesion process (Nieswandt et al. 2001). However, in the absence of both $\alpha_2\beta_1$ and GPVI, platelet adhesion to collagen under flow is completely abolished (Sarratt 2005).

Firm Adhesion and Platelet Activation Is Mediated by GPVI

In distinction to many platelet receptors that are G-coupled protein receptors, GPVI belongs to the immunoglobulin superfamily (Clemetson et al. 1999), and its downstream signalling pathways involve Src family kinases. GPVI is

thought to be exclusive to platelets and megakaryocytes, and it has been estimated that there are approximately 9600 copies per platelet (Burkhart et al. 2012). GPVI is the major receptor for collagen, but is also activated by other endogenous ligands, including laminin (Inoue et al. 2006) and adiponectin (Riba et al. 2008), and the exogenous ligand CRP (Knight et al. 1999). GPVI also potentiates platelet activation in response to thrombin by mechanisms that are independent of Src kinases and Syk (Hughan et al. 2007) (Fig. 3). Platelets that lack either GPVI or a functional FcR-γ-chain display severely impaired thrombus formation at high shear stress (Best et al. 2003), suggesting that it is likely to have an important role during the high shear conditions of ACS. GPVI is present as a monomer on the resting platelet membrane and becomes a dimer on platelet activation, thereby increasing its affinity for collagen (Loyau et al. 2012). There is an increase in levels of the GPVI dimer in response to ADP and VWF, and the levels of GPVI dimers correlate with P-selectin expression (Loyau et al. 2012). It has recently been demonstrated that GPVI is also a receptor for fibrin (Alshehri et al. 2015). Binding of GPVI to fibrin promotes thrombin generation and thus amplifies platelet activation (Mammadova-Bach et al. 2015), which demonstrates an important role of GPVI in thrombus growth and stability. This explains why deficiency of GPVI increases time to occlusion following arterial injury as well as inhibiting initiation of thrombus formation in animal models (Alshehri et al. 2015). Inhibition of GPVI also decreases platelet responses to ADP, thrombin and epinephrine by approximately 20 % (Boylan et al. 2006), which suggests that GPVI is involved in amplifying platelet responses to these agonists.

Patients who are deficient in GPVI display impaired collagen-induced aggregation and adhesion and have a variable defect in haemostasis, which can be mild or severe (Grüner et al. 2005; Li et al. 2007). Consistent with this, patients with coronary artery disease with polymorphisms of GPVI also display a reduction in platelet reactivity to collagen as determined by the PFA-100 platelet assay (Lepäntalo et al. 2006). Mice with a germline knockout of GPVI and anti-GPVI antibody-treated mice display greatly reduced adhesion and aggregation to collagen and reduced thrombus formation at the site of arterial injury, at the expense of a moderate increase in bleeding time (Grüner et al. 2005; Li et al. 2007; Ungerer et al. 2011; Goebel et al. 2013). In animal models, soluble GPVI dimer inhibits platelet adhesion and aggregation to sites of vascular injury (Massberg 2003). Phase I studies have also shown that the same soluble dimeric GPVI-Fc fusion protein, Revacept, inhibits collagen-induced platelet aggregate formation in humans ex vivo (Ungerer et al. 2011). This approach also appears to improve cerebral infarct size and functional outcomes in animal models of stroke (Goebel et al. 2013) but has not yet been tested in ACS patients. Interestingly, in silico approaches have identified that losartan, a commonly used antihypertensive, may also inhibit platelet GPVI, which was confirmed by its inhibitory effects on collagen-induced platelet aggregation (Taylor et al. 2014). Kistomin, which is a snake venom metalloproteinase, has also been identified to have anti-GPVI effects as it cleaves both GPIb and GPVI, which inhibits VWF and collagen-induced platelet adhesion and aggregation, respectively (Hsu et al. 2008).

GPVI appears to also have an important role in maintaining vascular integrity during inflammation, whereas G protein-coupled receptors, such as the ADP receptors and TPα, appear to be dispensable in this process in animal models (Boulaftali et al. 2013). However, this role of GPVI appears complex and in some respects paradoxical. Platelet GPVI appears to enhance injury of the vessel wall caused by neutrophils, but also supports subsequent platelet adhesion, promoting repair of neutrophil-induced vascular breaches in animal models (Gros et al. 2015).

Summary of Platelet Adhesion

Under arterial shear stress, platelet adhesion is critically dependent on VWF and collagen. Initial adhesion and activation are mediated by GPIb-V-IX binding to VWF. This activates $\alpha_2\beta_1$, which facilitates platelet adhesion and initiates rolling. Firm adhesion is then mediated by GPVI, which also activates platelets. In addition, emerging evidence suggests an important role of GPVI as a receptor for fibrin.

Platelet Activation and Aggregation in Acute Coronary Syndromes

Following initial adhesion to the endothelium, platelets become activated by a number of specific intracellular signalling pathways, resulting in activation of the $\alpha_{IIb}\beta_3$ receptor on the surface of platelets (Fig. 2). Fibrinogen then cross-links activated $\alpha_{IIb}\beta_3$ receptors on adjacent platelets, which causes platelet aggregation. There are a number of mechanisms by which the platelet activation is amplified, involving the release of dense granules and interactions with leukocytes and the coagulation system.

GPIb and GPVI Initiate Platelet Activation During Acute Coronary Syndromes

Following plaque rupture, platelet adhesion to collagen is a potent stimulus for platelet activation. Activation of GPVI by collagen initiates platelet activation and induces

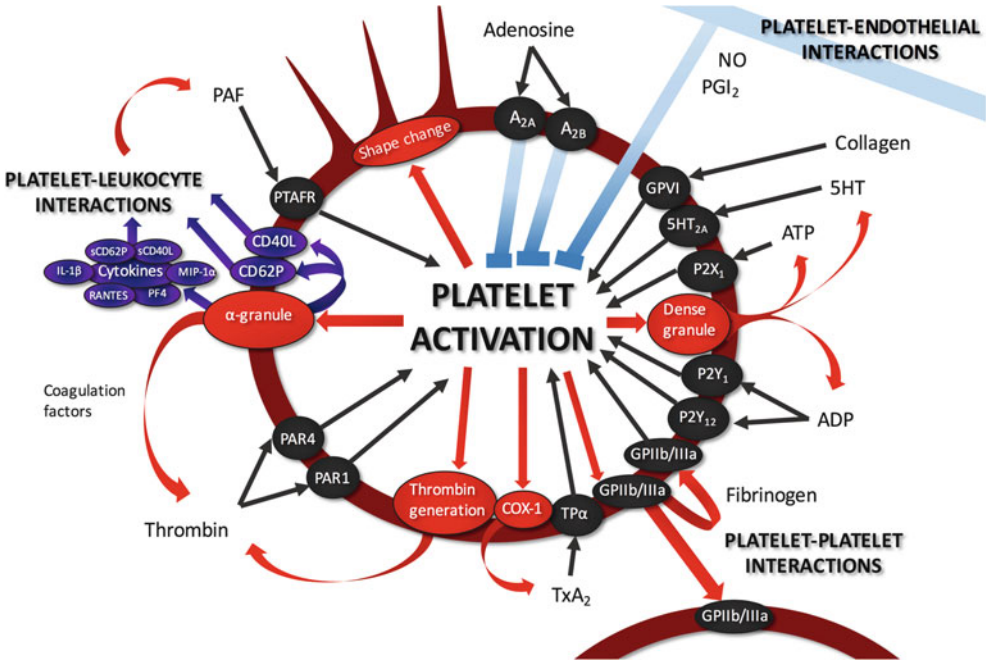

Fig. 2 Platelets are activated by multiple agonists, which act on surface receptors, leading to platelet activation, secretion of granules and generation of thrombin and thromboxane A_2

conformational changes in $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$ that increase their affinity for adhering to collagen and other platelets, respectively (Lecut et al. 2004). VWF and soluble agonists induce dimerisation of GPVI and thereby increase its affinity for collagen, further potentiating platelet activation (Loyau et al. 2012). The GPVI receptor is upregulated in response to pathological shear and by components of the coagulation cascade, particularly factor Xa (Al-Tamimi et al. 2011, 2012; Naitoh et al. 2015). The receptor is shed upon platelet activation, mediated by the ADAM family of metalloproteinases, which also mediate the shedding of many other platelet membrane receptors (Bender et al. 2010). Surface expression of the collagen receptor GPVI is upregulated during ACS and correlates with expression of platelet P-selectin (Bigalke et al. 2006) suggesting that it may be a marker of platelet activation.

Platelet Activation Leads to αIIbβ3 Activation and Platelet Aggregation

$\alpha_{IIb}\beta_3$ is an adhesion receptor that belongs to the integrin superfamily and is a heterodimer composed of an α (α_{IIb}) and a β (β_3) transmembrane subunit (Coller and Shattil 2008). In the resting state, there are approximately 40,000–80,000 complexes present on the platelet membrane, and $\alpha_{IIb}\beta_3$ is only able to weakly bind fibrinogen, which is sufficient to allow uptake of fibrinogen into α-granules (Coller and Shattil 2008). The number of $\alpha_{IIb}\beta_3$ receptors on the surface membrane rapidly increases following platelet activation, which also induces conformational changes in the receptor allowing it to bind fibrinogen, VWF and fibronectin (Coller and Shattil 2008). This inside-out signalling has been described as the final common pathway of platelet activation as it is downstream of all other platelet activation signalling pathways (Coller and Shattil 2008). Fibrinogen molecules have two binding sites for $\alpha_{IIb}\beta_3$ and act as bivalent ligands, forming cross-links between activated $\alpha_{IIb}\beta_3$ receptors on different platelets, resulting in platelet aggregation (Coller and Shattil 2008). In addition, platelet $\alpha_{IIb}\beta_3$ receptors are activated by ligand binding, resulting in outside-in signalling, which is mediated by Src family kinases (Fig. 3) and causes platelet activation (Coller and Shattil 2008).

Intravenous platelet $\alpha_{IIb}\beta_3$ inhibitors are potent inhibitors of platelet aggregation and have been used for the treatment of ACS (Grove et al. 2015). However, platelet inhibition during ACS has increasingly focused on the use of platelet $P2Y_{12}$ inhibitors (Roffi et al. 2016). As $\alpha_{IIb}\beta_3$ antagonists increase the risk of major bleeding, their use is now largely limited to high-risk situations during PCI such as primary PCI for STEMI or as a "bailout" therapy for procedure-related thrombus formation (Grove et al. 2015).

Platelet Release of ADP and Subsequent Activation of Platelet $P2Y_{12}$ Receptors Is a Central Amplification Process

Platelet response to ADP is mediated by two ADP receptors, namely, $P2Y_1$ and $P2Y_{12}$. $P2Y_1$ is coupled to G_q (Fig. 3) and initiates calcium mobilisation, platelet shape change and transient platelet aggregation in response to ADP (Gachet

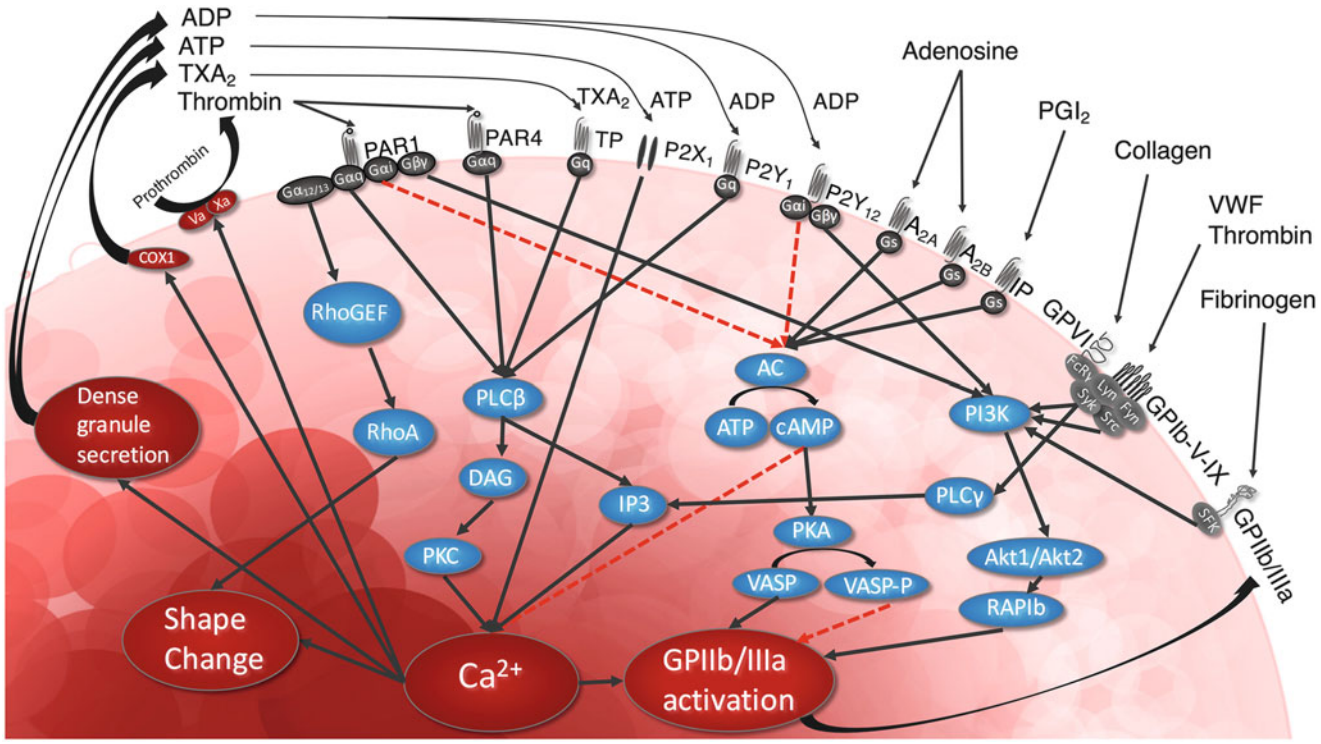

Fig. 3 Intracellular signalling following platelet activation

2012). Few attempts have been made to target $P2Y_1$ receptors pharmacologically since they are expressed in many tissues throughout the human body, including the heart, blood cells, neural tissues and other organs, making off-target effects very likely (Gachet 2012). Platelet $P2Y_{12}$ receptors are coupled to G_i and inhibit adenylyl cyclase activity, thereby decreasing levels of cyclic adenosine monophosphate (cAMP) (Gachet 2012). $P2Y_{12}$ also activates the PI3K signalling pathway, which mediates robust platelet aggregation (Cosemans et al. 2006). Platelet activation in response to ADP triggers release of platelet dense granules, which also contain ADP. The released ADP has autocrine effects that amplify the response of the activated platelet and paracrine effects that stimulate other platelets (Gachet 2012). Amplification of platelet activation by the $P2Y_{12}$ receptor has a central role in amplifying the response of platelets to other agonists (Storey et al. 2000). In addition, $P2Y_{12}$ receptors are expressed in few cell types other than platelets (Gachet 2012), which makes them an attractive target for antiplatelet pharmacotherapy. Many successful platelet $P2Y_{12}$ inhibitors have been developed and now rank amongst some of the most commonly used medications worldwide (Storey 2011). Platelet $P2Y_{12}$ inhibitors are capable of inhibiting the response of platelets to ADP and multiple other agonists, as they inhibit a central amplification pathway (Storey et al. 2000). The potent $P2Y_{12}$ inhibitors prasugrel and ticagrelor are currently recommended as first-line treatments for patients with ACS, in addition to aspirin (Roffi et al. 2016).

The Platelet Agonist Thromboxane A_2 Is Synthesised upon Platelet Activation

Arachidonic acid is formed by phospholipase A_2, which hydrolyses membrane phospholipids. Arachidonic acid is then rapidly converted by cyclooxygenase (COX-1) in platelets into prostaglandin G_2, which is then converted into prostaglandin H_2 (PGH_2) by peroxidase (Patrono et al. 2005). Thromboxane synthase converts PGH_2 into thromboxane A_2 (TxA_2), which can diffuse out through the platelet membrane to then act upon platelet TP receptors to amplify platelet activation (Patrono et al. 2005). Aspirin inhibits COX-1, thereby reducing the synthesis of TxA_2, which strongly inhibits arachidonic acid-induced platelet aggregation and moderately inhibits collagen-induced platelet aggregation (Storey et al. 2000). In citrate-anticoagulated platelet-rich plasma, aspirin also inhibits ADP- and adrenaline-induced platelet aggregation (Storey et al. 2000). However, these effects are not seen at physiological levels of calcium, which suggests that the arachidonic acid pathway has a limited role in platelet activation under physiological conditions (Heptinstall and Mulley 1977).

The antiplatelet properties of low-dose aspirin are of great benefit in patients with ACS (Collaboration 2002). Since the successful introduction of aspirin, it is now used routinely in combination with platelet $P2Y_{12}$ inhibitors (Storey 2011). Further studies are therefore needed to determine optimal usage of aspirin when it is used on a background of potent $P2Y_{12}$ inhibition (Thomas and Storey 2014a). Specific thromboxane receptor (TP) inhibitors have also been developed. Ridogrel, a combined TXA_2 synthase and TP receptor inhibitor, is the only such drug to have been tested in patients with ACS. However, ridogrel did not improve indices of reperfusion in patients with STEMI undergoing thrombolysis compared to aspirin and further development of TP receptor inhibitors has since ceased (investigators 1994).

Amplification of Platelet Activation by Protease-Activated Receptors

Platelets express two different receptors for thrombin, namely, PAR1 and PAR4 (Leger et al. 2006). Thrombin is the most potent activator of platelets and is thought to exert the majority of its effects through PAR1 (Leger et al. 2006). PARs have an unusual mechanism of action, in that a cryptic ligand within the receptor is unmasked by proteolytic cleavage and the tethered ligand then interacts with the receptor moieties (Leger et al. 2006). PAR1 activates $G_{12/13}$, resulting in marked shape change and formation of pseudopodia, as well as dense granule release (Fig. 3). PAR1 is also linked to G_q, which increases intracellular calcium and activates αIIbβ3 (Leger et al. 2006). Whilst PAR1 has a high affinity for thrombin and is activated at subnanomolar concentrations of thrombin, PAR4 has a lower affinity and is cleaved more slowly (Leger et al. 2006). Despite this, PAR4 is able to mediate robust increases in intracellular calcium and platelet aggregation, mediated by G_q (Leger et al. 2006).

The PAR1 receptor antagonist vorapaxar initially showed great promise in early-phase studies as it appeared to reduce platelet aggregation without adversely affecting haemostasis. However, in patients with ACS, vorapaxar increased the risk of bleeding and only showed a trend for cardiovascular benefits (Tricoci et al. 2012). Vorapaxar did significantly reduce the incidence of adverse cardiovascular events in patients with stable coronary artery disease with a prior history of MI and has recently been licensed for this indication (Morrow et al. 2012).

Summary of Platelet Activation

Following adhesion to the endothelium, platelets become activated in response to VWF and collagen in addition to a number of soluble mediators, which activates specific intracellular signalling pathways. These signalling pathways induce calcium mobilisation, shape change and activation of $\alpha_{IIb}\beta_3$, which is cross-linked with $\alpha_{IIb}\beta_3$ on adjacent platelets by fibrinogen. This results in platelet aggregation.

Platelet-Leukocyte Interactions

There are a number of mechanisms by which activated platelets interact with leukocytes and the endothelium. Activated platelets express the adhesion molecule P-selectin on their surface membrane, which interacts with its corresponding ligand, P-selectin glycoprotein ligand (PSGL)-1, on monocytes, neutrophils and eosinophils (Thomas and Storey 2015b). This mediates the formation of platelet-leukocyte aggregates, and circulating levels of platelet-monocyte aggregates have been shown to be increased in patients with ACS (Michelson et al. 2001). Increased platelet expression of P-selectin despite antiplatelet therapy has been shown to be associated with a higher incidence of adverse cardiovascular events in patients with ACS (Thomas et al. 2014). Inhibition of P-selectin reduces the formation of platelet-monocyte aggregates in vivo (Tardif et al. 2013). A novel specific antibody against P-selectin, inclacumab, lowers levels of soluble P-selectin and shows trends towards reduced myocardial damage in patients with ACS, presumably mediated by reducing platelet-leukocyte interactions (Tardif et al. 2013).

Platelets also express CD40L on their surface membrane when activated. CD40L has a similar structure to TNFα and has effects that are similar (Thomas and Storey 2015b). Platelet CD40L acts on monocyte CD40 to increase monocyte expression of tissue factor, which exerts prothrombotic effects by activating the extrinsic coagulation cascade (Thomas and Storey 2015b). CD40L is also an important mediator of adaptive immune responses and the regulation of T cells in particular (Thomas and Storey 2015b). Patients with ACS have an increased plasma level of soluble CD40L, which is thought to derive from platelets since they are the main source (Blanchet et al. 2014). Reflecting high levels of platelet activation, elevated levels of CD40L are associated with an increased risk of mortality in patients with ACS (Blanchet et al. 2014).

Platelets Interact with Monocytes, Promoting the Release of Pro-inflammatory Cytokines

As well as containing many mediators of coagulation, platelet α-granules contain a large number of inflammatory mediators that serve no role in haemostasis (Thomas and Storey 2015b). Upon activation, platelets release cytokines

such as interleukin (IL)-1β, chemokine (C-X-C motif) ligand (CXCL) 1, PF4, CXCL5, CXCL7, IL-8, CXCL12, macrophage inflammatory protein (MIP)-1α and RANTES (Thomas and Storey 2015b). PF4, RANTES and MIP1α are important promoters of monocyte chemotaxis and adhesion to the endothelium and have been directly implicated in atherogenesis (Thomas and Storey 2015b). Levels of PF4, RANTES and MIP1α are increased during ACS (Blanchet et al. 2014), and high levels of RANTES are associated with more rapid subsequent progression of atherosclerotic plaques (Blanchet et al. 2014). Increased levels of RANTES and MIP1α are also both associated with a threefold increase in risk of mortality (de Jager et al. 2012; Blanchet et al. 2014).

The formation of platelet-monocyte aggregates increases monocyte release of pro-inflammatory cytokines, such as TNFα, MCP-1 and IL-8 (Thomas and Storey 2015b), which represents a mechanism by which platelets amplify systemic inflammation during ACS. Patients with ACS who have high levels of baseline inflammatory markers have an increased risk of subsequent adverse cardiovascular events and mortality (Thomas and Storey 2015c). Platelet $P2Y_{12}$ inhibitors have been shown to reduce systemic inflammation and also lower levels of inflammatory markers during ACS, which may contribute to their clinical benefit (Thomas and Storey 2015c; Thomas et al. 2015).

Platelets Interact with Neutrophils, Resulting in the Formation of Neutrophil Extracellular Traps

Neutrophil counts are often raised in patients with ACS, and there is evidence for a rapid burst of neutrophil activation and release of myeloperoxidase (MPO) in the first few hours of ACS, which is associated with platelet-neutrophil aggregate formation (Maugeri et al. 2012). Platelets interact with neutrophils to promote the formation of neutrophil extracellular traps (NETs), mediated by the platelet TLR4 receptor (Clark et al. 2007). NETs are normally extruded by neutrophils as a means of ensnaring bacteria and consist of cytoplasmic proteins and nuclear contents (Thomas and Storey 2015b). Whilst this may be beneficial to aid the clearance of bacteria, it is becoming increasingly clear that these NETs also play a significant role in the pathological inflammation and thrombosis (Thomas and Storey 2015b). In patients with STEMI, it has recently been demonstrated that a significant proportion of coronary thrombi are actually made up of NETs in close relation to platelets (Maugeri et al. 2014). Furthermore, it has also been shown that coronary NET burden is a predictor of subsequent infarct size (Mangold et al. 2015). Deoxyribonuclease hydrolyzes the DNA scaffold of NETs and has been shown to accelerate the lysis of coronary thrombi ex vivo, suggesting that NETs could be a pharmacological target for the treatment of ACS (Mangold et al. 2015).

Platelets Release Microparticles, Which Are Important Mediators of Inflammation and Coagulation and also Contain MicroRNA

Platelets release small membrane vesicles upon activation, known as microparticles (Biasucci et al. 2012). Platelets are a major source of microparticles, but other cell types, including endothelial cells, leukocytes and VSMCs, all release different types of microparticles as well (Vajen et al. 2015). Microparticles mediate pro-inflammatory and procoagulant interactions between many different cell types and have effects that include increasing the thrombogenicity of platelets and promoting monocyte interactions with the endothelium. Levels of platelet-derived microparticles are increased during ACS (Biasucci et al. 2012), suggesting their potential use as a biomarker or as a pharmacological target in patients with ACS.

miRNA are small non-coding RNA, which function as translational repressors to modulate gene expression (Willeit et al. 2013). They have a diverse range of effects across a range of cell types and have been shown to have important roles in modulating endothelial cell function and inflammatory responses. Interestingly, platelet microparticles appear to be a predominant source of miRNA in the plasma (Willeit et al. 2013). miR-126 and miR-223 are particularly abundant within platelets, and their release can be inhibited by platelet $P2Y_{12}$ inhibitors and aspirin (Willeit et al. 2013). In patients with ACS, levels of miR-126 and miR-223 both correlate with indices of platelet reactivity, which suggests that they may be useful as a novel marker of platelet activation in plasma (Mayr et al. 2014).

Platelets Mediate the Formation of a Stable Thrombus

In their resting state, platelets have an asymmetrical phospholipid membrane that is maintained by translocase. Upon activation, increased levels of cytoplasmic calcium inhibit translocase and activate scramblase, which enhances the expression of negatively charged phosphatidylserine on the outer membrane. This allows factor Xa and Va to form a prothrombinase complex on the surface membrane, which converts prothrombin into thrombin (Solum 1999). The produced thrombin activates platelet PARs and also leads to fibrin formation, which binds the developing clot together. In addition, platelets synthesise large quantities of plasminogen activator inhibitor (PAI)-1

and release this from α-granules upon activation (Brogren et al. 2004). The balance between clot formation and lysis is closely regulated by the fibrinolytic system, and tissue plasminogen activator (tPA) in particular plays an important role on clot lysis. PAI-1 inhibits the fibrinolytic action of tPA and thereby increases resistance to clot lysis, particularly in arterial thrombosis (Brogren et al. 2004). High plasma concentrations of PAI-1 have been demonstrated in patients with ACS and increased levels are associated with an increase in mortality (Collet et al. 2003). Platelet-monocyte aggregate formation has also been linked with altered fibrinolytic status during ACS, which may be related to the intermediate monocyte phenotype in particular (Shantsila et al. 2012). In patients with ACS, there is a dynamic cycle between prothrombotic and prothrombolytic processes, which occur simultaneously (Falk et al. 2013). This leads to intermittent flow obstruction and distal embolisation, which may contribute towards myocardial microvascular obstruction and is more common following plaque erosion rather than rupture (Falk et al. 2013).

Summary of Platelet-Leukocyte Interactions

Activated platelets express P-selectin on their surface membranes, which interacts with PSGL-1 on leukocytes and mediates the formation of platelet-leukocyte aggregates. In addition, platelets release numerous pro-inflammatory cytokines (Table 2) from their α-granules upon activation. More recently it has also been shown that platelets interact with neutrophils, mediating the formation of NETs, which are prothrombotic and contribute to the scaffolding of the thrombus.

Table 2 Major platelet receptors and corresponding ligands

Receptor	Type	Ligand
GPIb-V-IX	Membrane receptor complex	VWF Thrombin
$\alpha_2\beta_1$	Membrane glycoprotein	Collagen
GPVI	Membrane glycoprotein	Collagen Fibrin
αIIbβ3	Integrin complex	Fibrinogen VWF
$P2Y_1$	G protein-coupled receptor	ADP
$P2Y_{12}$	G protein-coupled receptor	ADP
$P2X_1$	Ligand-gated ion channel	ATP
PAR1	G protein-coupled receptor	Thrombin
PAR4	G protein-coupled receptor	Thrombin
TPα	G protein-coupled receptor	Thrombin
$5HT_{2A}$	G protein-coupled receptor	Serotonin
A_{2A}	G protein-coupled receptor	Adenosine
A_{2B}	G protein-coupled receptor	Adenosine

Platelet Contribution Towards Microvascular Obstruction and Risk of Subsequent Restenosis and Adverse Cardiovascular Events

After atherosclerotic plaque rupture, the thrombus rapidly grows in size and may obstruct, or partially obstruct, the coronary artery, leading to myocardial ischaemia that may be fatal. Acute total occlusion of a coronary artery by thrombus usually results in STEMI, and contemporary management of this revolves around emergency primary percutaneous coronary intervention (PCI) to reopen the affected artery. The aim is to achieve this as quickly as possible, to minimise the duration of myocardial ischaemia. However, even when successful primary PCI is prompt and potent antithrombotic agents are administered, myocardial ischaemia persists in a significant proportion of patients due to microvascular obstruction further downstream of the initial obstruction (Niccoli et al. 2016). Platelets contribute towards some of the main mechanisms of microvascular obstruction, which involve ischaemia, reperfusion injury and distal embolisation (Niccoli et al. 2016). Platelet-neutrophil aggregates damage the endothelium of the microvasculature by releasing inflammatory mediators and vasoconstrictors (Niccoli et al. 2016). Additionally, platelet NOX2 is upregulated during microvascular obstruction, which exacerbates the underlying pathophysiology by promoting phospholipase A_2 activity and generating TxA_2, a potent vasoconstrictor and platelet agonist (Niccoli et al. 2013). Patients with STEMI that is complicated by microvascular obstruction have higher levels of platelet-monocyte aggregates, platelet-neutrophil aggregates and activated $\alpha_{IIb}\beta_3$ than those without microvascular obstruction (Zalewski et al. 2012). Furthermore, levels of platelet-derived microparticles have been shown to be increased at the site of coronary plaque rupture, and higher levels are associated with microvascular obstruction in patients with STEMI (Porto et al. 2012). In animal models, neutrophils release NETs during myocardial ischaemia-reperfusion, which contributes to the pathophysiology of the condition (Brinkmann and Zychlinsky 2012). Interestingly, deoxyribonuclease is able to degrade the backbone of NETs and is effective at reducing the ischaemic region and infarct size in this situation (Ge et al. 2015).

Following atherosclerotic plaque rupture, there is evidence to suggest that platelets play an important role in progression of atherosclerotic plaques. By forming a thrombus over the site of atherosclerotic plaque rupture, platelets may contribute towards atherosclerosis by releasing pro-inflammatory mediators and enhancing the recruitment of monocytes (Libby 2000). In an animal model, $P2Y_{12}$-deficient mice displayed a significant reduction in thrombus and neointima formation following arterial injury (Evans et al. 2009). Further bone marrow transplantation experiments suggested that the reduction in neointima formation was primarily due to platelet $P2Y_{12}$ deficiency rather than VSMC $P2Y_{12}$ deficiency (Evans

et al. 2009). This demonstrates a mechanism by which platelet $P2Y_{12}$ inhibitors may reduce restenosis following PCI in patients with ACS. In addition, platelet activation and secretion of dense granules releases ATP, which may act on VSMC P2X receptors, thereby promoting VSMC proliferation and migration (Erlinge 1998).

Treatment with a $P2Y_{12}$ inhibitor, in addition to aspirin, is recommended for at least a year after ACS (Roffi et al. 2016). The more recent and potent $P2Y_{12}$ inhibitors ticagrelor and prasugrel are recommended as first-line treatments for patients with ACS (Roffi et al. 2016). It has become clear that approximately a third of patients do not display adequate inhibition of platelet reactivity whilst on treatment with the older $P2Y_{12}$ inhibitor clopidogrel (Aradi et al. 2015). The reasons for this poor response to clopidogrel are multifactorial and incompletely understood, but in part relate to genetic polymorphisms (Thomas and Storey 2014b) and drug-drug interactions amongst other factors (Thomas and Storey 2011). High platelet reactivity to ADP despite treatment with clopidogrel is associated with an increased risk of subsequent adverse cardiovascular events in ACS patients (Aradi et al. 2015). Studies have investigated whether this poor response to clopidogrel can be ameliorated by increasing the dose or changing to prasugrel, but unfortunately have not shown any significant benefit so far (Collet et al. 2015). However, even with the use of potent platelet $P2Y_{12}$ inhibitors, patients with ACS continue to have an increased risk of mortality, demonstrating the need for novel developments in antithrombotic strategies.

Summary

Platelets are central to all stages of the pathophysiology of ACS (Table 3). Platelets release many pro-inflammatory mediators, such as PF4, RANTES and sCD40L, which have been implicated in the progression of advanced atherosclerotic plaques. Following plaque rupture or erosion, platelets bind to exposed VWF and collagen, mediated by GPIb, $\alpha_2\beta_1$ and GPVI. Initial platelet activation is then amplified by platelet release of soluble agonists, such as ADP, TxA_2 and thrombin, which stimulates further platelet activation in an autocrine and paracrine manner. Fibrinogen cross-links activated platelet $\alpha_{IIb}\beta_3$ receptors, causing platelet aggregation, and the procoagulant activities of platelets drive the development of a stable fibrin-bound clot. Emerging evidence also suggests that platelet-leukocyte interactions have an important role in clot formation and microvascular obstruction. Aspirin and $P2Y_{12}$ inhibitors have made a tremendous impact on improving outcomes from ACS, which paves the way for novel antiplatelet strategies to further benefit patients with ACS by targeting currently unexploited mechanisms.

Table 3 Summary of the major roles of platelets in the pathophysiology of ACS

Pathophysiology of ACS	Platelet involvement
Progression of advanced atherosclerotic plaque	Activated platelets promote leukocyte recruitment to the endothelium by upregulating expression of ICAM-1 and release of MCP-1 Platelet release of PF4, RANTES and CD40L promotes macrophages to infiltrate atherosclerotic plaques, change phenotype and produce collagen-degrading MMPs (Gawaz et al. 2000; Hundelshausen et al. 2005; Libby 2013) OxLDL induces the formation of platelet-monocyte aggregates, which promotes monocyte extravasation and enhances foam cell formation (Badrnya et al. 2014)
Platelets adhere to exposed subendothelial components, initiating thrombus formation	Platelet GPIb initiates platelet adhesion and activation by binding exposed VWF (Delaney et al. 2012) Platelet $\alpha_2\beta_1$ mediates adhesion by binding exposed collagen (Jarvis et al. 2002; Kuijpers et al. 2003) Platelet GPVI acts synergistically with α2β1 to facilitate adhesion and potently activates platelets in response to collagen (Jarvis et al. 2002; Kuijpers et al. 2003)
Activated platelets aggregate at the site of plaque rupture	Fibrinogen cross-links activated $\alpha_{IIb}\beta_3$ receptors on adjacent platelets, causing aggregation (Coller and Shattil 2008)
Platelet activation is amplified in an autocrine and paracrine manner	Platelets release ADP from their dense granules, which activates platelet $P2Y_{12}$ ADP receptors, causing further activation (Storey et al. 2000) Platelets synthesise thromboxane A_2, which acts on platelet TP receptors (Patrono et al. 2005)
Stable thrombus occludes, or partially occludes, the coronary lumen	Platelets activation induces the formation of a prothrombinase complex on their surface membrane, which converts prothrombin into thrombin (Solum 1999) Thrombin activates platelet PARs and also promotes fibrin generation, which consolidates clot formation (Leger et al. 2006)
Inflammation induced by ACS is mediated by platelet-leukocyte interactions	Platelet-monocyte aggregate formation promotes monocyte release of pro-inflammatory cytokines (Thomas and Storey 2015b) Platelet-neutrophil interactions induces NET formation and may play an important role in the pathophysiology of microvascular obstruction

Take Home Messages

- Platelets play a role in the development of atherosclerosis and in the formation of a thrombus after atherosclerotic plaque rupture.
- If a thrombus occludes the coronary artery, this may lead to an acute coronary syndrome.
- Inhibition of platelet-specific receptors has proved to be an exceptionally successful approach in the treatment of acute coronary syndromes.
- Although many receptor antagonists have been investigated, several receptors have still not been targeted in patients with acute coronary syndromes, which offer the potential for exciting, novel antiplatelet strategies.

Platelets in Acute Ischemic Stroke

Guido Stoll, Christoph Kleinschnitz, and Bernhard Nieswandt

Abstract

Ischemic stroke and myocardial infarction are the major causes of death and disability worldwide. Rapid restoration of blood flow by pharmacological thrombolysis and/or mechanical thrombectomy is the mainstay of acute stroke treatment, but does not guarantee a favorable outcome. Reperfusion injury denotes the acute, paradoxically harmful aspect of blood flow return in the ischemic brain which involves platelet activation and, surprisingly, immune cell recruitment. In experimental stroke, glycoprotein (GP)Ibα facilitated tethering of platelets to the postischemic brain endothelium by binding to von Willebrand factor (VWF), while firm adhesion and platelet activation were mediated by GPVI signaling. Accordingly, blocking of platelet GPIbα or GPVI, as well as reducing circulating VWF, dramatically improved stroke outcome by protecting the microvasculature during reperfusion and in addition accelerated recanalization during thrombolysis. Despite interfering with platelet function, no bleeding complications occurred, in contrast to devastating intracranial hemorrhages observed after blocking platelet aggregation via $\alpha_{IIb}\beta_3$. It will be essential to further dissect pathological platelet functions and activation pathways involved in reperfusion injury from those indispensable as gatekeepers of hemostasis in the stroke-injured brain. The pathophysiology of acute stroke is even more complex since it involves concerted detrimental actions of platelets and T-cells, referred to as "thrombo-inflammation," which await further elucidation.

Introduction

Stroke is a leading cause of death worldwide and significantly contributes to permanent disability in the aging world population Global Burden of Disease Study 2013 collaborators 2015). Cerebral ischemia accounts for roughly two thirds of strokes, while the remaining cases are caused by primary intracerebral hemorrhages (ICH) (Krishnamurthi et al. 2013) which are not covered in this chapter. Atrial fibrillation (AF) and high-grade internal carotid artery (ICA) stenosis represent the major sources of cerebral thromboembolism (Lip and Lane 2015; Stoll and Bendszus 2006). Thromboembolic occlusion of major or multiple smaller intracerebral arteries leads to impairment or cessation of the downstream blood flow (Fig. 1a, b) which triggers a plethora of consecutive pathological events in the brain leading to ischemic brain injury (Stoll et al. 1998; Dirnagl et al. 1999). For decades, prevention has been the mainstay of stroke treatment. Anticoagulation is the treatment of choice for prevention of cardiogenic thromboembolism in AF patients (Lip and Lane 2015), while thromboembolism emerging from atherosclerotic plaques of extracranial

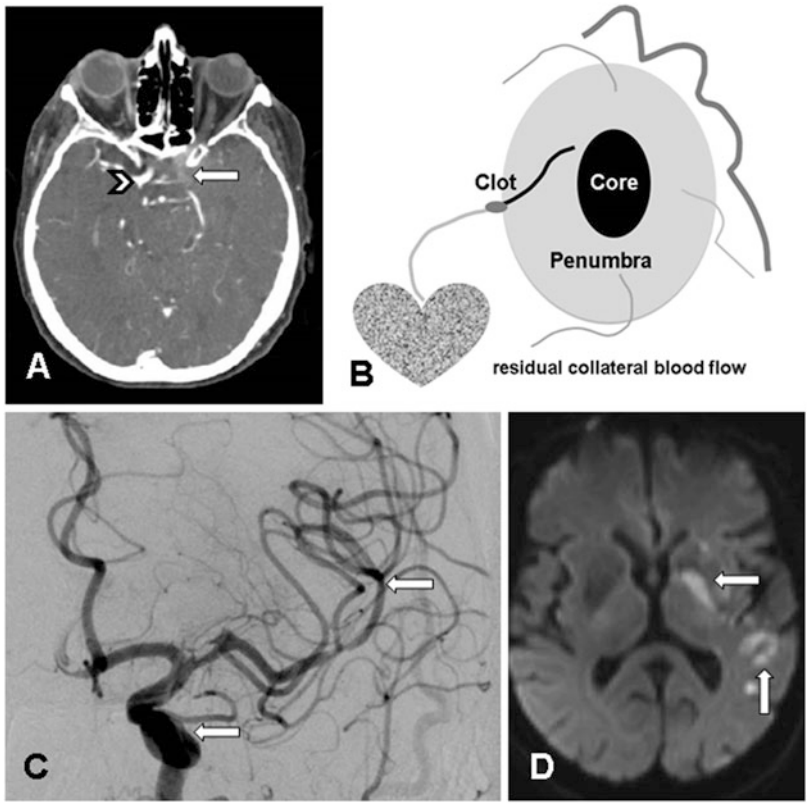

Fig. 1 Successful recanalization and favorable clinical outcome in a patient with acute internal carotid artery (ICA) occlusion. (**a**) CT angiogram on admission showing a patent distal ICA on the right side (*arrowhead*) and a missing contrast enhancement due to occlusion of the left ICA (*arrow*). Clinically, the patient exhibited hemiplegia on the right side and was aphasic. (**b**) Depicts the penumbra concept: After occlusion of a major cerebral artery (like in this patient), severe hypoxia occurs in the center of the corresponding vascular territory (core), while in the surround, called penumbra, residual blood flow is maintained by collaterals. Thereby, the penumbra contains salvageable brain tissue upon successful reperfusion. (**c**) Shows a conventional digital subtraction angiogram after successful removal of the vessel-occluding clot by mechanical thrombectomy. Note recanalization of the ICA and the branches of the MCA (*arrows* in **c**). According to a good clinical outcome with a residual hemiparesis and mild aphasia, diffusion-weighted magnetic resonance imaging, the most sensitive sequence for detection of ischemic brain lesions, showed only small embolic lesion areas, which appear white (*arrows* in **d**)

vessels is amenable to carotid endarterectomy/stenting (Stoll and Bendszus 2006) and/or conventional antiplatelet therapies (Sandercock et al. 2014). The clinical aspects of antiplatelet therapy in primary and secondary stroke prevention are discussed in chapter by Spokoysy and Albers (2017 in this volume); we here focus on the pathophysiological role of platelets in the acute phase of stroke, e.g., within 24 h of symptom onset, with emphasis on reperfusion injury of the brain. While immune cell recruitment has been thoroughly analyzed up to weeks after stroke onset (Stoll et al. 1998; Gelderblom et al. 2009) to the best of our knowledge, no similar studies on secondary recruitment of platelets and their role within the brain parenchyma in the subacute and chronic stages of infarct maturation are available. There is evidence that lesion-induced accumulation of platelets promotes survival of adult neural stem cells in the brain (Kazanis et al. 2015), and, moreover, platelets play a decisive role in wound healing (Nurden 2011). Whether platelets are involved in lesion maturation and tissue remodeling after brain ischemia, and if late outcome could be modified by antiplatelet treatment, is completely unknown and therefore not covered in this chapter. Prompt application of antiplatelet drugs in stroke patients is currently based solely on their effects on secondary prevention of recurrent thromboembolic events (Sandercock et al. 2014).

Acute Stroke Treatment: Thrombolysis and Mechanical Thrombectomy

The main goal of treatment in acute ischemic stroke is recanalization of occluded extra- and intracranial vessels (Fig. 1). Intravenous thrombolysis by recombinant tissue-type plasminogen activator (rt-PA) within 4.5 h after symptom onset introduced in 1995 was the only proven effective treatment for acute stroke (The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group

1995). Broad clinical experience showed that recanalization was the strongest predictor of good clinical outcome, but it also became obvious that only a low rate of recanalization could be achieved by intravenous thrombolysis alone in proximal vessel occlusion, e.g., occlusion of the ICA or the M1 segment of the middle cerebral artery (MCA) (Bhatia et al. 2010). This prompted further clinical trials evaluating intra-arterial thrombolysis and mechanical thrombectomy using stent retriever systems which at the beginning revealed equivocal results. The recent MR CLEAN trial (Berkhemer et al. 2015) was the first to document superiority of mechanical thrombectomy over pharmacological thrombolysis alone and has changed stroke care worldwide (Grotta and Hacke 2015). Five hundred patients with acute stroke were randomized to standard thrombolysis with and without intra-arterial thrombectomy within 6 h of symptom onset. Although the reperfusion rate of 58.7 % in MR CLEAN was relatively low as compared with previous,

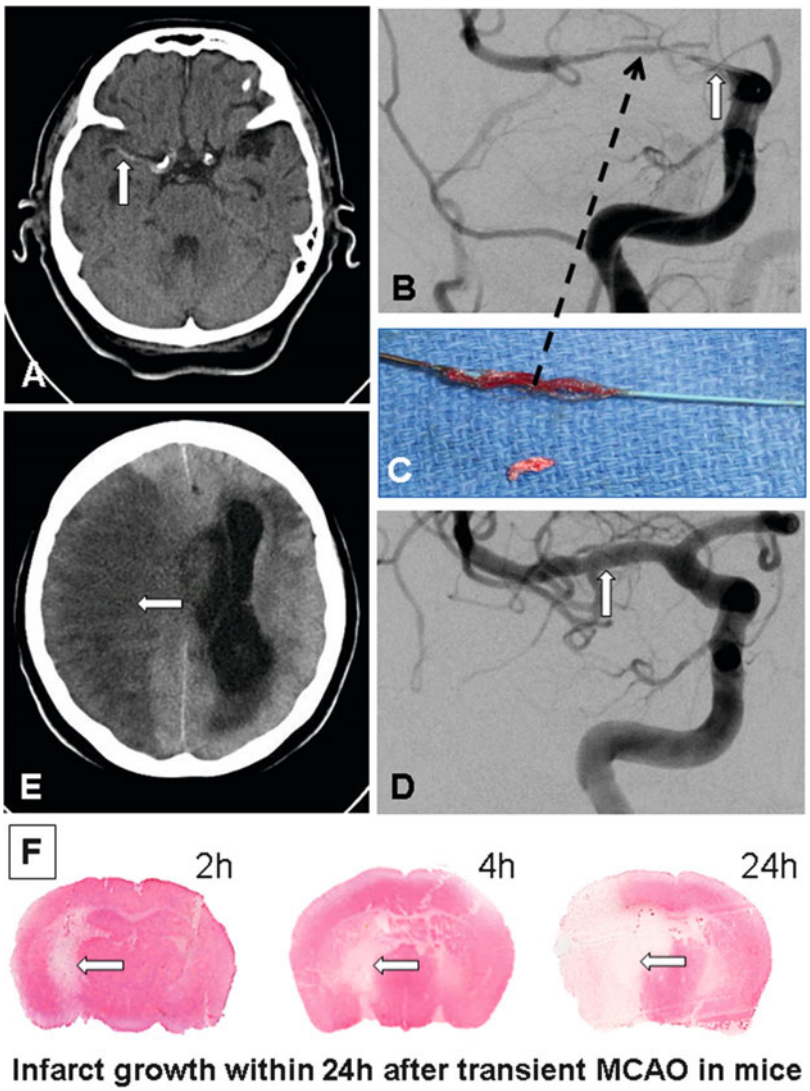

Fig. 2 Infarct development despite successful recanalization. A patient with acute left-sided hemiparesis due to occlusion of the right middle cerebral artery (MCA). The intravascular clot appears white on the native CT scan (*arrow* in **a**). A catheter device (stent retriever) is advanced through the femoral artery into the internal carotid artery and further upward to the proximal end of the intravascular clot within the MCA; the fresh clot is penetrated (*white arrow* in **b** denotes proximal site of occlusion), captured by the devise, and a stent then extended which facilitates immediate restoration of blood flow. The stent retriever system containing the former vessel-occluding clot (shown in **c**) is then removed and the patency of the MCA completely restored (*arrow* in **d** depicts the reperfused MCA segment). Despite successful recanalization, the patient unfortunately developed a large MCA infarction due to reperfusion injury (**e**). This common clinical situation can be mimicked by the transient MCA occlusion model in mice: (**f**) show infarct development in mice after 1 h of MCAO by TTC staining, an indicator for vital tissue. Dark areas show vital brain tissue, while pale areas are necrotic marked by arrows. Note that 2 h and 4 h after reperfusion, cortical areas are still spared from ischemic brain damage, but despite recanalization a full-blown MCA infarct inevitably develops within 24 h

clinically equivocal trials which were 80 % or higher, for the first time there was an absolute difference in the rate of functional independence (modified Rankin score 0–2) in favor of the intervention (32.6 % vs. 19.1 %) (Berkhemer et al. 2015). After publication of MR CLEAN, a number of concurrent clinical studies were prematurely halted after interim analyses confirming these encouraging results (Grotta and Hacke 2015). Mechanical thrombectomy increases the number of acute stroke patients with successful restoration of blood flow and favorable outcome (Fig. 1), but a considerable number of patients still develops severe neurological deficits or die, despite recanalization (Fig. 2). The number needed to treat for a good functional outcome in one patient is around four to six over all thrombectomy trials. The mechanisms underlying infarct growth despite recanalization are largely unknown, but there is increasing evidence from animal studies that platelets are critically involved.

The Concept of Reperfusion Injury After Brain Ischemia and Early Observations Regarding the Function of Platelets Herein

As discussed, revascularization therapies in stroke patients aim to rescue brain tissue at risk, the so-called ischemic penumbra (Jung et al. 2013), by restoring the patency of an occluded major supplying artery (recanalization) (Fig. 1) and the downstream capillary blood flow (reperfusion) (Soares et al. 2010). Importantly, recanalization does not necessarily facilitate reperfusion (Nour et al. 2013). The phenomenon that "blood does not flow despite recanalization" has been termed "no-reflow" phenomenon (Ames et al. 1968), and the paradoxically harmful aspect of blood flow return in transiently ischemic organs has been termed "reperfusion injury" (Hallenbeck and Dutka 1990; del Zoppo and Mabuchi 2003). In the brain, conversion of the luminal surface of the postischemic endothelium within the microvasculature from an anticoagulant to a procoagulant membrane has been proposed as one key mechanism of these harmful events (Hallenbeck and Dutka 1990). In support of this notion, Del Zoppo and colleagues could show that ^{111}In-labeled platelets are deposited in the ischemic basal ganglia early during reperfusion in a primate model of transient middle cerebral artery occlusion (tMCAO) (Del Zoppo et al. 1986). Electron microscopic examination of the microvasculature within the ischemic region further demonstrated aggregates of degranulated platelets together with fibrin and leukocytes and provided direct evidence that platelet activation occurs in the ischemic zone (Okada et al. 1994). Baboons treated with ticlopidine, a first generation P_2Y_{12}-ADP receptor inhibitor, in combination with heparin displayed a significant reduction in platelet deposition and in the number of microvascular occlusions in the ischemic basal ganglia (Del Zoppo et al. 1986). In clinical practice, platelet aggregation inhibitors, most notably acetylsalicylic acid (ASA), are routinely given to ischemic stroke patients not amenable to recanalization treatments within 48 h of symptom onset (Sandercock et al. 2014). This recommendation is based on the results of two major clinical trials involving more than 40,000 participants, in which treated patients had a moderate, but statistically significant, benefit on stroke outcome (CAST (Chinese Acute Stroke Trial) Collaborative Group 1997; International Stroke Trial Collaborative Group 1997). It is widely held, however, that the primary effect of ASA was due to reduction of early recurrent stroke rather than halting ongoing subacute lesion development in the brain (Jauch et al. 2013). A recent retrospective, case-control study in 3025 patients with first-ever ischemic stroke, however, provided class II evidence that patients with pre-stroke antiplatelet agent use were partly protected in the acute phase as they showed decreased stroke severity (Jung et al. 2015). On the other hand, treatment of stroke patients with ASA immediately after intravenous thrombolysis provided no evidence for a beneficial antithrombotic effect, but was associated with early deterioration caused by an increased rate of ICH (Zinkstok et al. 2014) (Fig. 4). Thus, although the protective role of platelet aggregation inhibitors in primary and secondary stroke prevention is well established (CAPRIE Steering Committee 1996; Bhatt et al. 2006) (see Spokoyny and Albers (2017)), the functional role of platelets during the acute stroke phase is less well established and awaits further clarification (Sandercock et al. 2014). The task is to dissect detrimental platelet effects in reperfusion injury from their essential function as gatekeepers of hemostasis in acute stroke. The tremendous progress made in our understanding of the mechanisms of platelet activation, as well as the receptors and signaling molecules involved (as described in detail in other chapters of this book), allows translational research to better define the role of platelets during cerebral ischemia. Thereby the transient middle cerebral artery occlusion model (tMCAO) of focal cerebral ischemia is widely used (Braeuninger et al. 2012). Usually a filament is inserted into the ICA of rodents and further advanced intracranially to occlude the MCA for variable time periods. In most studies the final stroke volume is assessed around 24 h after onset of ischemia. The extent of ischemic brain damage depends on the occlusion time until reperfusion is allowed by removal of the filament. It is important to note that despite reperfusion, infarcts further develop and maturate within the following 24 h. In mice a MCA occlusion time of 1 h finally leads to complete infarction of the MCA territory, but infarcts gradually grow during reperfusion as shown in Fig. 2f [for further details see Braeuninger et al. (2012)]. Thus, the tMCAO model partly mimics the clinical situation in which patients with a thrombotic MCAO undergo thrombolysis or mechanical thrombectomy and, in

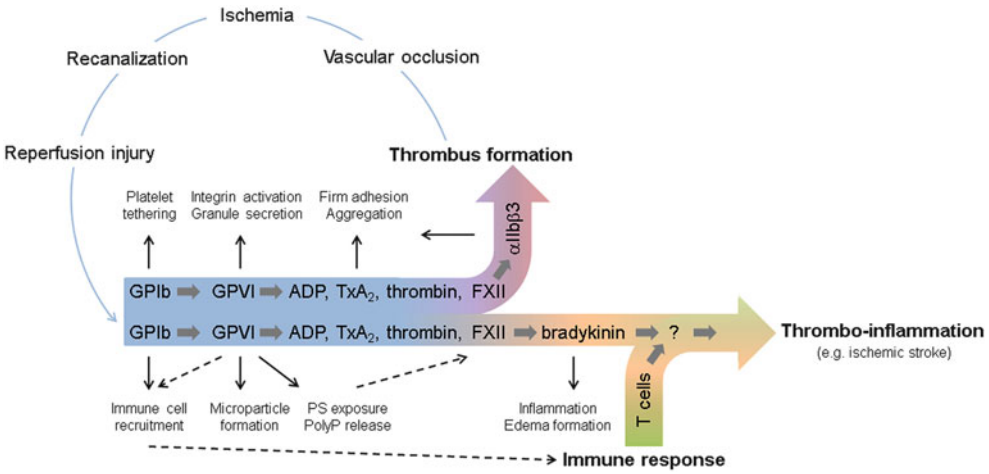

Fig. 3 Distinct but overlapping mechanisms drive thrombus formation and thrombo-inflammatory responses. GPIb mediates platelet tethering at the site of vascular injury, but also participates in immune cell recruitment during inflammatory responses. The central activating collagen receptor on the platelet surface, GPVI, supports platelet activation and triggers granule release which is essential for the secretion of ADP and TxA_2 that together with locally produced thrombin potentiate platelet activation. In parallel, strong cellular activation via GPVI culminates in the exposure of procoagulant phosphatidylserine (PS) and the release of inorganic polyphosphates (PolyP) which fuels coagulation and potently activates FXII, respectively. Additionally, GPVI signaling has been implicated in immune cell recruitment and inflammation via microparticle formation. Integrin $\alpha_{IIb}\beta_3$ (GPIIb/IIIa) is essential for stable thrombus formation which may lead to occlusion of diseased vessels and ischemia. Recanalization of a previously occluded vessel is often accompanied by reperfusion injury associated with damage to the affected tissue which triggers platelet recruitment to the site of injury. However, downstream signaling events may diverge from those leading to thrombus formation. Here, activation of FXII may also trigger formation of pro-inflammatory bradykinin which, in synergy with T-cells, contributes to a profound thrombo-inflammatory response, such as found in ischemic stroke. The mechanisms of T-cell recruitment and downstream effector molecules in this process are still elusive

significant numbers, develop ischemic infarcts, despite successful recanalization.

Detrimental Role of Platelets in Reperfusion Injury of the Brain

Platelet Tethering: GPIbα/VWF

To be able to adhere to the arterial wall under high shear flow conditions (> ~500 s^{-1}), platelets must be slowed down. This process, named tethering, depends on GPIb-V-IX, a structurally unique receptor complex exclusively expressed in platelets and megakaryocytes (Berndt et al. 2001) (Fig. 3). Platelet GPIbα binds to the A1 domain of immobilized von Willebrand factor (VWF) exposed on the surface of the vessel wall (Savage et al. 1996). VWF can be released from Weibel-Palade bodies of endothelial cells or α-granules of platelets (Kanaji et al. 2012). Although sufficient to support platelet binding, this adhesive interaction is characterized by a rapid dissociation rate. Firm platelet adhesion depends on cellular activation which is induced by other receptors such as the collagen receptor GPVI which is enabled to bind its ligand once the platelet is decelerated and in contact with the injury site (Nieswandt and Watson 2003) (Fig. 3). The VWF-binding site on GPIbα can be blocked in mice by Fab fragments of the antibody p0p/B which abrogates platelet tethering and adhesion under high shear flow conditions (Massberg et al. 2003). Treatment of mice with anti-GPIbα Fab prevented infarct development in ischemic stroke when given preventively before or therapeutically shortly after tMCAO during reperfusion (Kleinschnitz et al. 2007). Perfusion- and diffusion-weighted imaging employing ultrahigh-field magnetic resonance imaging (MRI) revealed that anti-GPIbα treatment secured permanent reperfusion after removal of the vessel-occluding filament, while in untreated mice blood flow steadily decreased leading to cerebral infarctions (Pham et al. 2011). Although tail bleeding times were strongly elevated in anti-GPIbα Fab-treated mice, no increase in ICH was detected histologically and on MRI scans, which represents the main obstacle for anti-thrombotic therapy during the acute stroke phase in clinical practice (Zinkstok et al. 2014). Moreover, the therapeutic effects were durable for at least 1-week follow-up after tMCAO (Kleinschnitz et al. 2007). Recently, these findings could be confirmed in aged and comorbid mice (Kraft et al. 2015). Atherosclerotic $Ldlr^{-/-}$, streptozotocin-treated diabetic, as well as hypertensive mice were likewise protected against reperfusion injury upon treatment with anti-GPIbα Fab after tMCAO. This is important because it has often been criticized that experimental findings in healthy laboratory animals do not reflect the real world situation in which stroke patients display multiple vascular risk factors that could modify or diminish treatment responses.

Phospholipase D (PLD) isoforms become activated downstream of major platelet signaling pathways including GPIbα, and PLD1 has been shown to be required for the formation of stable thrombi. Platelets from *Pld1*$^{-/-}$ mice displayed impaired $\alpha_{IIb}\beta_3$ integrin activation in response to major agonists and defective GPIbα-dependent aggregate formation under high shear flow conditions (Elvers et al. 2010). *Pld1*$^{-/-}$ mice were protected from ischemic stroke in the tMCAO model, whereas the animals showed normal tail bleeding times and, importantly, no ICH after stroke induction (Elvers et al. 2010). Pharmacological inhibition of PLD was similarly effective, opening a new and safe antithrombotic strategy in reperfusion injury of the brain downstream of GPIbα (Stegner et al. 2013b).

The critical role of GPIbα/VWF interactions in stroke development after tMCAO could further be substantiated in *Vwf*$^{-/-}$ mice. Infarct volumes were reduced by 60 % in these mice compared to wild-type control (Kleinschnitz et al. 2009), and reconstitution of plasma VWF by hydrodynamic gene transfer restored the susceptibility of mutant mice to cerebral ischemia (De Meyer et al. 2010). Further experiments using bone-marrow chimeric mice revealed that not only endothelial-derived VWF but also VWF stored in α-granules of platelets contributes to infarct development after tMCAO (Verhenne et al. 2015). In support of a major role of VWF/GPIbα interactions in cerebral ischemia, increased serum VWF concentrations have been found in the acute phase in patients (Kraft et al. 2014), and, moreover, VWF levels could be established as an independent stroke risk factor (Bongers et al. 2006).

Ultra-large VWF released from endothelial Weibel-Palade bodies into the circulation is rapidly cleaved by the enzyme "a disintegrin-like and metalloproteinase with thrombospondin repeats-13" (ADAMTS13) to reduce its high thrombotic activity (Sadler 2008). Thereby surplus VWF remote from a vascular lesion is cleared to avoid uncontrolled clotting and to limit thrombus growth. After 30 min of tMCAO, mice usually develop small infarcts restricted to the basal ganglia in contrast to an occlusion time of 1 h which leads to a complete MCA infarct within 24 h (Braeuninger et al. 2012). Thus, 30 min of tMCAO is a stroke model suitable for testing the role of factors expected to accelerate infarct development. In further support of an important pathophysiological role of VWF in stroke development, *Adamts13*$^{-/-}$ mice showed a dramatic increase in infarct volumes when compared to wild-type mice after 30-min tMCAO (Zhao et al. 2009; Fujioka et al. 2010). Vice versa, infusion of recombinant human ADAMTS13 into wild-type mice immediately before reperfusion reduced infarct volumes and improved neurological outcome in the 1-h tMCAO model (Zhao et al. 2009). Thus, blocking of GPIbα/VWF interactions or enhancing VWF clearance by ADAMTS13 consistently mitigated reperfusion injury after tMCAO and, remarkably, was not associated with bleeding complications despite increased tail bleeding times in these mice.

Momi and colleagues took this approach one step further toward a clinical application (Momi et al. 2013). They induced a complete MCA occlusion in guinea pigs by intravascular photothrombosis and treated the animals immediately with nanobodies directed against the A1 domain of VWF named ALX-0081. Surprisingly, ALX-0081, when given within 15 min after tMCAO in guinea pigs, facilitated thrombus dissolution and rapid, almost complete reperfusion similar to the fibrinolytic agent rt-PA which served as an active control substance and is commonly used in acute stroke patients. Independent from its thrombolytic effect at the site of vessel occlusion, ALX-0081 treatment in addition improved microvascular patency in the ischemic hemisphere and neurological outcome (Momi et al. 2013). Accordingly, disruption of platelet cross-linking by GPIbα/VWF inhibitors disaggregated the external layer of occlusive thrombi and restored vessel patency even at a stage when thrombi were resistant to fibrinolysis or traditional antithrombotic drugs (Le Behot et al. 2014). Collectively these studies suggest that GPIbα/VWF inhibitors may be suitable to accelerate recanalization during thrombolysis or mechanical thrombectomy and further protect the microvasculature during reperfusion as shown by ultrahigh-field MRI (Pham et al. 2011).

Platelet Adhesion/Activation: GPVI

GPIbα/VWF binding facilitates tethering of platelets to the vessel wall, but does not allow firm adhesion which requires cellular activation. At sites of endothelial damage, this is mainly mediated by GPVI, the principal activating platelet collagen receptor (Nieswandt and Watson 2003; Stegner et al. 2014) (Fig. 3). Upon activation GPVI non-covalently associates with the Fc receptor (FcR)γ-chain, and this complex signal through tyrosine phosphorylation cascades downstream of the FcRγ-chain-associated immunoreceptor tyrosine-based activation motif (ITAM) (Berlanga et al. 2002). Platelets in which GPVI has been depleted by antibody treatment in vivo do not respond to collagen (Nieswandt et al. 2001; Nieswandt and Watson 2003). To elucidate a putative role of platelet-collagen interactions during reperfusion injury of the brain, GPVI was either depleted in platelets by the anti-GPVI antibody JAQ1 (Kleinschnitz et al. 2007) or binding of platelets to the vessel wall was blocked by Revacept, a recombinant soluble dimeric GPVI-Fc, which occupies subendothelial collagen-binding sites for the receptor (Goebel et al. 2013). Both treatments led to a significant reduction of microvascular thrombus formation and reduced infarct volumes after tMCAO (Kleinschnitz et al. 2007; Goebel et al. 2013). These findings indicate that firm platelet adhesion is an

important step in the pathophysiology of reperfusion injury in the brain. In further support of this notion, elevated plasma levels of soluble GPVI were detected in patients with acute thrombotic stroke, but not in patients with transient ischemic attacks in which vessel-occluding thrombi rapidly and spontaneously dissolve (Wurster et al. 2013). Blocking of GPVI function can also be achieved by targeting tyrosine kinases and adaptor proteins downstream of GPVI (Stegner et al. 2014). The spleen tyrosine kinase (Syk) is such an essential signaling mediator downstream of the ITAM receptor GPVI (Poole et al. 1997). Accordingly, *Syk*$^{-/-}$ mice were protected from ischemic stroke and pharmacological blockade of Syk likewise ameliorated infarct development and clinical outcome (van Eeuwijk et al. 2016).

Platelet Aggregation and Formation of Occlusive Thrombi

Following initial adhesion of platelets to the extracellular collagen matrix, extension of the thrombus requires amplification of the initial platelet response, further recruitment of circulating platelets, and platelet aggregation which is mediated by GPIIb/IIIa (integrin $\alpha_{IIb}\beta_3$) (Shattil and Ginsberg 1997) (Fig. 3) and other secretory platelet components (Nurden 2011). Earlier studies already described that partial pharmacological blockade of $\alpha_{IIb}\beta_3$ receptors in the tMCAO model reduced platelet and fibrin accumulation in the microvasculature as well as infarct volumes after tMCAO (Choudhri et al. 1998; Abumiya et al. 2000; Ishikawa et al. 2004). It became apparent, however, that the therapeutic window of $\alpha_{IIb}\beta_3$ inhibition was very narrow since near complete inhibition of platelet aggregation regularly led to large ICH. We reassessed efficacy and safety of anti-$\alpha_{IIb}\beta_3$ treatment in ischemic stroke by using $(Fab)_2$ fragments of the mouse $\alpha_{IIb}\beta_3$-blocking mAb, JON/A (Bergmeier et al. 2002) in young (Kleinschnitz et al. 2007) and aged, comorbid mice (Kraft et al. 2015). JON/A-$F(ab)_2$ treatment had no significant effect on peripheral platelet counts, but completely inhibited ex vivo platelet aggregation in response to different stimuli resulting in dramatically prolonged tail bleeding times (Bergmeier et al. 2002). In confirmation of previous studies, most mice with a virtually complete receptor blockade died mainly due to ICH, but, in contrast, the few surviving animals exhibited comparable infarct volumes as controls (Kleinschnitz et al. 2007). Reduction of $\alpha_{IIb}\beta_3$ blockade to 80 % or 70 % decreased bleeding-related mortality, but infarct volumes and neurological outcomes were not different from vehicle-treated mice. Similar results have been obtained in a clinical stroke trial that was prematurely stopped due to a dramatic increase in ICH in the anti-$\alpha_{IIb}\beta_3$-treated group (Adams et al. 2008). In transgenic mice lacking the GPIIb (and thus GPIIb/IIIa), cerebral infarct size was reduced at 24 h after tMCAO (Massberg et al. 2005). The reasons for these discrepant results are currently unclear, but it is conceivable that pharmacological blockade of $\alpha_{IIb}\beta_3$ could have different effects on reperfusion injury in the brain than $\alpha_{IIb}\beta_3$ deficiency. Further studies are necessary to clarify whether $\alpha_{IIb}\beta_3$-mediated platelet aggregation as the final step of platelet activation is involved in reperfusion injury of the brain or dispensable as hypothesized recently by us (Stoll et al. 2010; Nieswandt et al. 2011) (see "Platelet-Immune Interactions in Reperfusion Injury of the Brain").

Thrombus stability not only depends on platelet aggregation via $\alpha_{IIb}\beta_3$ but also on secretory platelet products. Platelets contain α- and dense granules which are released following adhesion to collagen or other matrix components as well as in response to agonists such as ADP and thrombin (Nurden 2011). Alpha-granules contain more than 300 proteins which are required for the propagation and stabilization of platelet-rich thrombi, while dense granules contain small, nonprotein molecules such as calcium, serotonin, ADP, and ATP. *Nbeal2*$^{-/-}$ mice, which lack α-granules and thereby reproduce the gray platelet syndrome, exhibit reduced adhesion on collagen and impaired thrombus growth at high shear rates and could not form occlusive thrombi in vascular injury models (Deppermann et al. 2013). Munc13-4 is a limiting factor for platelet granules release (Ren et al. 2010). Mice carrying an inactivating point mutation are not able to release dense granules, and α-granule release is diminished (Ren et al. 2010). In support of a critical role of granule release in reperfusion injury in the brain, both *Nbeal2*$^{-/-}$ and Munc13-4 mice were protected in the tMCAO model (Deppermann et al. 2013; Stegner et al. 2013a). An important component of the dense granule releasate is inorganic polyphosphate (PolyP), which acts as a potent activator of coagulation factor XII (FXII), the starting point of the intrinsic pathway of coagulation as well as inflammatory pathways through the formation of bradykinin (Muller et al. 2009). FXII deficiency or blockade was shown to markedly reduce cerebral infarct growth after tMCAO (Kleinschnitz et al. 2006; Hagedorn et al. 2010), but it remained unclear whether this protective effect was primarily based on reduced pro-coagulatory or pro-inflammatory activity in the acutely ischemic brain, or both (Fig. 3).

Platelets Are Gatekeepers of Hemostasis in the Ischemic Brain

Hemorrhagic transformation (HT) is a frequent complication of acute ischemic stroke, in particular after thrombolysis (Jickling et al. 2014) (Fig. 4a). In contrast to other organ systems, the brain is escluded from the circulation by the blood-brain barrier (BBB) which controls and limits the access of fluids and cells. As an early consequence of

cerebral ischemia, the BBB breaks down (Engelhardt et al. 2014; Knowland et al. 2014), mainly due to activation of matrix metalloproteinases which degrade the basal lamina around brain vessels (Hamann et al. 1996). The rate of HT is higher after transient MCAO with reperfusion than after permanent MCAO and further increases when reperfusion is delayed (Lu et al. 2009). Thus, there is a dilemma when blocking platelet functions during reperfusion in the brain: prevention of reperfusion injury may increase the risk of HT or overt ICH? As described above blockade of $\alpha_{IIb}\beta_3$ is associated with an extremely high risk of ICH in experimental (Kleinschnitz et al. 2007; Kraft et al. 2015) as well as clinical stroke (Adams et al. 2008; Kellert et al. 2013) and, even after ASA treatment in conjunction with thrombolysis, additional protective effects were offset by an unacceptable increase in ICH (Zinkstok et al. 2014). Accordingly, baseline antiplatelet use is associated with an increased risk of post-rt-PA symptomatic ICH in acute stroke (Cucchiara et al. 2009). This also applies to the intact, non-ischemic brain: improved efficacy of platelet inhibition in cardio- or cerebrovascular disorders, e.g., arterial stenoses and stenting, is often neutralized by a higher incidence of ICH (Gachet 2015) (Fig. 4b). Recently, it was reported in patients that a subset of procoagulant platelets, so-called COAT platelets, were increased in non-lacunar strokes, and lower levels were associated with acute hemorrhagic complications (Prodan et al. 2015) indicating a putative role in stroke hemostasis. It is therefore important to understand how platelets act to prevent ICH especially in the stroke-injured brain.

The most simple question one could imagine is how many platelets are needed for hemostasis. We induced thrombocytopenia of variable degree in mice by injection of polyclonal anti-GPIbα antibodies which deplete circulating platelets in mice without involving immune effector mechanisms (Nieswandt et al. 2000). Mice with significantly reduced platelet counts down to a range of 99–25 platelets/nL were still able to arrest bleeding in the tail bleeding test, and only after reduction to <2.5 % of control, bleeding no longer stopped spontaneously (Morowski et al. 2013). When thrombocytopenic mice were challenged by tMCAO, full-blown MCA infarcts developed unless platelet counts were reduced <10 % of normal (Morowski et al. 2013). Importantly, no HT or ICH was observed in these stroke-protected mice despite severe thrombocytopenia. These findings indicate that significant thrombocytopenia does not protect from reperfusion injury in the brain and that a very low count of intact platelets is sufficient to maintain hemostasis similar to clinical observations in idiopathic thrombocytopenic purpura (Neunert et al. 2013). Goerge and coworkers further showed that the propensity of thrombocytopenic mice to bleed depends on the local tissue environment (Goerge et al. 2008). Thrombocytopenic mice did not bleed spontaneously, but major hemorrhages occurred in the skin and lung when an additional local inflammatory stimulus was set. As outlined in detail below, ischemic stroke exhibits a significant extrinsic inflammatory component (Stoll et al. 1998). In support of the concept that inflammation predisposes to HT, thrombocytopenic mice (<2.5 % of normal) undergoing tMCAO exhibited multiple hemorrhagic foci (Goerge et al. 2008). In the skin, the presence of platelets prevented bleeding during inflammation, and this protective effect was unexpectedly also seen in mice lacking functional GPIbα, VWF, or GPVI indicating that tethering and firm adhesion of platelets via classical adhesion receptors were not required for hemostasis. This is in accordance with studies in the tMCAO model, in which mice lacking GPIb, VWF, or GPVI were stroke protected, but did not develop ICH (Kleinschnitz et al. 2007, 2009). Thus, it appears that the mechanisms by which platelets contribute to the pathogenesis of ischemic brain injury are different from those required to maintain hemostasis following ischemia/reperfusion which raises the intriguing possibility that strong platelet inhibition can be achieved without dramatically increasing the risk of (spontaneous) intracranial

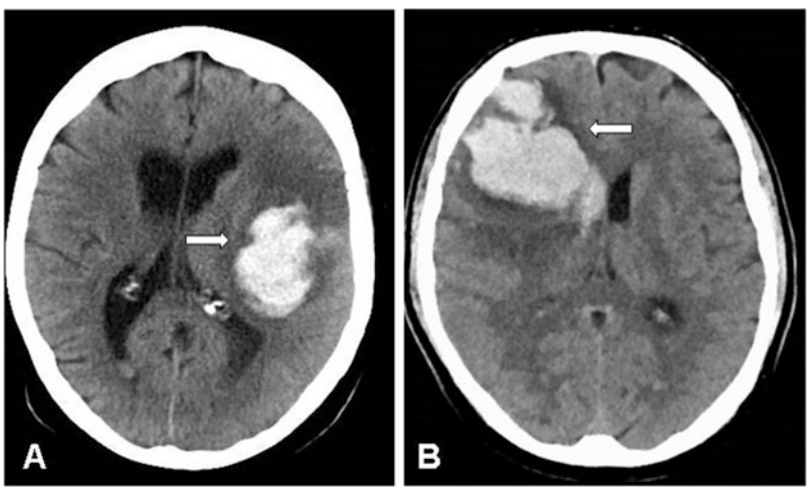

Fig. 4 The brain is vulnerable to intracranial hemorrhage (ICH). (**a**) CT scan of an ICH in the left hemisphere (*white* area marked by *arrow*) occurring spontaneously after thrombolysis using rt-PA. (**b**) Shows a frontally located ICH (*white* area marked by *arrow*) which occurred after arterial stenting under double platelet inhibition by ASA and ticagrelor

bleeding. Studies in the skin and lung moreover showed that platelets lacking G protein-coupled receptor signaling, thereby not responding to thrombin, ADP, and thromboxane A_2, were still protected against inflammation-induced bleedings, while blocking of the ITAM signaling pathway led to massive hemorrhages (Boulaftali et al. 2013). It is unclear whether this also applies to ischemic stroke. Interestingly, lack of Munc13-4 resulted in severely defective platelet aggregate formation (Savage et al. 2013), but mice did not develop increased ICH after tMCAO, in sharp contrast to mice with massive ICH in a parallel group in which $\alpha_{IIb}\beta_3$ was blocked (Stegner et al. 2013a). To improve stroke outcome and safety during recanalization procedures, it is mandatory to understand which platelet functions secure hemostasis during acute brain ischemia, a so far widely neglected field in experimental stroke research. At subacute and late stroke stages beyond 24 h, additional factors such as proteases, vascular remodeling (Jickling et al. 2014), and macrophage responses (Gliem et al. 2012) contribute to HT or prevent it, but at this stage the use of antiplatelet drugs is less critical and of proven value for secondary stroke prevention (Sandercock et al. 2014).

Platelet-Immune Interactions in Reperfusion Injury of the Brain

Brain ischemia has traditionally been regarded as a pure thrombotic disorder, but already more than 20 years ago, experimental and human studies revealed that immune cells infiltrate the brain after cerebral ischemia, and cytokines which orchestrate immune responses are upregulated within the ischemic brain parenchyma (Stoll et al. 1998; Lambertsen et al. 2012). The complex immune cell-brain interactions during the subacute and chronic phases of ischemic stroke have been reviewed elsewhere (Iadecola and Anrather 2011; Chamorro et al. 2012); here we focus on the role of T-cells and platelets during reperfusion early after cerebral ischemia (Fig. 3). In a seminal study, Yilmaz and colleagues showed that immune-deficient *Rag1*$^{-/-}$ mice which lack B- and T-cells are protected against cerebral ischemia in the tMCAO model (Yilmaz et al. 2006). These surprising data were soon confirmed thereafter (Kleinschnitz et al. 2010). Both studies revealed that adoptive transfer of T-cells into *Rag1*$^{-/-}$ mice restored susceptibility to ischemic brain damage, while B-cell transfer had no effect. A detailed immunological analysis showed that the detrimental T-cell effects in reperfusion injury of the brain largely were antigen independent and conferred by all major subclasses of T-cells, e.g., $CD4^+$, $CD8^+$, natural killer T-cells, etc. Surprisingly, also regulatory T-cells were deleterious (Kleinschnitz et al. 2013), and boosting of regulatory T-cells by CD28 agonist further increased ischemic brain damage (Schuhmann et al. 2015). FTY720 is an immunomodulator clinically approved for treatment of multiple sclerosis patients which rapidly reduces peripheral lymphocyte counts by blocking the egress of lymphocytes from lymphoid organs. FTY720, when given immediately before reperfusion in the tMCAO model, improved outcome (Kraft et al. 2013), a finding that could also be reproduced in a pilot trial of acute stroke patients who were treated by thrombolysis and in addition received FTY720 (Zhu et al. 2015). Thus, although it is too early for firm conclusions, it appears that T-cell responses are also critically involved in acute human stroke. The profound detrimental effect of T-cells is not unique for brain ischemia but rather represents a general pathophysiological phenomenon during organ reperfusion (Eltzschig and Eckle 2011). Importantly, thrombus formation itself was not altered in stroke-protected *Rag1*$^{-/-}$ mice as assessed in two standardized in vitro and in vivo thrombus formation models. Platelets from *Rag1*$^{-/-}$ mice normally adhered to collagen fibers and formed aggregates on collagen-coated surfaces in a whole-blood perfusion system under high shear conditions. In addition, vessel occlusion times were identical compared to immune-competent mice after $FeCl_3$-induced injury on mesenteric arterioles (Kleinschnitz et al. 2013). Taken together, these findings showed that brain damage after ischemia cannot merely be explained by a thrombotic event in the microcirculation. Taking into account the unequivocal contribution of T-cells to reperfusion injury, we coined the term "thrombo-inflammation" (Stoll et al. 2010; Nieswandt et al. 2011) (Fig. 3), a concept supported by the fact that detrimental T-cell effects are platelet dependent (Kleinschnitz et al. 2013). We could show that *Rag1*$^{-/-}$ mice were still protected from ischemic brain injury when platelets had been removed before adoptive transfer of detrimental T-cells (Kleinschnitz et al. 2013). Platelets can influence lymphocyte function and vice versa (Li 2008). In the liver $CD4^+$ T-cells have been shown to interact with platelets in postischemic sinusoids during reperfusion via platelet CD62P (P-selectin) (Khandoga et al. 2006). The molecular mechanisms underlying the concerted detrimental actions of T-cells and platelets in the brain are still elusive, but the encouraging results obtained by both experimental studies and a recent clinical pilot trial warrant further investigations to disclose the mystery of reperfusion injury and the paradoxically harmful restoration of blood flow in the brain.

Take-Home Messages

- Successful restoration of cerebral blood flow by thrombolysis and/or mechanical thrombectomy is the mainstay of acute stroke treatment, but recanalization alone does not guarantee a favorable outcome.

(continued)

- Reperfusion injury denotes the acute, paradoxically harmful aspect of blood flow return in the ischemic brain which involves platelet activation and immune cell recruitment.
- In experimental animals, blocking of platelet GPIbα or GPVI, as well as reducing circulating VWF, dramatically improved stroke outcome by protecting the microvasculature during reperfusion and further accelerated recanalization during thrombolysis without bleeding complications.
- Contrastingly, interfering with platelet aggregation by blocking $\alpha_{IIb}\beta_3$ led to devastating intracranial hemorrhages in acute experimental and human stroke.
- Before clinical application it is essential to further dissect pathological platelet functions and activation pathways involved in reperfusion injury from those indispensable as gatekeepers of hemostasis in the stroke-injured brain.
- The pathophysiology of reperfusion injury in acute stroke is even more complex and involves concerted detrimental actions of platelets and T-cells, referred to as "thrombo-inflammation," which awaits further elucidation.

Acknowledgments Work in the authors' laboratories was supported by the Deutsche Forschungsgemeinschaft, Bonn (SFB 688 A1, A13, B1, B7). We thank our numerous colleagues who contributed to the research cited in this article: Deya Cherpokova for preparing Fig. 3, Dr. Michael Schuhmann for Fig. 2F, and Prof. Dr. Làszló Solymosi, Head of the Department of Neuroradiology, University Hospital of Würzburg, for providing CT scans and angiograms of stroke patients.

Platelets in Deep Venous Thrombosis and Pulmonary Embolism

Ingrid Pabinger, Julia Riedl, and Simon Panzer

Abstract

Platelets have important roles in the development of venous thromboembolism (VTE). In experimental studies, including animal models of venous thrombosis, platelets were found to augment thrombus formation in the venous system, and the importance of the interaction between platelets and the plasmatic coagulation system for the development of VTE was shown. Furthermore, studies on patients with acute VTE and on patients at high risk for VTE have revealed that markers of platelet activation are elevated in these settings, and platelet markers, such as soluble P-selectin, might serve as biomarkers of acute VTE or to indicate patients with a high risk of VTE. Most convincingly, antiplatelet therapy with aspirin was found to reduce risk of VTE after orthopedic surgery and risk of recurrent VTE after a first event and might be an additional therapeutic option. The therapeutic effect of aspirin in the prevention of VTE proves the concept that platelets are important players in thrombosis of the venous system.

Introduction

Platelets and platelet activation are best known for their key role in the pathophysiology of arterial thrombosis, and antiplatelet therapy is a main concept in the treatment of atherothrombotic diseases. The situation is less clear in deep vein thrombosis (DVT) and pulmonary embolism (PE), together referred to as venous thromboembolism (VTE). Platelet involvement in VTE has long been viewed to have a minor role, as venous thrombi consist of a fewer amount of platelets in comparison to arterial thrombi. However, today, growing evidence suggests an important role of platelets also in VTE. Experimental studies show that platelets are essential in initiation and augmentation of venous thrombosis. Platelet indices, such as mean platelet volume, were found to be associated with the risk of VTE, and most convincingly, randomized clinical trials for the evaluation of antiplatelet agents in VTE prophylaxis show an effective reduction in the risk of VTE after orthopedic surgery and a reduced risk of VTE recurrence after a first episode if patients have been treated with aspirin. This chapter highlights the most important findings on the role of platelets in VTE.

Deep Venous Thrombosis and Pulmonary Embolism

VTE is the third most frequent cause of vascular death after myocardial infarction and stroke worldwide. The mean incidence of VTE is approximately 1–2 per 1000 per year and increases exponentially with age (Naess et al. 2007; ISTH Steering Committee for World Thrombosis Day 2014). The etiology of VTE is multifactorial, and this was first described in the nineteenth century by Rudolf Virchow, who proposed that three factors are crucial for the development of VTE

(known as "Virchow's triad"): alterations in blood flow ("stasis"), alterations of the blood components, and damages to the vessel wall. Today, multiple risk factors for VTE have been identified (Reitsma et al. 2012) that are related to one of the three categories of "Virchow's triad": Stasis of the venous blood flow after immobilization, for example, is a well-known risk factor of VTE. Thrombophilic changes of blood components, such as genetic mutations of coagulation factors (factor V Leiden mutation, prothrombin mutations, etc.), were identified to be associated with risk of VTE. Finally, in experimental studies endothelial activation was found to be crucial for the formation of a clot (Mackman 2012). In conclusion, VTE is a multifactorial disease, influenced by multiple inherited and acquired risk factors. This chapter focuses on the contribution of platelets, the cellular part of the coagulation system, to the development of VTE.

Platelets in the Pathophysiology of Deep Venous Thrombosis and Pulmonary Embolism

From a classical point of view, platelets are key mediators in the pathophysiology of thrombosis in the arterial system, whereby they attach to injured vessel walls after rupture of an atherosclerotic plaque under high shear stress and induce formation of a platelet-rich "white" clot (Mackman 2008). In contrast, venous thrombi are proposed to form over an intact vessel wall in a low shear system through multifactorial processes and are rich in fibrin and trapped red blood cells ("red clots") (Mackman 2008). However, platelet hyperaggregability and shortened platelet survival in patients with deep vein thrombosis were described already decades ago (Wu et al. 1976). In addition, the presence of platelets in venous thrombi (Sevitt 1970) suggests their involvement in thrombus formation. Activated platelets interact with the plasmatic coagulation system, exposing the main fibrinogen receptor $\alpha_{IIb}\beta_3$, which also serves as a receptor for von Willebrand factor, and other important plasma coagulation proteins. Further, the platelet glycoprotein (GP) Ibα, of the platelet GPIb-IX-V complex, binds von Willebrand factor (VWF) or thrombospondin (TSP) and is co-associated with the platelet-specific collagen receptor, GPVI (Arthur et al. 2005). The GPIb-IX-V/GPVI adhesion-signaling complex initiates platelet activation and aggregation and thus thrombus formation in response to vascular injury and collagen exposure. GPIbα also regulates coagulation through a specific interaction with thrombin and other coagulation factors, reviewed in Gardiner and Andrews (Gardiner and Andrews 2014). Activated platelets expose negatively charged phospholipids and provide a procoagulant surface, thereby promoting the generation of thrombin (Heemskerk et al. 2002). In a rat model, thrombus formation was reduced in thrombocytopenic animals as compared to animals with a normal platelet count. In this model, thrombus formation was induced by ligation of the inferior vena cava and infusion of low dosage of tissue thromboplastin. Platelet reduction did not inhibit thrombus formation with high tissue thromboplastin concentrations; however, an 87 % reduction of thrombus formation with low concentration of tissue thromboplastin was observed, pointing to an important role of platelets at least at mild thrombogenic stimuli (Herbert et al. 1992). Another study on VTE in the rat showed that the antiplatelet agents aspirin and clopidogrel reduce thrombus formation after adriamycin-induced VTE (Bernat and Herbert 1994). In a more recent study, the interaction between platelet GPIbα and von Willebrand factor (vWF) was found to be a crucial step in a mouse model of VTE. In this model, DVT was induced by flow restriction in the inferior vena cava only (Brill et al. 2011). Furthermore, platelets propagate the formation of venous thrombi by recruiting and interacting with leukocytes and by inducing the release of neutrophil extracellular traps (NETs) (von Brühl et al. 2012). In the latter study, a mouse model of DVT by flow restriction in the inferior vena cava was combined with intravital imaging techniques, allowing in vivo tracking of platelets during thrombus formation. This study showed that platelets are recruited to the developing thrombus very early after flow restriction and support the accumulation of leukocytes. Further, GPIbα was essential for the effects of platelets in propagating thrombosis, pointing to an important role of platelet GPIbα in VTE.

Platelet Biomarkers in Deep Venous Thrombosis and Pulmonary Embolism

Multiple studies focused on the evaluation of platelet count, platelet volume, and soluble markers of platelet activation for risk prediction of first or recurrent VTE and on the value of these parameters for diagnosis and prognosis of VTE.

Biomarkers of Increased Platelet Activation

Currently, the most extensively studied biomarker of platelet activation is soluble P-selectin (sP-selectin). P-selectin is an adhesion molecule that is located in the alpha-granule of resting platelets and that becomes translocated to the platelet surface upon platelet activation and degranulation. Once on the surface, it is cleaved and a soluble part, sP-selectin, is released into the circulation. sP-selectin in plasma can also derive from the Weibel-Palade bodies of endothelial cells upon their activation, but the bulk amount of sP-selectin is platelet derived (Fijnheer et al. 1997; Jilma-Stohlawetz et al. 2014). Levels of sP-selectin are elevated in patients with acute VTE (Smith et al. 1999; Rectenwald et al. 2005; Gremmel

et al. 2011) and in patients with recurrent VTE (Ay et al. 2007). A meta-analysis including 11 studies, comprising 586 VTE patients and 1843 controls, reconfirmed that sP-selectin is significantly elevated in acute VTE and concluded that sP-selectin might be a biomarker for the diagnosis of VTE (Antonopoulos et al. 2014). High sP-selectin levels also predict risk of recurrent VTE after a first unprovoked event (Kyrle et al. 2007) and risk of VTE in cancer patients (Ay et al. 2008). However, despite numerous data pointing to an important role of sP-selectin for a diagnosis and risk prediction of VTE, there are so far no rapid and standardized methods for its measurement in clinical routine, currently limiting its clinical applicability as a marker (Blann 2014).

Another biomarker of platelet activation is the soluble form of CD154 or CD40 ligand (CD40L). CD40L is located in the platelet alpha-granules and becomes translocated to the platelet surface upon their activation. Once on the surface, it is cleaved and a soluble form of CD40L (sCD40L) is released into the circulation. sCD40L can be measured in plasma as a biomarker of platelet activation. The CD40-CD40L axis has important functions in the adaptive immune system, such as activation of antigen-presenting cells, and the discovery of CD40L on platelets points to a role of platelets in adaptive immunity (Elzey et al. 2011). sCD40L was found to be elevated in patients with acute coronary syndrome, and in these patients, it is associated with worse clinical outcome (Ferroni et al. 2012).

Two studies investigated levels of sCD40L in patients with VTE. Levels of sCD40L were higher in patients with acute PE compared to healthy controls (Kaya et al. 2011), whereas sCD40L levels were not different in patients with a history of spontaneous VTE and controls (Migliacci et al. 2007).

In a matched nested case-control study, embedded within an observational study on cancer patients, levels of sCD40L, measured before the beginning of chemotherapy, were not found to be associated with risk of cancer-associated VTE (Riedl et al. 2015).

In conclusion, current data suggest that there is no role for measuring sCD40L to predict risk of VTE; however, it might be a biomarker of acute VTE.

Platelet factor (PF)-4 is another important biomarker of platelet activation, which is stored in the platelet alpha-granules, from where it is released upon platelet activation. It was found to have procoagulatory activity in vitro; however, its biological function in vivo is not yet fully understood (Kowalska et al. 2010). In a clinical study, levels of PF-4 were found to be increased in patients with acute VTE (Blanke et al. 1987). Another study found high amounts of PF-4 to be associated with an increased risk of VTE in patients with pancreatic cancer (Poruk et al. 2010). However, a study by our group found no association between levels of PF-4 and risk of VTE in patients with different types of cancer, (Riedl et al. 2015) suggesting a minor role of PF-4 for risk prediction of VTE. It has to be noted, however, that release of PF-4 is prone to artificial platelet activation during sample processing, which might explain diverging results of studies and which also currently further limits the clinical applicability of PF-4 as a biomarker of VTE.

Platelet Count

In the general population, platelet count is not a risk factor for VTE, which was shown in large observational studies on community-dwelling individuals that found no relationship between platelet count and risk of first VTE event (Tsai et al. 2002; van der Bom et al. 2009).

High Platelet Counts and Risk of VTE

Cancer patients are at high risk for developing VTE, with an estimated risk of up to 20 % per year, depending on cancer site, stage, and several other factors. Platelets seem to have a very special role in the development of VTE in cancer patients. Cancer cells have the ability to activate and aggregate platelets directly, and thus they are anticipated to be involved in VTE formation and also in the progression of the malignant disease [reviewed in Riedl et al. (2014), illustrated in Fig. 1]. In cancer patients, an elevated platelet count, measured prior to the initiation of chemotherapy, was found to be associated with risk of VTE (Khorana et al. 2005; Simanek et al. 2010). In the Vienna Cancer and Thrombosis Study (CATS), the risk of patients who had a platelet count above the 95th percentile of the whole cohort (>443 G/l) had a fivefold higher risk to develop VTE compared to patients with a platelet count below that cutoff (Simanek et al. 2010). A platelet count of 350 G/l or more has also been incorporated into a risk prediction score to identify cancer patients undergoing chemotherapy in the outpatient setting who are at a high thrombotic risk (Khorana et al. 2008). Interestingly, data from a population-based study from Norway revealed that a high platelet count, measured several years before the diagnosis of cancer, is associated with an elevated risk of VTE in subjects who later develop cancer (Jensvoll et al. 2014). In contrast, platelet count was not associated with risk of VTE in subjects who remained cancer-free, and it was concluded that platelet count might specifically play a role in the pathogenesis of cancer-associated VTE.

Very high platelet counts (>1000 G/l) are often seen in patients with essential thrombocythemia (ET), a myeloproliferative disorder (MPN) with increased platelet production and high risk of arterial and venous thrombosis. Interestingly, extreme thrombocytosis was not found to be a risk factor for VTE in these patients but rather for bleeding events, as very high platelet counts can cause acquired von Willebrand syndrome (vWS) (Reikvam and Tiu 2012; Kreher et al. 2014). This assumption that a relative shortage of von Willebrand factor ensues if platelet counts are high

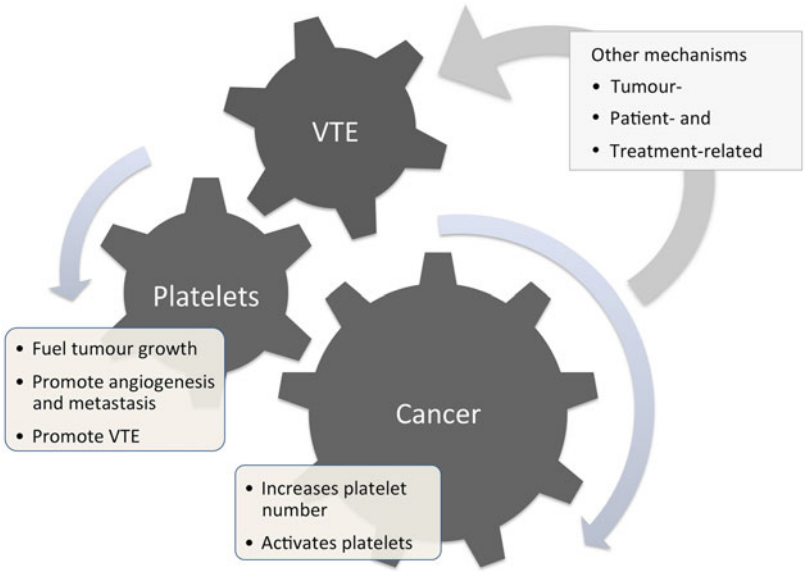

Fig. 1 Proposed mechanisms of how cancer and platelets influence each other and thereby contribute to the development of VTE: As VTE is a multifactorial disease, platelets are only one aspect of how hypercoagulability develops in cancer

and thus consuming all von Willebrand factor is further exemplified in another observation: In more than 40,000 patients, who received anticoagulatory drugs for acute VTE, a very low (<80 G/l) as well as a very high (>450 G/l) platelet count were associated with a high risk of bleeding in comparison to normal platelet counts (Di Micco et al. 2013).

Low Platelet Counts and Risk of VTE

In certain diseases, a low platelet count might also be associated with an increased risk of VTE. This is obviously the case in disseminated intravascular coagulation, where arterial but even more frequent venous thromboembolic events might occur (Wada et al. 2013). Also in a certain subgroup of cancer patients, those with high-grade glioma, a low platelet count was found to be a risk factor for VTE and was also an important parameter in development of a score to identify patients with a high risk of VTE. The score contains platelet count (<196 G/l) and soluble p-selectin (>51.9 ng/ml). The cumulative VTE probability after 12 months was 9.7 % for score 0 ($n = 76$, neither low platelet count nor elevated sP-selectin), 18.9 % for score 1 ($n = 59$) and 83.3 % for score 2 (low platelet count and elevated sP-selectin $n = 6$) (Thaler et al. 2014). Thus this score, which contains numbers of platelets and a soluble platelet activation marker, could be of help to identify high-grade glioma patients at low risk or high risk of VTE.

Another disease that is associated with a slightly increased risk of VTE despite a low platelet count is immune thrombocytopenia (ITP) (Rodeghiero 2015). During the studies with thrombopoietin-stimulating agents (TPAs), a slightly increased risk of venous thrombotic events was observed in the treatment group but also in the group of patients on standard care (Kuter et al. 2010; Rodeghiero et al. 2013; Rodeghiero and Ruggeri 2015). However, major risk factors for VTE in ITP seem to be higher age, splenectomy, and personal risk factors (Rodeghiero 2015). Higher reactivity of platelets is thought to be the underlying mechanisms for VTE in ITP patients (Psaila et al. 2011). The activation of platelets during treatment with TPAs was studied in two prospective studies (Psaila et al. 2012; Haselboeck et al. 2013). Activation of platelets was seen in non-treated patients, those on corticosteroids, and those on TPAs, and the activation was not more pronounced in eltrombopag-induced platelets (Haselboeck et al. 2013), indicating that platelet activation alone does not suffice for the risk for VTE in ITP patients.

Mean Platelet Volume

The mean platelet volume (MPV), a parameter which indicates platelet size, was proposed to reflect platelet activity, as it is associated with platelet aggregation, (Thompson et al. 1982) release of thromboxane B2 (Jakubowski et al. 1983), and increased expression of the platelet adhesion molecule and fibrinogen receptor $\alpha_{IIb}\beta_3$ (Giles et al. 1994). Clinical studies have shown that high MPV is a risk factor for a variety of thromboembolic diseases (Leader et al. 2012), such as myocardial infarction (Slavka et al. 2011) or stroke (Greisenegger et al. 2004; Bath et al. 2004), and for increased risk of overall vascular disease-associated mortality (Slavka et al. 2011). High MPV was also found to be associated with the risk of developing VTE in a large population-based study from Norway, especially with the risk of unprovoked VTE

(Brækkan et al. 2010). In contrast, studies on cancer patients revealed that a high MPV in those patients is associated with lower risk of cancer-associated VTE (Riedl et al. 2013; Ferroni et al. 2014). In conclusion, platelet size seems to be relevant for the development of VTE, but the influence of platelet size on VTE risk differs between patient subgroups (idiopathic VTE vs. cancer-associated VTE).

Pharmacological Inhibition of Platelet Function for Prevention and Treatment of Deep Venous Thrombosis and Pulmonary Embolism

Pharmacological interventions for treatment and prevention of VTE are mainly based on administration of anticoagulants including heparins, vitamin K antagonists, and novel, direct oral anticoagulants (DOACS). These substances are regarded first choice for the prevention and treatment of VTE. However, evidence has been presented that antiplatelet agents, specifically aspirin, can also be effective in primary prevention of VTE in surgery and for secondary prevention of VTE after a first event of venous thrombosis or pulmonary embolism.

Primary prevention of VTE is recommended in a variety of clinical situations and diseases with increased risk of VTE. The most important one is surgery, and among the surgical procedures, orthopedic and tumor surgery bear the highest risk of VTE. This chapter will only highlight the role of aspirin and not of anticoagulants for prevention of venous thromboembolic events. The effect of aspirin on a decrease of the risk of VTE is regarded as plausible due to the effect of platelets on thrombus formation and thrombus growth, which has been outlined in the introduction and discussed in the literature (Becattini et al. 2012).

There are only very limited and no recent studies in general surgery in which aspirin was systematically investigated. Data on the efficacy and safety of aspirin in non-orthopedic, non-traumatic surgery date back to the 1980s. These studies were reviewed by the Antiplatelet Trialists' Collaboration in 1994 (Cohen et al. 1994). Diagnosis of deep vein thrombosis at that time was made either by systematic radiolabeled fibrinogen uptake scan or by venography.

In the aspirin group, 178/1434 (19.4 %) patients and in the control group (open or placebo) 369/1459 (27.1 %) developed objectively confirmed deep vein thrombosis, which means an odds reduction of 37 % (8 % standard deviation) for aspirin. When pulmonary embolism was evaluated 16/3408 (0.5 %) on aspirin and 58/3419 (1.7) controls developed pulmonary embolism, which means a 71 % (with 14 % standard deviation) odds reduction, differences were statistically significant. The Antiplatelet Trialists' Collaboration group evaluated rate of bleeding together in trials that included general and orthopedic surgery. There was an increase of transfusion requirements and also other complications, such as hematoma or wound infections in the aspirin group.

One randomized double-blind study comparing aspirin with unfractionated heparin was conducted by Vinazzer et al. in patients with elective general surgery (Vinazzer et al. 1980). Five hundred mg of aspirin were compared to 5000 IU of unfractionated heparin twice daily, 1210 patients were included into that study. Deep vein thrombosis as the primary outcome was based on obligatory Doppler imaging. No statistically significant difference was found in the rates of deep vein thrombosis (3.9 versus 2.4 %) or pulmonary embolism (0.3 each), and the risk of bleeding was also similar (0.7 % each). Due to lack of data with more recent high-quality and large studies, aspirin cannot generally be recommended as thrombosis prophylaxis in general surgery and of course also not in tumor surgery.

There is one very large study (pulmonary embolism prevention = PEP trial) in patients with hip fracture surgery (13.356 patients) or elective hip replacement (5.088 patients) surgery. This is the largest study performed so far in orthopedic/traumatic surgery. Patients received either 160 mg aspirin or placebo for 35 days in routine care, and additional thrombosis prophylaxis was allowed, if deemed necessary by the investigator. Only symptomatic events were recorded and an independent blinded committee adjudicated the events. Patients with hip fracture surgery on aspirin had a significantly reduced rate of PE compared to those on placebo; the effect on DVT was also a significant reduction. Taken together, aspirin lead to a proportional reduction of PE and DVT of 36 %. Deaths due to bleeding were not increased in patients with aspirin; however, bleeding requiring transfusion was significantly ($p = 0.04$) increased. Remarkably, death from PE was reduced significantly in the aspirin group (18 in the aspirin group versus 43 in the placebo group), which corresponded to a 58 % rate reduction of fatal PE ($p = 0.02$). In other words, aspirin prevented four fatal PEs per 1000 patients. Due to perceived changes in the primary outcome and changes in the sample size during the study, this trial was criticized (Falck-Ytter et al. 2012). However, despite some limitations of the study design, aspirin is regarded as option for thrombosis prophylaxis in orthopedic surgery by a number of specialists and in guidelines (Falck-Ytter et al. 2012).

There are several clinical conditions with considerably increased risk of VTE also in nonsurgical patients. The highest risk can be found in cancer patients with a probability to develop VTE of up to 30 % after 6 months in certain subgroups (Ay et al. 2010). An easy and convenient prevention would be a big advantage for cancer patients at high risk of VTE. Aspirin would fulfill these criteria, but its potential in preventing VTE in this patient population has not been specifically investigated in patients with solid tumors, so far.

However, in observational studies, no effect on the frequency of VTE in patients, who were on aspirin for other reasons, was found (Lötsch et al. 2014).

Patients with multiple myeloma who are treated with thalidomide or lenalidomide in combination with chemotherapy and/or dexamethasone have a high risk of VTE, and therefore primary thromboprophylaxis is recommended. In patients with multiple myeloma, thromboprophylaxis with aspirin was proven to be as effective as low-molecular weight heparin (Larocca et al. 2012) and was studied and compared to LMWH and warfarin in patients with multiple myeloma on thalidomide and chemotherapy (Palumbo et al. 2011). Although within the first 3–6 months the VTE risk was lowest in patients on LMWH, no difference between the three groups was observed after 9 months. Thus aspirin is frequently used as thrombosis prophylaxis in patients with multiple myeloma during antineoplastic treatment with thalidomide or lenalidomide in combination with chemotherapy and/or dexamethasone.

Furthermore, patients with MPNs, such as ET or polycythemia vera (PV), have a high risk of vascular events and should receive primary thromboprophylaxis. Current guidelines recommend the use of aspirin in PV and in ET patients, which harbor the JAK2 mutation (Kreher et al. 2014). In PV, these recommendations are based on a randomized trial that showed a significantly reduced rate of cardiovascular events and also a reduction—although not statistically significant—in VTE events (Landolfi et al. 2004). In ET, conclusive data are lacking; however, a retrospective analysis showed that in the subgroup of patients with the JAK2 mutation, aspirin significantly reduced the risk of VTE (Alvarez-Larrán et al. 2010). Aspirin should not be given to patients with platelet counts > 1000 G/l or acquired vWS, as these patients have a high bleeding risk.

Patients with antiphospholipid antibodies have also an increased risk of VTE, and primary prevention would be an option in high-risk patients. One placebo-controlled trial, the Antiphospholipid Antibody Acetylsalicylic Acid (APLASA) study investigated the efficacy and safety of aspirin in 98 asymptomatic patients with persistently positive antiphospholipid antibodies comparing aspirin 81 mg daily vs. placebo for prevention of arterial or venous thrombosis (Erkan et al. 2007). Aspirin was not superior to placebo with regard to new onset of venous or arterial thrombosis (HR, 1.04; 95 % CI, 0.69–1.56), but bleeding was also not increased.

A subgroup analysis of the Women's Health Study of asymptomatic individuals with hereditary thrombophilia (factor V Leiden, prothrombin G20210A variation) failed to demonstrate an effect of aspirin on the rate of VTE (HR, 0.83; 95 % CI, 0.50–1.39) (Glynn et al. 2007).

Aspirin did not prevent flight-associated VTE compared to control; however, long-term data are not available as follow-up of the study participants ended when they left the airport (Cesarone et al. 2002).

Prevention of Recurrent Deep Venous Thrombosis and Pulmonary Embolism

Two recent, randomized placebo-controlled double-blind, multicenter trials evaluated the effect of aspirin for the prevention of recurrent VTE after completion of an initial course of anticoagulant treatment. Both studies had a similar design and compared aspirin, 100 mg once daily, to placebo in patients with unprovoked VTE who had completed initial anticoagulant therapy: The Warfarin and Aspirin (WARFASA) study assessed the benefit of aspirin, given over a 2-year period, in comparison to placebo and found a significantly reduced risk of VTE in the aspirin group (6.6 % vs. 11.2 %) with no increase in the risk of major bleeding (Becattini et al. 2012). The second trial, Aspirin to Prevent Recurrent Venous Thromboembolism (ASPIRE), had a longer study period of up to 4 years and found no significant reduction in the VTE rate in the aspirin group [4.8 % per year for aspirin vs. 6.5 % per year for placebo; hazard ratio (95 % confidence interval) with aspirin 0.74 (0.52–1.05), $p = 0.09$] (Brighton et al. 2012). However, the combined rate of major vascular events in this trial, including VTE, myocardial infarction, stroke, or cardiovascular death, was reduced significantly by 34 %, without increasing the risk of bleedings.

Moreover, a predefined meta-analysis of data from both trials was performed and separately published (Simes et al. 2014). Key data from the two trials as well as from the combined analysis are shown in Table 1. In the combined

Table 1 Summary and key data from two recent randomized, controlled trials comparing low-dose aspirin (100 mg daily) vs. placebo for the prevention of recurrent VTE after completion of an initial anticoagulant treatment episode for a first episode of unprovoked VTE, as well as data from the predefined combined analysis of the two studies

Study name	Total number of patients randomized	Median follow-up period (months)	Risk of VTE/year, aspirin vs. placebo [HR for aspirin (95 % Confidence interval)]	Risk of major bleeding/year, aspirin vs. placebo
WARFASA	403	23.9	6.6 % vs. 11.2 % [0.58 (0.36–0.93), $p = 0.02$]	0.3 % vs. 0.3 %
ASPIRE	822	37.2	4.8 % vs. 6.5 % [0.74 (0.52–1.05), n.s.]	1.1 % vs. 0.6 % (n.s.)
Combined analysis	1224	30.4	5.1 % vs. 7.5 % [0.68 (0.51–0.90), $p = 0.008$]	0.5 % vs. 0.4 % (n.s.)

n.s. not significant

analysis, the authors showed a significant risk reduction for VTE in aspirin users, and altogether it was concluded that aspirin can safely reduce the recurrence rate of VTE by approximately 30 % (Simes et al. 2014). Of interest, the absolute rate of fatal recurrent VTE in patients on aspirin (0.16 per 100 patient-years, 95 % confidence interval (CI) 0.03–0.40) was as low as in those on direct oral anticoagulants (DOACS) (0.18 per 100 patients-years, 95 % CI, 0.06–0.37) and vitamin K antagonists (0.14) per 100 patient-years (95 % CI, 0.04–0.32). In the placebo group the rate of fatal VTE was approximately twice as high (0.38 per 100 patient-years, 95 % CI 0.18–0.65) (Wu et al. 2015). Thus, with regard to occurrence of a fatal VTE after a first VTE, aspirin seems not to be inferior to DOAC and vitamin K antagonists and most likely superior to placebo. It can be hypothesized that in patients on aspirin, although the overall recurrence rate is higher than in patients on DOACS or vitamin K antagonists, emboli, potentially leading to the death of a patient, are either less frequent and/or smaller. When the composite endpoint of fatal bleeding and fatal recurrent VTE was evaluated, aspirin was, as expected, superior to placebo and even, rather unexpected, the rate was lower than in patients on DOACs or Vitamin K antagonists. Of course it has to be kept in mind that the number of these events is low, that the studies were not powered for these outcomes, and that there was no direct comparison with all three treatment options.

Although these data support the use of aspirin in patients with unprovoked VTE who terminated initial anticoagulant treatment, there are so far no final data directly comparing aspirin with anticoagulants. It is well known that anticoagulatory drugs reduce risk of recurrent VTE by more than 80 % (Kearon et al. 2012), which is superior to the risk reduction observed in aspirin users, and new oral anticoagulants, which do not need regular blood controls and dose adjustment, have made anticoagulant treatment nowadays more convenient compared to the use of vitamin K antagonists. More data on the use of either aspirin or new direct oral anticoagulants for the prevention of recurrent VTE will derive from a currently ongoing study, which compares the direct oral anticoagulant rivaroxaban in two doses to aspirin 100 mg for the extended treatment of VTE (EINSTEIN CHOICE). This study plans to include a total of 2850 patients (Weitz et al. 2015).

Conclusion

In conclusion, platelets play an important role in VTE. Experimental studies demonstrate the involvement of platelets in the formation of venous thrombi. Platelets release soluble proteins, which may be used as biomarkers to improve risk prediction of VTE. sP-selectin is the most studied biomarker and was shown to predict risk of recurrent VTE after a first event and risk of cancer-associated VTE. Finally, clinical studies have proven that platelets are a therapeutic target for primary and secondary prophylaxis of VTE. The use of aspirin is relatively safe, cheap, and widely available and has proven to be effective for prevention of VTE in different settings. A study that directly compares aspirin with the direct oral anticoagulant rivaroxaban for extended thromboprophylaxis after VTE is currently ongoing and will soon provide more information on the risks and benefits of either aspirin or anticoagulants in long-term secondary prevention of VTE.

Take-Home Messages

- Experimental studies provide evidence for an important role of platelets in the formation of venous thrombi.
- Platelet biomarkers, such as soluble P-selectin, are elevated in patients with acute VTE and predict risk of recurrent VTE and cancer-associated VTE.
- Although anticoagulant drugs are the first line of therapy used for reducing risk of VTE after orthopedic surgery and risk of recurrent VTE after a first event, also antiplatelet therapy with aspirin has been shown to be effective in these indications and might provide an additional therapeutic option.

Gene Regulation of Platelet Function

Dmitri V. Gnatenko, Zongdong Li, and Wadie F. Bahou

Abstract

Normal function of blood platelets is a complex multistep process that is crucial for maintenance of hemostasis and wound healing. Abnormality of platelet function may cause bleeding or thrombosis and may result in death. Platelet function is regulated by many genes, miRNAs, mRNAs, and proteins at different phases of megakaryocyte maturation and thrombopoiesis. Information on genes that regulate platelet function is obtained from studies of blood disorders using a candidate gene approach, a functional approach, or by using genome-wide association studies. Recent advances in DNA sequencing technologies and in meta-analysis of genome-wide association studies data and epigenomic, transcriptomic, and functional information have allowed identification of novel genes and noncoding genomic DNA regions that play an important role in platelet formation and function that affect thrombotic risk. This chapter is focused on genes that are known to regulate main platelet functions and on novel approaches to identify and characterize platelet-related genes.

Abbreviations

AHC	Alternating hemiplegia of childhood
ET	Essential thrombocythemia
GPS	Gray platelet syndrome
GWAS	Genome-wide association study
HPS	Hermansky–Pudlak syndrome
MK	Megakaryocytes
MPV	Mean platelet volume
P	*p*-value
PBMC	Peripheral blood mononuclear cells
PC	Platelet count
PCR	Polymerase chain reaction
RNAseq	RNA sequencing
RT	Reactive thrombocytosis
SAGE	Serial analysis of gene expression
VWF	von Willebrand factor
WT	Wild-type control subjects

Introduction

Platelets are anucleate circulating peripheral blood cells that are crucial for basic biologic processes such as maintenance of normal hemostasis, inflammation, and wound healing. Platelets retain megakaryocyte-derived mRNAs (Gnatenko et al. 2003; Bugert et al. 2003; Bray et al. 2013; Rowley et al. 2011) and have evolved unique adaptive signals for maintenance of genetic and protein diversity (Denis et al. 2005; Weyrich et al. 1998) (Fig. 1). Quiescent platelets generally display minimal translational activity, although maximally activated platelets retain the capacity for protein synthesis, with implications for modulating arthritis-associated inflammation (Boilard et al. 2010) or the production of platelet progeny in vivo (Schwertz et al. 2010). Platelets are characterized by mean platelet volume and count, which vary from one individual to another, and platelet functions such as aggregation, adhesion, signaling, storage and secretion of content of α and dense granules, and others. Platelets that exhibit functional extremes convey a commensurate increased risk for thrombosis or bleeding. Interestingly, the propensity for such extremes has been shown to be heritable (Jones et al. 2007; O'Donnell et al. 2001; Bray et al. 2007;

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_70

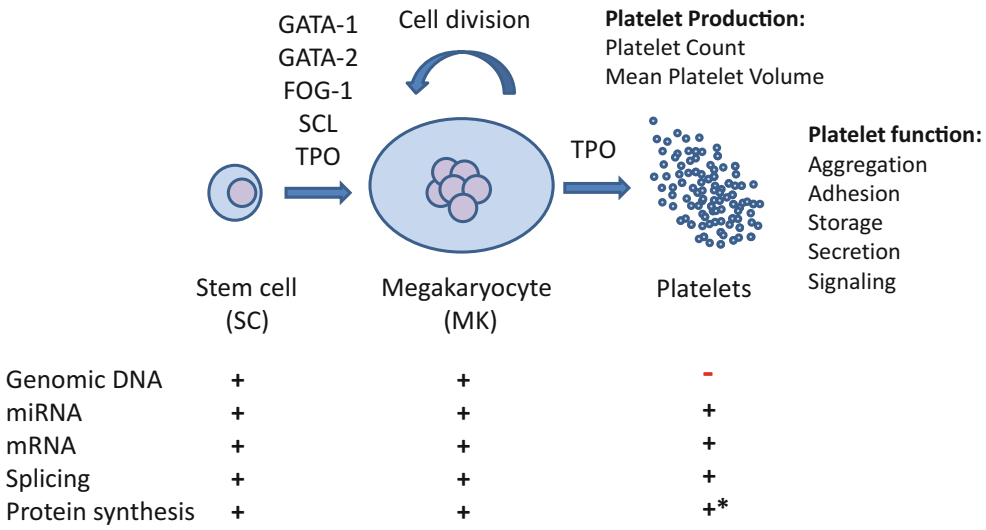

Fig. 1 Simplified schema of platelet production and function. Stem cells differentiate toward megakaryocytes (MK), and platelets are generated from MK as a result of thrombopoiesis. Platelets retain MK-derived miRNA, mRNAs, and proteins but lack genomic DNA. Selection of mRNAs for packaging into platelets is an active process, so transcriptomes of MK and platelets are significantly different. Platelets also retain competent pathways capable of converting precursor miRNAs into mature miRNAs and splice pre-mRNA into mRNAs. *Asterisk* circulating platelets generally display minimal translational activity, although they are capable for protein biosynthesis upon activation

Westbury et al. 2015), and accumulating evidence has established the critical genetic regulation of platelet function, using both genomic and transcriptomic approaches. Although recent advancements in genomics and bioinformatics have allowed identification and characterization of genes and noncoding regions of the human genome that are involved in regulation of platelet function, an understanding of underlying processes remains limited.

Platelet function is a complex multistep process with the potential for genetic regulation at multiple stages of activation. Once a blood vessel is damaged, platelets are exposed to the components of the extracellular matrix, particularly to collagen. This interaction triggers a long chain of receptor–ligand interactions that results in platelet activation and ultimately leads to the formation of a stable platelet plug or thrombus. This process consists of at least three phases (initiation, extension, and consolidation), each of which is achieved through a tightly regulated coordination of distinct receptor/ligands interactions. Thus, many candidate gene approaches apply these well-characterized interactions for gene/SNP-hunting strategies. For example, the initiation phase begins when plasma von Willebrand factor (VWF) binds to collagen via its A3 domain, resulting in structural change. The A1 domain of altered VWF binds to the platelet membrane receptor glycoprotein Ib-IX-V complex (GPIb complex). Then GPIbα or GPIb makes direct contact with VWF. This interaction leads to the adhesion of platelets to exposed thrombogenic surfaces such as sites of vessel wall injury. In parallel, the platelet-specific receptor glycoprotein VI (GPVI) and platelet integrin $\alpha_2\beta_1$ are involved in the formation of the platelet monolayer on the collagen surface.

During the extension phase, more platelet proteins come into action. Most of the receptors engaged in the extension phase are members of the G protein-coupled receptor family. Signaling from these receptors triggers conversion of prothrombin to thrombin at the membrane of activated platelets and release of active compounds from platelet α-granules and δ-granules. During extension phase, activated platelets release agonists that trigger a cascade of events leading to the activation of additional platelets in closest proximity to the site of vessel injury. Activated platelets secrete the contents of their α-granules and δ-granules into the surrounding blood to induce secondary stimulation and to activate other platelets. In the consolidation phase, platelet-to-platelet aggregation is mediated by the binding of fibrinogen and VWF to the activated platelet integrin $\alpha_{IIb}\beta_3$ (also known as GPIIb-IIIa). This results in assembly of a fibrin network and generation of platelet aggregates (thrombus). Nonetheless, candidate gene approaches are limited, and open architectural systems designed for more robust (and unbiased) gene discovery remain applicable for the dissection of platelet genes regulating function and disease susceptibility. In this chapter we will review the genetic regulation of platelet function focusing on geno/phenotypic data modulating thrombotic risk. Novel methodologies focusing on transcriptomic and biomarker identification in platelet-associated thrombotic risk will also be reviewed.

Unraveling Genetic Regulation of Platelet Function

To date, considerable information has been generated on genes that regulate platelet function and affect risk of thrombosis. These genes encode for platelet membrane proteins, cytoskeleton proteins, kinases, proteins involved in cellular

trafficking, transcription factors, proteins of signal transduction pathways, proteins involved in megakaryocyte development, and others. Information on genes that play important roles in regulation of platelet function comes from several types of studies. The first type includes studies of various platelet diseases (inherited or acquired) associated with functional abnormalities and has resulted in identification and characterization of many of the receptor/ligand interactions modulating key platelet functions. The second type of studies uses candidate gene approach. In the past these studies focused mainly on genes that were considered to be important in platelet function, typically platelet receptors and signaling proteins. This approach requires large cohorts of subjects to detect rare variants and to elucidate their effects with sufficient statistic power. More promising approach is functional genomics that allows characterization of a larger number of potential gene candidates. This group of studies includes large-scale genome-wide association studies (GWAS) and meta-analyses of multiple sets of data. These studies represent an examination of many common genetic variants in different individuals to see if any variant is associated with a trait, focusing mostly on associations between single-nucleotide polymorphisms (SNPs) and certain phenotype. GWASs allowed characterization of coding and noncoding regions of human genome that contribute to normal platelet function. More recently, a novel approach has been developed that combines several independent GWAS into one large meta-analysis. Although results of such meta-analyses need thorough validation, this approach represents the most powerful tool to date to identify and characterize genes and genomic loci that play important role in thrombopoiesis and platelet function.

Interestingly, information on genes that regulate platelet function comes also from studies of other diseases where platelet abnormalities have been observed. Thus, based on the presence of secretory organelles, platelets are thought to share some morphological and functional features with neurosecretory cells (Pletscher 1986). Using platelets as model cells to study neuropathology is a concept that has been utilized since the early 1960s (Goubau et al. 2014). Significant variability of platelet characteristics such as aggregation and dense granule secretion (Yao et al. 1994), monoamine oxidase and platelet phospholipase A2 activity (Marcolin and Davis 1992; Gattaz et al. 1995), serotonin metabolism (Yao et al. 1996), and others (Kaiya et al. 1990) has been documented for patients with schizophrenia. Many of these platelet characteristics, including serotonin (Borgdorff and Tangelder 2012) and monoamine oxidase activity (Mosnaim et al. 1990), play a role in migraine exacerbations. Furthermore, variability of platelet characteristics has been reported for patients with Parkinson disease [altered monoamine oxidase type B activity (Finch et al. 1995; Husain et al. 2009)], autism [decreased platelet activity (Safai-Kutti et al. 1985) and platelet hyperserotonemia (Anderson et al. 2002; Hranilovic et al. 2009)], and Alzheimer disease [expression level and metabolism of amyloid precursor protein (Davies et al. 1997; Jelic et al. 2013) and elevated level of activated platelets (Casoli et al. 2013)].

Platelet Receptors and Thrombohemorrhagic Risk

Platelet receptors play a crucial role in platelet function. Among them are receptors involved (i) in platelet adhesion via glycoprotein (GP)VI (Trifiro et al. 2009), $\alpha_2\beta_1$ integrin (Ajzenberg et al. 2005), or VWF-GP1bα (Afshar-Kharghan et al. 1999), (ii) in fibrinogen-dependent platelet aggregation via $\alpha_{IIb}\beta_3$ integrin (Michelson et al. 2000), or (iii) in platelet signaling (Fontana et al. 2006; Hetherington et al. 2005). It was demonstrated that abnormalities of genes that encode platelet receptors severely affect platelet function (Table 1). Two platelet receptors play key role in collagen binding that initiates platelet activation—the integrin $\alpha_2\beta_1$ and the platelet-specific receptor GPVI. Polymorphism in these receptors results in altered receptor expression (Kunicki et al. 1997) and increased risk of acute myocardial infarction (Joutsi-Korhonen et al. 2003). ADP receptors $P2Y_1$ and $P2Y_{12}$ play major role in ADP-mediated platelet aggregation. Different polymorphic variants have been reported in the genetic region encoding for both genes located on chromosome 3 (Cavallari et al. 2007; Fontana et al. 2003). A study focused on 97 candidate genes involved in collagen and adenosine diphosphate (ADP) signaling pathways characterized 17 novel independently associated SNPs (from total 1327 SNPs) in 500 healthy Northern European subjects (Jones et al. 2009). Some of them were associated with increased risk of coronary and peripheral artery disease. Interestingly, polymorphism at *rs*1472122, located in this genetic region on chromosome 3, was associated with platelet function (Jones et al. 2009).

Studies of genetic basis of Bernard–Soulier syndrome (characterized by a prolonged bleeding time, thrombocytopenia, and extremely large platelets) demonstrated involvement of four separate genes—*GPIBA*, *GPIBB*, *GP9*, and *GP5* (Salles et al. 2008; Bolton-Maggs et al. 2006). These genes encode platelet-specific receptors and mutations affect binding of VWF, P-selectin, and other agonists, severely altering normal platelet function. Studies of platelet-related bleeding disorders, such as Glanzmann thrombasthenia, caused by mutations in integrins α_{IIb} [glycoprotein (GP) IIb] or β_3 (GP IIIa), have provided important insight into genes that regulate platelet function (Nurden and Nurden 2011; Lecine et al. 1998). Scott syndrome is a rare inherited disorder caused by defective scrambling of phospholipids in blood cells including platelets (Salles

10	*PEAR1*	Platelet endothelial aggregation receptor 1	Decreased platelet response to agonists	No known phenotype	Jones et al. (2009) and Faraday et al. (2011)

et al. 2008). This results in decreased fibrin formation at site of vascular injury due to lack of thrombin generation and phosphatidylserine expression (Morel et al. 2011). It was demonstrated that heterozygous missense mutation in ATP-binding cassette transporter A1 (gene *ABCA1*) (Albrecht et al. 2005) and mutation at the splice-acceptor site of the gene *TMEM16F* that causes premature termination of encoded transmembrane protein 16F (Suzuki et al. 2010) play a significant role in this disease.

SNPs in gene *PEAR1* (encoding platelet endothelial aggregation receptor) are associated with increased platelet response to agonists and increased PEAR1 protein expression after platelet degranulation. Later, sequencing confirmed that variation at *rs*12041331 accounted most strongly ($P = 2.07 \times 10^{-6}$) for the relation between the *PEAR1* gene and platelet function phenotype (increased platelet aggregability) (Faraday et al. 2011).

Many platelet stimulatory agonists mediate signaling via G proteins by binding to G protein-coupled receptors (Van Geet et al. 2009). The alpha subunit of the stimulatory G protein (GSα) regulates level of cyclic adenosine monophosphatase in cells. GSα is encoded in GNAS, an imprinted region on chromosome 20q13 that gives rise to several transcripts, antisense transcripts, and noncoding RNAs. The complexity of the GNAS cluster results in ubiquitous genomic imprints, tissue-specific GSα expression, and multiple genotype–phenotype relationships. Phenotypes associated with genetic and epigenetic abnormalities of the GNAS region include Albright's hereditary osteodystrophy (AHO), pseudohypoparathyroidism types Ia (PHPIa) and Ib (PHPIb), and pseudopseudohypoparathyroidism (PPHP). A variable degree of platelet GSα hypofunction was demonstrated in these patients (Freson et al. 2008).

Non-receptor Platelet Proteins and Thrombohemorrhagic Risk

Many other proteins are known to play significant role in platelet function. Among them are transcription factors, kinases, cytoskeletal proteins, proteins involved in signal transduction, and others (Table 2). It was demonstrated that several transcription factors play important roles during magakaryopoiesis that affect thrombopoiesis and platelet function. Thus, mice lacking transcription factor NFE2 have a late arrest in megakaryocyte maturation, resulting in profound thrombocytopenia (Lecine et al. 1998). Forkhead box protein 3 (*FOXP3* gene) is another transcription factor,

which is believed to be restricted to a subset of regulatory T cells and is required for their development (Fontenot and Rudensky 2005). Humans with IPEX (immune dysregulation, polyendocrinopathy, enteropathy, x-linked) and the scurfy [Foxp3(sf)] mouse have mutations in the *FOXP3* gene that lead to a host of pathologies including autoimmunity and skin diseases. Interestingly, scurfy mice and some humans with IPEX are also thrombocytopenic. Human and mouse megakaryocytes express *FOXP3* mRNA and protein. Recently it was demonstrated that *foxp3*-deficient mice and human megakaryocyte progenitors exhibit proliferation defects (Bernard et al. 2009). Striking platelet abnormalities were observed in both an IPEX patient and *foxp3*(sf) mice. Impaired platelet spreading and release of TGF-beta and CD40 ligand (CD40L) were repeated. *Foxp3*(sf) mice were thrombocytopenic and had increased platelet volume and altered serum levels of CD40L, TXB(2), and TGF-beta. It was demonstrated that mutations or reduced expression of another transcription factor and a member of forkhead box proteins, forkhead box G1 (*FOXG1*), results in abnormal platelet production (Goubau et al. 2013a).

Megakaryocyte maturation is a complex process that includes proplatelet formation—rearrangement of the cytoskeleton that results in formation of long cytoplasmic extensions (Thon et al. 2010). These extensions are needed to transport platelet granules and organelles to forming platelets. Cytoskeletal proteins play crucial role in this process. Actin-binding protein filamin A is a 280 kD protein that cross-links actin filaments into orthogonal networks in cortical cytoplasm and participates in the anchoring of membrane proteins for the actin cytoskeleton. Filamin A, encoded by the *FLNA* gene, is a widely expressed protein that regulates reorganization of the actin cytoskeleton by interacting with integrins, transmembrane receptor complexes, and second messengers. Filamin A is also a predominant filamin isoform expressed in platelets. In platelets, FLNA tethers the principal receptors ensuring the platelet–vessel wall interaction, end binding of glycoprotein Ibα and integrin $\alpha_{IIb}\beta_3$, to the underlying cytoskeleton. Patients with filaminopathy A often have defective platelet adhesive functions and thrombocytopenia (Nurden et al. 2011; Berrou et al. 2013; Falet 2013).

Studies of other diseases, not directly related to platelets, often contribute to our understanding of genetic regulation of platelet function. Alternating hemiplegia of childhood (AHC) is a rare syndrome with repeated hemiplegic episodes, paroxysmal events, and global neurological impairment. Recently, exome sequencing by two independent groups revealed de novo missense mutations in the *ATP1A3* gene (Palmgren and Nissen 2011), coding for the isoform α3 of the sodium/potassium ion channel that maintains ion gradients. Platelets from AHC patients presented with structural and functional abnormalities of granules positive for the lysosomal marker CD63 (Di Michele et al. 2013). Though AHC platelets have a normal number of dense granules with a normal total ATP content, they present an abnormal dense core structure. Therefore, the mild platelet activation after epinephrine stimulation which results in a delayed release of dense granules can be due to the abnormal granule reorganization before release, such as observed after platelet spreading on fibrinogen. Indeed granules positive for the lysosomal marker CD63 (including dense granules) in AHC cases seem to fuse and centralize more than in control platelets before secretion.

Recently, studies of a family of five children affected with a novel autosomal recessive bleeding disorder with small-platelet thrombocytopenia identified a homozygous deleterious nonsense mutation 393G>A in *FYB* gene. This gene encodes adhesion and degranulation-promoting adaptor protein (ADAP), a hematopoietic-specific protein involved in platelet activation, cell motility and proliferation, and integrin-mediated cell adhesion. Platelets from such patients showed increased basal expression of P-selectin and PAC-1, and reduced increments of activation markers after stimulation with ADP, as detected by flow cytometry; they also showed reduced pseudopodium formation and the presence of trapped platelets between the fibrin fibers after thrombin addition, as observed on scanning electron microscopy (Levin et al. 2015).

Aquaporin 7 (*AQP7*) belongs to the aquaglyceroporin family, proteins that transport glycerol and water. AQP7-deficient mice develop obesity, insulin resistance, and hyperglyceroluria. Homozygous mutation of AQP7 (G264V) (Goubau et al. 2013b) has been reported as a possible cause of psychomotor retardation and hyperglyceroluria in three unrelated children. Platelets from these children demonstrated reduced ATP secretion and an absence of a secondary aggregation wave after epinephrine stimulation. Electron microscopy revealed round platelets with centrally located granules. Vascular protein sorting-associated protein 33B is encoded by *VPS33B* gene in human genome. Recent study demonstrated that this protein is essential for alpha granule biogenesis and patients have enlarged platelets with strongly reduced number of alpha granules and reduced aggregation response (Lo et al. 2005). An important, but poorly characterized, role of signaling through integrins and receptor tyrosine kinases adds further complexity to the final phase of clot formation. Current research indicates an essential role for outside-in signaling through integrins and via receptor tyrosine kinases, including members of the Eph kinase family (Kunicki and Nugent 2010).

Several epidemiological and twin studies suggest that the extent of platelet aggregability may be heritable (Rissanen

and Nikkila 1979; Berg 1981; Burton et al. 2007; Nikpay et al. 2015). Although definitions for platelet responsiveness tend to differ among studies, it is now widely accepted that platelet aggregation ex vivo in response to agonist stimulation varies considerably among healthy individuals. In an analysis of 359 healthy people, it was demonstrated that a minority consistently showed hyperresponsiveness (≥65 % maximal platelet aggregation) after stimulation with ADP, collagen, epinephrine, collagen-related peptide, or ristocetin (Yee et al. 2005). Female gender and higher fibrinogen levels were significantly associated with hyperresponsiveness, and hyperreactivity to one agonist tended to persist with others in the assays studied. Recently, GWAS study of 2.5 million SNPs with platelet aggregation responses to three agonists (ADP, epinephrine, and collagen) identified associations of seven loci with platelet aggregation near or within *GP6*, *PEAR1*, *ADRA2A*, *PIK3CG*, *JMJD1C*, *MRVI1*, and *SHH*. Six of these loci replicated at $P < 0.05$ in an additional cohort (Johnson et al. 2010).

Gray platelet syndrome (GPS) is a predominantly recessive platelet disorder that is characterized by mild thrombocytopenia with large platelets and a paucity of α-granules, frequently associated with moderate bleeding. Recently, exome sequencing identified gene NBEAL2 as the causative gene for this disease (Albers et al. 2011). It encodes for *neurobeachin*-like protein 2 that has no known function but is a member of a gene family that is involved in granule development. Silencing of nbeal2 in zebrafish abrogated thrombocyte formation.

Similar to defects of α-granules, abnormalities of δ-granules severely affect platelet function. The bulk of our knowledge concerning dense granule deficiency disorders derives from studies of Hermansky–Pudlak syndrome (HPS), a rare disorder associated with oculocutaneous albinism (decreased pigmentation) and bleeding problems due to a platelet abnormality (platelet storage pool defect). To date, there are nine known genes and genomic loci that cause HPS (Gunay-Aygun et al. 2004; Cullinane et al. 2011). These genes include *HPS1*, *AP3B1*, *HPS3*, *HPS4*, *HPS5*, *HPS6*, *DTNBP1*, and *PLDN*.

Aspirin, nonsteroidal anti-inflammatory drugs like indomethacin, and other drugs severely affect platelet function. Platelet response to these drugs is regulated at the gene level. Thus, it was demonstrated that polymorphism in platelet receptors $P2Y_1$, $P2Y_{12}$, and ITGB3 is associated with an aspirin-resistance phenotype (Jefferson et al. 2005; Lev et al. 2007). Genetic variability in *PTGS1* gene, encoding for platelet cyclooxygenase COX-1 (an enzyme involved in the conversion of arachidonic acid to the potent platelet agonist thromboxane), is associated with platelet response to aspirin and platelet aggregation (Maree et al. 2005). Despite recent progress, our understanding of genetic regulation of platelet responses to drugs remains limited. Future studies will certainly identify more genes and genomic loci that regulate platelet–drug interactions. This information will ultimately lead to a better understanding of platelet function and result in more personalized use of platelet-affecting drugs.

Mean Platelet Volume, Platelet Count, and Thrombotic Risk

Mean platelet volume (MPV) and platelet count (PC) are highly inheritable and affect platelet function, although they significantly vary from one individual to another. Recent studies identified multiple genes and noncoding regions in human genome that are associated with MPV and PC and demonstrated that they correlate with agonist-induced platelet function (Nurnberg et al. 2012; Kunicki et al. 2012; Huczek et al. 2005). Furthermore, MPV has been suggested as an independent cardiovascular risk factor (Slavka et al. 2011). MPV is also associated with megakaryopoiesis and beta-thromboglobulin release (Bath and Butterworth 1996). Whole genome expression analysis revealed highly significant association of the SNP *rs*342293 (located on chromosome 19) with MPV in healthy subjects (Soranzo et al. 2009; Meisinger et al. 2009; Shameer et al. 2014; Qayyum et al. 2012). Analysis of electronic medical records identified five chromosomal regions associated with PC and eight regions associated with mean platelet volume ($P < 5 \times 10^{-8}$) (Shameer et al. 2014). This study identified 20 SNPs that affect PC and 22 SNPs that affect MPV.

Recent advances of sequencing technology in conjunction with rapidly expanding knowledge of the human genome and development of modern bioinformatics approaches have made it possible to combine several GWAS studies into one meta-analysis. Such an approach represents a very powerful tool for identification of genes, genomic regions, and individual SNPs that play crucial role in platelet formation and function. The study of Gieger et al. remains the largest platelet-focused meta-analysis of GWAS so far (Gieger et al. 2011). In this study, analysis of 66,867 individuals of European ancestry identified 68 genomic loci that are reliably associated with platelet volume and establishing novel regulators of megakaryopoiesis and platelet production. Findings of this meta-analysis are independently validated using gene silencing in model organisms, stem cell differentiation, and analysis of transcriptomic information. Later, results of this mega-analysis have been validated in cohorts with different ethnic backgrounds (Lo et al. 2011; Qayyum et al. 2012).

Using 13 independent studies related to mean platelet volume (18,600 individuals totally) and 23 studies related to platelet count (48,666 individuals totally), the authors performed meta-analysis linking these two parameters to

~2.5 million mapped SNPs (Gieger et al. 2011). Initially, association between these parameters and each SNP was tested using an additive model within each study. Then, study-specific test statistics was combined into a fixed-effect meta-analysis, and the level of spurious associations was reduced. Overall, 68 independent genomic regions were identified that were associated with mean platelet volume and platelet count [p-value (P) $< 5 \times 10^{-8}$], of which 52 were new and 16 have been previously characterized in Europeans. Of these, 43 loci were associated with platelet count and 25 with platelet volume. To validate these results, these associations were tested in subjects of south Asian and Japanese origin, demonstrating significant similarity.

A large proportion of these genomic loci (46 out of 68) were associated with SNPs located in gene-coding regions of human genome, including several key genes—regulators of hemostasis (*ITG2AB, F2R, GP1BA*), megakaryopoiesis (*THPO, MEF2C*), and platelet lifespan (*BAK1*). During further narrowing of the analysis, 54 "core" genes were selected as either containing a SNP or located within 10 kb from a SNP associated with platelet volume or count. Ingenuity pathway analysis demonstrated that these genes demonstrate significant overrepresentation in biological pathways such as hematological disease, cancer, or regulation of cell cycle.

Interestingly, core genes tend to have significantly higher expression in megakaryocytes than in other blood cell types. To confirm this, umbilical cord blood-derived hematopoietic stem cells were differentiated toward precursors of blood cells, and genome-wide expression microarrays were used to study levels of gene expression. Core genes showed significant increase of expression over time in megakaryocytes, but not in erythroblasts ($P = 1.5 \times 10^{-6}$ and 0.77, respectively) (Gieger et al. 2011), demonstrating that these genes indeed play an important role in megakaryopoiesis and platelet formation.

To further evaluate biological role of these genes in megakaryopoiesis and platelets, 15 of core genes were silenced in *D. rerio* or *D. melanogaster* (Table 3). Silencing of four genes in *D. rerio* (orthologues of *AK3*, *JMJD1C*, *RNF145*, and *ARHGEF3*) resulted in the ablation of both primitive erythropoiesis and thrombopoiesis. Silencing of the orthologue of *TPM1* gene (tropomyosin 1 α) abolished formation of platelets, but not erythrocytes. For only one core gene, *EHD3*, silencing did not reveal any hematopoietic phenotype, even though two platelet-associated SNPs are located inside noncoding regions of this gene. Interestingly, silencing of gene *AK3*, located at 2699 kb from platelet-associated SNP, resulted in ablation of erythropoiesis and thrombopoiesis in *D. rerio*. One possible explanation is involvement of the region around this SNP in regulation of expression of this gene. Silencing of four other core genes (orthologues of *DNM3*, *BRF1*, *PSMD13*, *ZFPM2*) in *D. melanogaster* resulted in significant and reproducible differences in the number of produced erythrocytes and platelets.

Taken together, these data demonstrate the efficiency of a gene identification approach using meta-analysis of GWAS data. This study not only identified novel genes involved in megakaryopoiesis and platelet formation and function. It also validated these findings on several levels, including transcriptome studies during differentiation of stem cells toward precursors of blood cells and gene silencing using model organisms *D. rerio* and *D. melanogaster*.

Platelet Transcriptome and Platelet Function

In addition to regulation on genomic level, platelet function is also regulated at transcription and translation levels. Accumulating evidences suggest that miRNAs play significant role in regulation of platelet transcriptome. It was demonstrated that platelets retain a competent miRNA pathway capable of converting precursor miRNAs through functional Dicer/Argonaute 2 (*Ago2*) complexes (Landry et al. 2009), with evidence that Ago2-miRNA-223 complexes specifically regulate expression of the functionally important platelet purinergic $P2Y_{12}$ adenosine diphosphate (ADP) receptor. Additional evidence suggests that miRNAs (miR28) can modulate expression of the c-*mpl* thrombopoietin (Tpo) platelet receptor (Girardot et al. 2010) and that miR96-mediated regulation of endobrevin/*VAMP8* (vesicle-associated membrane protein 8) affects human platelet functional responsiveness (Kondkar et al. 2010). The potential importance of a functionally competent miRNA pathway is further highlighted by the enrichment of platelet miRNAs compared with other hematopoietic cells, such as granulocytes and megakaryocytes (Landry et al. 2009). It was shown that distinct platelet phenotypes can be genetically classified using a restricted set of mRNA or miRNA biomarkers (Gnatenko et al. 2010; Xu et al. 2012).

Platelets retain megakaryocyte-derived miRNAs and mRNAs (Gnatenko et al. 2003; Bugert et al. 2003; Bray et al. 2013; Rowley et al. 2011) but do not contain genomic DNA. Platelets also possess a functional spliceosome, a complex that processes pre-mRNAs in the nuclei of other cell types (Denis et al. 2005). Spliceosome components are present in the cytoplasm of human megakaryocytes and in proplatelets that extend from megakaryocytes. Primary human platelets contain essential spliceosome factors including small nuclear RNAs, splicing proteins, and endogenous pre-mRNAs. In response to integrin engagement and surface receptor activation, platelets precisely excise introns

Table 3 Core genes identified using metadata analysis (Gieger et al. 2011) of GWAS studies and validated in platelet formation using model organisms *D. rerio* and *D. melanogaster*

SNP (trait)	Core gene (distance from SNP, kb)	Protein	Phenotype in model organism
*rs*1094144 (MPV, PLC)	*DNM3* (0)	Dynamin 3	Overproliferation of plasmatocytes

MPV mean platelet volume, *PLC* platelet count

from interleukin-1β pre-mRNA, yielding a mature message that is translated into protein. It was also shown that quiescent human platelets express pre-mRNA of tissue factor (coagulation factor III or thromboplastin, gene symbol *F3*), an essential cofactor for the activation of blood coagulation, and in response to activation, splice this intronic-rich message into mature mRNA (Schwertz et al. 2006).

Platelets have evolved unique adaptive signals for maintenance of genetic and protein diversity (Denis et al. 2005; Weyrich et al. 1998). Although the platelet transcriptome varies from one individual to another, more significant differences were demonstrated between platelet transcriptome of healthy subjects and patients with myeloproliferative disorder essential thrombocythemia (Gnatenko et al. 2003; Bugert et al. 2003; Bray et al. 2013; Rowley et al. 2011). This suggests potential use of mRNAs as biomarkers for diagnostics and prognostics of platelet disorders and also adds complexity to the understanding of genomic regulation of platelets function. Selection of mRNAs for packaging into platelets is an active process, as evident by significant difference between platelet and megakaryocyte transcriptomes (Cecchetti et al. 2011).

Initial studies, performed using microarray and serial analysis of gene expression (SAGE), provided first panoramic overview of human platelet transcriptome (Gnatenko et al. 2003; Bugert et al. 2003; McRedmond et al. 2004; Dittrich et al. 2006) and demonstrated that it includes 1500–3000 individual mRNA transcripts, some of which are platelet restricted. Recently, application of RNA sequencing technology (RNAseq) provided deeper view into RNA content of human platelets (Rowley et al. 2011; Bray et al. 2013). Comparison of human and mouse platelet transcriptomes revealed expression of 8582 human genes and 6012 mouse genes (RefSeq database), with 4990 genes overlap (<58 % overlap). In addition to mRNA transcripts, these studies revealed diverse classes of noncoding RNAs, including pervasive antisense transcripts to protein-coding loci, numerous abundant microRNAs, and thousands of novel unannotated long and short intronic transcripts (Bray et al. 2013). Efficient purification of platelets and separation of them from other blood cells, especially from leukocytes, are challenging. Considering size and RNA content of one platelet comparing to one leukocyte, even low-level contamination of platelet sample with leukocytes may significantly affect transcript profile. It is not excluded therefore that some low-abundant transcripts detected in platelets actually come from contaminating leukocytes. Nevertheless, platelet mRNA profiling information is consistent in literature.

In addition to polymorphism, variability of expression levels of key platelet proteins may affect platelet function. For example, expression level of the platelet integrin $\alpha_2\beta_1$ is highly variable in healthy subjects, and platelets expressing higher levels have an increased ability to bind collagen (Roest et al. 2000; Kunicki et al. 1993) and have elevated density of this receptor on platelet surface.

Platelet Transcriptomic Studies Designed to Evaluate Thrombotic Risk

The application of gene profiling has been used in clinical diseases associated with thrombosis using either platelets or peripheral blood mononuclear cells (PBMC) as the cellular source. Two studies have reported gene expression changes associated with ischemic stroke, differing in the use of PBMC (Moore et al. 2005) or neutrophils (Tang et al. 2006). The studies of platelet transcriptome revealed quantitative differences between acute and stable coronary artery disease (Healy et al. 2006). In particular, platelet mRNA profiling from patients with acute ST-segment-elevation myocardial infarction (STEMI, $n = 16$) or stable coronary artery disease ($n = 44$) identified 54 differentially expressed transcripts. The strongest discriminators of STEMI were *CD69* and myeloid-related protein-14 (MRP-14, gene symbol *S100A9*).

Essential thrombocythemia (ET) is a rare chronic blood disorder characterized by the overproduction of platelets by megakaryocytes in the bone marrow (Beer and Green 2009). It may, albeit rarely, develop into acute myeloid leukemia or myelofibrosis. The most common symptoms are bleeding, clotting, headache, nausea, vomiting, abdominal pain, visual disturbances, dizziness, fainting, and numbness in the extremities. Collectively, ET platelets demonstrated greater number of expressed transcripts in comparison with normal controls, although considerably less than the number of transcripts generally found in nucleated cells (Gnatenko et al. 2003, 2005). A class prediction model of thrombocytosis has been generated based on expression levels of 11 platelet-expressed mRNA biomarkers as studied by microarray and quantitative PCR (Gnatenko et al. 2010). In total, platelet transcript profiles of 126 subjects were studied by microarray—48 healthy control subjects (WT), 38 patients with reactive thrombocytosis (RT), and 40 patients with ET (24 of which contained the *JAK2*V617F mutation). Cross-platform consistency was validated using alternative transcript profiling method. Class prediction algorithms were developed to assign phenotypic class between the thrombocytosis cohorts and by *JAK2* genotype. Using microarray data, an 11-biomarker gene subset (*WASF3*, *CTNS*, *HIST1H2AG*, *ACOT7*, *LAPTM4B*, *TGFB2*, *TPM1*, *H3F3A*, *APP*, *NGFRAP1*, *CLEC1*) is discriminated among the three cohorts with 86.3 % accuracy, with 93.6 % accuracy in two-way class prediction (ET vs. RT). Subsequent quantitative PCR analysis established that these biomarkers were 87.1 % accurate in prospective classification of a second cohort. A 4-biomarker gene subset (*HIST1H1A*, *SRP72*, *C20orf103*, *CRYM)* predicted *JAK2* wild-type ET in more than 85 % patient samples using either microarray or quantitative PCR profiling, with lower predictive capacity in *JAK2* $V^{617}F$ mutant ET patients. These results establish that distinct genetic biomarker subsets can predict thrombocytosis class using routine phlebotomy. Furthermore, these results confirmed discriminant power of 11-biomarker subset in distinguishing ET from RT irrespectively of the platform technology used for transcript profiling. Although these genes are not known yet to play a direct role in platelet function, the variability of their expression levels is associated with abnormal platelet production and may increase thrombotic risk. Furthermore, transcript profiling of these mRNAs in circulating platelets using microarray, quantitative PCR, or fluorescent microbeads (Gnatenko et al. 2005, 2008, 2010; Huang et al. 2013) can be used for the diagnostics of ET, currently done by exclusion.

Conclusion

It is clear that recent progress in technology and in approaches to analyze human genome has resulted in considerable advances in our understanding of the genetic basis of platelet function and its contribution to thrombotic risk. As we illustrated in this chapter, meta-analyses of multiple genome-wide association studies in conjunction with traditional candidate gene approach and functional studies allowed identification of many genes and noncoding regions of human genome that affect platelet function. In the near future, when whole exome and genome sequencing will become a routine, we anticipate identification of novel genomic loci—candidates that define platelet function and affect thrombotic risk. To further understand genetic regulation of platelet function associated with risk of thrombosis, system biology approach is needed. Such approach would focus on studies of platelet functional responses as quantitative trait loci linked to overall platelet responsiveness. It would integrate genomic and transcriptomic information to variability of platelet activation and disease outcome (O'Donnell et al. 2001).

Take-Home Messages

- Genetic factors play a key role in substantial variation of platelet production and function seen among both healthy subjects and patients. To date, it is known that platelet function is regulated by many genes that encode various proteins. Among them are platelet receptors, transcription factors, kinases, cytoskeletal proteins, proteins involved in signal transduction, and others. Abnormalities of these genes often severely affect platelet function, resulting in disease or death.
- In addition, single-nucleotide polymorphism in certain noncoding regions of human genome is shown

(continued)

to affect platelet function. Despite significant progress in our understanding of human genome, little is known about molecular mechanisms of such effects.

- Platelet production and function are also regulated at transcription level. For example, studies of platelet transcriptome identified mRNA and miRNA biomarkers of essential thrombocythemia and revealed quantitative differences between acute and stable coronary artery disease that are associated with increased thrombotic risk.
- Rapidly expanding knowledge of human genome leads to identification of novel genes that affect platelet function. In the future, meta-analyses that combine multiple genome-wide association studies will identify more genes and genome regions that contribute to platelet formation and function.

Platelets and Bacterial Infections

Matthew T. Rondina, Olivier Garraud, and Hansjörg Schwertz

Abstract

Platelets are circulating blood cells classically known for their key roles in mediating hemostasis and vascular wall repair. Platelets also possess a dynamic repertoire of effector functions in the immune continuum that span from rapid innate immune responses to more delayed adaptive and acquired immune activities. Platelets express a wide array of structural and functional characteristics of host defense effector cells that augment host defenses to bacterial infections. Platelets display a diverse range of surface ligands and receptors that recognize and bind bacteria, including complement receptors, FcγRII, toll-like receptors (TLRs), and integrins conventionally described in the hemostatic response, such as $\alpha_{IIb}\beta_3$ and GPIb. Both direct and indirect binding of bacteria, bacterial toxins, and other agonists to platelets via fibrinogen, fibronectin, C1q, or von Willebrand factor (vWF) may result in platelet activation. Platelets may also internalize bacteria, although the function and fate of these host defense mechanisms remain incompletely understood. Once activated, platelets transform from quiescent discoid forms to amoeboid cells that chemotax to and target microbial pathogens or ligands displayed by tissues injured during infectious insults. Upon activation and subsequent degranulation, platelets secrete an array of multifunctional host defense and antimicrobial peptides that act as direct anti-infective agents and coordinate additional molecular and cellular host defenses. Platelets also release soluble immunomod-

ulatory factors that play crucial roles in the formation of neutrophil extracellular traps (NETs), resulting in bacterial elimination but also enhancing thrombosis in disease situations. Therefore, platelets are increasingly recognized as key effector cells in immune and inflammatory responses to host infection. The multiplicity of events underscores the complexity of platelet–bacterial interaction and illustrates the emerging view that platelets are important sentinel and effector cells in host defenses against pathogens.

Introduction

Due to their high number in the circulation, platelets may be the first blood cell that encounters bacteria circulating systemically. As such, platelets have been suggested to be key sentinels residing within the vascular space. The amount and variety of functional immunoreceptors define these small cells as complex and unique blood "all-purpose" elements and weapons. Nevertheless, the recognition of platelets as fully functional immune cells is still controversial, primarily due to their lack of a nucleus and their structural "simplicity." In the last decade, a multitude of previously unrecognized and dynamic functions have been discovered for platelets. These emerging functions are comprehensive and adaptive and span the immune continuum. Many of these newly recognized functions are essential for pathogen surveillance, host defenses and containment, and wound healing (Hamzeh-Cognasse et al. 2015; Vieira-de-Abreu et al. 2012; Weyrich et al. 2003; Weyrich and Zimmerman 2004). In this chapter, we will discuss the role of platelets as innate and adaptive immune cells and the relationship of immune activities of platelets to their hemostatic effector functions.

We will first focus on platelet–bacterial interactions, platelet-released immunomodulatory molecules, and platelet-mediated host defense systems. We will also discuss the intersection of bacterial infection and thrombosis, the interactions of platelets with other classic immune cells, and the necessary cross talk between platelets and neutrophils in neutrophil extracellular trap (NET) formation.

Platelet–Bacterial Interactions: One-on-One

When talking about platelets and their potential to interact with bacteria, there are several different possible mechanisms of interaction (Fig. 1). First, bacteria themselves bind host plasma proteins, which have a

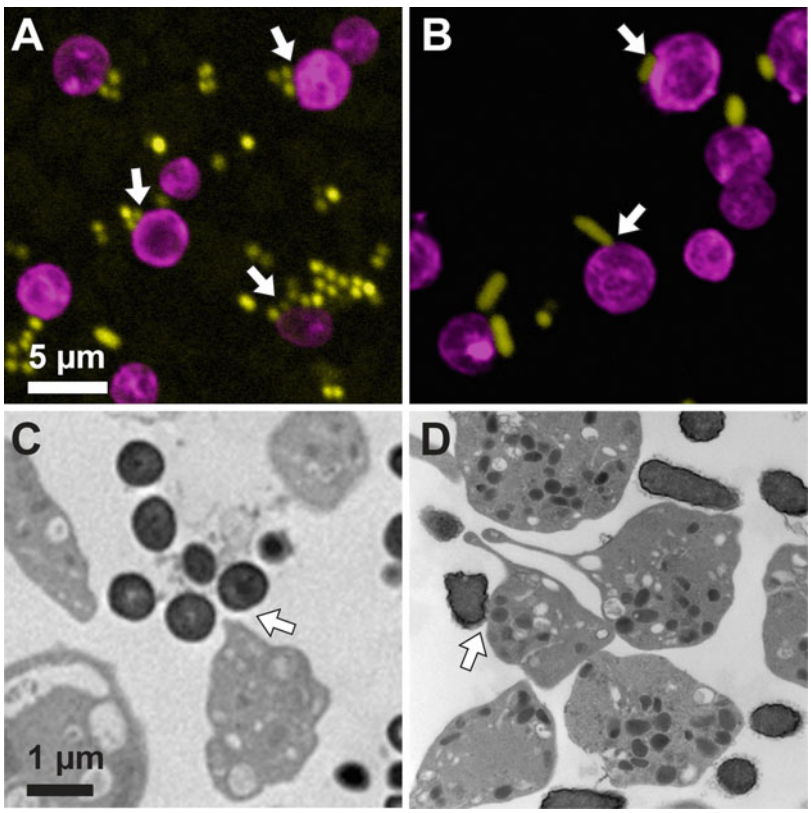

Fig. 1 Human platelets directly interact with bacteria. Human platelets were incubated with bacteria for 2 h. (**a**) Platelets were incubated with *S. aureus* or (**b**) *E. coli*, fixed, spun down, and subsequently stained using Topro-3 for DNA-containing bacteria (*yellow*) and wheat germ agglutinin (WGA, magenta). *White arrows* indicate sites of platelet–bacterial interaction. Platelets were analyzed using transmission electron microscopy (TEM) after being incubated with *S. aureus* or (**c**) *E. coli* (**d**). *White arrows* indicate sites of platelet–bacterial interaction

corresponding receptor on the platelet surface. Second is the direct binding or adhesion to platelet receptors or the platelet surface. Third is the interaction of secreted bacterial products, exotoxins, or bacterial degradation product with platelet surface receptors. Since platelets express a diverse array of surface receptors, these interactions are highly complex and may result in different activation patterns.

Indirect Interactions

The Integrin $\alpha_{IIb}\beta_3$ (GPIIb–IIIa)

The platelet fibrinogen receptor $\alpha_{IIb}\beta_3$ is a key mediator of the hemostatic function of platelets. The engagement of the integrin by fibrinogen leads to platelet adhesion, aggregation, and activation via outside-in signaling events and is a pharmaceutical target in several disease scenarios (Bennett et al. 1999, 2009; Coller 1997). One family of bacteria that provides an example for direct fibrinogen and fibronectin binding to platelets is the genus *Staphylococci*. Binding of *Staphylococci* to tissues and the extracellular matrix is a critical step in establishing infection of a host organism. To achieve this, *Staphylococci* express surface receptors belonging to the microbial surface components recognizing adhesive matrix molecules (MSCRAMM) family (Josefsson et al. 1998). Some of the most common examples of MSCRAMM are listed in Table 1. While these various MSCRAMMs are highly similar proteins, they bind to fibrinogen via very heterogeneous binding sites. For example, the C-terminal region of the fibrinogen g-chain is the binding site for ClfA, Fbl, and FnbpA and B (McDevitt et al. 1994; Mitchell et al. 2004; Ni Eidhin et al. 1998). In contrast, ClfB binds to the C-terminal region of the fibrinogen a-chain, and SdrG on the b-chain (Flock et al. 1987; Brennan et al. 2009). Besides *Staphylococci* there are other bacteria, which can engage with fibrinogen. These include the two members of the *Streptococcus* family. *Streptococcus pyogenes* and *Streptococcus mitis* can bind fibrinogen via the M1 protein and lysine, respectively (Cox et al. 2011). While serving as an indirect receptor for bacterial adhesion to platelets, $\alpha_{IIb}\beta_3$ can also be directly bound by several bacterial surface proteins, which is discussed in more detail below.

Involvement of Glycoprotein Ibα (GPIbα)

GP1bα is an essential and integral part of the von Willebrand factor (vWF) binding complex on the platelet surface, which is comprised of GPIbα, GPIbβ, GPIX, and GPV (Bennett et al. 2009). The GPIb/IX/V complex is a key mediator of primary hemostasis. In addition, some bacteria are capable of binding to vWF, docking onto the platelet surface via engagement of the GPIb/IX/V complex. Similarly, protein A from *S. aureus* is capable of binding to vWF, promoting thrombus formation in vitro and under conditions of flow (Claes et al. 2014; O'Seaghdha et al. 2006; Thomer et al. 2013). *Helicobacter pylori* also directly binds to platelet vWF, although the ligand on *H. pylori* mediating this interaction has not yet been identified. These interactions ultimately cause platelet aggregation (Byrne et al. 2003). Besides the vWF-mediated binding of GPIb by bacteria, the glycoprotein can also be directly bound with some bacterial surface proteins, a mechanism discussed in more detail below.

Binding to Platelets via Complement Receptors

It is well known that the complement system can activate platelets by inducing the expression of procoagulant factors, such as prothrombinase complex, on the surface of the cells (Peerschke et al. 2010). Furthermore, both complement pathways—the conventional as well as the alternative pathway—are known to interact with bacteria via complement proteins bound to the bacterial surface (Gadjeva 2014). Upon activation, platelet surface expression of gC1q-R, the receptor for C1q, increases. This enables platelets to indirectly bind bacteria coated with C1q on their surface (Peerschke et al. 2003). Moreover, platelet activation also triggers the increased surface expression of CD62P, a potent

binding partner for the complement protein C3b, leading to platelet-complement factor-coated bacteria interaction (Hamad et al. 2010). Complement-mediated platelet–bacterial interactions were also demonstrated for *S. sanguinis* and *S. aureus*, which induce complement-dependent platelet aggregation (Ford et al. 1996; Loughman et al. 2005).

Complement bacteria–platelet interactions provide a mechanism by which platelets may facilitate the destruction of bacteria by enhancing the complement cascade via surface-bound complement factors and exposed complement receptors. This process may also result in the potential destruction of platelets themselves by being targeted by the lytic activity of the complement system. The complement modulatory potential demonstrated by platelets highlights the immunologic function of this dynamic anucleate cell.

Expression and Functional Significance of the FcγRIIa Receptor

While the expression of the immune receptor FcγRIIa was previously thought to be reserved for classic immune cells, blood platelets also surface-express this receptor (Cassel et al. 1993), although only the Fcγ receptor has been identified in platelets to date. The general function of the immune receptor of the FcγRIIa class is to recognize and bind the Fc domain of immunoglobulin G (IgG). The Fcγ receptor demonstrates a higher affinity for complexed IgG and has a weaker affinity for monomeric IgG. Platelet FcγRIIa is also a key mediator of heparin-induced thrombocytopenia, where autoantibodies recognize the platelet factor 4 (PF4)–heparin complexes that bind to the platelet FcγRIIa (Greinacher 2015). In addition, bacteria recognized and bound by IgG can be attached to this platelet receptor and subsequently internalized (Worth et al. 2006). As platelets are the second most abundant circulating blood cell and express the FcγRIIa in a high copy number on their surface (Cox et al. 2011), platelets may be a significant, yet underappreciated mediator, of antibacterial responses during human infectious settings.

Direct Interactions

Role of Integrin $\alpha_{IIb}\beta_3$ (GPIIb–IIIa)

In addition to indirect platelet–bacterial interactions utilizing platelet surface receptors traditionally recognizing extracellular matrix, those receptors directly engage with bacterial surface proteins. The aforementioned *S. epidermidis* surface protein SdrG, in addition to binding fibrinogen, also directly targets platelet glycoprotein IIb–IIIa (Brennan et al. 2009). Furthermore, *S. aureus* uses one of its iron-regulated surface determinant (Isd) proteins (IsdB), which are usually used to ensure iron supply for the microbe via heme binding, to bind to integrin $\alpha_{IIb}\beta_3$ in the absence of plasma protein (Miajlovic et al. 2010). Specificity of this interaction was demonstrated using platelets treated with $\alpha_{IIb}\beta_3$ antibodies, a treatment resulting in complete inhibition of platelet–bacterial adhesion. Recently, *S. gordonii* was found to express a surface factor, termed platelet adherence protein A (PadA), which directly interacts with $\alpha_{IIb}\beta_3$ (Petersen et al. 2010).

Interaction with Glycoprotein Ibα (GPIbα)

GPIbα can also serve as a binding ligand by bacteria for direct engagement with human platelets. This interaction involves a family of highly glycosylated, serine-rich bacterial proteins. These proteins include serine-rich protein A (SrpA) from *S. sanguinis* (Plummer et al. 2005), glycosylated streptococcal protein B (GspB), and hemagglutinin salivary antigen (Hsa) from *S. gordonii* (Bensing et al. 2004). Moreover, the staphylococcal accessory regulator (Sar) P protein expressed by *S. aureus* also mediates direct adhesion of bacteria to platelets (Siboo et al. 2005).

Effects of Platelet–Bacteria Interactions on Aggregation

As discussed above, platelet–bacterial interactions include the engagement of platelet surface receptors traditionally viewed as primary mediators of hemostasis. As such, published evidence demonstrates that platelet aggregation is, at least, partially dependent on docking of bacteria with platelets. Once bacteria have bound to platelet surface $\alpha_{IIb}\beta_3$ via fibrinogen or fibronectin, platelet aggregation is initiated in a manner similar as seen with other fibrinogen-coated surfaces (Cox et al. 2011). The SrpA and GspB proteins of *S. sanguinis* and *S. gordonii*, respectively, bind platelets and are requisite for platelet aggregation. If these two proteins are genetically deleted, aggregation is eliminated (Cox et al. 2011). Bacteria-induced platelet aggregation can be shear dependent and shear independent. For example, *S. pyogenes* and *S. aureus* shear forces appear to be dispensable for the induction of platelet aggregation.

There remain aspects of platelet–bacterial interactions and resulting aggregation responses that are incompletely understood. For example, *S. gordonii*, which directly interacts with $\alpha_{IIb}\beta_3$ on platelets through its PadA protein, does not induce platelet aggregation (Petersen et al. 2010). It has been hypothesized that for some of these bacterial groups, binding of GPIb might result in rearrangements that bring other platelet surface receptors, such as FcγRIIa or $\alpha_{IIb}\beta_3$, together in closer proximity, thus promoting thrombus formation (Cox et al. 2011).

In addition to direct interactions leading to aggregation, other mechanisms are involved. Platelet activation induced by surface-bound *S. sanguinis* (via GPIb) results in the release of platelet dense granule content, namely, the vasoactive substances ATP and ADP, which can act via autocrine signaling to further amplify platelet activation. This

mechanism can be enhanced by *S. sanguinis* through the hydrolyzation of ATP to ADP by the surface-expressed ecto-ATPases. The additionally produced ADPs will increase platelet activation using the P2Y signaling pathway (Cox et al. 2011). Several reports highlighted the need for FcγRIIa involvement on platelet aggregation after bacterial adhesion (Cox et al. 2011). Nevertheless, the observed aggregation seemed to be independent of IgG, and therefore FcγRIIa receptors may have alternative functions in addition to what has been traditionally described. In this context, two publications reported a functional interplay between FcγRIIa and GPIb during bacterial stimulation, which might be the first step in signal transduction (Sullam et al. 1998; Sun et al. 1999). Since GPIb binds to FcγRIIa using the same binding motif as when binding to actin, one might speculate that an alternative functional role of FcγRIIa is mediated by cytoskeletal remodeling (Sun et al. 1999). Similarly, Newman et al. showed that the Src residue from $\alpha_{IIb}\beta_3$ phosphorylates the immunoreceptor tyrosine-based activation motif (ITAM) residue of FcγRIIa and thus amplifies the platelet activation signals (Boylan et al. 2008).

In other aspects, bacteria-induced platelet aggregation may be distinct from conventional agonist (ADP, ATP, and thrombin)-induced aggregation. For example, in "binary" aggregation, there is a bacterial density below which platelet aggregation is not observed and above which platelet aggregation is maximal (Kerrigan and Cox 2010). Furthermore, in the presence of bacteria, the lag time before platelet aggregation begins is longer than that observed with hemostatic activation. For some bacteria the lag time might be as long as 20 min, although in some settings, the lag time is dependent on bacterial density (Kerrigan and Cox 2010). There could be several explanations for these lag time variations, including different times required for platelet to bind and interact with bacteria or induction of a weak receptor response.

Bacterial Toxins and Platelets

It is well recognized that bacteria secrete toxins into the host circulation or release endotoxins when lysed or destroyed in other fashion. Members of the *Staphylococcus* family express alpha-toxin, which binds to the lipid bilayer membrane of platelets to form a pore, followed by a flow of calcium, similar to that induced by calcium ionophore (Arvand et al. 1990). Alpha-toxin-induced platelet activation was described to induce RNA splicing and protein synthesis events in platelets as well as the formation of platelet–bacterial aggregates (Rondina et al. 2011; Schubert et al. 2011). Other pore-forming toxins engaging with the platelet surface have been described. These include streptolysin O from *S. pyogenes* (Bryant et al. 2005) and pneumolysin from *Streptococcus pneumoniae* (Johnson et al. 1981). Furthermore, *Porphyromonas gingivalis* secretes a family of cysteine proteases called gingipains. These secreted toxins recognize the platelet protease-activated receptor (PAR) 1, cleaving it in a similar fashion to the natural ligand thrombin, thereby making it functional (Fitzpatrick et al. 2009). Some bacterial toxins have known superantigenic effects. Among those toxins are the family of staphylococcal superantigen-like (SSL) toxins, released by *Staphylococcus aureus* and *S. pyogenes.* One of them, SSL5, can directly interact with GPIba as well as having a direct affinity for GPIV (Cox et al. 2011).

Lipopolysaccharide (LPS) is one of the most important endotoxins expressed on the surface of Gram-negative pathogens. It can be recognized by toll-like receptors (TLRs) expressed by platelets. Platelet surface-expressed TLR-4 is capable of interacting with LPS, leading to platelet activation, P-selectin surface exposure, pre-mRNA splicing events, induction NETs (see later paragraphs), and protein synthetic events and may also contribute to the thrombocytopenia that commonly occurs in sepsis (Akinosoglou and Alexopoulos 2014; Rondina et al. 2011; Semple et al. 2011).

Bacterial-Triggered Release of Platelet-Derived Immunomodulatory Factors

Numerous inflammatory and immune modulating factors are stored in platelet α- and dense granules (Table 2). These molecules are released during platelet activation, modifying host immune responses (Fong et al. 2011; Karshovska et al. 2013; Vieira-de-Abreu et al. 2012; Weyrich and Zimmerman 2004). We will focus in this chapter on several of these molecules and their key signaling events. CD40L (CD154) is a well-established immunoregulatory molecule released by platelets. Platelets were also identified as the major source of circulating soluble CD40L (sCD40L) (Andre et al. 2002). It is known that bacterial ligands interacting with platelet surface TLR-2 (Assinger et al. 2012; Assinger et al. 2011; Cognasse et al. 2007) and TLR-4 (Assinger et al. 2012; Berthet et al. 2012; Cognasse et al. 2007; Ward et al. 2005) induce the release of sCD40L. CD40L is first exposed on the platelet surface membrane in trimeric form (the biologically most active form) and is then cleaved by proteolytic activity, yielding a soluble biologically active fragment. Although not definitely established, there is some evidence suggesting that matrix metalloproteinase (MMP)-9 cleaves the trimeric form of CD40L. The fragment, sCD40L, is recognized by a receptor, CD40, on B lymphocytes, monocytes, and endothelial cells (Blumberg et al. 2009). It should also be pointed out that the soluble form of platelet CD40L may also have an autocrine effect due to the presence of CD40 on the platelet surface (Garraud et al. 2013). sCD40L can facilitate T and B cell interactions leading to antibody production or inducing

Table 2 Inflammatory, antimicrobial, and immunomodulatory factors released by platelets

Function	Factor	Reported target cell
Pleiotropic inflammatory and immune modulators	*Histamine* *5-HT; serotonin*	ECs, monocytes, PMNs, NK cells, T and B cells, eosinophils Monocytes, macrophages
Inflammatory and immunomodulatory lipids	*TXA_2* *PAF*	Platelets, T lymphocyte, and macrophage subsets Platelets, PMNs, monocytes, macrophage, and lymphocyte subsets

Antimicrobial peptides	*Thrombocidins* *hBD-1, 2, 3*	No human cellular targets identified; microbicidal for several bacteria and fungi No human cellular targets identified; microbicidal for several bacteria
Cytokines	*IL-1b* *HMGB1* *sCD40L*	Monocytes, ECs, dendritic and macrophage subsets Macrophages, PMNs, ECs Monocytes, B lymphocytes, ECs, platelets

The table is not comprehensive, and additional signaling molecules are found in the platelet secretome; new factors continue to be identified. Some factors are not only secreted but also perform signaling roles while associated with the platelet plasma membrane or on the surfaces of platelet microparticles (e.g., PAF, IL-1β). Many factors also activate target cells in addition to immune effectors, such as fibroblasts and smooth muscle cells. Thrombocidins and hBDs are examples of a larger group of platelet microbicidal proteins (PmPs)
DC, dendritic cell; ECs, endothelial cells; ENA-78, epithelial neutrophil-activating protein-78; GRO-α, growth-regulating oncogene-α; 5-HT, 5-hydroxytryptamine; hBD, human beta defensin; HMGB1, high mobility group box 1; IL-1β, interleukin-1β; MCP-3, monocyte chemotactic protein-3; MIP-1α, macrophage inflammatory protein-1α; NAP2, neutrophil-activating peptide 2; NK, natural killer; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; PF4, platelet factor 4; sCD40L, soluble CD40 ligand; TGF-β, transforming growth factor β; TXA_2, thromboxane A_2

class switching of B lymphocytes (Elzey et al. 2005). In addition, sCD40L released from platelet storage pools (granules) induces cytokines, chemokines, and lipid mediators through the activation of CD40+ cells (Blumberg et al. 2009). These cytokines potentiate and modulate neutrophil functions in defense against Gram-positive and Gram-negative bacteria (Miedzobrodzki et al. 2008). Thus, sCD40L is one archetypal molecule that platelets use to orchestrate host defense responses with lymphocytes, endothelial cells, and other host defense effector cells.

Another platelet cytokine being of importance is platelet factor 4 (PF4), a known platelet kinocidin (this term will be elucidated in more detail in the next paragraph). Numerous studies have shown that PF4 plasma levels increase dramatically in the setting of a microbial challenge in vivo. For example, PF4 plasma levels increase during bacterial septicemia (Lorenz and Brauer 1988) and *streptococcal* nephritis (Mezzano et al. 1992). Soluble PF4 can bind to bacteria through its positive charge, thus forming a new recognition site for IgG and effector immune cells (Krauel et al. 2011, 2012). This mechanism is also true for Gram-negative bacteria, since PF4 presents an affinity for bisphosphorylated lipid A of lipopolysaccharide (LPS) bacteria. The newly formed complex is taken up the phagocytic cells. Platelet PF4 might thus facilitate the clearance of certain bacteria. In addition to the lymphocyte modulatory function, an array of bioactive molecules, released from platelets activated by microbial challenge, are chemoattractants for monocytes and neutrophils. These include platelet-derived growth factor (PDGF), platelet-activating factor (PAF), regulated on activation normal T cell expressed and secreted (RANTES) protein, macrophage inflammatory protein (MIP-1 alpha), monocyte chemoattractant protein, and PF4 (Clark-Lewis et al. 1993; Deuel et al. 1981; Tzeng et al. 1985; Semple et al. 2011; Weyrich and Zimmerman 2004).

Platelets Are an Integral Part of the Antimicrobial Host Defense System

The Internalization of Bacteria

In the 1970s, Clawson and colleagues studied the interaction between platelets and bacteria and observed the internalization of *S. aureus* into some platelets (Clawson 1973; Clawson et al. 1975; Clawson and White 1980). These

observations were confirmed by other investigators, especially for *S. aureus* (Youssefian et al. 2002). Youssefian et al. proposed that platelets have the ability to actively internalize or phagocytose microorganisms. This hypothesis was based on finding bacteria inside of vacuoles that were not connected to the open canalicular system (OCS) (Youssefian et al. 2002). Furthermore, it appears that bacterial internalization resembles morphologic evidence of platelet activation. In turn, platelets seem to gain enhanced capacity for bacterial internalization if been activated by bacteria or even conventional agonists (ADP or thrombin), indicating a common mechanism between activation and internalization. Interestingly, immunolabeling revealed that the engulfing vacuoles and the OCS were composed of distinct antigens. When *S. aureus* was engulfed by platelets, membranes expressed CD62P and $\alpha_{IIb}\beta_3$, but not GPIb, similar expression markers seen an activated platelet membrane. Moreover, endocytotic vacuoles containing *S. aureus* were demonstrated to fuse with α-granules, which contain platelet antimicrobicidal proteins. Because of its close proximity to the plasma membrane and the differential surface marker array, these vacuoles may be formed through invagination of the plasma membrane. Internalization of *S. aureus* has also been demonstrated in settings of ADP-induced platelet activation (Li et al. 2008). Under these activating conditions, *P. gingivalis* can also be internalized by platelets (Li et al. 2008). *P. gingivalis*, however, may also be internalized in the absence of activation, an observation not noted with *S. aureus*. While internalization of both bacteria results in them being found in vacuoles independent of the OCS, these findings suggest there may be unique mechanisms regulating the internalization of different bacterial species.

Platelet binding to bacteria using the FcγRII receptor could also initiate the internalization of IgG-bacteria complexes (Worth et al. 2006). In 2011, Antczak et al. demonstrated that platelets are capable of internalizing IgG-coated polystyrene beads (0.5–1.5 μm diameter) in a FcγRII-specific mechanism (Antczak et al. 2011). This endocytotic mechanism was inhibited by the actin-polymerization inhibitor cytochalasin D, demonstrating that actin cytoskeletal dynamics are an integral process of bacteria internalization. While these and other studies support the concept that platelets can internalize or endocytose bacteria, the final fate of these internalized microbes remains uncertain. Some have suggested that the absence of phagolysosomes in platelets precludes their ability to degrade or destroy bacteria (White 2006). Other lines of evidence suppose that the fusion of bacteria with platelet α-granules, which contain antimicrobicidal proteins, could result in pathogen destruction (Youssefian et al. 2002).

Platelets Release Antibacterial Effector Molecules Contributing to Host Defense

In addition to platelets' ability to directly interact with and internalize bacteria, platelets also release antimicrobial proteins and peptides. In 1901, Gengou demonstrated that the bactericidal activity of a previously identified molecule within serum (Fodor 1887), β-lysin, was derived from cells involved in the clotting of blood in a mechanism that was independent of complement (Gengou 1901). This may have been the first study to identify a role for platelets in antimicrobial host defense responses.

In 2010, Yeaman and colleagues proposed calling these antimicrobial molecules platelet microbicidal proteins (PmPs) (Yeaman 2010). These proteins are also known as thrombocidins. PmPs (predominantly PmP1 and PmP2) are released when platelets are activated by thrombin or bacteria. PmPs differ from classically described defensins by their molecular mass, their sequence, and the chains of lysine and arginine residues, which gives them a cationic charge. As with PARs (protease-activated receptors), PmPs must be cleaved by thrombin to become fully functional. The two PmP subunits then act in an autonomous, but complementary, manner, by alternating the permeability of the bacterial wall (Yeaman 2010). The ATP/ADP signaling pathway, utilizing the P2 receptors, primarily triggers the release of PmPs. The initial signal is further amplified by the release of platelet ADP, resulting in potentially autocrine activation of even neighboring platelets (Trier et al. 2008). Over the years, the PmP family was enlarged through the integration of kinocidins, which include those platelet-derived cytokines that have a direct bactericidal effect (Yang et al. 2003). This broad collection of antimicrobial peptides is released from human platelets following thrombin or bacterial stimulation. Similar to chemokines, kinocidins have been organized into classes, which are related to their structural immunobiology. The hallmark CXC motif is the defining element of α-kinocidins. This group includes PF4 (platelet factor 4), platelet basic protein (PBP), connective tissue-activating peptide (CTAP3), and neutrophil-activating peptide (NAP2). In contrast, RANTES is a member of the β-kinocidins, containing the typical CC-chemokine motif. Importantly, members of the α-kinocidin and the β-kinocidin subgroups have synergistic effects. For example, CTAP3 does not have an effect on the viability of *E. coli*. However, the presence of PF4 potentiates CTAP3 activity and thereby reduces the bacterial density significantly. This result is not obtained for PF4 alone (Tang et al. 2002). Using elaborate structural biochemical analyses, the 60–74 structural domain in PF4 was identified as being responsible for this synergistic activity (Yeaman et al. 2007). Kinocidins still also maintain their

primary role, which is the chemoattraction of leukocytes. This mechanism fosters cooperation between platelet and leukocyte factors in bacterial clearance, thus integrating different mechanisms in innate immunity (Agerberth and Gudmundsson 2006; Yeaman et al. 2007).

Kraemer et al. demonstrated that *S. aureus* growth decreases in the presence of human platelets (Kraemer et al. 2011). This platelet bactericidal effect was attributed to the expression of human β-defensin-1 (hBD-1), an antimicrobial peptide primarily expressed by epithelial cells, but also detectable in human blood (Fang et al. 2003). hBD-1 is present in $CD34^+$ hematopoietic progenitor cell-derived megakaryocytes and human platelets at both the messenger RNA (mRNA) and protein level and was localized to an extragranular cytoplasmic compartment. Moreover, treating platelets with *S. aureus*-derived α-toxin, a bacterial pore-forming product, resulted in hBD-1 secretion. Subsequent studies have found that other family members, including hBD-2 and hBD-3, are present in human platelets and possess potent microbicidal activity (Tohidnezhad et al. 2011, 2012).

Boilard and colleagues recently extended these findings, describing a new mechanism by which platelets modulate inflammatory responses by using bactericidal phospholipase (Boudreau et al. 2014). They demonstrate that activated platelets release respiratory-competent mitochondria inside microparticles or as free organelles. The authors further show that the platelet-derived mitochondria are a substrate for the secreted phospholipase A_2 IIA ($sPLA_2$-IIA), a phospholipase otherwise specific for bacteria. This substrate specificity may reflect the ancestral *Proteobacteria* origin of mitochondria. Upon mitochondrial membrane phospholipid hydrolysis by $sPLA_2$-IIA, platelets released a number of lysophospholipids (lyso-PAF, lyso-PC, lysoPE) and free fatty acids. The release of these products resulted in damaged structural integrity and the generation of mitochondrial DNA (mtDNA), a potent pro-inflammatory molecule. Taken together, these and other observations suggest that platelets are involved in infectious immune responses both directly through the release of antimicrobial factors and indirectly through the release of cytokines and other mediators.

Role of Platelets in the Development and Pathophysiology of Bacterial Sepsis

Sepsis is a common and often lethal infectious syndrome that is increasing in incidence. Dysregulated immune and hemostatic responses to pathogens, pathogen-associated molecular patterns, and microbial toxins are central to the pathogenesis of septic syndromes (Fig. 2) (Vincent and Abraham 2006).

Coagulopathy Induced by Septic Triggers

Up to 30–50 % of patients with severe sepsis or septic shock develop disseminated intravascular coagulation (DIC). DIC, in conjunction with peripheral consumption and destruction of platelets, impaired thrombopoiesis, and sequestration of platelets in the microvasculature in platelet–fibrin deposits contributes to thrombocytopenia in sepsis. Moreover, severe

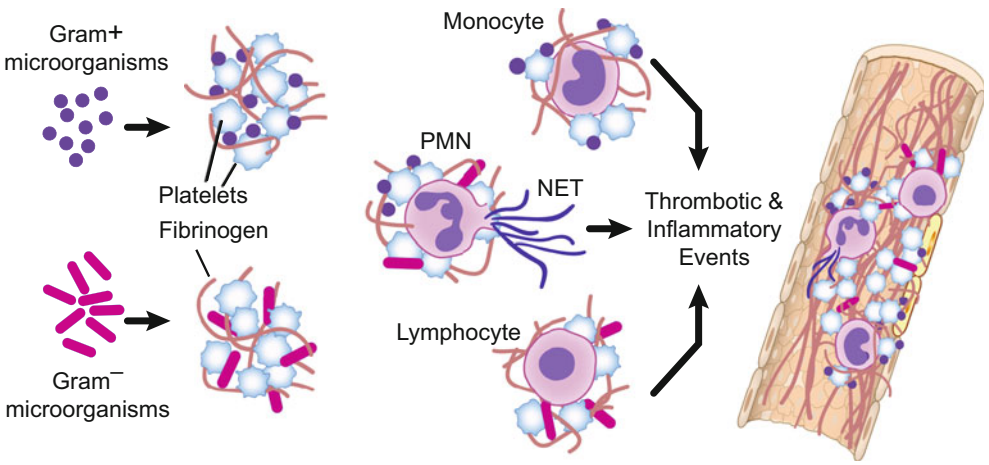

Fig. 2 Platelets interact with bacteria, recruit immune cells, and subsequently trigger inflammatory and thrombotic events. Activation of platelets by bacteria or microbial toxins can trigger platelet–bacterial aggregation or promote the interaction of activated platelets with monocytes, lymphocytes, and neutrophils. Interaction of platelets with leukocytes can also lead to NETosis and bacterial destruction. Platelet or platelet–bacteria/immune cell aggregate sequestration in microvascular beds can mediate increased local inflammatory signaling. In addition, the interaction with fibrinogen and the deposition of fibrin is a central pathophysiological process in sepsis. Furthermore, fibrin degradation products can modify platelet–cell interactions and contribute to the dysregulated hemostasis characteristic of sepsis

thrombocytopenia or a delayed recovery in the platelet count is associated with adverse outcomes from sepsis. As a result of the inflammatory response in sepsis, neutrophils synthesize and release tissue factor, which may initiate or amplify activation of the coagulation cascade, ultimately activating circulating platelets. Activated platelets have increased surface expression of adhesion molecules, promoting interactions with and binding to the damaged endothelial surface and subendothelial matrix proteins (Warkentin et al. 2003). Dysregulated activation of coagulation cascade leads to the deposition of platelet–fibrin thrombi and platelet sequestration in microvessels (Warkentin et al. 2003). Moreover, the formation of homotypic platelet–platelet aggregates and heterotypic platelet–bacteria, platelet–monocyte, and platelet–neutrophil aggregates (in conjunction with excessive thrombin generation and conversion of fibrinogen to fibrin) may further contribute to micro- and macrovascular sequestration and thrombosis (Evans et al. 1969; Gawaz et al. 1995). Thus, platelets are key mediator and effector cells involved in the pathophysiology of sepsis.

The Inflammatory Face of Platelets during Sepsis

First evidence for the inflammatory potential of platelets in sepsis comes from studies demonstrating that the amount of circulating sCD40L is increased in patients with sepsis when compared to healthy control subjects, although levels of sCD40L were independent of sepsis severity (Chew et al. 2010; Inwald et al. 2006; Lorente et al. 2011; Luo et al. 2014; Rahman et al. 2013; Zhang et al. 2011). In murine models of sepsis, sCD40L is released from platelets (Rahman et al. 2009), and matrix metalloproteinase-9, which cleaves platelet-derived CD40L, is increased (Rahman et al. 2012). sCD40L is a key molecule for the recruitment of neutrophils, via macrophage-1 antigen (Mac-1) expression on neutrophils to sites of infection or injury. Mice deficient in CD40L cannot activate neutrophils and do not develop edema or neutrophil infiltration in the lungs in settings of sepsis induced by cecal ligation puncture (CLP) (Asaduzzaman et al. 2009; Rahman et al. 2009).

Another host synthesized pro-inflammatory mediator generated during sepsis is PAF (Yost et al. 2010). PAF binds to its receptor, platelet-activating factor receptor (PAFR), a G-protein coupled receptor expressed by immune cells and platelets, leading to platelet degranulation, the release of inflammatory factors, and initiation of the coagulation cascade. The PAFR-related signaling cascade is usually tightly regulated to prevent excessive thrombo-inflammatory response. Nevertheless, during sepsis, this regulatory balance is shifted, and excessive PAF signaling leads to the activation of neutrophils, monocytes, and platelets, as well as to the formation of heterotypic platelet aggregates (Yost et al. 2010). As discussed above, activation of circulating platelets by bacterial triggers also causes the expression of cell surface receptors and the release of molecules that may further amplify immune responses (Semple et al. 2011). P-selectin (CD62P), which is expressed on the surface of platelets, and its receptor, P-selectin glycoprotein ligand-1 (PSGL-1) on leukocytes, are additional molecules with key functions during inflammatory and immune responses (Diacovo et al. 1996; Katz et al. 2011; Russwurm et al. 2002; Semple et al. 2011). The functional cross talk between P-selectin and PSGL-1 in conjunction with the leukocyte integrin $\alpha_M\beta_2$ (Mac-1) helps orchestrating the molecular events necessary for leukocyte recruitment (Semple et al. 2011; Weyrich and Zimmerman 2004).

Platelet Microparticles Fuel the Inflammatory Fire in Sepsis

Increased levels of circulating microparticles are also commonly detected in sepsis patients (Ogura et al. 2001). These membrane-enclosed vesicles can arise from different cell types, including granulocytes, monocytes, endothelial cells, and platelets (George 2008). Here, we will focus on platelet-derived microparticles in sepsis. Platelet microparticles (PMPs) are small phospholipid vesicles between 100–1000 nm in diameter that are released after budding from the platelet plasma membrane. As a result, PMP express the same antigens as their parent cells, i.e., $\alpha_{IIb}\beta_3$, GPIb, CD31, CD61, and CD62P (Vasina et al. 2010). Platelet-derived microparticles comprise the majority (e.g., approximately 70–90 %) of the pool of circulating microparticles (Burnier et al. 2009). In sepsis, microparticles can be produced via the stimulation of platelet TLR-4 by bacterial LPS (Brown and McIntyre 2011; Hashimoto et al. 2009; Kappelmayer et al. 2013), but also in response to the Shiga toxin (Ge et al. 2012). Formation of platelet microparticles results in an asymmetrical distribution of membrane phospholipids (Flaumenhaft et al. 2010; Italiano et al. 2010). Therefore, PMPs express highly procoagulant phosphatidylserines (PS) on their surface, although microparticles derived from platelets may be less procoagulant than monocyte-derived microparticles (Owens and Mackman 2011). Furthermore, in recent studies it was shown that two distinct subpopulations of microparticles exist: (1) PS-expressing and (2) PS-nonexpressing MPs. As surface phosphatidylserine-positive microparticles participate in the coagulation process, these data suggest that PS-nonexpressing MPs might have roles separate from the maintenance of primary hemostasis (Arraud et al. 2014; Cloutier et al. 2013).

Platelet microparticles are also capable of delivering immunomodulatory factors, such as IL-1β (Boilard et al. 2010), as well as interacting with other cells. For example, Provost et al. recently demonstrated that human platelet-derived microparticles contained functional Argonaute 2 (Ago2)–miR-223 complexes that were capable of regulating the expression of two endogenous genes in endothelial cells (Laffont et al. 2013). These findings support the concept that microparticles may act as intercellular carriers of functional cell components, thereby influencing the function of other circulating cell types. Boilard et al. even further refined the concept of microparticles being transport vehicles. These investigators demonstrated that platelet-derived microparticles were internalized by activated neutrophils in the endomembrane system via 12(S)-HETE, a hydroxyeicosatetraenoic acid produced through the activity of $sPLA_2$-IIA, which is present in inflammatory fluids (Duchez et al. 2015). Platelet microparticles can also be internalized by macrophages, leading to the differential expression of numerous miRNAs and mRNAs, including transcripts encoding for chemokine (C–C motif) ligand 4 (CCL4/MIP-1β), colony-stimulating factor 1 (CSF1), and TNF (Laffont et al. 2015). Additionally, platelet microparticle uptake by macrophages led to an increase in their phagocytic capacity (Laffont et al. 2015). These recently discovered functions of platelets and platelet-derived microparticles highlight once more the versatility of this anucleate cell and its key roles in inflammatory and immune disorders.

Platelets Induce NETosis in Sepsis

NET formation in response to bacterial invasion was first demonstrated by Brinkmann and colleagues in 2004 (Brinkmann et al. 2004). NETs consist of expulsed nuclear DNA that forms lattices, containing histones (H1, H2A, H2B, and H4), granule enzymes (elastase, myeloperoxidase), and antimicrobial proteins released by the PMN in parallel with extrusion of nuclear material (Brinkmann et al. 2004). NETs can be generated under both flow and static conditions, although there is some evidence that flow conditions enhance bacterial trapping (analogous to the human circulatory system) (Clark et al. 2007). NETs are long lattices that can be as large as 25 nm in diameter (Clark et al. 2007). These DNA/enzyme complexes accomplish both capture and killing of extracellular bacteria. In addition, antimicrobial activities can be blunted or subverted by endonucleases and DNases expressed by some microorganisms (Beiter et al. 2006; Buchanan et al. 2006). NETs are also implicated in vascular injury associated with neutrophil–platelet interactions in human sepsis (Clark et al. 2007). For example, Ma and Kubes demonstrated that a bacterial environment or stimulation using LPS resulted in the in vivo formation of NETs which trapped bacteria, reducing their growth, and blunted the severity of sepsis (Ma and Kubes 2008). Ma and colleagues further demonstrated that NETs were able to trap both Gram-negative and Gram-positive bacteria.

NETosis is an active mechanism occurring within 5–10 min after neutrophil stimulation and being distinct from apoptosis and necrosis (Brinkmann et al. 2004). There is evidence that reactive oxygen species (ROS) generation is a key event in NET formation (Fuchs et al. 2007; Yost et al. 2009). However, ROS generation and NET formation can be dissociated under some conditions, suggesting that the pathways and mechanisms regulating NET formation are more complex than previously appreciated (Chow et al. 2010; Marcos et al. 2010). Yost et al. found that the mammalian target of rapamycin (mTOR) regulates NET formation through induction of hypoxia-inducible factor 1α (HIF-1α). Citrullination of histones, release of mtDNA, and platelet hBD-1 also mediate key aspects of NET formation (Kraemer et al. 2011; Yousefi et al. 2009). In addition, platelet-derived microparticles containing mitochondria as well as mitochondria released from platelets into the circulation have been linked to NET formation. The hydrolysis of the mitochondrial membrane by $sPLA_2$-IIA also leads to the formation of inflammatory mediators inducing robust NET formation in an in vitro assay (Boudreau et al. 2014).

Nevertheless, while NETs may be key host defense mechanisms in response to bacterial invasion, NET formation may also have adverse effects on the microvascular circulation by promoting the formation of microthrombi, thereby also potentially preventing immune cells from reaching the bacteria. Emerging evidence implicates NET formation as injurious in many inflammatory and thrombotic diseases, including sepsis (Xu et al. 2009), coronary artery disease (Borissoff et al. 2013), microvascular thrombosis (Xu et al. 2009), and deep vein thrombosis (Fuchs et al. 2010). Recent work by Wagner and colleagues demonstrates that thrombin-stimulated platelets induce NET formation via P-selectin/PSGL-1 interactions (Etulain et al. 2015). These intriguing findings suggest that the P-selectin/PSGL-1 axis may be a potential therapeutic target for settings where dysregulated NET formation is considered injurious (Etulain et al. 2015).

Conclusion

Established and emerging evidence supports the role of platelets as dynamic sentinels and effector cells during bacterial infections. These previously unrecognized functions broaden the view of platelets as having complementary roles in both hemostasis and immune pathways. Furthermore, as platelets orchestrate key aspects of immune and

inflammatory responses, platelets are being studied as a potential therapeutic target in sepsis.

Take Home Messages

- Platelets are key sentinels and effector cells involved in the pathophysiology of sepsis.
- Platelet integrins mediate platelet–bacterial interactions.
- FcgRIIa on platelets coordinates antibacterial host responses.
- The final fate of internalized bacteria remains unclear and warrants further investigations.
- Platelets are involved in infectious immune responses both directly through the release of antimicrobial factors and indirectly through the release of cytokines and other mediators.
- The P-selectin/PSGL-1 axis may be a potential therapeutic target for settings of injurious NET formation.

Acknowledgments We thank Ms. Diana Lim for her excellent figure preparation. This work was supported by the NIH (HL112311 and HL126547 to M.T.R.), the NIA (AG048022 to M.T.R.), and the George E. Wahlen Department of Veterans Affairs Geriatric Research Education and Clinical Center (GRECC).

Virus–Platelet Associations

Edward L.G. Pryzdial, Bryan H. Lin, and Michael R. Sutherland

Abstract

Virus–platelet interplay is complex. Diverse virus types have been shown to associate with numerous distinct platelet receptors. This association can benefit the virus or the host, and thus the platelet is somewhat of a renegade. Evidence is accumulating to suggest that viruses are capable of entering platelets. For at least one type of RNA virus (dengue virus), the platelet has the necessary post-translational and packaging machinery required for production of replicative viral progeny. As a facilitator of immunity, the platelet also participates in eradicating the virus by direct and indirect mechanisms involving presentation of the pathogen to the innate and adaptive immune systems, thus enhancing inflammation by release of cytokines and other agonists. Virus-induced thrombocytopenia is caused by tangential imbalance of thrombopoeisis, autoimmunity, and loss of platelet function and integrity.

Introduction

The historical view that platelets solely participate as primary facilitators in hemostasis and thrombosis is now outdated. Reminiscent of roles played by their evolutionary counterparts in primitive organisms (Delvaeye and Conway 2009), it is now well-established that platelets directly modulate cells of the immune system through receptor-mediated cell contact with leukocytes and pathogens. In combination with these interactions, external stimuli induce secretion of cytokines and other cell modulators from platelet α-granules and dense granules to produce additional indirect effects on the cellular immune response. Moreover, in contrast to the bygone paradigms, the platelet proteome is not static. Platelets inherit from antecedent megakaryocytes a repertoire of mRNAs and the necessary post-transcriptional machinery to alter their protein composition (Schubert et al. 2014). Platelets survey their local environment, reacting dynamically to change, and are thus pivotally positioned during the defense against pathogens (Semple et al. 2011). Here, we focus on their complex interactions with viruses.

Many excellent review articles are available that recognize the importance of platelets in virology. In some cases, these highlight the effects of specific virus types (Chabert et al. 2015; Hottz et al. 2011), whereas others are more general (Assinger et al. 2014; Zapata et al. 2014). The ultimate message is that viruses trigger a complexity of biochemical and cellular events, often resulting in diminished platelet count, altered vascular permeability, and consequent bleeding diathesis. In this review, we revisit these ideas and add a temporal aspect to the emerging model. We speculate that platelets are more than immune modulators and "innocent" bystanders in the host response to viral infection and that, in the case of viruses with an RNA genome, platelets initially participate as a viral ally.

Virus Binding to Platelets

Platelets are not considered to be a primary host cellular target in virology. Therefore, to identify the receptors that bind viruses, other cell types are usually investigated. The virus–cell interaction is the key initiating step in the virus lifecycle and a logical target for development of antiviral agents. Based on the knowledge of receptors presented on typically studied cells, predictions can be made about whether platelets express the necessary receptors to facilitate specific virus interactions. To help explain platelet-related pathology as a result of infection of certain viruses, direct binding has been reported. Here we loosely divide these interactions on the basis of two principal hemostatic diseases in which direct virus–platelet interactions could logically be involved: thrombocytopenia and hemorrhagic fever (HF).

Thrombocytopenic Viruses When a foreign particle, such as a virus, binds directly to the platelet surface, it is reasonable to speculate that consequent immune recognition leads to a reduction in platelet count. Thus, virus-induced thrombocytopenia has been the rationale for investigating interactions between viruses and platelets. Table 1 lists viruses that correlate with thrombocytopenia without HF. Representing at least six virus families, these viruses range broadly in structure and genome organization and, with the exception of adenoviruses, are surrounded by a lipid bilayer envelope that contains both host cell- and virus-derived elements. Therefore, an adaptive immune response as a result of viral infection of platelets may involve both virus antigens and co-epitopes originating from virus and host factors, resulting in a reduced platelet count. Receptors on the platelet that associate with viruses have been identified and include integrins α5β1, $\alpha_{IIb}\beta_3$, and α5β3; the lectin, dendritic cell-specific intercellular adhesion molecule-3-grapping non-integrin (DC-SIGN); Toll-like receptors (TLRs) 2 and 4; coxsackie-adenovirus receptor (CAR); complement receptor 2 (CR2); C-X-C chemokine receptor type 4 (CXCR4); C-type lectin domain family 2 (CLEC-2); chemokine C-C motif ligand (CCL); and glycoprotein (GP) VI. Co-receptor systems involving more than one virus–platelet interaction may also exist, as in human immunodeficiency virus (HIV). In some cases, the platelet receptor is unknown (e.g., SARS-CoV).

A variety of methods have been used to establish specific receptors. Early inhibition studies involving adenovirus used purified matrix proteins, adenovirus penton base proteins, and synthetic peptides. Results suggested the importance of the α5 and β1/β3 integrins for infection of several cell lines (Stevenson et al. 1997; Wickham et al. 1993). Immuno- and electron microscopy studies have shown that platelet $\alpha_{IIb}\beta_3$ is also important for the binding of adenovirus (Gupalo et al. 2013). Further cellular studies implicated CAR (Bergelson et al. 1997) in the virus–platelet association and identified this receptor on platelets by flow cytometry and RNA isolation (Othman et al. 2007). Additional studies using immuno-inhibition and arginyl–glycyl–aspartyl (RGD) motif peptide mimics confirmed the importance of α5 integrins in adenovirus binding to platelets; however, they failed to detect CAR expression (Shimony et al. 2009).

Hepatitis C virus (HCV) is regularly associated with thrombocytopenia (Weksler 2007). Platelet glycoprotein GPVI has been implicated in HCV–platelet interaction through peptide and immuno-inhibition studies (Pugliese et al. 2004), purified protein assays, and virus binding assays (Zahn et al. 2006) and was shown to be important for infection and dissemination (Ariede et al. 2015; Zahn et al. 2006). DC-SIGN has also been demonstrated to be involved in HCV binding.

As in infection of other cell types, HIV has been shown to associate with platelets through a variety of cell-surface receptors (Youssefian et al. 2002). Platelet DC-SIGN, as identified by flow cytometry, western blotting, and PCR, can recognize and bind pathogen-associated molecular patterns (PAMPs) on HIV because immuno-inhibition results in decreased binding (Boukour et al. 2006; Chaipan et al. 2006). Using similar immuno-inhibition and flow cytometric approaches, CLEC-2 was identified as a platelet receptor for HIV (Chaipan et al. 2006). Additional putative receptors for HIV on platelets also include CXCR4, CCL3, and CCL5 (Flaujac et al. 2010).

Platelet integrins appear to serve as the main binding partner because they contain the common RGD motif. Therefore, the presence of integrin-binding sequences in several virus families suggests that integrins are important for platelet association and signaling, with effects leading to thrombocytopenia. Viral envelope glycoproteins can serve as sources of PAMPs and facilitate virus–platelet interaction via TLRs. This is suggested as a mechanism for cytomegalovirus (CMV)-induced thrombocytopenia. Evidence implicating direct binding and consequent cell stimulation as a result of CMV-encoded glycoprotein B and glycoprotein H interactions with TLR2 (Boehme et al. 2006) on platelets or neutrophils has been obtained from immunoprecipitation and immuno-inhibition studies of co-transfected human embryonic kidney and normal fibroblast cells, respectively (Assinger et al. 2014).

Platelets also have on their surface the complement receptor type 2 (CR2), which functions as a receptor for Epstein–Barr virus (EBV), as shown by cell and immuno-inhibition techniques (Ahmad and Menezes 1997; Hutt-Fletcher 2007). Whether this also protects the virus from complement-mediated innate immune clearance is not known.

Platelets have one class of receptor for the Fc domain of antibodies, FcγRIIA. Once virus-directed antibodies are generated by the adaptive immune response, "bridged" interactions can be facilitated by platelet FcγRIIA, as demonstrated for influenza A virus (IAV) (Boilard et al. 2014).

Table 1 Viruses correlating with thrombocytopenia

Virus	TCP	HF	Family	Genome	Receptor on Platelets	Virus Receptor	Other Cell Receptor	Platelet Entry
Adenovirus (Othman et al. 2007, Shimony et al. 2009, Zhang and Bergelson 2005)	Yes	No	Adenoviridae	DNA, non-enveloped	CAR $\alpha_{IIb}ß_3$ $\alpha_5ß_3$ $\alpha_5ß_1$ (?) sialic acid (?) TLR4 (?)	Fiber knob RGD of penton base	$\alpha_5ß_1$, $\alpha_5ß_3$, $\alpha_5ß_5$, TLR3, TLR4, TLR9, sialic acid	Yes
CMV (Agbanyo and Wasi 1994, Assinger et al. 2014, Boehme et al. 2006)	Yes	No	Herpesviridae	DNA, enveloped	TLR2 $\alpha_5ß_1$	gB, gH	TLR DC-SIGN	ND
EBV (Ahmad & Menezes 1997, Hutt-Fletcher 2007)	Yes	No	Herpesviridae	DNA, enveloped	CR2	gp350/220	CR2	ND
VZV (Rand & Wright 1998, Sloutskin et al. 2014, Zhu et al. 1995)	Yes	No	Herpesviridae	DNA, enveloped	HSP (?)	gE	HSP	ND
HSV (Caviness et al. 2008, Spear 2004)	Yes	No	Herpesviridae	DNA, enveloped	HSP (?)	gC, gD	HSP	ND
Influenza (Boilard et al. 2014, Danon et al. 1959, Le et al. 2015)	Yes	No	Orthomyxoviridae	RNA, enveloped	$\alpha_{IIb}ß_3$, FcγRIIa, sialic acid (?)	HA	Sialic acid FcγRIIa	Yes
HIV (Chaipan et al. 2006, Youssefian et al. 2002, Zapata et al. 2014)	Yes	No	Lentivirus	RNA, enveloped	CCL1,3,4 CXCR4 DC-SIGN CLEC-2	ENV protein	DC-SIGN	Yes
HCV (Ariede et al. 2015, de Almeidal et al. 2007, Zahn et al. 2006, Zahn and Allain 2005)	Yes	No	Flaviviridae	RNA, enveloped	DC-SIGN GPVI	E2	DC-SIGN Heparin CD81	ND
SARS-CoV (Imai et al. 2005, Li et al. 2003)	Yes	No	Coronaviridae	RNA, enveloped	CD13	gS	ACE2	ND

Viruses that induce only thrombocytopenia (*TCP*) and not hemorrhagic fever (*HF*) are listed. Those viruses that have an RNA genome (*red*) and are permissible to entry may be replicated by platelets. Viruses encoded by a DNA genome (*green*) cannot be replicated by platelets
αNβN member of the integrin family, *ACE2* angiotensin converting enzyme 2 receptor, *CAR* coxsackie-adenovirus receptor, *CCL* chemokine (C-C motif) ligand, *CD* cluster of differentiation, *CLEC-2* C-type lectin domain family 2, *CMV* cytomegalovirus, *CR* complement receptor, *CXCR4* C-X-C chemokine receptor type 4, *EBV* Epstein-Barr virus, *E* or *ENV* envelope, *DC-SIGN* dendritic cell-specific intercellular adhesion molecule-3-grapping non-integrin, *FcγRII* Fc gamma receptor II, *gp* or *g* glycoprotein, *GPVI* platelet glycoprotein VI, *HA* hemagglutin, *HCV* hepatitis virus C, *HIV* human immune deficient virus, *HSP* heparan sulfate proteoglycan, *HSV* herpes simplex virus, *ND* data not available in the literature, *RGD* arginine–glycine–aspartic acid peptide sequence, *SARS* severe acute respiratory syndrome, *TLR* Toll-like receptor, *VZV* varicella zoster virus, *?* proposed platelet receptor based on indirect cell studies

Making vaccine development difficult, some secondary viral infection mechanisms exploit antibody-dependent enhancement; examples are dengue virus (DENV) and HIV (Guzman et al. 2013). Although antibody-bridged binding to platelets has not been specifically documented for many viruses, it is reasonable to speculate that such viral immune complexes commonly form interactions with platelets. Similar to engagement of other receptors on the platelet surface, these multivalent adducts could crosslink the FcγRIIA, causing platelet activation.

Hemorrhagic Fever Viruses Whereas the bleeding phenotype inherent to thrombocytopenia is considered to be

predominantly caused by loss of platelets, the effects on hemostasis leading to virus-induced HF are typically far more complicated (Zapata et al. 2014). HF is characterized by the loss of blood homeostasis, leading to increased vascular permeability and bleeding, which can progress to shock. The causative agents of viral HF are enveloped RNA viruses from four families: Flaviviridae, Bunyaviridae, Arenaviridae, and Filoviridae (Table 2). These families contain well-known species such as Ebola and DENV that are featured as "headline news" because of the devastating and graphic illnesses these epidemic pathogens can cause. Some of the viruses are especially difficult to experimentally manipulate because of their biohazard classification level and, consequently, relatively little is known about their biochemistry. Nevertheless, receptors for viruses known to cause viral HF have been identified. Interestingly, these are similar to those receptors characterized for viruses as predominantly thrombocytopenic: β1/β3 integrins, lectins, and TLRs. Therefore, it is not surprising that HF viruses can also result in thrombocytopenia.

Using specific antibody inhibition and virological plaque-forming assays, DC-SIGN and heparan sulfate proteoglycan (HSP) were demonstrated to be important in DENV binding to platelets (Hottz et al. 2013b; Simon et al. 2015) Interestingly, additional binding sites were expressed by pretreating platelets with the agonist thrombin (Simon et al. 2015). Whether these are the same type of receptor is unknown. Employing a transduced cell model of infection, DC-SIGN has also been shown to be involved as a receptor in Ebola virus infection (Alvarez et al. 2002). Mutagenesis, binding, and RNA interference experiments have implicated Axl (Shimojima et al. 2007) and Tyro3 (Hunt et al. 2011) in Ebola's complex cell engagement mechanism. These observations suggest that multiple receptors are occupied in the Ebola–platelet interaction. Interestingly, similar platelet surface molecules may bind Lassa virus, as indicated by the identification of DC-SIGN, Axl, and Tyro3 as receptors using cell binding and infection assays (Shimojima et al. 2012). In addition, the results of immunoblot and competition assays involving purified virus suggested that α-dystroglycan is a Lassa virus receptor (Cao et al. 1998). Neutralizing antibody experiments have implicated β3 integrins in the interaction between cells infected with hantavirus and platelets (Gavrilovskaya et al. 1999; Gavrilovskaya et al. 2010). Although cell and platelet receptors remain elusive for some HF viruses, it is possible that a particular receptor may function across an individual virus family.

Virus–Platelet Interactions with Moderate Pathology Although virus–platelet interactions leading to life-threatening effects are well-known, there are also a number of viruses that bind to platelets without serious hematological pathology. Predominately from the Picornaviridae family, these non-enveloped RNA viruses cause enteric, throat, and nasal infections. Although not directly confirmed as analogous functional receptors for picornavirus on platelets, β1 and β3 integrins are known to facilitate interactions with receptors on other cell types. Studies following surface expression of mutated proteins in CHO cells and antibody inhibition studies have identified integrin $\alpha_2\beta_1$ as a binding partner for both rotavirus and echovirus (Coulson et al. 1997; Fleming et al. 2011). Utilizing an antigenic inhibition model and CHO transfection, members of the β1 and β3 integrin families were shown to mediate parechovirus infection (Triantafilou et al. 2000). This suggests the potential for binding recognition with the integrin known to be expressed on the platelet surface. It is somewhat puzzling that thrombocytopenia is not induced because engagement of these receptors by other viruses is consistent with this outcome. Consequently, integrins may not be the only common denominator resulting in this virus-mediated hemostatic disorder.

Virus-Induced Platelet Activation Platelets circulate in a resting state and are stimulated by ligand–receptor engagement. It is clear that protein and carbohydrate receptors on the surface of platelets bind viruses from many distinct families (Tables 1, 2, and 3). Indeed, it is not surprising that the interactions known to exist between viruses and platelet receptors can facilitate platelet activation. Interactions with DENV grown in culture have been shown to induce platelet shape changes, as monitored by atomic force and electron microscopy (Ghosh et al. 2008). DENV has also been demonstrated to cause the exposure of P-selectin and procoagulant phospholipid on the platelet surface (Hottz et al. 2013b; Simon et al. 2015), and to initiate apoptosis-like markers, including caspase activation and mitochondrial permeability changes (Hottz et al. 2013b), Similarly, HIV can induce microparticle release and other hallmarks of platelet activation (Wang et al. 2011) that are related to plasma virus levels (Mayne et al. 2012). Differential response to platelet agonists in HIV-infected individuals points to functional changes in platelets, with implications for thrombosis (Satchell et al. 2010). Interestingly, additional studies further implicated HIV treatment strategies in the development of hyper-responsive platelets (Falcinelli et al. 2013; Gresele et al. 2012). Although the direct effect of virus binding on platelet activation has not been studied extensively, outside-in signal-induced platelet changes are probably a general characteristic, regardless of the type of virus.

Virus Replication by Platelets

Entry Cell binding is the first step used by all viruses to exploit the host's cellular replication apparatus. Without

Table 2 Hemorrhagic fever viruses with putative platelets interactions

Virus	TCP	HF	Family	Genome	Receptor on Platelet	Virus Receptor	Other Cell Receptor	Platelet Entry
Dengue virus (Noisakran et al. 2009, Simon et al. 2015, Tassaneetrithep et al. 2003)	Yes	Yes	Flaviviridae	RNA, enveloped	$\alpha_5ß_3$ DC-SIGN HSP FcγRIIa,	GPE	DC-SIGN, LSIGN	Yes
Yellow Fever	ND	Yes	Flaviviridae	RNA, enveloped				ND
Kyasanur forest disease virus)	ND	Yes	Flaviviridae	RNA, enveloped				ND
Alkhumra virus	ND	Yes	Flaviviridae	RNA, enveloped				ND
Hantavirus (Gavrilovskaya et al. 1999, Gavrilovskaya et al. 2010)	Yes	Yes	Bunyaviridae	RNA, enveloped	$\alpha_{IIb}ß_3$, $\alpha_5ß_1$ (?)	GN, GC	$\alpha_{IIb}ß_3$, $\alpha_5ß_3$, $\alpha_5ß_1$	ND
Rift valley fever (de Boer et al. 2012)	ND	Yes	Bunyaviridae	RNA, enveloped	HSP (?)		HSP	ND
Severe fever with thrombocytopenia syndrome (Jin et al. 2012)	Yes	Yes	Bunyaviridae	RNA, enveloped				ND
Crimean–Congo hemorrhagic fever	Yes	Yes	Bunyavirus	RNA, enveloped				ND
Chikungunia virus (Long et al. 2013)	ND	Yes	Togaviridae	RNA, enveloped		GP	DCIR	ND
Lassa (Kunz et al. 2005, Shimojima et al. 2012, Zapata et al. 2014)	ND	Yes	Arenaviridae	RNA, enveloped	DC-SIGN	GPC	α - DG Tyro3, DC-SIGN, Axl,	ND
Lujo	ND	Yes	Arenaviridae	RNA, enveloped				ND
Machupo	ND	Yes	Arenaviridae	RNA, enveloped				ND
Guanarito	ND	Yes	Arenaviridae	RNA, enveloped				ND
Junin	Yes	Yes	Arenaviridae	RNA, enveloped				ND
Ebola (Alvarez et al. 2002, Shimojima et al. 2007, Zapata et al. 2014)	Yes	Yes	Filoviridae	RNA, non-enveloped	DC-SIGN (?) α5ß1 (?)	GP	Tyro3, DC-SIGN, Axl, $\alpha_5ß_1$, NPC1	ND
Marburg	ND	Yes	Filoviridae	RNA, non-enveloped				ND

Viruses that cause hemorrhagic fever (*HF*) are listed. All known HF viruses are RNA viruses and therefore if entry into platelets is permissible, they can be replicated. Dengue virus is the only one for which evidence of platelet-mediated replication has been investigated. HF viruses that interact with platelets span many virus families, as highlighted by the different colors. Some of these viruses are also known to induce thrombocytopenia (*TCP*) and, although data is not available in the literature (*ND*) for each, it cannot be excluded

αNβN member of the integrin family, *α-DG* alpha-dystroglycan, *Axl* Axl receptor tyrosine kinase, *DC-SIGN* dendritic cell-specific intercellular adhesion molecule-3-grapping non-integrin, *DCIR* dendritic cell immunoreceptor, *G* or *GP* glycoprotein, *HSP* heparan sulfate proteoglycan, *LSIGN* liver/lymph node-specific intercellular adhesion molecule-3-grapping non-integrin, *NPC1* cholesterol transporter Niemann-Pick 1, *Tyro* tyrosine-protein kinase receptor, *?* proposed platelet receptor based on indirect cell studies

Table 3 Virus–platelet interactions with moderate hemostatic effects

Virus	TCP	HF	Family	Genome	Receptor on Platelet	Virus Receptor	Other Cell Receptor	Platelet Entry
Rotavirus (Coulson et al. 1997, Fleming et al. 2011)	No	No	Reoviridae	RNA, non-enveloped	α2ß1 sialic acid (?)	VP4	α2ß1, sialic acid	ND
Coxsackie (Bergelson et al. 1997)	No	No	Picornaviridae	RNA, non-enveloped	CAR	VP1	CAR α5ß3, α5ß5	ND
encephalomyocarditis virus (Koupenova et al. 2014)	No	No	Picornaviridae	RNA, non-enveloped	TLR7			Yes
Echovirus (Triantafilou et al. 2000, Triantafilou and Triantafilou 2001)	No	No	Picornaviridae	RNA, non-enveloped	α2ß1 (?)		α2ß1 α5ß3	ND
Parechovirus (Triantafilou et al. 2000, Triantafilou & Triantafilou 2001)	No	No	Picornaviridae	RNA, non-enveloped	α5ß1 (?)	VP1	α5ß3, α5ß1	ND

Mostly from the Picornavirus family, certain viruses have been reported to interact with platelets without inducing thrombocytopenia (*TCP*) or hemorrhagic fever (*HF*). These interactions may be indicative of the role of platelets in the innate immune response
αNβN member of the integrin family, *CAR* coxsackie-adenovirus receptor, *ND* data not available in the literature, *TLR* Toll-like receptor, *VP* virus protein, *?* proposed platelet receptor based on indirect cell studies

question, platelets have that binding capacity. The second step in the virus lifecycle is cell entry. Two general mechanisms of cell entry can be initiated upon contact between an animal virus and a target host cell. Most viruses traverse the plasma membrane using the endocytic machinery intrinsic to the cell, whereby the virus is engulfed by a vesicular structure for intracellular transport (Ghigo 2010). Within these endosomal compartments, low pH typically induces the release of genetic contents from the viral nucleocapsid. Based on microscopic morphology and biochemistry, nearly a dozen viral endocytosis mechanisms have been discerned (Cossart and Helenius 2014; Mercer et al. 2010). A second entry mechanism is used exclusively by enveloped viruses. After receptor-mediated cell surface binding, both virus- and host-encoded (Derry et al. 2007) proteins on the virus envelope can engage to form a conformational fusion complex that merges the envelope and plasma membrane.

In contrast to the known interactions between viruses and platelets, little evidence of platelet entry has been documented. Immunogold electron microscopy revealed that purified HIV is trapped within platelet endosomal structures (Youssefian et al. 2002). Another entry mechanism was suggested by colocalization of purified adenovirus with the surface-connected channels of the platelet open canalicular system (Stone et al. 2007). Purified IAV and platelets enabled observation by electron microscopy of the surface association and uptake of virus-like particles into vacuolar structures (Danon et al. 1959). Furthermore, virus-like particles have been reported in the platelets of DENV-infected patients, although these difficult experiments lacked confirmation of virus (Noisakran et al. 2009). Electron microscopy has also been used to demonstrate encephalomyocarditis virus (EMCV) uptake by platelets in a murine model of infection (Koupenova et al. 2014). To confirm their endocytic capabilities, purified platelets have been shown to engulf *Staphylococcus aureus* (Youssefian et al. 2002) and liposomes that were engineered for drug delivery (Chan et al. 2015). Although viral entry mechanisms are not known, molecular details following the transfer of synthetic particles into platelets suggests that several simultaneous endocytotic pathways are involved (Chan et al. 2015). These pathways may have dynamin dependence as a common aspect and involve caveolae- or clathrin-mediated uptake (Mercer et al. 2010). Thus, observations of virus uptake by platelets are supported by the availability of entry mechanisms for other particle types.

Viral Protein Synthesis Platelets associate with both DNA- and RNA-containing viruses. Assuming successful entry and release of genetic material into the platelet, only RNA viruses replicate because platelets are DNA transcription incompetent. The list of RNA viruses with known or suspected platelet interactions is extensive and highlighted in Tables 1, 2, and 3. Platelets contain all of the post-transcriptional apparatus necessary for potential assembly

of an infectious RNA virus. To demonstrate that platelets can translate viral RNA, purified platelets inoculated with purified DENV have been shown to produce viral nonstructural protein 1 (NS1), as detected by Western blot analysis (Simon et al. 2015). Because the DENV single-stranded RNA (ssRNA) must first be translated as a polyprotein, the finding that NS1 had the predicted molecular weight of the mature protein implied that the functional DENV protease complex (NS2B/NS3) was also properly translated and processed by the platelets (Simon et al. 2015). Thus, platelets not only facilitate the initial step in the virus lifecycle, specific surface engagement (Tables 1, 2, and 3), but also have the means to allow penetration of the virus into the cytoplasm and occupation of the platelet translational mechanism.

Virus Replication Replication of viral genomic material has been followed as a surrogate for functional virus-encoded polymerase generation. In these studies, the mRNAs of all four serotypes of purified DENV in combination with purified platelets were enhanced (Simon et al. 2015), which substantiated an earlier preliminary report (Onlamoon et al. 2010). These studies were extended using virus plaque formation assays in combination with a translation inhibitor and demonstrated that the virus is properly assembled, resulting in production of infectious progeny by platelets (Simon et al. 2015). Interestingly, platelet units stored under blood bank operating conditions also produced new DENV (Sutherland et al. 2016). A generalized model is presented in Fig. 1, highlighting the emerging concept that platelets could be a reservoir for permissive RNA viruses. The concept is based on (1) significant literature demonstrating that many types of virus bind directly to platelets; (2) several studies showing platelet entry; and (3) generation of infectious DENV progeny by platelets.

Although evidence suggests that platelets could be recruited by RNA viruses as conspirators for replication, it is conceivable that only platelet subsets can fulfill this role. As an example, ~20 % of platelets are positive for DC-SIGN (Hottz et al. 2013b) and may account for binding to HIV, DENV, HCV, Ebola, and LASV, which are known to use DC-SIGN for cell surface attachment (Tables 1, 2, and 3). Furthermore, TLR2 is found on a subset of ~14 % of platelets and is involved in at least the CMV interaction (Boehme et al. 2006). Some platelet-interacting viruses are known to use co-receptor systems, of which candidate receptors are found on platelets. But, whether these too are distributed as subpopulations, like DC-SIGN and TLR2, has not been evaluated. Of these functionally distinct classes of platelets, only some may be permissive to entry and replication after binding.

Platelet Immune Response Against Viruses

Platelets may initially harbor and replicate certain viruses (Simon et al. 2015). But, as known facilitators and modulators of the immune response to pathogen invasion (Jenne and Kubes 2015), platelets also competently present bound viruses to leukocytes for clearance. To enhance this innate immune recognition, the association of viruses with platelets induces the release of cytokines, which causes local infiltration of immune cells. Many platelet surface molecules mediate leukocyte cross-talk and have an essential effect on viral infection. The modulation of platelet function by viruses, leading to their ultimate involvement in innate and adaptive immunity, is summarized in Fig. 2.

Toll-Like Receptors TLRs (Cognasse et al. 2015) are a family of innate immune regulators that recognize pathogen-associated molecular patterns (PAMPs), which are markers associated with viruses, bacteria, and fungi that lead to neutrophil-mediated pathogen destruction. Known to recognize ssRNA, typical of many platelet-interacting viruses (Tables 1, 2, and 3), platelet TLR7 was identified as vital for EMCV clearance by platelets (Koupenova et al. 2014). Interestingly, this receptor is expressed within endosomes and its functional involvement implies endocytosis of the virus by the platelet. Penetrance of EMCV was TLR7 dependent, with activation of TLR7 resulting in the release of the α-granules that house proinflammatory cytokines, leading to neutrophil aggregation, endothelial cell adhesion, and inflammation. The TLR7 platelet response was shown to contribute to host survival, as EMCV levels decreased and there were no observable prothrombotic events as a consequence of potential platelet activation (Koupenova et al. 2014).

Unlike TLR7, TLR2 is expressed on the platelet surface. CMV was found to associate predominately with the TLR2-positive platelet subpopulation (Boehme et al. 2006). As seen using flow cytometry, CMV induces rapid surface expression of P-selectin, leading to the release of proinflammatory CD40 ligand and interleukin-1β cytokine from the platelets (Assinger et al. 2014). CMV-induced TLR2 activation was confirmed by antigenic inhibition and could be blocked by inhibiting phosphoinositide 3-kinase signaling. Vascular endothelial-derived growth factor (VEGF) is a proangiogenic cytokine that is released by TLR2-induced platelet activation and involved in endothelial migration, proliferation, and increased vascular permeability (Assinger et al. 2014). To add further to the many links reported between CMV and vascular disease (Al-Ghamdi 2012; Bruggeman 2000), this TLR2-mediated VEGF release can allow leukocyte recruitment to an atherosclerotic plaque, promoting growth (Holm et al. 2009).

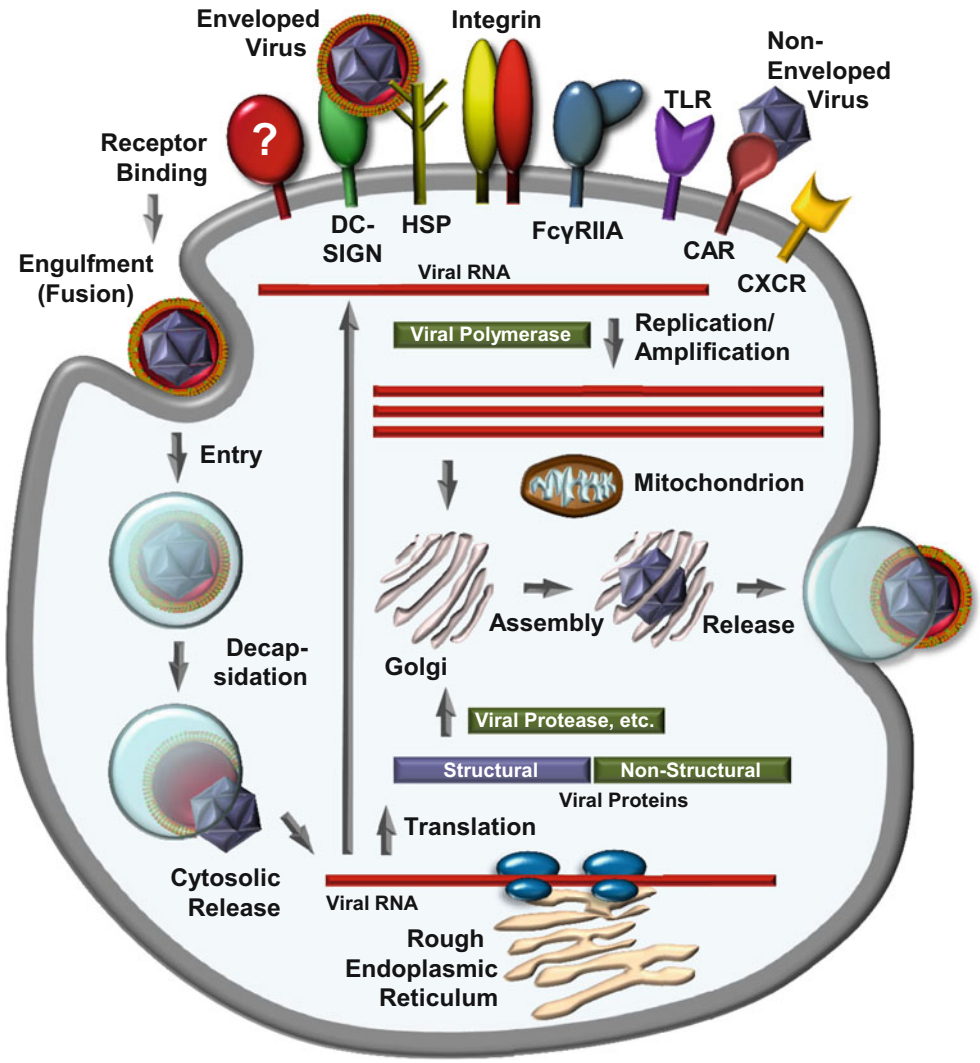

Fig. 1 Virus replication by platelets. Examples of virus receptors present on the surface of the platelet are shown spanning the platelet membrane. Examples of an enveloped virus (DENV binding to the co-receptors DC-SIGN and HSP) and a non-enveloped virus (adenovirus binding to CAR) are depicted. This receptor engagement triggers mechanisms that can involve dynamin-dependent engulfment processes, leading to entry into the platelet as an endosomal inclusion. At least for DENV, which has an RNA genome unlike adenoviruses, evidence is accumulating that suggests viral genomic material is released from the nucleocapsid into the cytoplasm, where it is translated by platelet ribosomal complexes or used as a template for replication by the virus-encoded polymerase. Other virus-encoded genes contribute to controlling the function of the cell or post-translational modification of the viral proteins, including proteolytic maturation if the viral genome is organized to produce a polyprotein. The viral structural proteins and genome copies are then transported to the platelet Golgi apparatus, where they are assembled and delivered to the exterior by exosomal transport or possibly by cell disruption (not shown). Platelet mitochondria are available for energy-demanding aspects of the mechanism

Integrins Consisting of a broad group of homologous heterodimeric proteins (Bennett et al. 2009), cell surface integrins are fundamental to the important platelet–leukocyte connection. In addition to the role of integrins in facilitating numerous direct platelet–virus interactions (Tables 1, 2, and 3), they are also important in processes leading to immune clearance of blood-borne viruses. One example is through the recruitment of dendritic cells by the interaction of platelet surface junctional adhesion molecule-C (JAM-C) and dendritic cell integrin $\alpha_M\beta_2$ (Langer et al. 2007). Trafficking of cytotoxic T lymphocytes (CTLs) to sites of infection can be mediated by platelet activation (Iannacone et al. 2005). In the case of hepatitis B virus (HBV), CTLs enter the liver parenchyma and accumulate where HBV may reside and replicate. CTL activity lowers the virus count, but unfortunately contributes to progression of liver damage (Iannacone et al. 2005).

The HIV-1 transactivator of transcription protein (Tat) directly interacts with platelets, resulting in their activation and degranulation (Wang et al. 2011). This mechanism requires the β3 integrin and chemokine receptor CCR3 to be expressed on the platelet surface. This involvement of integrins was unambiguously demonstrated using a β3

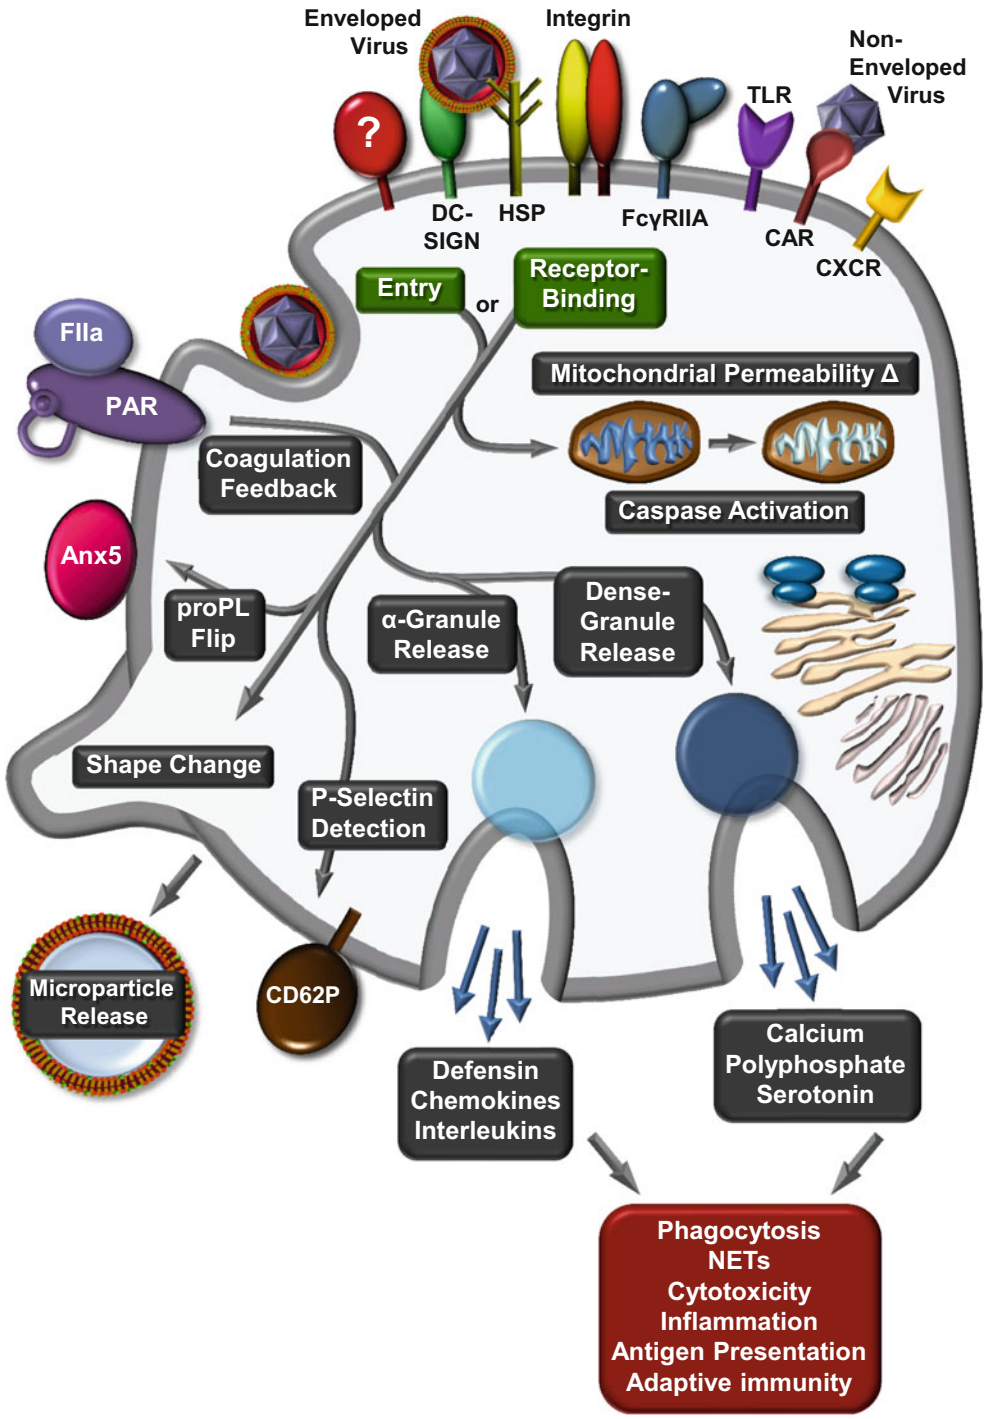

Fig. 2 Virus-induced platelet modulation leading to immune clearance. Platelet receptor binding or possibly entry of the virus induces outside-in platelet signaling, with morphological and biochemical effects to the platelet. Typical platelet "activation" markers are expressed, such as exposure of procoagulant phospholipid (proPL) as measured by annexin V (Anx5) binding and P-selectin (CD62P). Platelet microparticles may be released. The proPL surface can propagate the hypercoagulable state often induced by some of these viruses by enabling assembly of clotting enzyme complexes, where neighboring platelet surface PARs can be activated by thrombin (FIIa) in a feedback-amplified manner to further promote platelet modulation. Virus–platelet engagement has been shown to induce caspase activation and mitochondrial membrane potential changes indicative of an apoptotic state, which similarly occurs for megakaryocytes (not shown) with consequent reduction in thrombopoeisis. Virus-induced platelet stimulation causes the release of α-granule and dense-granule contents. This has profound stimulatory effects on all cells of the immune system, orchestrating localized innate and adaptive responses against virus invasion

knockout mouse model (Wang et al. 2011). Virus-induced platelet degranulation involves the release of proinflammatory CD40 ligand, which promotes platelet–monocyte complex formation via platelet P-selectin and monocyte P-selectin glycoprotein ligand-1 (PSGL-1) (Singh et al. 2014). This was demonstrated by injecting wild-type mice with recombinant soluble CD40 ligand and analyzing cell associations by flow cytometry. The platelet–monocyte complexes derived from HIV-1 infected donors exhibited enhanced adhesion to human brain microvascular endothelial cells, suggesting a role for platelets in HIV-associated neuroinflammation (Singh et al. 2014).

Selectins Although not as extensive as integrins, selectins are also a family of cellular adhesion receptors. Selectins recognize various carbohydrate structures found on opposing surfaces. Platelets constitutively store P-selectin (i.e., CD62P) in α-granules. In response to stimulus-induced activation, P-selectin is transported to the platelet surface where it mediates tethering to numerous cell types. Important to the role of platelets in orchestrating the immune response, platelet surface P-selectin mediates adhesion through association with PSGL-1 found on the neutrophil surface. P-selectin on platelets also interacts with PSGL-1 on a subset of Th1 leukocytes. Thus, when binding of viruses to the platelet surface triggers platelet activation and P-selectin expression on the surface, innate immune clearance of the pathogen is facilitated.

Protease-Activated Receptors Hemostasis and inflammation are regulated and linked by protease-activated receptors (PARs) (Rothmeier and Ruf 2012). Four PAR types have been identified and are implicated both in virus replication (Aerts et al. 2013; Khoufache et al. 2013; Sutherland et al. 2012) and in the host innate response to viral infection (Antoniak et al. 2013). Enveloped viruses can assemble and activate coagulation enzyme complexes directly on their surface, which mediate PAR stimulation. Through these pathways, PAR1 and PAR2 on human umbilical vein endothelial cells have been shown to enhance HSV1 infection in vitro (Pryzdial et al. 2014). A similar mechanism may stimulate virus-bound platelets, which express high levels of PAR1. A more recent study showed that IAV induced platelet activation and aggregation through platelet-surface PAR, which exacerbated acute lung injury (Le et al. 2015). This injury was attributed to the resulting massive inflammation through platelet-induced recruitment of neutrophils to the lung.

Chemokine Receptors Chemokine receptors are members of the G-protein-coupled receptor family, whose major functions include cellular recruitment via chemokine recognition. Several chemokine receptors (CCR1, CCR3, CCR4, CXCR1, and CXCR4) bind to select ligands, resulting in enhancement but not initiation of inflammatory pathways, platelet aggregation, hemostasis, and thrombosis (Zarbock et al. 2007). Activated platelets also secrete numerous chemokines, such as CXCL7 and CXCL8. CXCL7 promotes chemotaxis, adhesion to endothelial cells, and degranulation of neutrophils (Schenk et al. 2002), whereas CXCL8 is important in recruitment of neutrophils (Baggiolini et al. 1994). Active CD40L is secreted by platelets in response to stimulation and binds endothelial CD40, eliciting chemokine secretion and increasing the expression of adhesion molecules on the endothelium (Henn et al. 1998).

Platelet α-granule contents have been shown to limit the spread of HIV-1 in co-cultured T cells (Solomon et al. 2013). CXCL4 (platelet activating factor) and CXCL7 are the most abundant chemokines in the α-granules of platelets (Blair and Flaumenhaft 2009). In particular, CXCL4 released by activated platelets binds to HIV-1 major viral envelope glycoprotein, gp120, proximal to the essential CD4-binding site (Auerbach et al. 2012). The resulting steric inhibition reduced HIV-1 infection by 80 % compared with non-activated platelets using a HIV-1-sensitive cell line that uses reporter gene constructs to quantify infection (Solomon et al. 2013). CXCL4 stimulates neutrophil–endothelial cell attachment and also acts as a co-stimulator of TNF in the release of neutrophil secondary granules (Kasper and Petersen 2011), as further means of enhancing localized immune cell influx.

The proinflammatory cytokine interleukin (IL)-1β is synthesized by platelets as a precursor protein and cleaved by caspase-1 to produce an active form that is released in microparticles (Hottz et al. 2013b). DENV2 was shown to induce IL-1β synthesis directly and secretion from platelets by activating the assembly of a nucleotide-binding domain leucine-rich repeat-containing protein (NLRP3) inflammasome, which controls caspase-1 activity (Hottz et al. 2013a). Generally, IL-1β is important in the acute-phase response, where proteins such as C-reactive protein, complement components, and fibrinogen are produced to destroy or contain microbes (Morrell et al. 2014). Although aiding in the immune response, the IL-1β released from platelets during DENV infection contributes to increased endothelial permeability, thrombosis, and dysregulated hemostasis (Hottz et al. 2013a).

Defensins Defensins are cationic antimicrobial peptides that are key elements in the innate immune system. They act on bacteria, enveloped viruses, and non-enveloped viruses. There are many forms of these small 4–5 kDa peptides, with human platelets expressing β-defensins (hBD) 1, 2, and 3 (Kraemer et al. 2011; Tohidnezhad et al. 2011; Tohidnezhad et al. 2012). Immunofluorescence studies in vitro showed that the inclusion of a selective agonist of neutrophils (phorbol 12-myristate 13-acetate) or platelet PAR1 (thrombin receptor agonist peptide 1) induced

secretion of an adhesive complex from neutrophils, identified as a pathogen "snare." The molecular networks were identified as being composed of long uncoiled strands of DNA and were named neutrophil extracellular traps (NETs) (Brinkmann et al. 2004). NET release is induced by β-defensin 1 secreted from activated platelets (Kraemer et al. 2011). Although most NET involvement in pathogen defense has been elucidated using bacteria, super-resolution structured illumination microscopy revealed that HIV-1 virus particles are also captured by NETs (Saitoh et al. 2012). When these entrapped virus particles were extracted, their infectivity was reduced as a result of highly enriched levels of α-defensin and myeloperoxidase within the NETs.

In addition to HIV-1, hBD-2 is also known to inhibit human respiratory syncytial virus (RSV) entry into human lung epithelial cells, as followed by ^{35}S-labeled RSV uptake (Kota et al. 2008). It was also shown through electron microscopy and buoyant density profiles that hBD-2, but not hBD-1, disrupted the viral envelope, possibly because the cationic nature of the peptide led to lipid destabilization (Kota et al. 2008). HIV-1 induced hBD-2 and hBD-3 expression in human oral epithelial cells, which associated directly with HIV-1 and neutralized infection in vitro (Quinones-Mateu et al. 2003). IAV hemagglutinin and hBD-3 binding also resulted in inhibition of epithelial cell infection (Leikina et al. 2005). hBD-3 was shown to alter fusion between IAV, sindbis virus, baculovirus, and synthetic target membrane by crosslinking virus surface proteins (Leikina et al. 2005). Although reasonable to speculate, it is not known whether platelet-derived hBD-2 and hBD-3 mediate similar direct antiviral effects.

Other Secreted Platelet Components Human donor platelet concentrates contain unknown antiviral activity that reduced the viral titer of poliovirus 1, adenovirus 5, and vaccinia virus by approximately 2.63 ± 0.5 to 5.6 ± 0.9 log units (Maurice et al. 2002). The same group also observed platelet activation in all virus–platelet co-cultures with epithelial monolayers (Vero cells); recent knowledge (Flaujac et al. 2010) suggests that platelet releasate is the antimicrobial factor(s) in these studies.

Defensins and cytokines are stored in platelet α-granules. However, dense granule constituents such as adenosine diphosphate (ADP) (Packham and Rand 2011), polyphosphates (polyP) (Smith and Morrissey 2014), and serotonin (Jedlitschky et al. 2012) also have immune-modulating properties (Morrell et al. 2014). These have not been as well characterized for a role in viral innate immunity as those contained in α-granules. Nevertheless, the release of platelet dense granule contents by viruses has been investigated in CMV infection. This was mediated by platelet surface TLR2 occupation. Furthermore, inhibition of the ADP receptor, $P2Y_{12}$, identified ADP release as an important trigger for secondary platelet activation (Assinger et al. 2014). Dendritic cells also express $P2Y_{12}$ and their stimulation increases antigen endocytosis and processing (Vanderstocken et al. 2010), which could involve localized platelet response to pathogen interactions. PolyP induces proinflammatory responses by acting on the nuclear factor κB (NF-κB) pathway in vascular endothelial cells (Bae et al. 2012). PolyP can also interact with chromatin-associated nuclear proteins such as high mobility group box 1 (HMGB1) to amplify proinflammatory responses (Dinarvand et al. 2014). Because HMGB1 is also secreted by platelets (Maugeri et al. 2012), polyP warrants continued study as a bridge between platelets and innate immunity, especially in the context of complement, which is suppressed by polyP (Wat et al. 2014) and could be a viral survival mechanism.

Virus-Induced Thrombocytopenia

According to some estimates, approximately two-thirds of acute thrombocytopenia cases are preceded by viral infection (Rand and Wright 1998). This strikingly high correlation suggests mechanisms directly linking the virus to the platelet, such as receptor-mediated binding (Table 1). In contrast to viral thrombocytopenia, viral HF (Table 2) is thought to be driven by severe suppression of innate immunity and the resulting cytokine flood that counters systemic virus replication. HF can also result in a reduced platelet count, but through mechanisms indirectly involving platelets, as detailed in excellent reviews elsewhere (Feldmann and Geisbert 2011; Messaoudi and Basler 2015; Zapata et al. 2014). Here, we overview five primary pathways that simultaneously contribute to viral thrombocytopenia in the absence of HF: decreased thrombopoeisis, direct and indirect virus interactions with platelets and megakaryocytes (tipping the intricate balance between thrombopoeisis and platelet clearance), altered platelet function, and virus-induced immune response against platelets.

Decreased Thrombopoeisis Viral infection results in production of interferon, which has antiviral activity. However, type I interferons can also inhibit megakaryocytes, resulting in impaired platelet production (Rivadeneyra et al. 2015). Megakaryocyte growth and differentiation is stimulated by thrombopoietin (TPO), which is predominantly produced in the liver (Giannini et al. 2002). Impaired liver function is consequently detrimental to TPO production and the resulting thrombocytopenia often suffered by chronic HCV patients correlates with low TPO and attenuated thrombopoeisis (Giannini et al. 2002; Wenzel et al. 2010).

Direct impairment of platelet production as a result of viral replication in megakaryocytes was observed in vitro for HIV, HCV, DENV, and CMV (Basu et al. 2008; Crapnell et al. 2000; Li et al. 1999; Sato et al. 2000; Sridharan et al. 2013). An increase in cell death via apoptosis and decreased megakaryocyte differentiation are probable reasons for reduced platelet production. For example, HIV infection of megakaryocytes resulted in downregulation of the TPO receptor c-Mpl (Gibellini et al. 2013), causing reduced sensitivity to thrombopoeisis induction. To further investigate this mechanism, umbilical cord blood hematopoietic progenitor cells that were induced by TPO toward a megakaryocytic lineage in vitro have been used as a model for HIV infection. The virus surface glycoprotein gp120 interacts with CD4 on these cells (Gibellini et al. 2007), resulting in specific protein and mRNA changes that elevate TGF-β1 levels and decrease tumor necrosis factor (ligand) superfamily, member 13 (TNFSF13) levels. Both of these effects contribute to inhibition of megakaryocytic proliferation and promote apoptosis (Gibellini et al. 2007). Further evidence supporting the concept that viral thrombocytopenia involves attenuated thrombopoiesis comes from an elegant humanized mouse model showing that DENV infection reduces platelet production (Sridharan et al. 2013). Thus, viral infection has the capacity to reduce thrombopoeisis by direct effects on the megakaryocyte, conceivably involving the same surface receptors for specific viruses that have been identified on platelets and other cells (Tables 1, 2, and 3).

Direct Virus–Platelet Associations Activation of platelets, degranulation, and recruitment of neutrophils and dendritic cells contribute to phagocytosis of platelet fragments by leukocytes. The final clearance of these potentially virus-laden particles is in the spleen and liver (Bondanza et al. 2001; Grozovsky et al. 2010; Koupenova et al. 2014). CMV- or EMCV-mediated activation of platelets via TLR2 or TLR7, respectively, enhanced the interaction between platelets and neutrophils, resulting in platelet clearance (Assinger et al. 2014; Koupenova et al. 2014). In a similar manner, hantavirus also induced platelet activation and clearance by binding to platelet surface integrins $\alpha_v\beta_3$ and $\alpha_{IIb}\beta_3$ (Gavrilovskaya et al. 2010). The interaction of hantavirus with platelets also contributed to viral dissemination and activation of endothelial cell functions, thereby increasing vascular permeability (Feldmann and Geisbert 2011; Gavrilovskaya et al. 2010).

Adenovirus correspondingly induces thrombocytopenia, as seen when adenovirus gene therapy vectors are intravenously administered to rhesus macaques and mice (Othman et al. 2007; Wolins et al. 2003). Current literature indicates that CAR mediates the binding of adenovirus to platelets, enabling subsequent entry (Othman et al. 2007; Shimony et al. 2009). The virus–platelet interaction is predominantly localized to sites of intercellular complex formation, implying that CAR expression is enhanced in response to platelet activation (Gupalo et al. 2011). Similar to the effects reported for other viruses, platelet activation is probable upon the initial association of adenovirus and platelet-surface CAR.

The IAV envelope has neuraminidase activity that cleaves sialic acid on the surface of platelets (Madoff et al. 1964). Removal of more than 15 % of total sialic acid on rabbit platelets caused complete platelet clearance within 1 h of administering ^{51}Cr-labeled platelets into rabbits (Greenberg et al. 1975). The removal of circulating platelets was presumably caused by recognition of exposed terminal galactose residues by scavenger cells expressing the asialoglycoprotein receptor (Sorensen et al. 2009). This adds to the repertoire of virus-clearance mechanisms that can be facilitated through direct virus–platelet association.

Indirect Virus–Platelet Associations Platelets express Fc receptors that allow recognition of immune complexes or aggregated immunoglobulin. In addition to PAR-1 activation by thrombin, IAV can activate platelets through low-affinity FcγRIIA signaling (Boilard et al. 2014). For this to occur, IAV must be decorated with anti-IAV IgG. Crossreactive antibodies resulting from immune recognition of different IAV strains (H1N1 versus H3N2) was sufficient to produce this effect. When wild-type mice (which do not express FcγRIIA) and transgenic mice expressing human FcγRIIA were challenged intravenously with a sublethal dose of H1N1, there was a drop in circulating platelet count in only the transgenic mice. This indicates that platelet homeostasis is affected by the accessibility of Fc receptors on platelets, supporting the link to pathogenic thrombocytopenia (Boilard et al. 2014).

Activation of endothelial cells has been implicated in adenovirus-induced thrombocytopenia. In these studies, the release of ultralarge von Willebrand factor (vWF) from the Weibel–Palade bodies (Gupalo et al. 2011) was evaluated using a murine model. Adenovirus induced thrombocytopenia in wild-type animals but, in sharp contrast, vWF knockout mice were protected from a reduced platelet count (Gupalo et al. 2011). Thus, endothelial vWF could contribute in an indirect manner to virus-induced thrombocytopenia by supporting platelet aggregation through interactions with platelet surface GP1b, (the vWF receptor). Clearance of these platelet aggregates is subsequently facilitated by splenic macrophages or Kupffer cells in the liver (Othman et al. 2007).

Systemic inflammation as a result of viral infection can result in platelet interactions and increased clearance, as demonstrated during IAV, rhinovirus, and CMV infections (Bouwman et al. 2002). The mechanism involves mononuclear leukocytic release of CXCL4. DENV infection was

used in a subsequent study and resulted in increased inflammation, vascular permeability, and platelet aggregation and activation (Yang et al. 1995).

Altered Platelet Function Thrombocytopenia can result from virus activation of platelets or endothelial cells, which induces cell–cell adhesion processes via expression of integrin and selectin function (Zapata et al. 2014). The flipside is that inhibition of platelet aggregation can also result in impaired platelet function. DENV infections have been shown to stimulate platelet-directed IgM autoantibodies that inhibit ADP-induced platelet aggregation (Lin et al. 2001). Although these autoantibodies have an effect on immune clearance of platelets, they also affect the development of HF. For hantavirus, this can include renal syndrome resulting from defective platelet aggregation (Cosgriff et al. 1991). Other HF viruses such as Lassa virus, Junin virus, and Ebola virus have inhibitors of platelet aggregation, but these have not been identified (Cummins et al. 1989; Cummins et al. 1990, Feldmann and Klenk 1996). Additionally, vaccinia virus causes impairment of platelet aggregation induced by ADP, collagen, or thrombin (Bik et al. 1982). Ebola virus infection also results in increased levels of type I interferons, which downregulate platelet production and function (Rivadeneyra et al. 2015; Villinger et al. 1999).

Virus-Induced Immune Response Against Platelets The molecular relationship between autoantibodies against platelet proteins and viral infection is complex and not yet clearly understood. Virus-induced thrombocytopenia typically worsens as damage to the liver progresses and can deteriorate into a more severe clinical complication (Aref et al. 2009). Anti-platelet autoantibodies are linked to immune thrombocytopenic purpura (ITP) (Liebman 2008). Secondary ITP can result from vaccines such as measles-mumps-rubella (MMR) (incidence of 1 in 40,000 administrations) or infections with homologous herpes family viruses, hepatitis C, HIV, hantavirus, and severe acute respiratory syndrome coronavirus (Goeijenbier et al. 2012; Liebman 2008).

Non-AIDS early HIV-1 infections can result in ITP induced by autoimmune antibodies. Affinity purification of circulating serum immune complexes in HIV patients identified an anti-HIV IgG1 antibody that recognizes amino acid residues 49–66 of the integrin β3 subunit that induces platelet vessiculation (Nardi et al. 2001). The complement pathway was ruled out in this reaction because neither the $F(ab')_2$ fragment of the antibody raised against integrin β3 residues 49–66 in wild-type mice nor treatment with full-length antibody in C3-deficient mice could affect platelet microparticle formation (Nardi et al. 2001). Peroxide generation was monitored through the use of an intracellular fluorescent probe and revealed a novel mechanism by which the autoantibody induced damage in platelets through a NADPH oxidase peroxide-generating pathway (Nardi et al. 2001). Similar outside-in signaling events could be generated by other virus-induced platelet autoantibodies.

ITP occurs in 20 % of HCV patients and is potentially attributed to the presence of antibodies that are crossreactive with HCV core envelope 1 protein and platelet β3 integrin (Rajan et al. 2005; Zhang et al. 2009). The crossreactivity was found by using the antibody specific for integrin β3 residues 49–66 to screen a phage-display peptide library (Zhang et al. 2009). The recognized peptides were then aligned with the viral genome to define similarities. The matched peptides were rationally designed as tools to inhibit the binding of autoantibodies to platelets or to produce platelet antibodies with functional effects (Li et al. 2005; Zhang et al. 2009). This approach was similarly used to discover molecular mimics in the HIV-1-encoded negative regulatory factor (nef) protein (Li et al. 2005), both leading toward therapeutic design in virus-induced thrombocytopenia.

Antibody crossreactivity between antiviral antigens and platelet antigens has been demonstrated during DENV infection (Cheng et al. 2009). Pairwise sequence alignment analysis programs were used to annotate homologous peptide sequences between DENV NS1 and platelet protein disulfide isomerase (PDI) (Cheng et al. 2009). This tool identified several sequence homologies, of which amino acid residues 311–330 (P311–330) was the most dominant epitope recognized by both anti-NS1 and anti-PDI, as determined by ELISA (Cheng et al. 2009). The P311–330 antibodies generated from hyperimmunized mice bound platelet PDI and inhibited both thiol isomerase activity and platelet aggregation induced by ADP (Cheng et al. 2009). The presence of anti-platelet autoantibodies with anti-DENV activity in DENV patient sera is associated with thrombocytopenia and the severity of the disease during the acute phase of secondary DENV infection (Saito et al. 2004). However, the direct implication of these crossreactive antibodies in DENV pathogenesis has not yet been elucidated. The discovery that platelets can translate and express NS1 (Simon et al. 2015) suggests that viral antibodies might not be crossreactive with platelets, but actually recognize the virus-encoded gene product expressed on the platelet, further complicating vaccine development.

Conclusion

Associations between viruses and platelets can lead to pathology. Viral infection often precedes thrombocytopenia and, therefore, an understanding of the mechanisms that facilitate virus–platelet interactions, their direct effect on platelets, and indirect effects on the cellular environment can lead to therapeutic control. This is a difficult challenge because platelets also help to eradicate viruses by steering

innate and adaptive immune responses. Thus, ideal therapeutic control of virus-induced thrombocytopenia can discretely manage both the detrimental and positive involvement of platelets in viral infection.

Take Home Messages

- Diverse virus families can bind to platelets, resulting in mild to severe clinical outcomes.
- Virus–platelet interplay results in changes to innate and adaptive immunity.
- Platelets replicate the RNA genome of permissive viruses, which can contribute to pathology.

Platelets in Malarial Infection: Protective or Pathological?

Simon Foote, Gaétan Burgio, and Brendan McMorran

Abstract

Platelets play an ambiguous role in a malarial infection. On the one hand, platelets have been implicated adversely in cerebral malaria. They stick to the cerebral endothelium and mediate the adhesion of infected erythrocytes, with the postulated outcome of increasing severity or of even mediating this disease. On the other hand, platelets bind to infected red cells in the periphery and activate and release the cytokine PF4. This, in turn, binds to the Duffy antigen on the red cell and is thought to be internalised and enters the parasite food vacuole which it then destroys, killing the parasites. The control of platelet levels during an infection is also discussed with a view to understanding the thrombocytopenia that frequently accompanies a malarial infection.

Malaria is a haematological disease. All its clinical consequences are due to its erythrocytic life stage. Therefore, given its intimate sharing of a biological niche with platelets, it is not surprising that the parasite, living within the red cell, interacts with the platelet. Malarial parasites are single cellular eukaryotic organisms that are introduced into the host through the bite of an infected Anopheles mosquito. These sporozoites travel to the liver where they undergo many rounds of replication and, upon erupting from the hepatocyte as small merozoites, infect red cells. Their lifecycle in the host is thereafter centred on the red cell. Rounds of erythrocytic invasion, replication and lysis continue until the host develops an adaptive immune response that kills all parasites. An effective immune response against malarial parasites takes years to develop as the parasite population houses a staggering suite of antigenic variation. The lifecycle is continued by the development of dimorphic sexual stages (gametocytes) that complete the lifecycle in the mosquito after ingestion by a mosquito. Gametocytes undergo meiosis in the mosquito. This produces recombinant, segregated parental chromosomes in the progeny. If the mosquito ingests more than one type of parasite, sporozoites will be produced with different combinations of variant antigens resulting in an immunologically unrecognisable parasite to hosts previously infected with either parental parasites.

Platelets are known to be involved in all but the hepatic stage of infection. They are inhibited during mosquito feeding and removed during the erythrocytic stages. They appear to both ameliorate infection by killing parasites and compromise the host by mediating adhesion of infected erythrocytes to the vascular wall. These various roles of the platelet will be discussed in detail in this chapter.

Platelet Inhibition by Feeding Mosquitoes

The saliva from the female *Anopheles stephensi* contains many compounds that prevent the clotting of blood, allowing the smooth feeding of the mosquito. It is during this feeding that malarial sporozoites are injected into the host. The anopheline antiplatelet protein (AAPP) has been isolated from mosquito saliva and has significant inhibitory effects in the prevention of platelet aggregation in the presence of collagen (Yoshida et al. 2008). It inhibits binding of platelets to collagen as well as inhibiting platelet-platelet binding. When used

as a candidate antiplatelet agent in mice, it ameliorated a mouse thrombosis model without excessively increasing the bleeding time. Its antiplatelet activity compared well to that of aspirin (Hayashi et al. 2012).

Thrombocytopenia Is a Feature of a Malarial Infection

A constant companion to a malarial infection is a decrease in parasite density. This thrombocytopenia was seen early in rodent infection experiments in the 1950s (Fabiani et al. 1958), but has been regularly (and frequently) reported over the decades since. Thrombocytopenia is fairly consistently seen in models of human malaria; thus, it is seen in hamsters infected with *Plasmodium berghei*, a rodent malaria (Essien et al. 1984), in *P. vinckei*-infected mice (Reiner et al. 1991) and *P. chabaudi*-infected mice (McMorran et al. 2009) (Fig. 1) and is quite severe in *P. knowlesi*-infected macaque monkeys (Abildgaard et al. 1975).

There are four major human malarias, *P. ovale*, *P. vivax*, *P. malariae* and *P. falciparum*. Thrombocytopenia is a common feature of all these malarias (Chimalizeni et al. 2010; Dennis et al. 1967; Essien 1989; Jeremiah and Uko 2007; Kehinde et al. 2005; Ladhani et al. 2002; Leowattana et al. 2010; Paul 1990; Shaikh et al. 2011; Soupison et al. 1995; Spitz 1946; Taylor et al. 2008; Touze et al. 1990). However it is *P. falciparum* and *P. vivax* that are the most extensively analysed. Patients with *P. vivax* infections have anecdotally lower platelet counts, epitomised by a study from Papua where both *P. falciparum*- and *P. vivax*-infected trial enrollees had their platelets measured. Significantly lower levels were associated with *P. vivax* infection (Taylor et al. 2008).

The proportion of malaria-infected patients with thrombocytopenia varies from study to study (Chimalizeni et al. 2010; Gerardin et al. 2002; Ladhani et al. 2002). However, there is little doubt that the majority of patients with malaria show some level of thrombocytopenia. Percentages range from close to 100 % of all malaria-infected individuals being thrombocytopenic, in an early study in Singapore (Beale et al. 1972), to 85 % of infected children in India (Prasad et al. 2009) and to 56 % of children in Kenya (Ladhani et al. 2002). Moreover, platelet numbers are decreased in asymptomatic as well as symptomatic malaria (Jeremiah and Uko 2007; Kehinde et al. 2005).

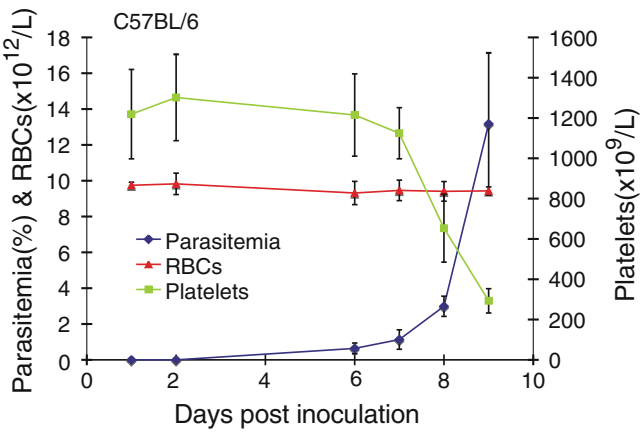

Fig. 1 Platelet, parasite and RBC kinetics in a *P. chabaudi* infection in mice. The rise of parasitaemia is directly reflected in a fall in platelets at a time early in infection when the red cell number remains unchanged

Clinical Corollaries of Malarial Thrombocytopenia

Early reports associated the severity of malarial thrombocytopenia from falciparum malaria with severe malaria (Gassner et al. 1979). This has been corroborated by more recent reports (Gerardin et al. 2002) where severe malaria and thrombocytopenia are linked and where thrombocytopenia was seen as an independent predictor of death. However, there are other reports showing that there is no direct link between the level of thrombocytopenia and the severity of malaria (Chimalizeni et al. 2010; Ladhani et al. 2002). The most reliable association of thrombocytopenia is with the level of parasitaemia, with an inverse correlation seen between platelet and parasite densities. In a study in Malawi, 1811 children with cerebral malaria were compared with 521 children with bacterial meningitis. The children with malaria had fewer platelets, but, again, there was no correlation between the level of thrombocytopenia and parasite density. What is true for severe malaria is also true for asymptomatic malaria (Jeremiah and Uko 2007; Kehinde et al. 2005) where the correlation between thrombocytopenia and parasite density is not great. So, it would appear that if there is an association with severe malaria that is independent of parasitaemia, then its effect is not large.

The second possible clinical correlate of a malaria-associated thrombocytopenia is the presence of a propensity to bleed. However, bleeding is not common in malarial infections. Studies looking at clotting parameters report conflicting results with abnormalities in prothrombin time, activated thromboplastin time and thrombin time (Prasad et al. 2009). However, these changes were not seen in another study reported by Mohanty et al. (1988). Nonetheless, abnormalities in platelet function were observed by Prasad et al. who reported hypoaggregation of platelets with ADP and ADR in greater than 90 % of all cases (Prasad et al. 2009), although there were very few examples of bleeding. Bleeding has been reported however in severe cases of malaria with frequencies above 5 % (Srichaikul 1993) and is seen at frequencies of 55 % in autopsy cases (Boonpucknavig et al. 1984).

The most common site of haemorrhage is seen in the retinas of children with malaria, part of the malaria retinopathy, which is a quartet of changes common in cases of malaria (Beare et al. 2006, 2009; Lewallen et al. 2008).

The relationship between retinal haemorrhage and clotting deficiencies and/or platelet changes has not been studied.

Cause of Malarial Thrombocytopenia

A loss of platelets during malarial infection may be caused by an increase in the consumption or destruction of platelets, or by a decrease in their production, or by a combination of both. That there might be a decrease in the production of platelets is based on the observation that erythropoiesis is suppressed by malarial parasites (Miller et al. 1989; Mohan and Stevenson 1998; Yap and Stevenson 1991). However examination of the bone marrow from thrombocytopenic malaria-infected patients showed no decrease in the number of megakaryocytes and, indeed, a megakaryocytosis in one patient (Beale et al. 1972). Despite recent studies appearing to exonerate thrombopoiesis from malaria-mediated suppression (de Mast et al. 2010), Casals-Pascual and colleagues showed in a large cohort of children infected with malaria, and with thrombocytopenia, that the level of platelets was inversely correlated with circulating IL10 levels (Casals-Pascual et al. 2006). They pointed to the known thrombocytopenic effect of IL10 administration caused by a decrease in megakaryocytosis (Sosman et al. 2000) could be also causing the thrombocytopenia seen in malaria patients with raised IL10.

There have been many suggestions as to why platelets are being cleared during malarial infection; these include disseminated intravascular coagulation (DIC), immune-mediated destruction, pooling within the reticuloendothelial system, sequestration in the microcirculation and malaria-mediated apoptosis. Early studies reported DIC as a cause of thrombocytopenia (Jaroonvesama 1972; Spitz 1946), and these observations resulted in the use of heparin in severe malaria. However, these observations have not been validated, and there is now significant data to show that DIC is not common in malaria (Beale et al. 1972) and that DIC is not the cause of most malaria-related thrombocytopenias (Skudowitz et al. 1973). There continue, however, to be isolated reports of DIC in end-stage severe malaria cases, so it is possible that DIC is a rare complication of late-stage malarial infections (Gassner et al. 1979; Pukrittayakamee et al. 1989; Reid and Nkrumah 1972). Given that platelet number begins to decrease early in infection, it is unlikely that this is due to DIC.

Immune-mediated clearance of platelets during malarial infection has been proposed as a mechanism underpinning thrombocytopenia. In a study of 28 patients infected with mainly *P. vivax*, Kelton and colleagues showed that platelet-associated IgG, in the presence of malarial antigens, bound platelets (Kelton et al. 1983). In a single case study, Conte identified platelet-associated IgG and IgM, and antibodies binding to the platelet antigens CD41 and CD49b (Conte et al. 2003). However, there was no evidence given that these were responsible for the thrombocytopenia. In a similarly small sample from Japan, platelet-associated antibodies were found in two patients with *vivax* malaria (Yamaguchi et al. 1997). The common thread linking these different studies is that upon treatment with antimalarial drugs, the binding of either IgG or IgM disappeared. This is inconsistent with a hypothesis of autoimmune antiplatelet antibodies, as, presumably, these would persist some time after the malarial infection was cleared. This phenomenon appears to more resemble heparin-induced thrombocytopenia where antibodies directed against PF4-heparin complexes are captured by platelet Fc receptors, causing the activation and removal of platelets (Kasthuri et al. 2012). This disease is stopped when heparin administration is ceased. In a similar fashion, the binding of IgG to platelets in malarial infection requires the presence of malarial antigens and stops as soon as antigen is withdrawn upon successful treatment of disease.

Malaria is often accompanied by splenomegaly. The increase in splenic size is due to an accumulation of macrophages, and these phagocytose both infected and noninfected red cells (Russell et al. 1946). There have been suggestions that platelets pool in these large spleens and are phagocytosed by the reticuloendothelial system (Skudowitz et al. 1973). However, there is no correlation between splenic size and platelet density (Beale et al. 1972). Karanikas and colleagues performed scintography on radiolabelled platelets in normal and malaria-infected patients. They did not find pooling in the spleen, even in individuals with very large spleens. In fact the distribution of platelets was indistinguishable from control individuals. They did however see a greatly reduced platelet half-life (Karanikas et al. 2004). Sodeman et al. infected rhesus monkeys with *P. cynomolgi* and saw no differences in platelet number between splenectomised and intact animals. These data would tend to rule out the reticuloendothelial system in playing a large role in the clearance of platelets in malarial infection.

Platelet death can be mediated through a process analogous to apoptosis in nucleated cells. This is initiated through activation of platelet caspases. In a mouse model of malaria, caspases have been shown to be activated causing platelet apoptosis (Piguet et al. 2002). This was associated with an increase in the number of circulating platelet microparticles, a possible corollary of platelet apoptosis. The thrombocytopenia in these mice could be decreased with pretreatment with anti-CD40L antibodies or with caspase inhibitors, indicating that apoptosis was initiated by CD40L and that caspases were crucial.

The Role of Platelets in the Pathophysiology of the Malarial Infection

Platelets may modulate the clinical consequences of malarial infection through two major routes and perhaps a number of less well-studied pathways. These include multiple

observations that platelets, through their ability to bind both infected and noninfected red cells and the endothelium, may be the major mediator of cerebral malaria. Alternatively, and not exclusively, platelets have been shown to bind to infected red cells and to kill the parasites within. While both these mechanisms appear contradictory, they may both be active in a malarial infection. However, they both rely on an important attribute of the platelet: its ability to adhere to both the red cell and the endothelium.

Cytoadherence of Platelets During Malarial Infection

Platelets bind to infected red cells in both mouse and human malaria. The binding molecules on the platelet side of this interaction have been well studied and include CD36, ICAM1 and gC1qR (Mayor et al. 2011). The adhesion phenomenon is seen as platelet-mediated rosetting, clumping or infected red cell binding to purified receptors. Infected red cells also bind to the endothelium, and it is through this sequestration from the reticuloendothelial system that parasites are able to reproduce more effectively. Given that some of the receptors that bind infected red cells to platelets are also present on the endothelium of the microcirculation, there is the possibility that adhesion to platelets is a side effect of the development of endothelial binding by infected red cells to avoid splenic clearance.

Binding of Platelets to Infected Red Cells and Endothelium and the Development of Cerebral Malaria

Cerebral malaria, along with severe malaria anaemia, is the major mechanism of mortality in patients infected with *P. falciparum*. The exact pathophysiology of cerebral malaria has yet to be elucidated. However, the disease is characterised by a high mortality rate of at least 20 % and by a profound coma from which most people who survive do so with little or no neurological sequelae, although a small percentage do go on to retain a neurological deficit. The pathology appears to involve the physical binding of infected red cells to the endothelial cells of small vessels in the brain. This is usual in many organs, but in the brain it produces cerebral malaria. There are also immunological causes to the syndrome which may explain the majority of the pathology as a mechanical cause due to obstruction alone, but this is not consistent with the excellent outcome in most surviving patients.

Platelets must be involved however as early observations reported that platelets are seen in plugs in cerebral blood vessels. In an electron microscopic study looking at the brains of malarial patients who had died from *P. falciparum*-induced cerebral malaria, abnormal infected red cells with surface knobs were seen binding to endothelium. Although there were some small number of uninfected cells, most were infected, and some of these lesions contained platelets (Pongponratn et al. 1985). This observation has prompted the hypothesis that cerebral malaria is caused by the binding of platelets to infected red cells and that this mediates their adhesion to the endothelial surface (Biswas et al. 2007). In addition, platelets may activate and release mediators for the immune response that ensues. However, more recent, electron ultrastructural studies have not been able to repeat these early findings. So, in 2003 a study looking at a large number of children who had died from cerebral malaria found that only 6 % of all cerebral lesions contained platelets (Pongponratn et al. 2003). This would indicate that, perhaps, platelets do not play an important role in cerebral malaria than had been thought.

Unfortunately there is no perfect animal model for cerebral malaria (White et al. 2010). The model that is most published is the murine malaria, *P. berghei*, which produces a cerebral malaria-type syndrome early in the infection in susceptible mouse strains. However the pathophysiology is quite different from human cerebral malaria. The lesions seen with most *P. berghei*-infected mice involve very few infected cells, and most of the lesions contain uninfected red cells and large mononuclear phagocytic cells. This is very different from human cerebral malaria where the large mononuclear cells are absent, and the lesions contain very few uninfected cells. It is, however, possible that there are some shared effector pathways between the human and mouse cerebral malaria (Grau and Craig 2012).

There is a burgeoning literature implicating platelets in the pathophysiology of *berghei* malaria in mice. Mice infected with the murine parasite *P. berghei* develop cerebral malaria early in the infection, but only in strains of mice susceptible to disease. Platelets have been implicated in the pathology of this disease from several types of evidence; platelet binding to the endothelium of cerebral microvessels is increased in *P. berghei*-infected mice, and anti-C41 antibody depletion of platelets early in the infection prevents cerebral malaria (Sun et al. 2003; van der Heyde et al. 2005). The observation that either ICAM-1 or P-selectin deficiency also prevents the development of cerebral malaria would indicate that platelets play a role and that binding to the endothelium via either ICAM-1 or P-selectin is part of that role (Sun et al. 2003). However, mice with platelets cleared one or two days before the onset of cerebral malaria were not protected (van der Heyde et al. 2005), which would counter the argument that adherent platelets play a role in the development of cerebral malaria as there were no platelets present in these mice, and yet the development of cerebral malaria continued unabated.

Further evidence that platelets play a role in cerebral malaria comes from the ameliorating effects on the development of cerebral malaria in mice deficient for the platelet protein, platelet factor 4 (PF4) or its chemokine receptor CXCR3 (Srivastava et al. 2008). Prevention of activation of platelets with aspirin also decreased the severity of cerebral malaria in the *berghei* model (Srivastava et al. 2008). That platelet-derived PF4 might be playing a more complex role in the development of cerebral malaria is suggested by studies that show that in animals PF4 drives monocyte cytokine production and that depletion of monocytes gives rise to resistance to cerebral malaria in the *berghei* model. Furthermore, PF4-deficient mice show less trafficking of monocytes to the brain, a PF4 effect mediated through expression of KLF4 (Srivastava et al. 2010). In support of these findings is the observation that mice, either lacking the platelet-activating factor (PAF) receptor or being treated with a PAF receptor antagonist, have an ameliorated response to cerebral malaria (Lacerda-Queiroz et al. 2012).

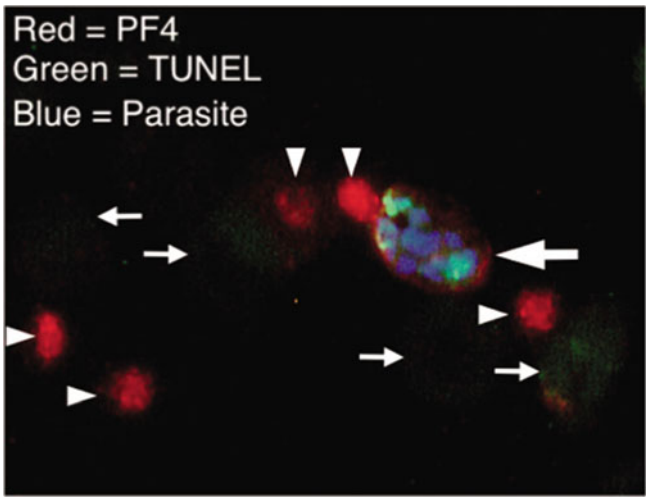

Fig. 2 Immunofluorescent image of platelets binding to both infected and uninfected red cells. Note that PF4 (*red stain*) is only released onto the erythrocyte if there is a parasite within the cell. And also the PF4-coated parasite is Tunel positive, i.e. dead

Platelets May Offer Protection Against the More Severe Effects of a Malarial Infection

Early studies have shown that purified platelets added to a culture of *P. falciparum* inhibit the growth of the parasites (Peyron et al. 1989). This inhibition of growth was only dependent on the presence of the platelets. This observation was replicated nearly a decade later where Polack et al. showed that antibody depletion of platelets resulted in animals that were more susceptible to a *P. berghei* infection than intact animals. McMorran et al. reproduced the mouse findings in an *Mpl* knockout mouse that has only 10 % of the normal number of circulating platelets. These mice had an enhanced survival when infected with the murine malaria, *P. chabaudi*, and their parasitaemia was lower than intact animals. These results were repeated with purified platelets in culture with *P. falciparum*. Both in the mouse and in culture, platelets preferentially bound to infected cells (Fig. 2), although noninfected red cells also bound. Parasites in cells bound to platelets were killed (McMorran et al. 2009). Killing of parasites by platelets required activation of the platelet, and killing was blocked by inhibition of platelet activation by aspirin. Aspirin is a common antipyretic drug in the developing world, and this observation may bring doubt to the wisdom of the continued use of aspirin in malarial infections.

The molecular basis of this killing was PF4, released by activation of platelets upon binding infected red cells. PF4 entered the red cell through the Duffy antigen, which is a chemokine receptor. In most Africans, there is a null allele of the Duffy antigen which is fixed as a homozygous allele in most of sub-Saharan Africa. Red blood cells from individuals with this allele are unable to mediate killing of the parasite by platelets (McMorran et al. 2012). Love and colleagues demonstrated that PF4 only accumulated within infected cells and kills parasites by lysing the parasite's digestive vacuole (Love et al. 2012).

The role that platelet-mediated parasite killing has on the outcome following a malarial infection is not known. At least in mouse experiments, it greatly improves survival, but this mechanism of innate immunity is not available to most Africans due to their Duffy negativity status. As most malarial deaths occur in Africa, the extent (if any) that the lack of protection by platelets plays in malaria in Africa has not been studied.

These results show that platelets also have a significant protective role against malaria. This is in contrast with the role that platelets play in the pathology of cerebral malaria. This collection of somewhat disparate effects of platelets have been coalesced into a unified hypothesis by Aggrey et al. (Aggrey et al. 2013) who have suggested that platelets regulate the acute-phase response in a malarial infection. Certainly, platelets produce a large array of immunoreactive molecules, comprising PF4, RANTES, CSCL7 and IL-β1. Acute-phase proteins are the earliest response to infection; are molecules produced by the liver in response to IL-6, IL-1β and TGF-β; and are molecules that are toxic to the parasite and slow the replication of the malarial parasite and promote survival of the host. Later in infection, the parasite mediates an inflammatory reaction and aids in the cytoadhesion of infected red cells which leads to an increase in the pathology of infection and decreases host survival.

However, just to underscore the fact that there is still much to learn about platelets and their role in malaria, Chapman et al. reported data that shows that platelets have the ability to present parasite antigens on a class II MHC molecule (Chapman et al.

2012). They have proteasomes, β_2-microglobulin and HLA, can present parasite antigen and stimulate $CD8^+$ T cells. This raises the important question as to whether platelets also play a role in the adaptive immune response.

Take Home Messages

- Thrombocytopenia is common in malarial infections of all species.
- Platelet bind preferentially to malarial infected red cells.
- Platelet binding only to infected red cells activate and release contents of alpha vesicles.
- Platelets binding to infected red cells results in the death of malarial parasites.
- Platelet Factor 4 (PF4) is the platelet effector molecule from platelets that causes parasite death.
- PF4 binds to the Duffy Antigen. Duffy negative-infected red cells are resistant to platelet-mediated parasite killing.

Platelets: "First Responders" in Cancer Progression and Metastasis

David G. Menter, Jennifer S. Davis, Stephanie C. Tucker, Ernest Hawk, John D. Crissman, Anil K. Sood, Scott Kopetz, and Kenneth V. Honn

Abstract

A long-standing postulate in oncology is that platelets facilitate cancer metastasis (Menter et al. Cancer Metastasis Rev 33:231–269, 2014; Menter et al. Invasion Metastasis 7:109–128, 1987; Gasic et al. Proc Natl Acad Sci USA 61:46–52, 1968; Woods Bulletin der Schweizerischen Akademie der Medizinischen Wissenschaften 20:92–121, 1964). As their most critical biological response, platelets serve as "first responders" during the wounding process and hemostasis. As a part of the metastatic process, platelet receptors recognize complexes of tumor cell receptors and surface-bound matrix proteins or cellular products as they invade blood vessels. This recognition triggers platelet activation and platelet-tumor cell interactions. Once activated by tumor cells, platelets change shape, degranulate, and release proteins, growth factors, bioactive lipids, and other factors that recruit additional platelets and immune cells along with initiating thrombogenesis. Extensive membrane changes occur at bilayer interfaces between platelets and tumor cells. Tumor cells form extensive membrane/cytoskeletal processes that heavily interdigitate with a central platelet aggregate and involves the uptake of platelet fragments and mitochondria. These interactions are thought to result in the suppression of immune recognition/cytotoxicity or the promotion of cell arrest at the endothelium or entrapment in the microvasculature. These responses all support survival and

spread of cancer cells and the establishment of secondary lesions. Additional mechanisms of the platelet-metastasis relationship may include the production of platelet exosomes or extravascular migratory behavior of platelets helping to drive cancer progression or preconditioning of secondary metastatic sites. In contrast to the many mechanisms involved in platelet-metastasis relationships, little is known about the role of platelets in precancerous lesion development. This paucity of knowledge exists despite numerous large randomized clinical trials illustrating the cancer preventive effects of nonsteroidal anti-inflammatory drugs (NSAIDs), particularly aspirin in reducing the cancer incidence, mortality, and metastasis. Aspirin covalently acetylates and inactivates platelet cyclooxygenase 1 and thereby eliminates all downstream prostaglandin production from arachidonic acid (AA) by platelets. This includes the key bioactive lipid involved in platelet activation, thromboxane A_2 (TxA_2). Another prostaglandin, prostacyclin (PGI_2), counterbalances and inhibits platelet activation (Honn et al. Science 212:1270–1272, 1981). Metabolically, the genesis of TxA_2 and other bioactive lipids are also impacted by ω-3 polyunsaturated fatty acid substrate substitution for AA. Although not well studied, this places platelets not only at the center of the metastasis discussion but also the progression of premalignancies. Since neoangiogenesis produces leaky blood vessels during early cancer progression, it stands to reason that platelets are the "first responders" to extravasate, activate, and release their stroma-stimulating, proangiogenic, chemoattractive, and immunomodulatory contents. These normal platelet functions and products undoubtedly promote precancerous lesion progression as a series of cyclic amplification events. Platelets are suspected to have a key role within the full spectrum of the cancer progression continuum, which makes limiting their first response an important target for both prevention and therapy.

Platelets in Cancer Metastasis

Platelets as "First Responders"

"First responders" are a perfect moniker for platelets as active participants in the hemostasis, wounding, immune, and metastatic processes (Menter et al. 2014; Gasic et al. 1968; Woods 1964). Platelets are often neglected or overlooked during in vivo experimental or pathologic observations. This is partly due to their small size/volume (mean platelet volumes range is 9.7–12.8 femtoliter or spheres 2.6–2.9 μm in diameter) and the requirement for ultrastructural analysis to effectively observe morphologic or activational structural changes in individual platelets (Fig. 1). Aggregates of activated platelets can be detected by immunohistochemistry at the microscopic level, but this is not routinely done (Qi et al. 2015). As a part of their functional biophysical dynamics, the platelet discoid shape, small size/volume, and physical characteristics cause them to segregate toward the outer fluid shear fields of flowing blood (Fedosov et al. 2014; Kumar and Graham 2012; Tokarev et al. 2011a, b; Lee et al. 2009). Normal human numbers range between 150,000 and 400,000 platelets per microliter (μl), and the concentration of platelets near the vessel wall in vivo is two to three times greater than at the vessel core. Thus, their overall biophysical properties in circulation facilitate platelet distribution toward the endothelial surfaces of vessel walls. Platelet flow patterns, near-wall excess, and proximity enhance their ability to encounter and recognize any lesions in the vascular wall due to a laceration or wound. These platelet recognition properties include the exposure of the subendothelial basement membrane or underlying matrix induced by wounding or endothelial retraction (Menter et al. 1987d; Crissman et al. 1988; Walsh et al. 2015; Kim et al. 2013; Spectre et al. 2012). Platelets can also actively migrate across the inflamed vascular wall in response to stromal cell-derived factor 1 (SDF1 or CXC chemokine ligand 12:CXCL12) and into tumor extravascular spaces (Goubran et al. 2014; Unwith et al. 2015; Schmidt et al. 2012; Kraemer et al. 2010; Brandt et al. 2000; Stone et al. 2012). Platelets can also release SDF1: CXCL12, CXCL1 (GRO-α), CXCL4 (PF4), CXCL5 (ENA-78), CXCL7 (PBP; βTG), and CXCL8 (IL8) among numerous other cytokines and chemokines from storage granules that can potentially initiate the migration and invasion of additional platelets, immune cells (macrophages and leukocytes), endothelial progenitor cells, and tumor cells (Kraemer et al. 2011; Chatterjee et al. 2011; Shenkman et al. 2004; Gleissner et al. 2008). A case for first respondership is further strengthened by the discovery of CXC chemokine receptor 4 and 7 (CXCR4, CXCR7), the cognate receptors for SDF1: CXCL12 on platelets (Rath et al. 2014, 2015; Rafii et al. 2015; Chatterjee et al. 2014b). Expanding upon the concept

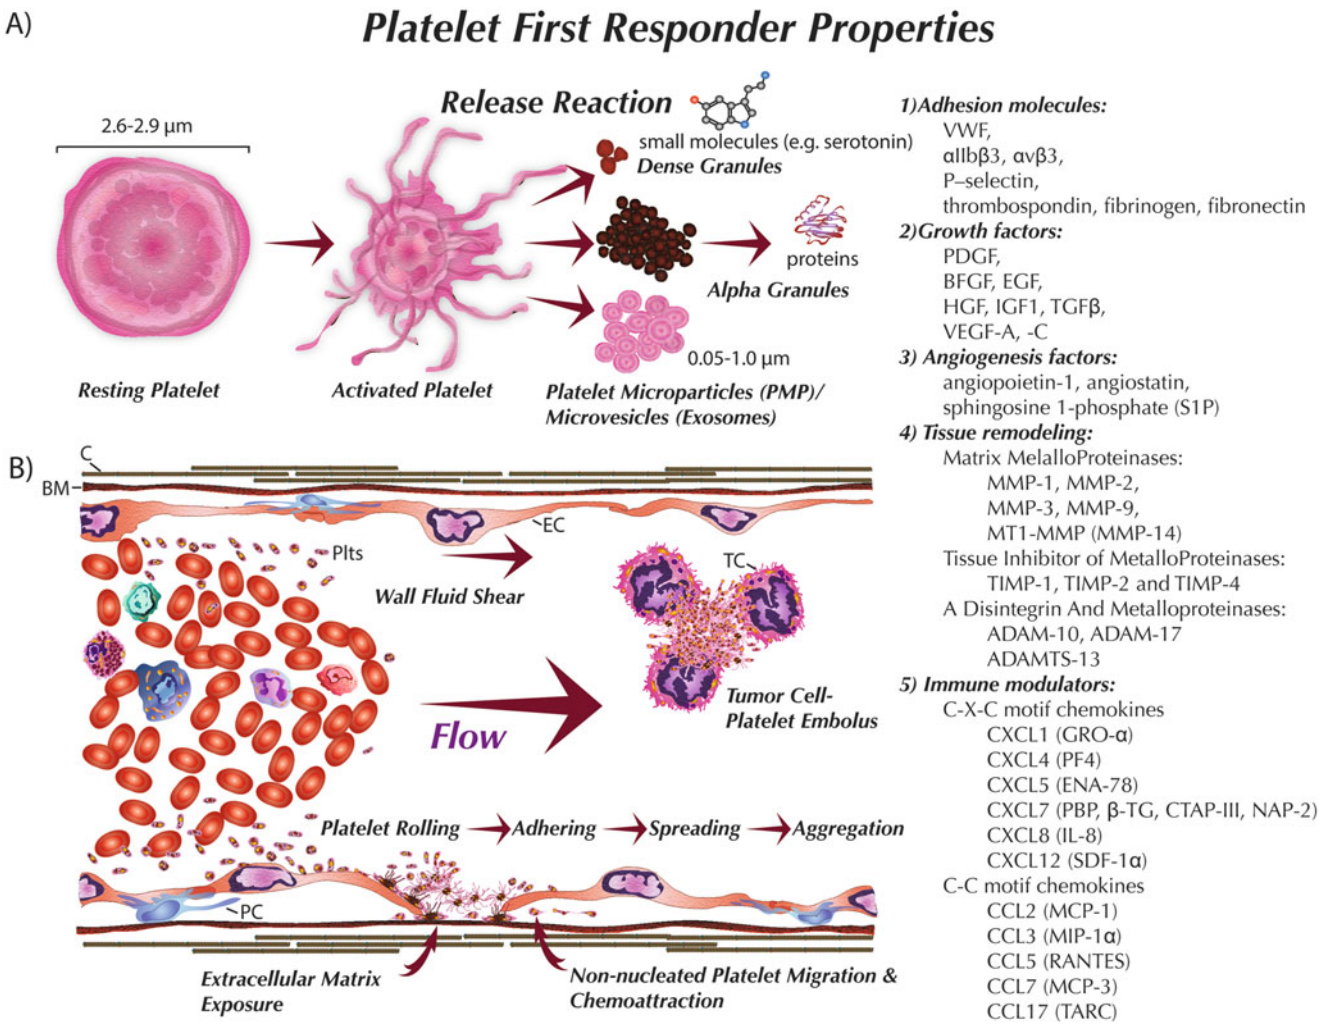

Fig. 1 Platelet first responder properties. (**a**) The activation of platelets is triggered by tumor cells and microenvironmental factors and constitutes an integral part of their first responder properties. This involves shape change and the release reaction. Multiple components that are released into the microenvironment include dense granules, alpha granules, and platelet microparticles (PMP) or microvesicles. The factors released include (1) adhesion molecules, (2) growth factors, (3) angiogenesis factors, (4) tissue remodeling factors, and (5) immune modulators, among others. (**b**) Due to their biophysical and biological properties, platelets accumulate near blood vessel walls within the fluid shear parameters of flowing blood. This enables them to elicit first responses to lesions in the vasculature and the exposure of extracellular matrix. This can lead to the migration of nonnucleated platelets into the perivascular space. As tumor cells enter the blood stream, they can interact with platelets to form heterotypic emboli. *EC* endothelial cell, *PC* pericyte, *BM* basement membrane, *C* collagen, *TC* tumor cell, *PLT* platelet

of migration during potential first responses, platelets are ideally suited for movement because of the highly active cytoskeletal responses linked to activation, adhesion, and aggregation (Menter et al. 1987d, e, 2014; Chopra et al. 1992; Bennett et al. 1999; Jackson et al. 2000; Machlus and Italiano 2013; Qi et al. 2015). Together with an active cytoskeleton, platelets are more streamlined, not only because they are small in size and have minimal displacement volume, but they are also unencumbered by the presence of nuclei, which limits the migration of other immune cells (Breckenridge et al. 2010; Ellingsen et al. 2000; Friedl et al. 2011). The lack of nuclei may also limit the distance that platelets can move into tissue; because of limited protein synthesis capabilities, they cannot indefinitely sustain the replacement of proteins (Bruce and Kerry 1987; Borisova and Markosian 1977). In addition as part of their immune surveillance properties, platelet can also recognize foreign bodies or invading pathogens (Menter et al. 2014; Rossaint and Zarbock 2015; Garraud et al. 2011; von Hundelshausen and Weber 2007). Due to these combined properties, during metastasis, circulating platelets can also elicit a first response to the exposure, sloughing, or active invasion of tumor cells into the blood stream at primary tumor sites. Obstruction of blood flow and angiogenesis associated with primary tumor growth are likely to further enhance the probability of platelet-tumor cell encounters through membrane interactions (Horejsova et al. 1995; Benazzi et al. 2014; Fein and Egeblad 2013). The net result is likely to be platelet activation either to

subdue cells at the primary site or generate tumor cell-platelet emboli in circulation (Menter et al. 1987b, 2014; Crissman et al. 1988). Based on such significant numbers in circulation, small size, biophysical shear properties, adhesion, aggregation, and streamline migration properties, platelets are well suited to serve as "first responders" to a variety of pathologic stimuli, including metastasis.

Tumor Cell: Migration, Invasion, and Intravasation

The proliferation and migration of cancer cells within primary tumors drives a number of events that can impact metastasis (Starke et al. 2014; Gritsenko et al. 2012; Friedl et al. 2012, 2014; Haeger et al. 2014). Direct impact can occur by shedding, sloughing, or active entry of tumor cells into the blood vessels. Based on single cell profiling of circulating tumor cells (CTCs), there is a large diversity of cells found in the circulation that reflect tumor heterogeneity (Deng et al. 2014; Powell et al. 2012). Within the diversity spectrum, CTCs also frequently exhibit stem cell properties (Tang et al. 2015). A variety of triggers can initiate entry of CTCs into the circulation. For example, decreased availability of blood vessels can increase the induction of hypoxia as tumors outgrow their blood supply and release of angiogenesis or wounding related factors (Pasula et al. 2012; Hellberg et al. 2010; Carmeliet 2005). These factors stimulate the formation of new blood vessels that are typically abnormal and leaky, enabling entry of tumor cells into the blood stream (Keskin et al. 2015; Nagy et al. 2012; Fukumura and Jain 2008). Although not extensively studied, there is also potential for leakage or migration of platelets into the tumor that may further enhance the angiogenesis/leaky blood vessel genesis cycle (Kisucka et al. 2006; Goubran et al. 2014; Schumacher et al. 2013; O'Byrne and Steward 2001). More aggressive tumor cells that enter the circulation often undergo epithelial-mesenchymal transition (EMT) (Satelli et al. 2015). In fact, direct signaling between platelets and cancer cells induces an EMT and promotes metastasis in vitro and in vivo (Labelle and Hynes 2012; Labelle et al. 2011; van Es et al. 2014). Cells with EMT characteristics are more fibroblastic in morphology and are typically much more motile and invasive as a result (Labelle et al. 2011; Labelle and Hynes 2012). These EMT cells are prone to actively invade blood vessels by using matrix metalloproteinase (MMP) to digest the extracellular matrix and basement membrane of blood vessels (Nistico et al. 2012). As part of the invasion process, interactions between platelets and tumor cells increase the production of MMP-9 (Labelle et al. 2011). This vascular tumor cell invasive process is termed intravasation and is considered an early dissemination step of the hematogenous metastatic cascade (Fidler 1978).

Tumor Cell-Platelet Recognition/Interaction: A Two-Way Street

Surface receptors abound on both platelets and tumor cells that trigger the primary response mechanisms which drive biologic function (Goubran et al. 2014; Menter et al. 2014). In the case of a nucleated platelets, the lack of nuclei and restricted protein synthesis capabilities limit the adaptation dynamics of platelet surface receptor expression, which is generally established during platelet genesis by megakaryocytes in the bone marrow (Menter et al. 2014). The genesis of heterogeneous populations of platelets that contain carbon copy surface receptor subsets from specific megakaryocytes capable of adapting to disease has not been well established but could have a key impact on cancer if this were true (Bakchoul and Sachs 2015; Penington et al. 1976). In contrast to platelets, nucleated tumor cells have both surface and nuclear receptors that respond to a variety of molecules. Tumor cells also retain the capacity to replace or increase receptor expression by upregulating gene expression and new protein synthesis as they adapt to their microenvironment (Menter et al. 2014).

Integrin and Collagen Receptors

Platelet-tumor cell encounters can be initiated by surface contacts. Integrins are one class of surface receptor molecules that interact with certain extracellular matrix proteins or by direct interactions and consist of α-subunit and β-subunit heterodimer complexes (Fig. 2a) (Menter and Dubois 2012). From the platelet side (pink text), integrin heterodimer receptor complexes include those for vitronectin (α_v/β_3:ITGAV/CD61), fibrinogen (α_{IIb}/β_3:CD41/CD61), laminin (α_2/β_1:CD49b/CD29), and fibronectin (α_5/β_1:ITGA5/CD29) (Menter et al. 2014; Grossi et al. 1987). On the tumor cell side (purple text), many of the same integrin heterodimer complexes can be involved in binding these matrix proteins along with other classes of integrins (Menter and Dubois 2012).

Additional matrix protein receptors include those for collagens. On the platelet side, in this case, collagen receptors are relatively unique to platelets that include GP_{Ib} complexes (consisting of GP_{IX}, $GP_{Ib\alpha}$, $GP_{Ib\beta}$, and GP_V subunits) as well as GP_{VI} (Menter et al. 2014). Tumor cells by contrast can express the entire range of collagen receptors including α_2/β_1 (Menter and Dubois 2012).

Cell Adhesion Molecules, Selectins, and Mucins

Cell adhesion molecules (CAMs) are transmembrane proteins that bind to extracellular matrix and cell-cell adhesion (Fig. 2b). The primary CAM expressed on platelets that

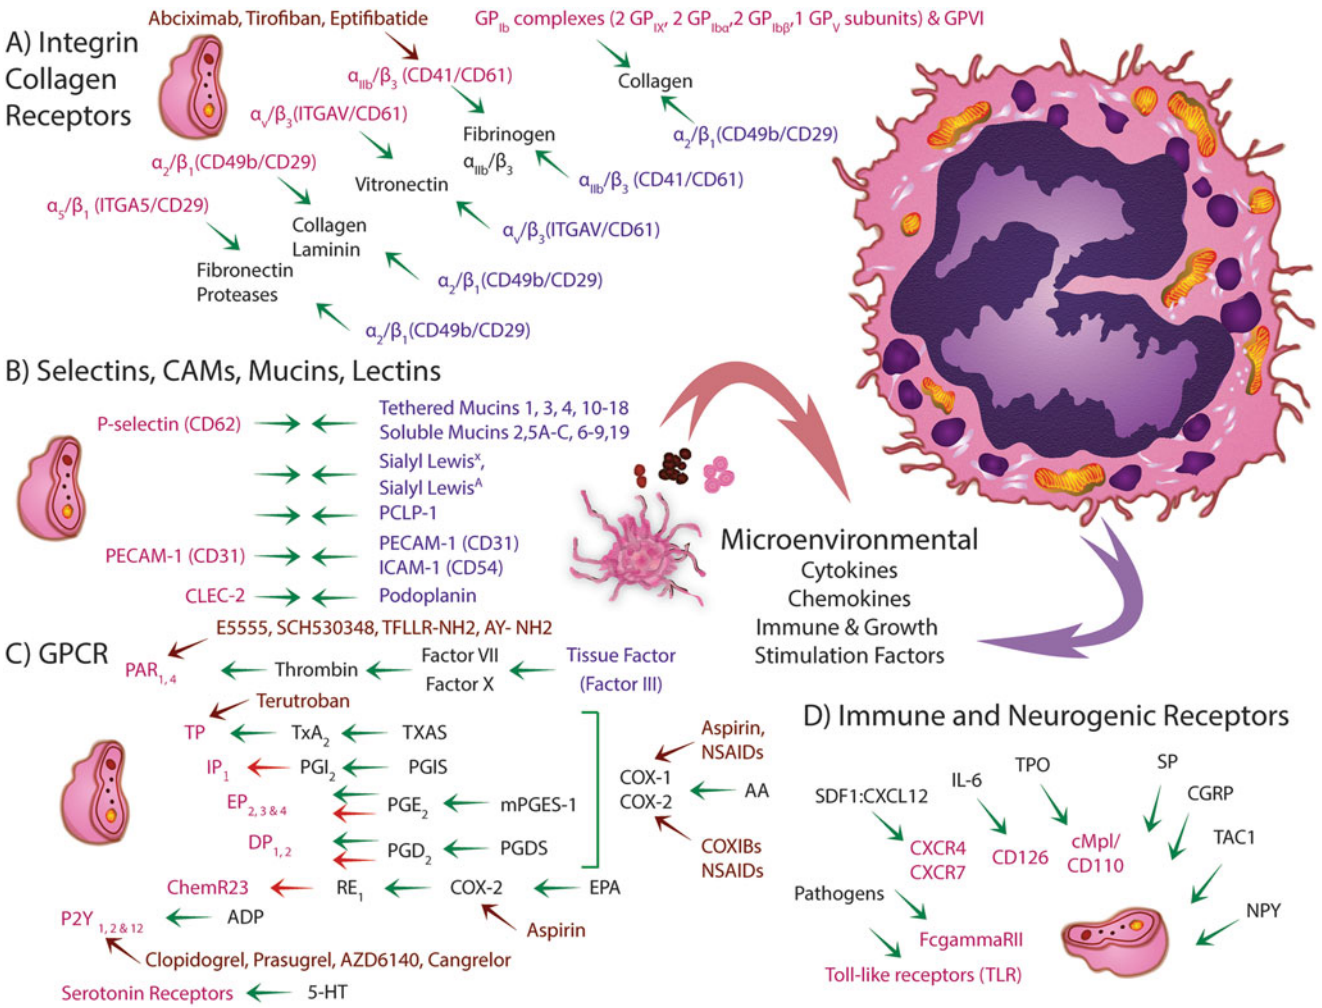

Fig. 2 Receptor and factors that mediate platelet-tumor cell interactions. Integrin and collagen receptors mediate cell-cell interactions between platelets and tumor cells along with collagen and extracellular matrix (ECM) proteins. (**a**) Platelet GPIb complexes recognize vWF tethers, along with thrombospondin, thrombin, $\alpha_M\beta_2$ integrin, kininogen, and clotting factors XI and XII. The GPIb complex consists of two sets of GPIX, GPIbβ, and GPIbα along with a centrally situated GPV protein. Adhesive contacts with collagen exposed by tumor cells are stabilized by GPVI. The $\alpha_{IIb}\beta_3$ integrin has the widest range of interactions and binds to fibrinogen, fibrin, fibronectin, vitronectin, thrombospondin, and vWF. Platelet $\alpha_{IIb}\beta_3$ integrin inhibitors include abciximab, tirofiban, and eptifibatide. Additional platelet and tumor cell integrins include: α_v/β_3(ITGAV/CD61; vitronectin receptors), α_2/β_1(CD49b/CD29; collagen, laminin receptors), and α_5/β_1 (ITGA5/CD29; fibronectin, protease receptors). (**b**) Selectins, cellular adhesion molecules (CAMs), mucins, and lectins can profoundly influence platelet-tumor cell interactions. P-selectin binds to a variety of carbohydrate-rich molecules including: Sialyl Lewis^x or Sialyl Lewis^A as well as tethered (1,3,4,10-18) or soluble (2,5A-C, 6-9,19) mucins and podocalyxin-like protein 1 (PCLP1). Podoplanin on tumor cells can interact with CLEC-2 on platelets. CAMs such as PCAM-1 (CD31) and ICAM-1 (CD54) also regulate platelet tumor cell interactions. (**c**) G protein-coupled receptors (GPCRs) mediate a wide variety of biological interactions. Tissue factor (thromboplastin or factor III) can form complexes with factor VII and factor X to generate thrombin that in turn binds to and activates protease-activated receptors (PAR) 1 or 4 on platelets, which can be inhibited by PAR-specific inhibitors, E5555, and SCH530348. Bioactive lipids also alter platelet-tumor call interactions. Arachidonic acid (AA) is converted by cyclooxygenase 1 and 2 to prostaglandins (PG) and are inhibited by aspirin, NSAIDs, and COXIBs. COX inhibition inhibits multiple downstream steps in the PG cascade. The key target includes the primary platelet-activating pathway: thromboxane A_2 synthase (TXAS) > TxA_2 > TxA_2 receptor (TP) that can be inhibited by a receptor antagonist, terutroban. This activation is countered by the endogenous prostaglandin I_2 synthase (PGIS) > PGI_2 > PGI_2 receptor (IP) inhibition. Other arms of the PG pathway also influence these heterotypic interactions. Another endogenous inhibitor includes resolvin-E1, a product of eicosapentaenoic acid (EPA). Nucleotide receptors can also activate platelets ADP/purinergic G protein-coupled receptors 1 and 12 (P2Y 1, 2 and 12) that are inhibited by clinically relevant receptor antagonists: clopidogrel, prasugrel, AZD6140, and cangrelor. Serotonin (5HT) receptors are also influenced by the uptake and release of 5-HT by platelets. (**d**) Immune receptors are involved in responses to pathogens, including FcgammaRIIB and toll-like receptors (TLR). Platelet genesis is influenced by IL-6 receptors CD126 and thrombopoietin (TPO) receptors cMpl/CD110. Platelet chemotaxis and migration are influenced by stromal cell-derived factor 1 (SDF1 or CXC chemokine ligand 12:CXCL12) through CXCR4 and CXCR7 receptors. Neuropeptides that include substance P (SP), calcitonin gene-related peptide (CGRP), and neurokinin A (NPY) stimulate inflammation when released into the microcirculation, where platelets are key responders that react by modulating arachidonate metabolic pathways. In terms of angiogenic response, the platelet-derived form of the sympathetic neurotransmitter neuropeptide Y (NPY) induces vasoconstriction and ischemic angiogenesis. *Pink text* platelet receptors and factors, *purple text* tumor cell receptors and factors, *maroon text and arrows* inhibitors, *green arrows* stimulation or interaction, *red arrows* inhibition

regulates binding to tumor cells is relatively uniformly expressed (PECAM-1:CD31) (Pang et al. 2015a; Coupland and Parish 2014; Aceto et al. 2014). On the tumor cell side, the expression of surface receptors is not as uniform and can vary extensively with tumor heterogeneity and adaptability (Gunning et al. 2008; Moins-Teisserenc et al. 2015; Raeisossadati et al. 2011). These tumor cell receptors include PCAM-1:CD31, intercellular (ICAM-1:CD54), and epithelial (EpCAM: CD326). Selectins are another family of CAMs consisting of single-chain transmembrane glycoproteins with lectin and cell adhesion properties that bind carbohydrate. Platelets express P-selectin (CD62), which interacts with a variety of carbohydrate-rich molecules produced by tumor cells that include numerically identified mucins that are either tethered (1, 3, 4, 10–18) or free (2, 5A–C, 6–9, 19). Some reports also show evidence of platelets actively recruiting ovarian cancer cells and upregulating tissue factor (Orellana et al. 2015). P-selectin also interacts with Sialyl Lewis^x or Sialyl Lewis^A as well as podocalyxin-like protein 1 (PCLP1) expressed by tumor cells. Platelets can also express C-type lectin receptor 2 (CLEC-2), which interacts with podoplanin on tumor cells (Menter et al. 2014; Goubran et al. 2015).

G Protein-Coupled Receptors (GPCR)

A series of cell-signaling G protein-coupled receptors (GPCRs) can help mediate interactions between platelets and tumor cells (Fig. 2c). Once again on the platelet side, the receptor/signaling networks are very complex (Boyanova et al. 2012; Menter et al. 2014). Tissue factor (thromboplastin or factor III) can form complexes with factor VII and factor X to generate thrombin, which binds to and activates protease-activated receptors (PAR) 1 or 4 on platelets (Menter et al. 2014; Goubran et al. 2014). Tissue factor-dependent thrombin is also enhanced by phospholipid-esterified eicosanoids in agonist-activated platelets (Thomas et al. 2010). The 12-lipoxygenase arachidonate metabolite, 12(S)-HETE, is a bioactive lipid that contributes to endothelial cell retraction as a free acid (Honn et al. 1994). However in its esterified form, after platelet activation, it appears to contribute to coagulation as a result of its translocation to the platelet outer surface. This is supported by the observation that in Scott syndrome, platelets that are defective in cell surface coagulation, the esterified HETE is not presented to the cell surface despite being made to the same degree as in thrombin-stimulated platelets from normal patients. Both the PAR1 and PAR4 agonists (TFLLR-NH_2 and AY-NH_2, respectively) stimulate esterification of 12(S)-HETE with PC and PE to a similar degree (Thomas et al. 2010).

Prostaglandin (PG) receptors are prominent GPCRs expressed by platelets that respond to PGs, which are also important bioactive lipids that profoundly alter platelet function. The PG receptor for thromboxane A_2 (TxA_2), for example, is among the strongest agonists to stimulate platelet activation via thromboxane receptors (TP) (Fontana et al. 2014; Gleim et al. 2013). A differently structured PG is prostaglandin I_2 (prostacyclin) that binds to a separate prostaglandin I_2 receptor (IP_1) and exhibits the strongest inhibition of platelets (Honn et al. 1981; Hubertus et al. 2014). Platelets also express PGE_2 receptors (EP 2, 3 and 4) and PGD_2 receptors that can activate or inhibit platelet function (Petrucci et al. 2011; Cooper and Ahern 1979; Hubertus et al. 2014). Platelets also express additional bioactive lipid receptors. One orphan receptor, *chem*erin *r*eceptor *23* (ChemR23; chemokine-like receptor1: CMKLR1) binds resolvin E_1, a bioactive lipid synthesized from ω3-polyunsaturated fatty acid eicosapentaenoic acid (EPA) found in fish oil that inhibits ADP-induced platelet activation (Fredman et al. 2010; Petrucci et al. 2011). This receptor also serves as a chemokine (C-C motif) receptor-like 2 (CCRL2) that binds chemerin contained in platelets, an adipokine/chemoattractant that has reported roles in inflammation, adipogenesis, and insulin resistance (Du et al. 2009). Tumor cells by contrast express a wide variety of PG receptors depending on tissue origin. Both cyclooxygenase 2 (COX-2) and microsomal PGE_2 synthase1 (mPGES1) are commonly upregulated in cancer, and the production of PGE_2 activates EP receptors (Menter et al. 2010).

Platelets express a number of additional GPCRs. These include thrombin/protease-activated receptors 1 and 4 (PAR 1 and 4) along with ADP/purinergic G protein-coupled receptors 1, 2, and 12 (P2Y 1, 2, and 12) (Franchi and Angiolillo 2015). Both sets of receptors typically trigger platelet activation, and a variety of clinically relevant inhibitors exist for target intervention (Raju et al. 2008). PAR1 and PAR4 are activated following thrombin cleavage that exposes a tethered ligand, which binds to PAR and causes a conformational change and interactions with G proteins (Fu et al. 2015; Wallace and Smyth 2013). Platelet PAR activation can lead to platelet aggregation and thrombosis as well as neutrophil recruitment (Fu et al. 2015; Wallace and Smyth 2013). In contrast, the binding of ADP to P2Y receptors mobilizes intracellular calcium ions via activation of phospholipase C that activates platelets (Cattaneo 2015; Liverani et al. 2014) along with stimulating tumor-cell transendothelial migration and metastasis (Schumacher et al. 2013).

Neurogenic Inflammation and Platelets

The connection between receptor-mediated neurogenic inflammation and cancer is being actively investigated for its role both in potentiating local tumor growth and perineural cancer invasion (Stopczynski et al. 2014; Liebig et al. 2009; Black 2002). Substance P (SP), calcitonin gene-

related peptide (CGRP), and neurokinin A (TAC1) are neuropeptides that stimulate inflammation when released into the microcirculation, where platelets are key responders that react by modulating arachidonate metabolic pathways (Gecse et al. 1999). In terms of angiogenic response, the platelet-derived form of the sympathetic neurotransmitter neuropeptide Y (NPY) is required for capillary angiogenesis during late-phase recovery from ischemic injury (Tilan et al. 2013) and is also produced in animals with hypertension (Ogawa et al. 1992), a condition whose association with cancer has long been suspected (Hamet 1996; Stocks et al. 2012). As a number of cells upregulate NPY to promote metastasis and NPY receptor has been described in the context of its role in cancer, it is conceivable that platelet-derived NPY provided through platelet-tumor cell interactions may also contribute to metastasis (Hong et al. 2015; Medeiros et al. 2012; Magni and Motta 2001).

Serotonin Receptors

Platelet dense granules contain serotonin (5-HT) that is taken up through serotonin transporter (SERT) activity to regulate 5-HT circulating levels (Mauler et al. 2015; Jedlitschky et al. 2012; Linder et al. 2007). More than 95 % of total body 5-HT is synthesized in the enterochromaffin cells of the intestine. Once released from platelets following stimulation, 5-HT binds to cognate receptors and induces vasoconstriction (Mauler et al. 2015; Jedlitschky et al. 2012; Linder et al. 2007). The role of platelet serotonin in malignancy has been pondered for decades (Crawford et al. 1967). Platelet-derived serotonin has been linked to tissue fibrosis (Dees et al. 2011) [considered a form of EMT, reviewed in Tucker and Honn (2013), Crooks et al. (2014), Lopez-Novoa and Nieto (2009)], where platelet aggregation has also been described (Kahaleh et al. 1982). Furthermore, serotonin may be a marker for hepatocellular carcinoma (Pang et al. 2015b; Pai et al. 2009) and has been proposed as a contributing factor to breast cancer (Pai et al. 2009). Platelet serotonergic mechanisms have also been invoked in bladder cancer (Pawlak et al. 2000).

Immune Response Receptors

Additional critical receptors that can impact interactions between platelets and tumor cells include those influencing immunomodulation (Fig. 2d). Platelets express a wide range of receptors that interact with pathogens (Hamzeh-Cognasse et al. 2015) including complement. These receptors include: FcγRII, toll-like receptors (TLR), and also integrins conventionally described in the hemostatic response, such as $\alpha_{IIb}\beta_3$ or GP_{Ib} (Hamzeh-Cognasse et al. 2015). Some of these receptors such as Fcγ receptor IIa can mediate platelet-tumor cell cross talk and initiate tumor cell-induced platelet secretion (TCIPS) (Mitrugno et al. 2014). Interactions with histocompatibility antigen also influence platelet behavior in cancer patients, but this has not been extensively studied (Messerschmidt et al. 1988). Also as previously mentioned, chemokine/cytokine release and subsequent binding to immune receptors on platelets or other cells in the local or systemic environment can stimulate the migration and growth of a variety of cells (Kraemer et al. 2011; Chatterjee et al. 2011, 2014a, b; Shenkman et al. 2004; Gleissner et al. 2008; Rath et al. 2014, 2015; Rafii et al. 2015).

Cancer-Induced Thrombocytosis

Finally, cancer-induced thrombocytosis significantly increases the number of circulating platelets and is linked to tumor cell proliferation (Bouvenot et al. 1977; Honn et al. 1992; Levin and Conley 1964; Cho et al. 2012). This constitutes an important link to Trousseau's syndrome, but the mechanisms responsible remained poorly understood until recently (Stone et al. 2012) when a multicenter study involving 619 ovarian cancer patients examined the associations between platelet counts and disease outcome (Stone et al. 2012; Davis et al. 2014). During this study, thrombocytosis was elevated in association with circulating levels of thrombopoietin (TPO) and interleukin-6 (IL-6). This elevation was associated with advanced disease and shortened survival in ovarian cancer patients and was verified in orthotopic mouse models (Stone et al. 2012). In pancreatic cancer studies as well, paraneoplastic thrombocytosis predicts poor prognosis in patients with locally advanced disease (Chadha et al. 2015). These tumor-liver-bone marrow-platelet feedback mechanisms are thought to occur through IL-6 receptors: CD126 (Marino et al. 2013) and TPO receptors: cMpl/CD110 (Hitchcock and Kaushansky 2014).

Anticoagulant Therapy for VTE Prevention in Cancer Patients

It is estimated that individuals with cancer have a fivefold higher incidence of venous thromboembolic events (VTEs) than the general population (Chao et al. 2011). Chemotherapy can also contribute to elevated levels of thrombosis. In healthy individuals, venous thrombosis can be the first manifestation of malignancy. Since the 1970s when the Veterans Administration Cooperative Study Program first tested warfarin in cancer patients, many other studies have examined agents that interrupt the coagulation pathway as a means to attenuate VTEs and impede cancer progression (Chao et al. 2011). Unfortunately, the doses of warfarin required to achieve therapeutic results were not without side effects

(Zacharski et al. 2005), and heparin required continuous intravenous administration (Hull et al. 1986). As a result of numerous clinical trials, low molecular weight heparin (LMWH or nadroparin) replaced unfractionated heparin (UFH) nearly 20 years ago as the preferred treatment and prophylaxis agent for several reasons (Chao et al. 2011; Salzman et al. 1980). Its chemical structural properties allow it to specifically inhibit factor Xa without all of the off-target serine protease inhibition seen with UFH. Compared to UFH, LMWH is easier to administer and significantly lowers recurrent thrombosis, major bleeding, and mortality (van Dongen et al. 2004). There is some suggestion that the beneficial effects of LMWH in treating cancer patients may be direct against the tumor cells in addition to the anticoagulant effect (Barni et al. 2014). Even with these advances and new reagents, a major concern to consider is the potential to induce heparin-induced thrombocytopenia (Wharin and Tagalakis 2014; Greinacher 2015).

To Decorate, Cloak, or Hold Tumor Cells: That Is the Question

As part of their function in immune surveillance, platelets interact with viral particles, bacteria, and parasites as well as virally transformed tumor cells (Chabert et al. 2015; Hamzeh-Cognasse et al. 2015; Kofman et al. 2013; Ahmed et al. 2014). Many of these interactions essentially help to decorate pathogens and trigger platelet aggregation and the release of factors that stimulate leukocyte activation and neutrophil extracellular trap (NET) formation (Hamzeh-Cognasse et al. 2015). In contrast, tumor cell-platelet interactions are postulated to suppress immune recognition/cytotoxicity and promote arrest at the endothelium or entrapment in the microvasculature. These responses support survival and spread of cancer cells and the establishment of secondary lesions. The current dogma suggests that once tumor cells enter the circulation, they can become enveloped or decorated by a coating of platelets that shields them from recognition by cytotoxic immune cells. While this notion has received support from numerous investigators, it may not be exactly what occurs. When examining heterotypic aggregates that formed during tumor cell-induced platelet aggregation (TCIPA), the platelets tend to cluster at the center, not the external surfaces (Menter et al. 1987a, c) (Fig. 3). In most cases the tumor cells are not completely enveloped enough following TCIPA to fully encase and hide the tumor cells from immune cells (Menter et al. 1987a, c, e). Furthermore, from a logistical standpoint, the feasibility of completely covering the large tumor cell surface area with much smaller platelets is in doubt.

Platelet Changes in Cancer Patients

Recent studies have demonstrated that there are profound ultrastructural changes in platelets from cancer patients as compared to normal controls or individuals with benign disease. Electron cryotomography (cryo-ET) was used to examine platelets from patients with invasive ovarian cancer and controls (either benign adnexal mass or free from disease). Significant morphological differences were detected between the cancer and control platelets including disruption of microtubules as well as altered numbers of mitochondria (Wang et al. 2015). Furthermore, RNA-seq studies have revealed that molecular pathway changes in tumor-educated blood platelets (TEPs), thus connecting them to systemic and local responses to tumor growth resulting in altered RNA profiles (Best et al. 2015).

Heterotypic Emboli, Platelet Interactions, and Extensive Membrane/Structural Changes

The heterotypic contacts between platelets and tumor cell lead to dynamic focal interactions during TCIPA (Menter et al. 1987a, c, e). As platelets cluster centrally during heterotypic aggregate formation, they change shape and degranulate and release proteins, growth factors, bioactive lipids, and other factors that recruit additional platelets toward the central core of the interaction (Menter et al. 1987a, c, e). Extensive membrane changes occur at the membrane interfaces between platelets and tumor cells. There is very little data on whether the tumor cells or platelets drive these membrane interactions, but they appear to be bidirectional. Extensive membrane/cytoskeletal tumor cell processes heavily interdigitate with a central platelet aggregate, demonstrating a very active process. As these interactions progress, extensive uptake of platelet fragments and mitochondria occurs into the tumor cells in vitro (Menter et al. 1987a, c, e). This interdigitation and uptake of platelet fragments by tumor cells are also observed in vivo following tail vein injections of syngeneic tumor cells into mice (Crissman et al. 1985, 1988; Menter et al. 1987b).

The engulfment of platelets or platelet particles such as mitochondria may be a form of emperipolesis or entosis. These are processes whereby cells take up other cells without degradation with varied outcomes (Xia et al. 2008; Rastogi et al. 2014). This is reminiscent of frustrated phagocytosis where organisms ride along the plasma membrane or become engulfed only to be subsequently released. Some metastatic tumor cells even take on behaviors of M2 polarized macrophages (Caruso et al. 2012; Djaldetti and Strauss 1982).

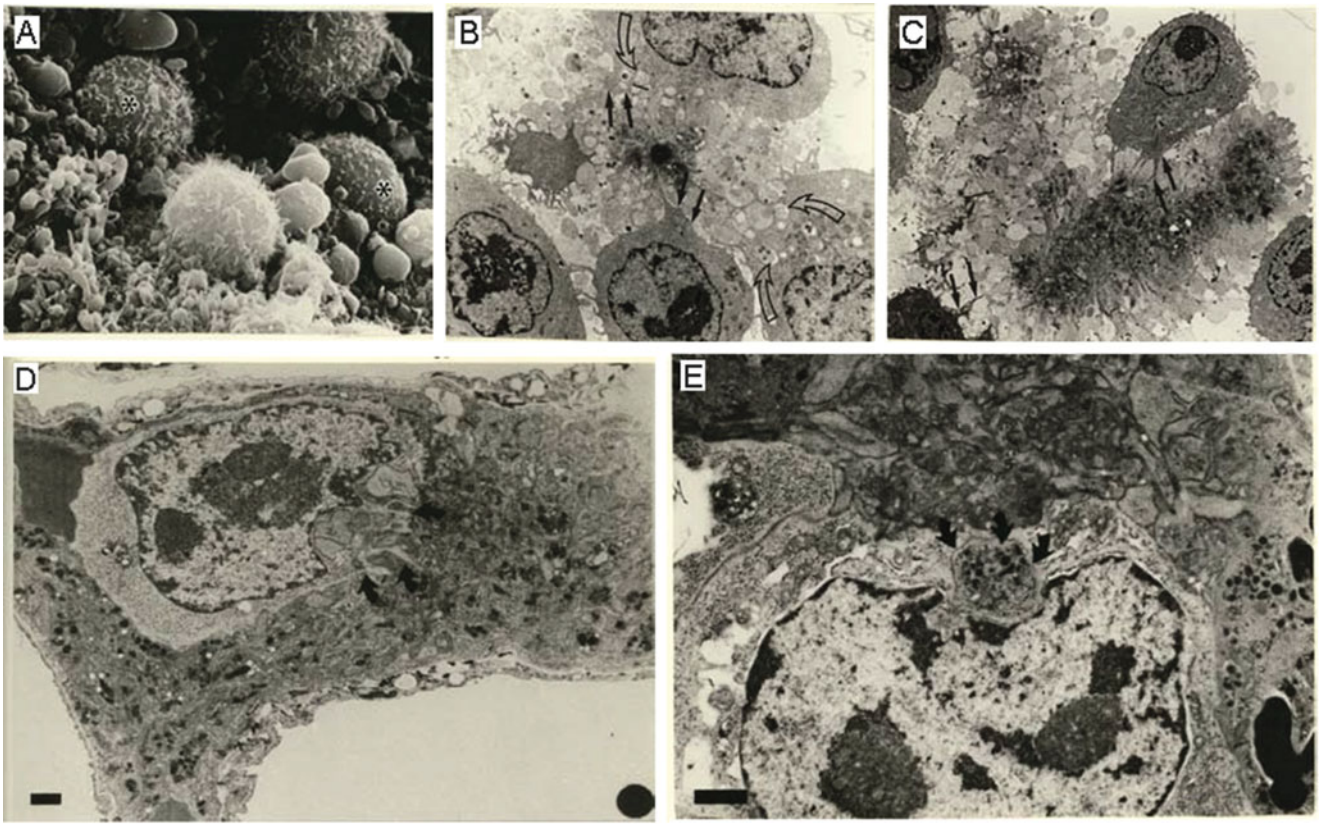

Fig. 3 Early events in platelet-tumor cell interactions. (**a**) Elutriated W256 tumor cells are shown interacting with platelets in an aggregometer cuvette at the plateau phase (10 min). A reduction in tumor cell surface microvilli occurs by this time (*asterisks*, scanning electron micrograph; magnification x3900). (**b**) Elutriated W256 tumor cells project small processes (*arrows*) into platelet aggregates by midphase of aggregation that become more (**c**) prominent and protrude deeper into forming platelet emboli as these interactions plateau (*arrows*) that associates with tumor cell engulfment of platelet fragments (*open arrows*) (transmission electron micrographs; magnifications—(**b**) x3000, (**c**) x4300). (**d**) Elutriated Lewis lung tumor cells form intravascular aggregates in the mouse lung that involves process penetration (*arrows*) into syngeneic C57Bl/6 platelet emboli, which occurs 2 min after tail vein injection and (**e**) engulfing platelet fragments (*arrows*; transmission electron micrographs; magnifications—(**d**) x6800, (**e**) x12,000, *scale bars* 1 μm). (**a–c**) Reprinted from Honn et al. (1983) with permission from S. Karger AG, Basel; (**d, e**) courtesy of Menter

While genomic and epigenetic elements are fundamental to the cancer continuum, the contribution of exosomes/microvesicles, free nucleic acid, and cytoplasmic elements is just as intriguing. It has been suggested that the reaction of the mitochondrial genetic system to genomic (nuclear DNA) stress response genes leads to mitochondrial dysfunction and could account for the marked increase in metabolic diseases and cancer (Wallace 2005; Brahimi-Horn et al. 2015). Studies have demonstrated that tumorigenic phenotypes can be down-modulated when mitochondrial DNA is ablated and can be complemented by reintroduction of mitochondria (Cavalli et al. 1997). Therefore, hyperpolarization of mitochondria in activated platelets and the observation that platelets release mitochondria to potentiate immune response (Zharikov and Shiva 2013; Boudreau et al. 2014) raise the specter that platelet mitochondria potentially make a direct contribution to malignancy by regulating tumor cells. Whether platelet mitochondria compensate for tumor cell mitochondrial deficits or augment some tumor cell function through genetic cross programming remains to be determined. With respect to the latter idea, mitochondrial transcription factor binding sites are seen throughout the nuclear genome. Coordinated regulation of nuclear genes in response to mitochondrial stress or mitochondrial uptake has not yet been established, but it is a topic being scrutinized (Haynes et al. 2013).

Secondary Sites, Exosomes, and Extravasation: Differences or Similarities?

Tumor cell exosomes play key roles in cancer progression and metastasis (Melo et al. 2014, 2015; Kahlert and Kalluri 2013; Milane et al. 2015; An et al. 2015; Robbins and Morelli 2014; Colombo et al. 2014). Functionally, these exosomes can influence the biology of both the local tumoral

and systemic environments (Kahlert and Kalluri 2013). Tumor cell exosome biogenesis often begins with endocytosis, then endosome genesis, followed by the formation of multivesicular bodies (MVBs) or by microvesicle formation (Huber and Holvoet 2015; Zhang et al. 2015). Exosomes formed within MVBs are released following membrane fusion into the surrounding microenvironment or circulation. Locally, release of tumor cell exosomes into the microenvironment can influence proliferation and chemoresistance and initiate fibroblast or immune cell activation and recruitment along with stimulating angiogenesis. Systemically, tumor cell exosomes can stimulate a hypercoagulable state, initiate preneoplastic niches at secondary metastatic sites, recruit bone marrow-derived hematopoietic and immune cells, or elicit immunosuppression (Lima et al. 2013). Classically by contrast, platelets contain numerous electron-dense subcellular organelles called alpha granules, electron-dense and very electron-dense granules, lysosomes, and dense bodies (Fukami and Salganicoff 1977). The many factors contained in these granules constitute what is commonly found in serum used to grow cancer cells in tissue culture and in regenerative medicine (Dhillon et al. 2014; Burnouf et al. 2013; Ross et al. 1978). These organelles are sometimes called secretory granules, since the appropriate stimuli causes degranulation that deposits granule contents in the extracellular surroundings. These organelles were identified and visualized by electron microscopy, microprobe analysis, secretion experiments, and subcellular fractionation studies from patients with platelet storage pool deficiency diseases. In many respects, this degranulation process can be equated with the formation of platelet microparticles (PMP), which are essentially very exosome-like (Goubran et al. 2015; Mezouar et al. 2014). Platelet extravascular migratory behavior and exosome deposition is likely to drive cancer progression or preconditioning of secondary metastatic sites (Goubran et al. 2015). Preventing platelet activation inhibits the P-selectin and integrin-dependent accumulation of cancer cell microparticles and reduces tumor growth and metastasis in vivo (Mezouar et al. 2015).

Blood-borne CTCs are commonly found in the blood stream of patients with metastases (Aceto et al. 2014; Li et al. 2015; Joosse et al. 2015). In a patient study of CTCs isolated from breast and prostate cancer patients, their presence correlated with poor prognosis (Aceto et al. 2014). This study focused on comparing single CTCs to CTC clusters and found that markers for platelets were present in both populations (Aceto et al. 2014). The presence of these clusters was also associated with high plakoglobin expression and poor prognosis (Aceto et al. 2014). Since plakoglobin plays an important role in the regulation of CAM interactions (Ilan et al. 2001; Rival et al. 1996; Reynolds et al. 1992, 1994), its upregulation may influence platelet/tumor cell heterotypic CTC cluster formation. In a separate randomized phase II trial, therapeutically targeting platelet function did not significantly change the number of CTCs in circulation in patients with metastatic breast cancer. Unfortunately, the number of circulating cells was lower than expected, so a more definitive study is needed (Roop et al. 2013). In early mouse studies, although large numbers of CTCs may be present in circulation, only those with specific characteristics survive to establish metastasis (Fidler and Nicolson 1978; Fidler 1975; Hart and Fidler 1980). In other mouse hematogenous metastasis studies, cell arrest at secondary sites precedes the establishment of lesions. This may occur by a variety of mechanisms. Tumor cell interactions directly with the vascular endothelium can initiate the process. In this case, the engagement of platelets can occur during or after tumor cell arrest has occurred, and platelets can fill in around arrested tumor cells. Tumor cell-platelet heterotypic interactions can also occur in suspension in flowing blood to initiate TCIPA. The resulting heterotypic platelet-tumor cell emboli can then undergo attachment or entrapment in secondary organ sites. Platelet-tumor cell emboli initially interact with vascular surfaces at cellular junctions or gaps in the endothelial cell monolayer (Menter et al. 1987e). Platelets are also capable of forming chains that tether tumor cells to these attachment sites (Menter et al. 1987e). As these cellular interactions progress, platelets engage both endothelial cell surfaces and gaps in the endothelial cell monolayer facilitating the linkage to tumor cell membranes (Menter et al. 1987e). In other studies, agent-based, computational, theoretical modeling simulated the basic dynamics of circulating tumor cell adhesion involving endothelial, neutrophil, and platelet interactions and proposed multiple therapeutic targets involving platelets (Uppal et al. 2014). Other studies have utilized intravital microscopy to visualize human red fluorescent protein (RFP) expressing HT29 (RFP-HT29) colon cancer cells injected into the spleens of GFP expressing nude mice (Tanaka et al. 2014). These studies revealed extensive interactions between GFP platelets and RFP-HT29 in liver sinusoids (Tanaka et al. 2012, 2014). Intravital imaging has also been done using a syngeneic C57/Bl6 mouse model, and interactions were shown to involve $\alpha_v\beta_3$ integrins on B16 melanoma cells to $\alpha_{IIb}\beta_3$ on platelets using blocking antibodies (Lonsdorf et al. 2012).

Tumor cells can exit the vasculature at secondary sites (Crissman et al. 1985), and platelets can facilitate this process known as extravasation (Coupland et al. 2012; Crissman et al. 1985; Fein and Egeblad 2013; Pang et al. 2015a; Schumacher et al. 2013). Thrombin activation involving platelet membranes can facilitate the activation of ECM degradation by tumor cells in a P-selectin and

$\alpha_{IIb}\beta_3$-dependent manner (Pang et al. 2015a). Taken together these studies support the notion of platelet involvement in the establishment of hematogenous metastasis.

New Thoughts: Platelets in Premalignancy

So What About Aspirin, Arachidonic Acid, and Omega-3 PUFA?

Meta-analyses of large randomized clinical trials (Bousser et al. 2011; Chan et al. 2012; Chan and Cook 2012; Cuzick et al. 2015; Goldstein and Rothwell 2012; Langley and Rothwell 2013, 2014; Rothwell 2013a) show that aspirin reduces the incidence (Algra and Rothwell 2012), metastasis (Rothwell et al. 2012), and mortality (Rothwell et al. 2012) of gastrointestinal and other cancers, especially adenocarcinomas (Algra and Rothwell 2012; Chan et al. 2012; Cuzick et al. 2015; Langley and Rothwell 2013; Rothwell 2013a, b; Rothwell et al. 2012). Despite substantial cumulative knowledge regarding cancer prevention by aspirin (Umar et al. 2016), little is known about the role of the primary target found in platelets during precancerous lesion development. Aspirin covalently acetylates Ser-530 and irreversibly inactivates platelet cyclooxygenase 1 (DeWitt et al. 1990; Rowlinson et al. 2000), thereby eliminating all downstream prostaglandin production from arachidonic acid by platelets. This includes the key bioactive lipid involved in platelet activation, thromboxane A_2 (TxA_2) (Fontana et al. 2014; Fitzpatrick and Gorman 1977; Hammarstrom and Falardeau 1977). Pronounced elevation of circulating TxA_2 levels accompanies CRC progression in familial adenomatous polyposis (FAP) patients (Li et al. 2015). As a strong platelet TP receptor agonist, TxA_2 produced by TxA_2 synthase in platelets is counterbalanced by an equally strong platelet inhibitory response by IP_1 receptors. IP_1 receptors are activated by PGI_2 that is produced by PGI_2 synthase in endothelial cells lining the vasculature. Both TxA_2 and PGI_2 have epoxide bonds that contain considerable molecular strain, which limits their half-life in circulation. Activation by TCIPA shifts this delicate eicosanoid balance triggering multiple pro-carcinogenic responses centered on platelets.

Diets rich in ω-3 PUFA, EPA, and docosahexaenoic acid (DHA) inhibit carcinogenesis (Holla et al. 2008; Schroeder et al. 2007; Yang et al. 2006, 2014a, b). EPA feeds into the COX-1 and COX-2 pathways to produce TXA_3 and PGE_3 lipid metabolites that are ineffective at PG receptor activation and protect against CVD and lung or colon tumorigenesis (Algra and Rothwell 2012; Chan et al. 2012; Chan and Cook 2012; Cuzick et al. 2015; Goldstein and Rothwell 2012; Holla et al. 2008; Langley and Rothwell 2013, 2014; Liyasova et al. 2010; Macdonald et al. 1999; Pinckard et al. 1968; Rothwell 2013a; Rothwell et al. 2012; Schroeder et al. 2007; Yang et al. 2006, 2014a). Taking aspirin in combination with EPA and DHA leads to the formation of resolvins, maresins, and protectins (Serhan et al. 2006, 2009; Spite et al. 2014; Spite and Serhan 2010; Krishnamoorthy et al. 2015; Serhan 2014). Resolvins were originally named for their ability to resolve inflammation. More specifically, aspirin-inactivated COX-2 generates a longer half-life R-epimer of resolvin-D_1 (Arita et al. 2005; Serhan et al. 2004; Sun et al. 2007) from DHA and resolvin-E_1 from EPA (Dona et al. 2008; Pirman et al. 2013). Although not well studied, this places platelets not only at the center of the metastasis discussion but also the progression of premalignancies.

Leaky Vessels, Extravasation, and "First Response"

The role of angiogenesis in premalignancy remains an important question, particularly how early this change occurs (Menakuru et al. 2008) (Fig. 4). Biomarkers of this process include factor VIII, CD31, and CD34. Increased microvascular density can occur in ductal carcinoma in situ (DCIS) (Menakuru et al. 2008; Sapino et al. 2001). These premalignant lesions range in size from 1 to 1.5 cm (Allegra et al. 2009). Newly formed vessels can be identified by CD105 (Fox and Harris 2004; Smith et al. 2012; Ratajczak et al. 2012; Dubinski et al. 2012; Marioni et al. 2011; Sapino et al. 2001). Platelet-derived thrombospondin 1 helps regulate angiogenesis and serves as a potential biomarker (Zaslavsky et al. 2010). The presence of highly permeable, disorganized, poorly formed, and leaky blood vessels contribute to progression in advanced cancers (Fang et al. 2011). These leaky vessels provide ample opportunity for platelet first responders to extravasate and enter the precancerous microenvironment. Once in the perivascular space, platelet activation triggers the release of growth-promoting factors found in serum. These serum factors are highly likely to provide a permissive and growth-promoting microenvironment for transformation.

Angiogenic and immune stimulation often switch on during premalignancy, before cells achieve the invasive state (Ferrati et al. 2012; Folkman et al. 1989). Many factors influence this switching, including microRNAs (Bergers and Benjamin 2003; Grandis and Argiris 2009). Switching has been elegantly demonstrated in the adenoma-adenocarcinoma transition of colorectal cancer and the transition from DCIS to invasive ductal carcinoma of the breast. Specifically, the initiation of angiogenesis accompanies dysplasia during adenoma formation in colorectal cancer progression (Staton et al. 2007) and hyperplasia during DCIS

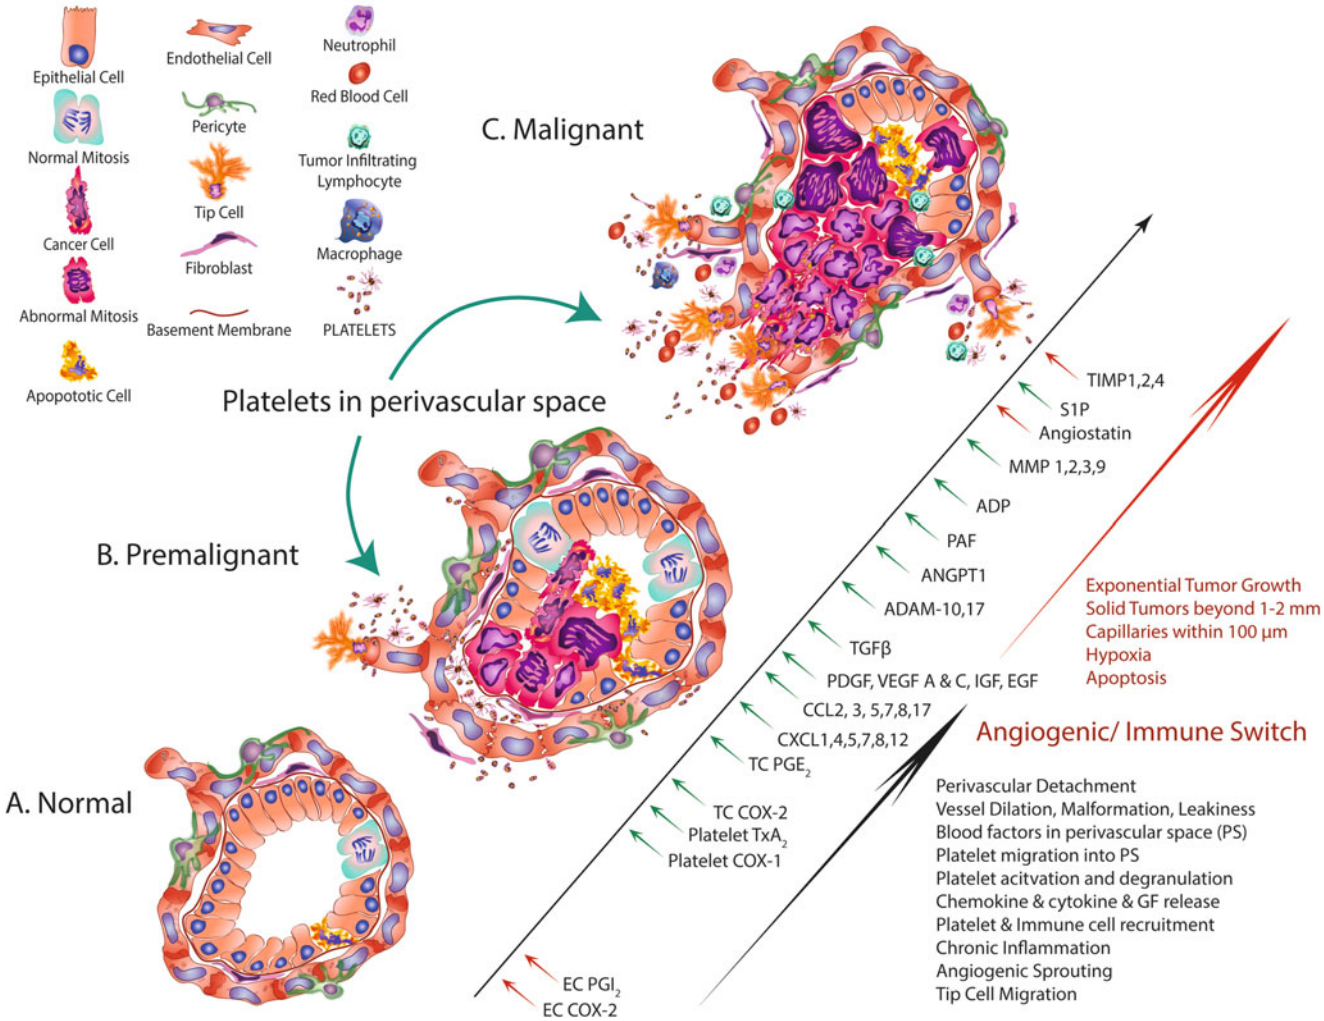

Fig. 4 Platelet influences on angiogenic and immune switches. Angiogenic and immune switches can turn on at different stages of carcinogenesis. (**a**) Biological maintenance of normal tissue involves a delicate balance between cell growth and apoptosis and homeostasis that is regulated by immune surveillance, tissue repair, and immune clearance. (**b**) Premalignant disease may involve the earliest stages of angiogenic and inflammatory switch activation. Premalignancy-associated inflammation triggers immune cell infiltration in response to cytokines and prostaglandins that promotes vessel dilation and the detachment of pericytes from blood vessels. During these early stages of premalignancy, blood factors accumulate in the perivascular space. This provides the opportunity for platelets to migrate into the perivascular space along with activation and the release of platelet granules containing vascular endothelial cell growth factor (VGEF), basic fibroblast growth factor (bFGF), platelet-derived growth factor (PDGF), epithelial growth factor (EGF), and angiopoietin-2 (Ang2) that enhances both angiogenic and immune switch activation. (**c**) The onset of malignancy, heightened hypoxia, and apoptosis further increases vessel leakiness, platelet activation, platelet migration, and granule release. The cycle accelerates as angiogenic sprouting and tip cell-mediated migration into the growing tumor lead to further recruitment of additional platelets, immune cells, and tumor cell migration and proliferation as cancer progression continues

progression to invasive breast cancer (Bluff et al. 2009). Mechanistically, mice that lack histidine-rich glycoprotein (HRG) exhibit an accelerated angiogenic switch and enhanced platelet activation, inducing molecular changes in the pre-tumorigenic environment accompanied by increased survival, angiogenesis, and EMT (Cedervall et al. 2013). Although more studies are needed, these effects suggest an early, vital role for platelets early in the premalignancy to malignancy transition. Abnormal or leaky blood vessels that arise during tumor-initiated angiogenesis provide adequate opportunity for the leakage or migration of platelets into the precancerous microenvironment. Subsequent activation and release of their stroma-stimulating, proangiogenic, chemoattractive, and immunomodulatory contents can then promote precancerous lesion progression as a series of cyclic amplification events. In support of this hypothesis, release of VEGF and other platelet factors occurs during early breast cancer (McDowell et al.

2005), and platelet $GP_{Ib\alpha}$ also increases in invasive intraductal breast carcinoma tissues (Oleksowicz et al. 1997). These early angiogenic and immunogenic switching events during premalignancy suggest that platelets are likely contributors to early cancer progression along with potential targets for early diagnosis (Han et al. 2014).

Immunotherapy?

Platelets are derived from megakaryocytes (Menter et al. 2014; Machlus and Italiano 2013), arising during the process of megakaryopoiesis from hematopoietic stem cell lineage that share commonalities with both lymphoid and granulocytic cells prior to differentiating toward hematopoietic progenitors. Specifically, in the bone marrow, hematopoiesis produces hemangioblasts that give rise to *hematopoietic stem* cells (HSCs) and *multipotent progenitor* cells (MPP) (Deutsch and Tomer 2013; Meng et al. 2012; Thon and Italiano 2010; Akbar et al. 2011). Genesis from MPP forms *common myeloid progenitor* cells (CMP) (Deutsch and Tomer 2013; Akbar et al. 2011; Thon and Italiano 2010; Meng et al. 2012) that give rise to *megakaryocyte-erythroid progenitor* (MEP) cells followed by *megakaryopoietic progenitors* (MKP) (Kanz et al. 1987). MKP then generate immature—followed by mature—megakaryocytes before finally generating platelets (Deutsch and Tomer 2013; Geddis 2010; Machlus and Italiano 2013; Tijssen and Ghevaert 2013; Meng et al. 2012). Immune thrombocytopenia (ITP) involves cellular checkpoints during the normal regulation of immunological self-reactivity and the development of B and T cells (Cines et al. 2009). This may occur through cell deletion, gene editing, induction of anergy, and extrinsic cellular suppression. When immune checkpoints fail, tolerance to self-antigens may be downregulated (Toltl et al. 2011; Cines et al. 2009). Checkpoint failure is a key target of immune checkpoint blockers that are being used in combination with interferon to overcome immune tolerance (Rafique et al. 2015). Importantly, platelet genesis and lineage development are also influenced by interferon (Rivadeneyra et al. 2015; D'Atri et al. 2015). With the advent of immune checkpoint cancer therapy, the influence of these agents may cross over to impact platelet biology and function (Topalian et al. 2015; Miller and Sadelain 2015; Gubin et al. 2014), which may also influence immune-related adverse events that are autoinflammatory in nature (Weber et al. 2015). Most notably, preclinical data demonstrate that pharmacologic inhibition or genetic deletion of COX-1 and COX-2 synergizes with anti-PD-1 blockade to induce the eradication of tumors more effectively than PD-1 treatment alone (Zelenay et al. 2015). Aspirin treatment was highly effective in synergizing with anti-PD1, but platelet function was not followed in these studies and deserves additional study (Zelenay et al. 2015). In view of their "first responder" properties, it is critical to develop a better understanding of this role or potentially harness platelets in some fashion to alter checkpoint blockade. One could envision taking bone marrow aspirates from cancer patients and engineering in vitro cultures of megakaryocytes (Nishikii et al. 2015; Hatami et al. 2015; Meinders et al. 2015; Panuganti et al. 2013; Thiele et al. 2012; Emond et al. 2012; Pallotta et al. 2009) to alter tumor recognition and inflammatory responses and reinfuse these reengineered platelets though adoptive bone marrow transfer.

Platelets: "First Responders" in the Complete Cancer Continuum

Platelets as vital contributors to the early stages of cancer formation are a new concept. Support for this notion comes from a variety of sources. One line of evidence is the long-standing link between chronic inflammation and the risk of developing colon cancer. Patients with inflammatory bowel disease or Crohn's disease, for example, are at high risk for developing colon cancer (Herszenyi et al. 2015; Burisch and Munkholm 2015; Sanduleanu and Rutter 2014). A potential association with platelet biology may be found in mean platelet volume changes that accompany Crohn's inflammatory disease states, among others (Kilincalp et al. 2015; Tang et al. 2015; Huang et al. 2013; Harris et al. 2011). Similarly, changes in mean platelet volume are found during adenoma formation (Kilincalp et al. 2015) along with colorectal cancer (Li et al. 2014; Kemal et al. 2014).

Additional support for this notion comes from $Apc^{min\backslash+}$ mouse crossbreeding with $P\text{-}selectin^{-\backslash-}$ (CD62P) knockout mice, which lack expression on activated platelets and reduced VEGF expression (Qi et al. 2015). These crosses resulted in reduced formation of low- and high-grade adenomas accompanied by decreased vessel density (Qi et al. 2015). This study also examined human adenomas and stages I–IV of CRC progression by IHC for CD41 (integrin GP_{IIb} subunit) positivity. Similar levels of platelet staining were observed in the polyp and stage I CRC tissues (Qi et al. 2015), suggesting that the platelets were already involved at the polyp stage. This CD41 staining increased in intensity with each progressive stage II–IV of CRC tumor development. Our group has also recently observed extravascular platelet structures in $Apc^{min\backslash+}$ polyps (Fig. 5).

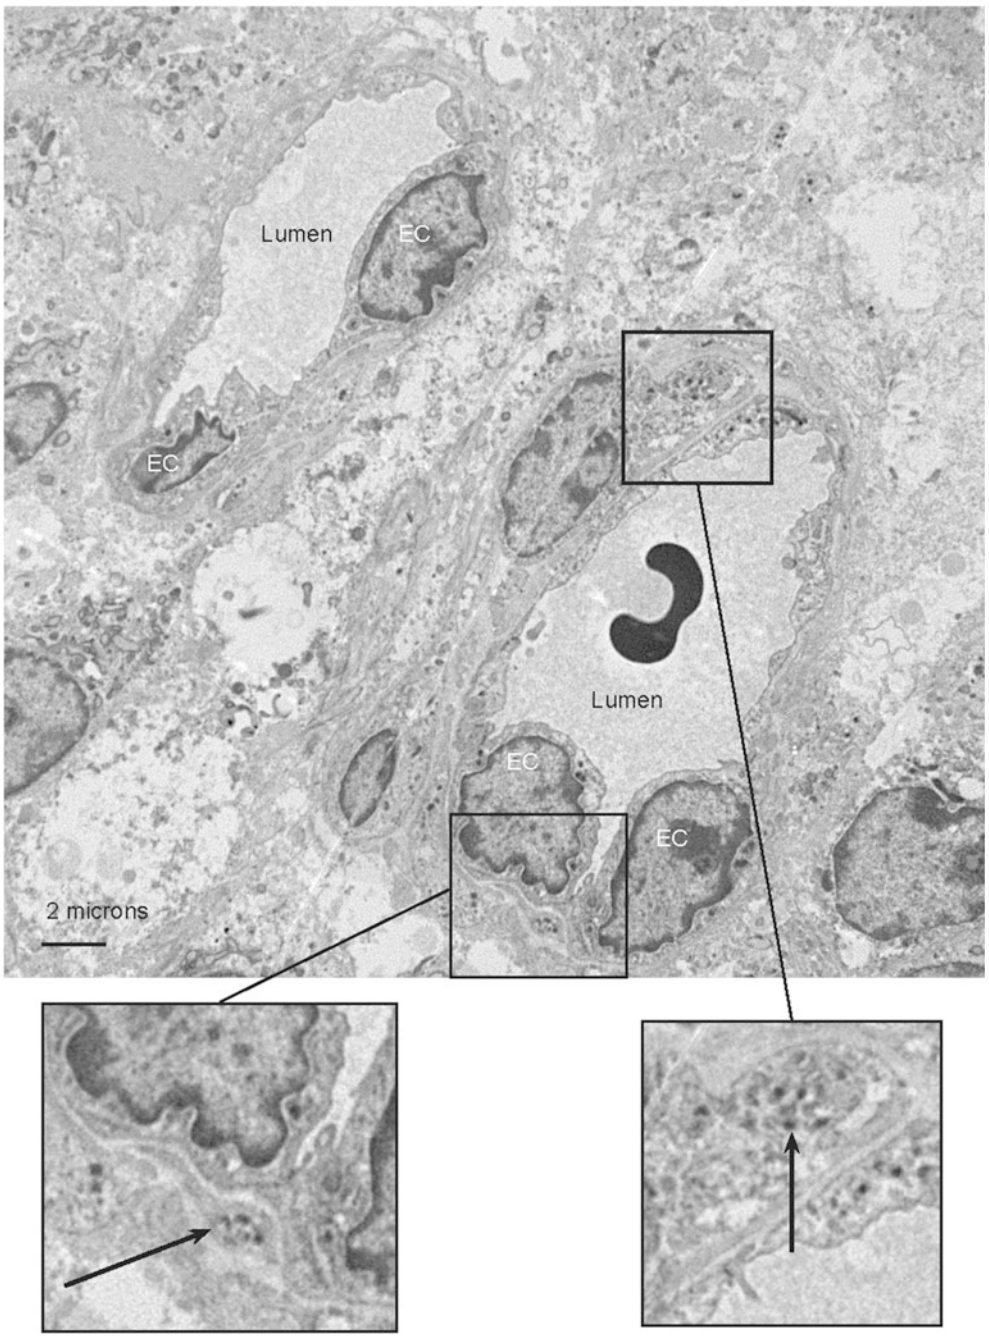

Fig. 5 Platelet migration into adenoma perivascular spaces. Ten-week-old adenomatous polyposis coli $Apc^{min\backslash+}$ mice were euthanized and necropsied, and the intestinal tract was excised and fixed. Adenoma polyps were dissected and processed for transmission electron microscopy. The examination of polyp tissue revealed platelet structures in the perivascular space of blood vessels (*arrows*; *insets*). These platelets were underlying endothelial cells (EC) and had exited the vascular lumen (x4000, *scale bars* 2 μm)

These data, along with our previous studies illustrating the dynamic activation of platelets in heterotypic platelet-tumor cell aggregates and syngeneic intravascular metastasis, highlight a role for platelets throughout the cancer continuum. Collectively, these data strongly suggest that altering the "first responder" capabilities of platelets is an important target for cancer prevention and therapy.

Take Home Messages

- Platelets are "First Responders" as active participants in the hemostasis, wounding, immune, and metastatic processes.
- Platelets are often neglected or overlooked during in vivo experimental or pathologic observations due to their small size and lack of defining nuclei.
- Surface receptors abound on both platelets and tumor cells trigger the primary response mechanisms that drive biologic function.
- When examining heterotypic aggregates that form during tumor cell-induced platelet aggregation (TCIPA), the platelets tend to cluster at the center.
- Platelets can also actively migrate across the inflamed vascular wall in response to a variety of microenvironmental and tumor factors.
- Additional critical receptors that can impact interactions between platelets and tumor include those influencing immunomodulation.
- Platelets serve as "First Responders" in the complete cancer continuum.

Platelets and Inflammatory Disorders of Connective Tissue

Jerry Ware and Steven R. Post

Abstract

The circulating blood platelet as a participant in inflammatory pathways has been the focus of intense investigation and the topic of several reviews and other chapters in this book (Franco et al. Blood. 126:582–588, 2015). Inflammation underlies the pathophysiologic response in many diseases, and therefore defining the role of the platelet in inflammatory responses is paramount to understanding the molecular basis of the disease process (Leslie. Science 328(5978):562–564, 2010). In this chapter, we focus on the historical background describing the role of platelets in connective tissue inflammation, with emphasis on studies linking platelets and rheumatoid arthritis. A link between platelets and the inflammatory response starts with an appreciation for platelets being a specific cellular entity restricted to higher mammals. Lower vertebrates, such as fish and birds, do not have platelets, but instead have a dual-functioning cell, the thrombocyte, that has both immune and hemostatic properties (see Momi and Wiwanitkit 2017). Thus, the divergence of thrombocyte function to multiple cell types, such as neutrophils, monocytes, and platelets, might be expected to result in functional overlap with some similar properties retained by each individual cell type in higher species. The participation of platelets in inflammation needs careful consideration given the widespread use of antithrombotic agents for prevention of cardiovascular events. Understanding the molecular basis of the platelet/inflammatory axis will also ensure the best practice decisions will be made for the treatment of cardiovascular disease and additional inflammatory conditions.

Platelets and Synovial Fluid

Two studies in 1978 surprisingly identified platelet antigen in the synovial fluid of patients with rheumatoid arthritis (Ginsberg et al. 1978; Yaron and Djaldetti 1978). At this time, the biochemical analyses of platelet function were primarily restricted to understanding the role of platelets in hemostasis and thrombosis. With regard to platelet antigen and synovial fluid, it was unclear whether the platelet contributed to the worsening of the disease or had been hijacked for its wound healing properties within a joint undergoing pathologic destruction. As an active participant in vessel healing, the platelet is well known to contain storage granules containing a plethora of growth factors that can stimulate tissue remodeling. So, while platelets were identified in the synovial fluid, whether they were the "yin" or "yang" of the inflammatory process was unknown (Mueller 2013).

A subsequent study in 1981 again reported platelet antigen in the synovial fluid of all 13 patients examined with adult rheumatoid arthritis (Endresen 1981). In contrast, this study reported a near absence of platelets in the synovial fluid from patients with osteoarthritis. Importantly, a positive correlation between the number of platelet aggregates

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_75

and the number of lymphocytes in synovial fluid was also observed (Endresen 1981). Thus, a link between platelets and an autoimmune response began to emerge, but it was not clear whether platelets were impacting rheumatoid arthritis in a positive or negative manner. A larger study followed in 1984 and again confirmed the presence of platelet antigen in the synovial fluid of 110 patients with various forms of arthritis (Farr et al. 1984). Of note, 50/50 patients with rheumatoid arthritis had platelet antigen in the synovial fluid (Farr et al. 1984) In addition, these investigators noted a direct link between circulating platelet count and higher level of platelet antigen in synovial fluid (Farr et al. 1984). Subsequent studies tended to focus on the release of growth factors from the platelet with little consideration as to whether the platelet's major effect in rheumatoid arthritis was "yin," "yang," or both (Endresen and Forre 1992).

Platelet Microparticles in the Synovial Space

Studies in the 1970s and 1980s established the presence of platelet antigen in synovial fluid, but it was not until much later that platelet microparticles were identified as the major contributor to the presence of platelet antigen in synovial fluid (Boilard et al. 2010a).

This observation was based on a careful examination of the platelet antigen and its fluorescence associated with structures smaller than expected for platelets and appearing to be in close proximity, or attached, to neutrophils. Flow cytometry studies confirmed a high level of CD41+ microparticles in the synovial fluid of patients with rheumatoid arthritis, which was not the case in an overwhelming majority of patients with a diagnosis of osteoarthritis (Fig. 1). The microparticles derived from platelets were the most abundant microparticle in synovial fluid supporting a connection between platelets and the pathology associated with rheumatoid arthritis.

The platelet microparticle is a membrane-derived particle released following some level of platelet activation (see Cointe et al. 2017) (Ardoin et al. 2007; Italiano et al. 2010; Pisetsky et al. 2012). It was the laboratory of David Lee (working at Brigham and Women's Hospital in Boston) who made the observation that platelet-specific antigen present in the synovial fluid of rheumatoid arthritis patients was largely restricted to fluorescent microparticles (Fig. 1). Whether the microparticles are generated by intact platelets within the synovial space or generated within the bloodstream and then migrate to the synovial space via interaction with leukocytes is still unknown.

Several mouse models of rheumatoid arthritis exist (Asquith et al. 2009). One of the more widely used models, the K/BxN serum transfer model, mimics many of the salient features of human autoimmune rheumatoid arthritis (Kouskoff et al. 1996). Generating severely thrombocytopenic mice in the K/BxN model established a direct link between joint inflammation and the presence of circulating platelets (Fig. 2) (Boilard et al. 2010a). By examining mice that were deficient in the expression of different platelet proteins, these investigators identified platelet surface antigens that could influence microparticle release. Genetic deficiency of platelet glycoprotein (GP) Ib-IX, the β3 integrin, thromboxane synthase, and COX-1 showed no noticeable difference in the development of arthritis using the K/BxN serum transfer model. In contrast, the absence of the murine platelet GPVI receptor reduced the arthritic phenotype, an effect that was correlated with the reduced ability of exogenous agonists, such as collagen, to stimulate platelet microparticle release (Boilard et al. 2010a). Although the mice still developed an inflammatory joint, the severity of

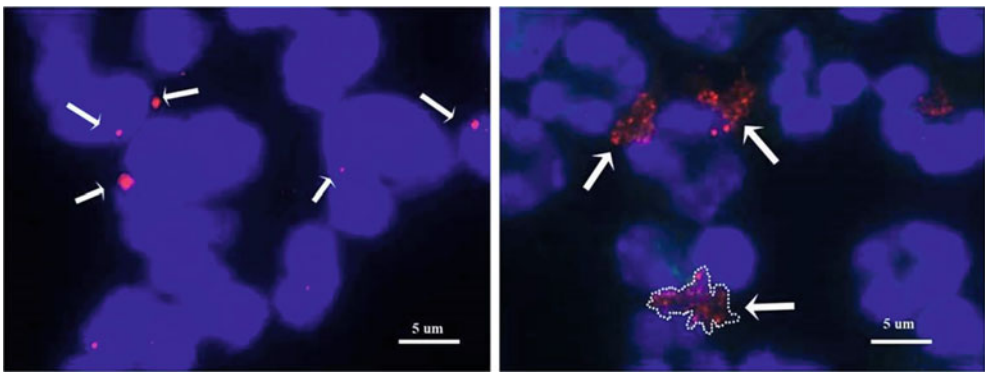

Fig. 1 Cytospin preparations of rheumatoid arthritis leukocytes either alone (*left*) or spiked with intact platelets from peripheral blood (*right*) were labeled with nuclear dye. Draq5 (*blue*) and stained with a platelet marker anti-CD41 (*red*). *Arrows* on the left identify punctuate platelet-specific microparticles of <1 μm diameter found associated with leukocytes, whereas *arrows* on the right identify intact platelets (2–4 μm diameter) spiked into the cell population, one of which is outlined with a *dotted line* [*from Boilard et al. (2010a, b). Reprinted with permission from AAAS*]

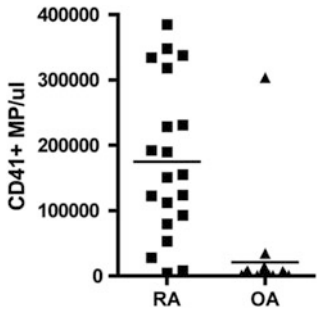

Fig. 2 Flow cytometric quantification of platelet microparticles (<1 mm as determined by size calibration beads) in rheumatoid arthritis (RA) and osteoarthritis (OA) synovial fluid (SF) after removal of leukocytes by centrifugation ($n = 20$ donors per group) [*from Boilard et al*. (2010a, b). *Reprinted with permission from AAAS*]

inflammation was significantly reduced supporting the conclusion that platelet GPVI and the GPVI-dependent release of platelet microparticles contribute to the inflammatory response of rheumatoid arthritis (Zimmerman and Weyrich 2010).

The extent to which these observations made in murine models of rheumatoid arthritis translate to human rheumatoid arthritis has still not been determined. Moreover, characterization of the human GPVI gene has revealed genetic haplotypes corresponding to altered in vitro platelet responses (Trifiro et al. 2009). A growing body of evidence has linked these haplotypes to pathologic responses in acute clinical settings including myocardial infarction and stroke (Bigalke et al. 2010a, b; Snoep et al. 2010). The haplotypes, referred to as *GP6a* and *GP6b*, differ in five codons resulting in three polymorphic amino acids in the extracellular portion of the GPVI (S219P, K237E, and T249A) and two polymorphic amino acids in the cytoplasmic tail (Q317L and H322N) (Trifiro et al. 2009). Relevant to platelet function, the polymorphisms associated with *GP6b* were shown to reduce the cytoplasmic interaction between the GPVI and Fyn/Lyn and attenuate the rate and extent of Syk phosphorylation (Trifiro et al. 2009). Whether these polymorphisms in GPVI affect the development of autoimmune disease, specifically rheumatoid arthritis, remains to be studied.

Platelet-Rich Plasma and Treatment of Osteoarthritis

Several studies demonstrate significant improvement using platelet-rich plasma in the treatment of osteoarthritis (see Alsousou and Harrison 2017). In defining the "yin-yang" relevance of platelets in the inflammatory response, the distinction between rheumatoid arthritis and osteoarthritis becomes important. Osteoarthritis is the more common of the two diseases and is typically the result of mechanical wear and tear on joints. In contrast, rheumatoid arthritis is the outcome of an autoimmune disease in which joints are being damaged by activation of an immune response. Thus, capitalizing on the platelet's wound healing properties seems logical for treating osteoarthritis, and the use of an autologous cocktail of growth factors represents a simple and straightforward nonsurgical alternative for repairing cartilage injuries (Xie et al. 2014). Based solely on studies of patients with rheumatoid arthritis, it would seem that platelet-rich plasma might be harmful when administered to the diseased joint, but this has yet to be examined. This does, however, highlight the very distinct pathophysiologic pathways contributing to rheumatoid arthritis and osteoarthritis.

The pro-inflammatory role of the platelet in rheumatoid arthritis and the repairing function of the platelet in osteoarthritis magnify the importance of making a definitive diagnosis in joint disease. Presumably, the pro-inflammatory properties of the platelet and/or platelet microparticles that worsen rheumatoid arthritis are also present in osteoarthritis. The storage granule cargo of the platelet is loaded with both pro-inflammatory and anti-inflammatory mediators (see chapter "Platelets and the Immune System"). In the case of administering platelet-rich plasma to a diseased joint, the key is likely the relative concentrations of the various pro- versus anti-inflammatory mediators. Studies have shown that some anti-inflammatory proteins are present at higher concentrations within the platelet than their corresponding pro-inflammatory counterparts (Woodell-May et al. 2011). For example, the concentration of the IL-1 receptor antagonist (IL-1Ra) is 23,000 times higher than that of IL-1α and 8,000 times higher than IL-1β (Woodell-May et al. 2011). This likely explains the pro-repair properties of platelet-rich plasma when used in the treatment of patients with osteoarthritis. The relative balance of pro- versus anti-inflammatory proteins in microparticles is not clear. Thus it might be speculated that concentrations of IL-1, which is considered to be a pro-inflammatory mediator in models of rheumatoid arthritis, are higher in platelet microparticles and may therefore contribute to the pathophysiology of autoimmune joint disease. This could be analogous to the proposed selective release of alpha granule components during platelet activation (Italiano et al. 2008), but clearly, more definitive studies investigating the mechanisms involved are warranted.

Platelet-Leukocyte Axis

Specific interactions between platelets and leukocytes (e.g., monocytes and neutrophils) represent a key axis in understanding the major contribution that platelets play in arthritic diseases. On a larger scale, this axis may represent one of the least understood but critically important

interactions impacting a wide range of inflammatory disease processes (Franco et al. 2015). As discussed in other chapters (see Evangelista et al. 2017), there is a growing interest in identifying the key receptors and ligands involved in platelet-leukocyte interactions and the consequences of altering this axis on the initiation and progression of disease. From this standpoint, the work that has been done, to date, describing platelet-dependent contributions to rheumatoid arthritis is an excellent starting point to better understand the role platelets play in the pathophysiology of rheumatoid arthritis and other chronic inflammatory disorders.

Antithrombotic Agents and Joint Inflammation

Given the role platelets play in a number of inflammatory diseases, it is important to fully understand the impact of the widely used platelet-specific antithrombotic drugs in patients with joint inflammation. This is particularly so given that the administration of clopidogrel in mouse models of rheumatoid arthritis worsens the disease (Boilard et al. 2010b). Agrawal et al. also observed a link between clopidogrel and arthritis in a rat model of peptidoglycan polysaccharide-induced arthritis (Garcia et al. 2011). Determining if these rodent observations translate to the human disease is important as even following its patent expiration, clopidogrel continues to be one of the most widely prescribed and best selling drugs in the world (Topol and Schork 2011). Importantly, several human case studies have suggested that clopidogrel administration worsened acute arthritis (Agrawal et al. 2013; Garg et al. 2000). Some have argued that implicating the use of clopidogrel to worsening of the arthritis could cost lives if patients are reluctant to take their antithrombotic medication for the treatment of concomitant cardiovascular disease (Green et al. 2002). Interestingly, some studies report that prasugrel, which like clopidogrel is a prodrug whose active metabolite blocks the $P2Y_{12}$ receptor, does not have a pro-arthritic effect (Agrawal et al. 2013). Clearly, more work is needed at the mechanistic level to understand the relationship between these widely prescribed drugs and the potential pro-inflammatory outcomes. Recently, it has been reported in allergic inflammatory models that there is a dichotomy of platelet activation via purinergic receptors with the P2Y1, a receptor being most important rather than $P2Y_{12}$ for pro-inflammatory actions of platelets (Amison et al. 2015).

Future Directions

The platelet's ability to modulate an inflammatory response places an abundance of pathophysiologic processes at the forefront of new and innovative investigations. The mechanistic basis of platelet microparticle formation and the influence on the diseased joint are likely to add paradigms easily applied to other immune-based diseases. Are the microparticles formed within the synovial space or do they migrate from the vasculature? It is easy to suggest collagen via activation of the GPVI receptor could drive microparticle formation, yet studies have also shown that laminin is also a GPVI ligand (Inoue et al. 2006). Platelets and neutrophils must presumably pass through a basement membrane region that separates the bloodstream from the synovial space. Other questions include does laminin, as a major protein of basement membranes, stimulate microparticle release?

From the clinical perspective, the large dataset information now being mined from patients who have undergone long-term treatment with antiplatelet drugs, such as aspirin and clopidogrel, is likely to be highly informative. Already, data has emerged linking aspirin with anticancer benefits (Rothwell et al. 2012a, 2012b). Perhaps some of this benefit is linked to the cancer/inflammation axis that is being recognized as a critical component of the tumor/stromal interaction. Likely, some of these interactions are playing a similar role in autoimmune diseases. Also relevant will be to examine whether the new class of direct $P2Y_{12}$ inhibitors are linked to worsening arthritic diseases, as has been described for clopidogrel. This information will be important both for the basic scientist unraveling the cellular and molecular mechanisms at play and also for the practicing clinician trying to provide guidance in the treatment of management of disease. Antiplatelet therapies for cardiovascular disease will continue to be important and lifesaving therapies, but how they affect other ongoing disease processes will need to be considered. So while the platelet's role in hemostasis and thrombosis could be considered a mature field and understood with great molecular detail, the future needs to take these same paradigms and apply them to the vast array of pathologies where the platelet may not be causing the disease but does have a significant impact on severity and how the disease is managed (Leslie, 2010).

Take Home Messages

- Platelets participate in the "yin and yang" of connective tissue inflammation.
- Platelet antigen is found in the synovial fluid of patients with rheumatoid arthritis.
- Release and sequestration of platelet microparticles to the synovial space worsens rheumatoid arthritis.
- Platelet-rich plasma can be therapeutic wound healer in osteoarthritis.
- The platelet/leukocyte axis may impact a wide range of inflammatory disease processes.
- Antithrombotic therapies can impact inflammatory diseases.

Platelets and Skin Disorders

Risa Tamagawa-Mineoka

Abstract

Recent accumulating evidence indicates that platelets act as effector cells in initiating and modulating inflammatory and immune responses in various organs including the skin. On activation in response to various factors such as chemokines and microbial toxins, platelets express adhesive and immune receptors such as P-selectin and Toll-like receptors on their surface and release soluble mediators such as chemokines, cytokines, and antimicrobial peptides. In patients with inflammatory skin disorders such as atopic dermatitis and psoriasis, platelets circulate in an activated state, and the degree of platelet activation correlates with disease severity. Platelets are deeply involved in the pathogenesis of several inflammatory skin disorders such as atopic dermatitis, contact dermatitis, psoriasis, urticaria, and infectious diseases via formation of platelet-leukocyte complexes, releasing chemotactic factors, inhibiting monocytic apoptosis, inducing neutrophil phagocytosis, promoting allergic sensitization, and releasing antimicrobial peptides.

Introduction

The skin is the largest organ of the human body that is in direct contact with the outside environment. The skin plays a key role in prevention of permeation or loss of water and other molecules, temperature regulation, and sensation. In addition, the skin functions as an important tissue in immune reactions by protecting the body from microbes and harmful external influences. Recent accumulating evidence indicates that platelets are involved in the development of inflammatory and immune processes in several organs including the skin, in addition to their well-established role in hemostasis and coagulation. The aim of this chapter is to review the involvement of platelets in the mechanisms of inflammatory and immune responses in the skin.

The Role of Platelets in the Pathogenesis of Atopic Dermatitis

Atopic dermatitis is a chronic, relapsing inflammatory skin disease characterized by epidermal barrier dysfunction, pruritus eczematous lesions, increased levels of T helper type 2 (Th2) cytokines such as interleukin (IL)-4 and IL-13, high serum IgE levels, positive immediate hypersensitivity to food or environmental allergens, and peripheral blood eosinophilia (Leung 2013). Interestingly, plasma levels of platelet-derived chemokines such as platelet factor-4 (PF-4, CXCL4) and β-thromboglobulin (β-TG, CXCL7), which are known as platelet activation markers, are greatly increased in patients with atopic dermatitis compared with those in healthy individuals (Tamagawa-Mineoka et al. 2008, 2009a, b; Nastalek et al. 2011). In addition, the levels of these chemokines correlate with disease severity (Tamagawa-Mineoka et al. 2008). Moreover, plasma levels of other platelet activation markers including platelet-derived microparticles, vascular endothelial growth factor, and platelet-derived growth factor are also elevated in atopic dermatitis patients compared to healthy controls

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_76

(Tamagawa-Mineoka et al. 2009a, b; Nastalek et al. 2011). These findings suggest that platelets circulate in an activated state in patients with atopic dermatitis and are involved in the pathogenesis of this disease. On the other hand, platelet aggregation induced by thrombin, adenosine diphosphate (ADP), and collagen is not increased in patients with atopic dermatitis compared with those in healthy controls (Rogala et al. 1999). Therefore, in atopic dermatitis, although the hemostatic function of platelets, such as the ability to aggregate, is not impaired, various inflammatory stimuli may activate platelets in circulating blood. It has been demonstrated that the incidence of ischemic stroke is increased in patients with atopic dermatitis (Su et al. 2014), implying that platelet activation may be possibly related to the pathogenesis of atopic dermatitis.

Platelets usually circulate in a resting state in blood and can be activated by a range of immunological and non-immunological stimuli including thrombin, ADP, collagen, chemokines, platelet-activating factor (PAF), thromboxane A2, lipopolysaccharide, other microbial toxins, and pathogens (von Hundelshausen and Weber 2007; Kasperska-Zajac et al. 2008; Katoh 2009; Semple et al. 2011; Tamagawa-Mineoka 2015; Tamagawa-Mineoka and Katoh 2016). Platelets express numerous kinds of chemokine receptor, CCR (CCR1, CCR2, CCR3, CCR4, CCR5, CCD6, CCR7, CCR8, CCR9, and CCR10) and CXCR (CXCR1, CXCR2, CXCR3, CXCR4, and CXCR5) on their surface (Gear and Camerini 2003; von Hundelshausen and Weber 2007; Kasperska-Zajac et al. 2008; Katoh 2009; Semple et al. 2011; Tamagawa-Mineoka 2015; Tamagawa-Mineoka and Katoh 2016). Several chemokines such as stromal cell-derived factor-1 (SDF-1, CXCL12) and thymus and activation-regulated chemokine (TARC, CCL17) induce platelet aggregation with ADP or thrombin, and platelet chemokines themselves can directly activate platelet function. Platelets also express both high-affinity IgE (FcεRI) (Hasegawa et al. 1999) and low-affinity IgE (FcεRII) receptors (Joseph et al. 1986). Engagement of FcεRI on platelets induces the release of serotonin (5-hydroxytryptamine, 5-HT) and regulated on activation, normal T cell expressed and secreted (RANTES, CCL5) (Hasegawa et al. 1999). These findings suggest that platelets may be activated via allergen or various soluble mediators such as chemokines. Moreover, patients with atopic dermatitis often scratch their skin due to severe itching. Therefore, platelet activation may occur by coagulation of blood on the scratched skin.

In a murine model of chronic allergic dermatitis induced by repeated allergen application that resembles some of the features of atopic dermatitis such as increased levels of Th2 cytokines in inflamed skin and elevated levels of serum IgE (Kitagaki et al. 1995, 1997), depletion of platelets circulating in blood greatly reduces the degree of skin inflammation as determined by skin thickness and leukocyte infiltration in inflamed skin (Tamagawa-Mineoka et al. 2007). Furthermore, the elevation of serum IgE levels and gene expression of Th2 in inflamed skin is decreased in platelet-depleted mice. On the other hand, the immediate-type hypersensitivity reaction is an important component of the pathogenesis of atopic dermatitis (Leung 2013). The mice that are sensitized and then challenged with the major egg white protein, ovalbumin, develop on immediate-type hypersensitivity reaction characterized by biphasic responses: early-phase and late-phase reactions. Although the early-phase reaction is not affected by platelet depletion, the late-phase reaction is reduced in thrombocytopenic conditions (Tamagawa-Mineoka et al. 2009a, b). In both murine models of chronic allergic inflammation and the immediate-type hypersensitivity reaction, cutaneous inflammation is increased by platelet infusion in platelet-depleted mice (Tamagawa-Mineoka et al. 2007, 2009a, b). These findings indicate that platelets are important for the development of cutaneous allergic inflammation.

Platelets contain a wide variety of mediators contributing to inflammation in three major types of storage granules: α-granules, dense granules, and lysosomes (Table 1) (von Hundelshausen and Weber 2007; Kasperska-Zajac et al. 2008; Katoh 2009; Semple et al. 2011; Tamagawa-Mineoka 2015; Tamagawa-Mineoka and Katoh 2016). Platelet

Table 1 Granules contents

α-granules
Chemokines
See Table 2
Growth factors
Platelet-derived growth factor, transforming growth factor-β, vascular endothelial growth factor, insulin-like growth factor
Cytokines
IL-1β, IL-33
Lipid mediators
PAF, prostaglandin E2, microparticles
Antibacterial proteins
Thrombocidins 1 and 2
Adhesion molecules
P-selectin, CD40 ligand, integrins (α2β1, α5β1, α6β1, αLβ2, $\alpha_{IIb}\beta_3$, αvβ3), thrombospondin, fibrinogen, fibronectin
Others
Albumin, IgG, IgM, IgA
Dense granule
ADP, adenosine triphosphate, Ca^{2+}, Mg^{2+}, polyphosphate, glutamate, serotonin, histamine
Lysosomal granule
β-Glucuronidase, β-N-acetylglucosaminidase, cathepsin D and E, lysosomal membrane proteins (LAMP-1, LAMP-2, and CD63)

Table 2 Platelet-derived chemokines

Chemokines	Cellular targets
CXC chemokine	
CXCL1 (growth-related oncogene-α)	Neutrophil
CXCL4 (PF-4)	Monocyte, neutrophil, T cell
CXCL5 (epithelial neutrophil-activating peptide-78)	Neutrophil
CXCL7 (β-TG, neutrophil-activating peptide-2)	Neutrophil, macrophage
CXCL8 (IL-8)	Neutrophil
CXCL12 (SDF-1)	T cell, monocyte
CC chemokine	
CCL1 (I-309)	T cell
CCL2 (macrophage chemotactic protein-1)	Monocyte
CCL3 (macrophage inflammatory protein-1α)	Monocyte, neutrophil, eosinophil
CCL5 (RANTES)	Monocyte, T cell, eosinophil
CCL7 (macrophage chemotactic protein-3)	Monocyte, T cell, eosinophil
CCL17 (TARC)	T cell

The table is adapted from the reference Tamagawa-Mineoka (2015), with permission

α-granules contain numerous chemokines, which are a superfamily of potent leukocyte chemotactic cytokines, and rapidly secrete mediators upon activation (Table 2) (Gear and Camerini 2003; von Hundelshausen and Weber 2007; Kasperska-Zajac et al. 2008; Katoh 2009; Semple et al. 2011; Tamagawa-Mineoka 2015; Tamagawa-Mineoka and Katoh 2016). It has been demonstrated that the gene expression of PF-4 is elevated in a mouse model of atopic dermatitis (Watanabe et al. 1999). PF-4 induces adhesion and chemotaxis of eosinophils (Bruijnzeel et al. 1993; Hayashi et al. 1994), which are often increased in circulating blood and in inflamed skin of atopic dermatitis. In addition, on activation, platelets from atopic dermatitis patients release a great amount of TARC (Fujisawa et al. 2002) which is deeply involved in the pathogenesis of atopic dermatitis (Leung 2013). In a hapten-induced atopic dermatitis murine model, injection of activated platelet supernatant into inflamed skin results in increased leukocyte infiltration, which is not blocked by pretreating platelets with neutralizing macrophage inflammatory protein-1α (MIP-1α, CCL3), RANTES, and TARC in the platelet supernatant (Tamagawa-Mineoka et al. 2007). These findings indicate that platelet-derived chemokines can induce leukocyte recruitment into inflamed skin lesions of atopic dermatitis.

In the chronic lesions of atopic dermatitis, there is dense infiltration of monocytes/macrophages. While unstimulated monocytes undergo apoptosis, apoptosis of monocytes is inhibited via stimulation by several inflammatory mediators (Katoh et al. 2000; Soga et al. 2007a). In addition, monocytes from patients with atopic dermatitis show a lower rate of apoptosis in vitro than those from healthy controls (Soga et al. 2007a). These findings suggest that monocytes/macrophages stimulated in the process of inflammation can prolong the survival and be related to the development of chronic inflammation. 5-HT, a monoamine neurotransmitter, is a major component of platelet dense granules as well as mast cell granules (von Hundelshausen and Weber 2007; Kasperska-Zajac et al. 2008; Katoh 2009; Semple et al. 2011; Tamagawa-Mineoka 2015; Tamagawa-Mineoka and Katoh 2016). 5-HT prevents apoptosis of monocytes (Soga et al. 2007a) and promotes monocyte differentiation into dendritic cells (Katoh et al. 2006). In addition, PF-4 promotes monocyte survival via suppression of apoptosis and induces monocyte differentiation into macrophages (Scheuerer et al. 2000). Moreover, apoptosis of monocytes can be suppressed by phagocytosis of platelets (Lang et al. 2002). These findings suggest that platelets may contribute to the establishment of chronic dermatitis by suppression of monocyte apoptosis.

Platelets also release important cytokines including IL-33 (Unno et al. 2014, 2015), which can activate Th2 cells, mast cells, and eosinophils and promote Th2-type immune responses (Moritz et al. 1998; Xu et al. 1998; O' Neill LA, Dinarello CA 2000; Schmitz et al. 2005). In patients with atopic dermatitis, serum IL-33 levels are greatly increased compared with those in healthy individuals (Tamagawa-Mineoka et al. 2014). Although it has been reported that the expression of IL-33 is increased in keratinocytes, endothelial cells, and fibroblasts of skin lesions in patients with atopic dermatitis (Pushparaj et al. 2009; Savinko et al. 2012), platelet-derived IL-33 may be also involved in the development of Th2 inflammation in atopic dermatitis. In addition, arachidonic acid metabolites are also important mediators in allergic skin inflammation. It has been demonstrated that platelets from patients with atopic dermatitis release a large amount of 12-hydroxyeicosatetraenoic acids (12-HETE) (Hilger et al. 1991). Stimulation of platelets with *Staphylococcus aureus*, which often colonizes the skin of atopic dermatitis patients, promotes the release of 12-HETE from platelets (Neuber et al. 1992). Therefore, platelet-derived arachidonic acid metabolites may be also related to the development of cutaneous inflammation.

Platelets express various kinds of functional surface receptors (von Hundelshausen and Weber 2007; Kasperska-Zajac et al. 2008; Katoh 2009; Semple et al. 2011; Tamagawa-Mineoka 2015; Tamagawa-Mineoka and Katoh 2016). Activated platelets are capable of increasing leukocyte rolling in cutaneous postcapillary venules, via the aggregate formation with leukocytes (Fig. 1) through a distinct set of adhesion molecules (Fig. 2) (Ludwig et al. 2004;

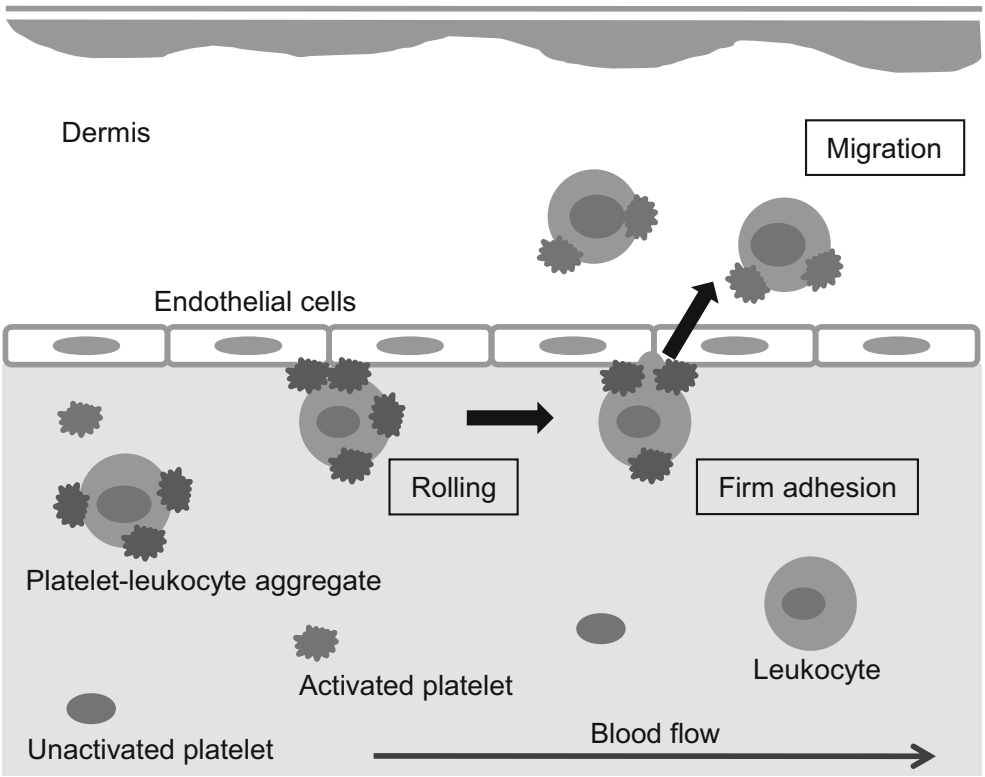

Fig. 1 Role of platelets in leukocyte recruitment from blood to the skin tissue. On activation, platelets bind leukocytes via several adhesion molecules in circulating blood. The complexes of platelets and leukocytes roll along the endothelium and transmigrate into subendothelial tissue. The figure is adapted from references Tamagawa-Mineoka (2015) and Tamagawa-Mineoka and Katoh (2016), with permission

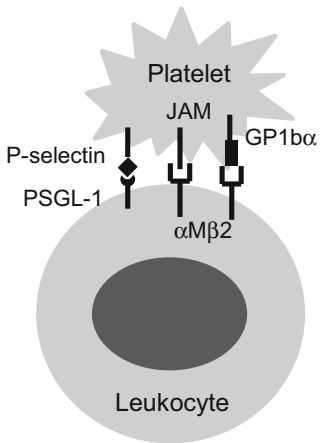

Fig. 2 Interaction of platelets with leukocytes via adhesion molecules. The interaction between platelet P-selectin and leukocyte PSGL-1 is the first step of complex formation, leading to the activation of integrins on the leukocyte surface and the firm adhesion of leukocytes to activated platelets. The figure is adapted from references Tamagawa-Mineoka (2015) and Tamagawa-Mineoka and Katoh (2016), with permission. *JAM* junctional adhesion molecule

von Hundelshausen and Weber 2007; Kasperska-Zajac et al. 2008; Katoh 2009; Semple et al. 2011; Tamagawa-Mineoka 2015; Tamagawa-Mineoka and Katoh 2016). P-selectin (CD62P) is one of the receptors that are important for formation of platelet-leukocyte complexes (von Hundelshausen and Weber 2007; Kasperska-Zajac et al. 2008; Katoh 2009; Semple et al. 2011; Tamagawa-Mineoka 2015; Tamagawa-Mineoka and Katoh 2016). On activation, platelets express P-selectin on their membranes or secrete this into plasma. By binding its major ligand, P-selectin glycoprotein-1 (PSGL-1), which is expressed on almost all kinds of leukocyte, platelet P-selectin supports the adhesion of polymorphonuclear cells, monocytes/macrophages, and lymphocytes (von Hundelshausen and Weber 2007; Kasperska-Zajac et al. 2008; Katoh 2009; Semple et al. 2011; Tamagawa-Mineoka 2015; Tamagawa-Mineoka and Katoh 2016). In murine models of chronic allergic inflammation and the immediate-type hypersensitivity reaction, P-selectin expression on platelets and an increased number of platelet-leukocyte complexes are increased in circulating blood. Interestingly, leukocyte infiltration into inflamed skin is increased by platelet infusion in thrombocytopenic conditions of these allergic dermatitis models, but is not restored by infusion of P-selectin-deficient platelets (Tamagawa-Mineoka et al. 2007, 2009a, b). These finding suggest that platelet P-selectin is important in formation of platelet-leukocyte aggregates and transmigration of them into inflamed skin tissue in atopic dermatitis.

The Role of Platelets in the Pathogenesis of Allergic and Irritant Contact Dermatitis

Allergic contact dermatitis is a common allergic inflammatory skin disorder characterized by eczematous lesions and depends on the delay-type hypersensitivity reaction. The contact hypersensitivity response consists of two phases:

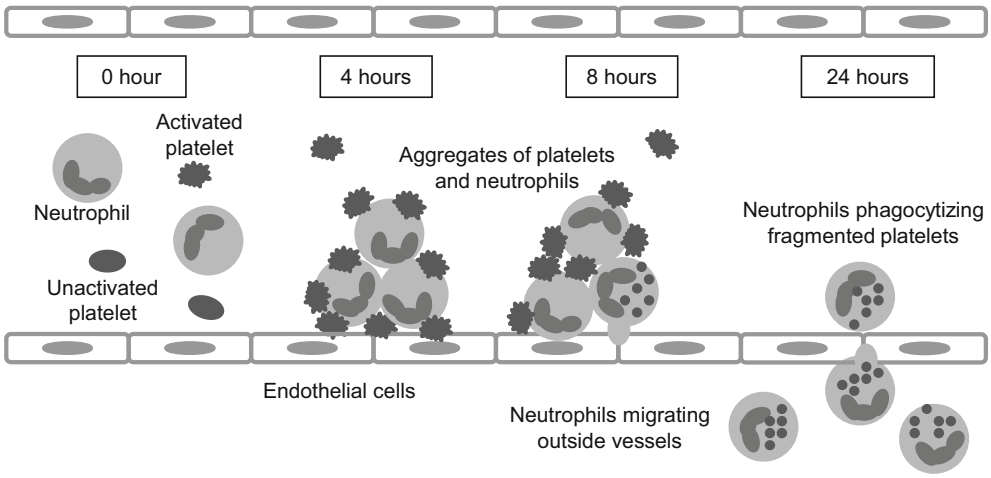

Fig. 3 Platelet interactions with neutrophils and the endothelium in the contact hypersensitivity response. Aggregates of platelets and neutrophils adhere to endothelial cells within the vessels at 4 h after allergen challenge. At 8 h, neutrophils ingesting fragmented platelets are found inside the vessels. At 24 h, the number of neutrophils ingesting fragmented platelets outside the vessels increases. The figure is adapted from references Daito et al. (2014) and Tamagawa-Mineoka (2015)

sensitization and elicitation. Deficiency of platelet P-selectin impairs the sensitization process in the contact hypersensitivity responses (Ludwig et al. 2010). On the other hand, the contact hypersensitivity responses are decreased after depletion of blood platelets in sensitized mice (Tamagawa-Mineoka et al. 2007), suggesting that platelets are also involved in the elicitation process. Furthermore, it has been demonstrated that platelets are activated via FcεRI and initiate the contact hypersensitivity responses by releasing 5-HT (Matsuda et al. 1997). These findings suggest that platelets are involved in both the sensitization and elicitation phases of the contact hypersensitivity responses by expressing immune-related receptors and releasing inflammatory mediators.

Neutrophils are the most abundant leukocytes in circulating blood. They migrate not only to sites of infection but also to the skin lesions in a mouse model of allergic contact dermatitis. It has been demonstrated that platelets bind to leukocytes, and the complexes of platelets and neutrophils adhere to endothelial cells within blood vessels at 4 h after allergen challenge in the contact hypersensitivity responses (Fig. 3) (Daito et al. 2014). At 4 to 8 h after challenge, neutrophils begin to phagocytose platelets, and neutrophils including fragmented platelets are found inside the vessels. At 24 h after elicitation, when the contact hypersensitivity responses peak, the number of neutrophils including fragmented platelets outside the vessels increases. These findings suggest that the process of phagocytization of platelets by neutrophils is related to leukocyte transmigration from blood to subendothelial tissue in allergic contact dermatitis.

In contrast to allergic contact dermatitis, irritant contact dermatitis occurs as a consequence of the direct action of chemical agents and shows non-antigen-specific cutaneous responses (Corsini and Galli 1988). The irritant reaction is characterized by edema and leukocyte infiltration in the skin. Depletion of platelets by an antiplatelet antibody decreases dermal edema in a murine model of irritant contact dermatitis, although leukocyte infiltration is not affected (Senaldi and Piguet 1997). Therefore, platelets also contribute to the pathogenesis of irritant contact dermatitis and are important for the development of edema, but not for leukocyte recruitment into inflamed sites.

Platelets are closely associated with other types of cutaneous immune reactions in addition to the immediate and delayed-type hypersensitivity reactions. Platelets induce recruitment of leukocytes into inflamed sites via the interaction of P-selectin on platelets interacting with PSGL-1 on leukocytes in a murine model of the cutaneous Arthus reaction (Hara et al. 2010). Moreover, platelets contribute to skin allograft rejection through the recruitment of T cells and increased inflammatory mediators (Xu et al. 2006; Swaim et al. 2010). These findings suggest that platelets initiate and sustain several types of immune reactions in the skin.

The Role of Platelets in the Pathogenesis of Psoriasis

Psoriasis is a chronic inflammatory immune-mediated disease characterized by scaly, red cutaneous plaques. Several epidemiological studies have demonstrated that psoriasis patients have an increased risk for developing thrombotic vascular diseases, including myocardial infarction, stroke (Kasperska-Zajac et al. 2005; Gelfand et al. 2006, 2009; Mehta et al. 2010; Boehncke et al. 2011), and thromboembolic events (Ahlehoff

et al. 2011). It has been demonstrated that chronic skin-specific inflammation promotes aortic inflammation and thrombosis in a murine model of psoriasiform skin disease (Wang et al. 2012). Recent studies have suggested that the persistent skin inflammation in psoriasis can develop into systemic inflammation which leads to dyslipidemia, insulin resistance, and endothelial dysfunction, resulting in thrombotic vascular diseases (Boehncke et al. 2011).

It has been also reported that psoriasis patients have platelet hyperaggregability. Platelet aggregation in vitro induced by thrombin or ADP is markedly increased in psoriasis patients compared with that in healthy individuals, and this elevated platelet aggregation is greatly reduced following improvement of psoriatic skin lesions (Hayashi et al. 1985; Chandrashekar et al. 2015). In addition, platelet activation markers such as platelet-derived chemokines, soluble P-selectin, and platelet-derived microparticles are also significantly elevated in blood of patients with psoriasis (Tamagawa-Mineoka et al. 2009a, b, 2010; Chandrashekar et al. 2015). These findings suggest that blood platelets are activated in patients with psoriasis. In addition to platelet-derived soluble mediators, mean platelet volume (MPV) and platelet distribution width (PDW) are regarded as indicators of platelet activation. Patients with psoriasis and psoriatic arthritis have higher levels of MPV and PDW in comparison with controls (Canpolat et al. 2010; Chandrashekar et al. 2015). Platelet volume is closely related to platelet function with large platelets producing a greater amount of soluble mediators such as thromboxane B2 or serotonin, and they express numerous adhesion molecules (Thompson et al. 1982; Martin et al. 1983). Furthermore, it has been reported that the expression of P-selectin on blood platelets is increased in patients with psoriasis in parallel with disease severity (Ludwig et al. 2004). Therefore, activated large platelets play important roles in the pathogenesis of psoriasis by releasing great quantities of mediators and adhesion molecules that may contribute to the development of thrombotic vascular diseases.

The Role of Platelets in the Pathogenesis of Urticaria

Urticaria is a common skin disease characterized by wheals, in which mast cell activation leads to acute inflammatory responses and with vasodilatation and increased permeability of small blood vessels. Several studies have been performed to assess platelet function in patients with urticaria. It has been reported that plasma levels of platelet activation markers including PF-4, β-TG, and soluble P-selectin are not different between patients with chronic idiopathic urticaria and control subjects (Kasperska-Zajac et al. 2005; Tamagawa-Mineoka et al. 2010). On the other hand, it has been demonstrated that in chronic urticaria patients with positive autologous serum skin test, MPV is greatly increased compared with chronic urticaria patients with negative autologous serum skin test or control subjects (Magen et al. 2010). In addition, MPV in the patients with positive autologous serum skin test correlates with the disease severity score. In patients suffering from cold urticaria, plasma levels of PF-4 are enhanced following a cold challenge test (Wasserman and Ginsberg 1984). Furthermore, packed platelets are histologically seen within vessel lumen in cold urticaria (Lawlor et al. 1989). Some previous studies have also demonstrated that the coagulation cascade is activated in chronic urticaria, leading to thrombin production (Lundblad and White 2005; Asero et al. 2007). Therefore, platelet activation may occur via activation of the coagulation cascade and may contribute to the mechanisms in some types of urticarial reactions.

The Role of Platelets in the Pathogenesis of Infectious Diseases

The skin has direct contact with the external environment, and there are, therefore, numerous opportunities to interact with various pathogens such as bacteria and viruses. Platelets are involved in innate immunity via interactions with pathogens (Semple et al. 2011). They express many Toll-like receptor (TLR) family members including TLR1, TLR2, TLR4, TLR6, and TLR9 (Shiraki et al. 2004; Blair et al. 2009). Platelet-expressed TLR2 (Aslam et al. 2006; Beaulieu et al. 2011) and TLR4 (Aslam et al. 2006; Blair et al. 2009) have important roles in inflammatory responses such as bacterial infections. Stimulation of platelets with bacteria via TLR2 induces aggregation, expression of P-selectin, and formation of platelet-neutrophil complexes (Beaulieu et al. 2011). In addition, stimulation of megakaryocytes via TLR2 leads to the production of platelets with increased proinflammatory gene and protein expression (Aslam et al. 2006). On stimulation via TLR4, platelets induce neutrophil activation and formation of neutrophil extracellular traps that contain proteolytic activity, leading to killing the bacteria (Clark et al. 2007).

Furthermore, platelets contain antimicrobial peptides such as β-defensins, thrombocidins, PF-4, RANTES, connective tissue-activating peptide-3, platelet basic protein, thymosin β-4, fibrinopeptide B, and fibrinopeptide A (Krijgsveld et al. 2000; Tang et al. 2002; Kraemer et al. 2011). Platelets can directly kill bacteria by releasing such antimicrobicidal peptides or by phagocytozing bacteria (Rogala et al. 1999; Krijgsveld et al. 2000; Tang et al. 2002; Kraemer et al. 2011). For example, platelet-derived β-defensins impair the growth of bacteria and induce neutrophil extracellular trap formation (Kraemer et al. 2011).

Many platelet-derived antimicrobial peptides are associated with the CC and CXC chemokine family and can induce recruitment of leukocytes to sites of infection in addition to their antimicrobial functions. In addition to bacterial infections, platelets are associated with infections with human immunodeficiency virus, influenza, and malaria (Morrell et al. 2014). It has been demonstrated that TLRs are deeply involved not only in infectious disorders but also in noninfectious inflammatory diseases including contact hypersensitivity responses (Nakamura et al. 2015). Therefore, platelets expressing TLRs may be possibly related to the pathogenesis of noninfectious inflammatory skin disorders.

Take-Home Messages

- Platelets circulating in blood are activated in several inflammatory diseases such as atopic dermatitis, psoriasis, and urticaria.
- Activated platelets express adhesive and immune receptors such as P-selectin, CD40 ligand, and Toll-like receptors on their surface.
- Activated platelets release soluble mediators such as chemokines, cytokines, and antimicrobial peptides.
- Platelets are involved in the pathogenesis of cutaneous inflammatory diseases, by increasing leukocyte rolling on the endothelium and recruiting leukocytes into inflamed skin via release of inflammatory mediators.
- Phagocytization of platelets by neutrophils is related to leukocyte transmigration from blood to subendothelial tissue in allergic contact dermatitis.
- Platelets directly kill the bacteria by releasing such antimicrobicidal peptides or phagocytizing the bacteria.

Acknowledgments The author thanks Professor Norito Katoh for reviewing this article.

Abstract

The role of platelets as inflammatory cells is now well established. Given the peculiar characteristics of the lung circulation, with a broad capillary bed, platelets are especially involved with the physiology of the lungs and play a key role in a number of inflammatory lung disorders. The platelet precursors, megakaryocytes, are detected in the lung microcirculation; moreover platelets with their endothelium-protective and vascular reparative activities contribute to the lung capillary blood barrier integrity. Given the function of the lungs as first wall against pathogen invasion, platelets participate in immune defence of the normal lung. On the other hand, platelets may turn into effectors of the inflammatory reaction of the lungs to allergens, to infectious agents, to chemical agents and may contribute strongly to the perpetuation of chronic inflammatory reactions, largely by their ability to interact with other inflammatory cells and the endothelium. In this chapter we provide an overview of the role of platelets in several inflammatory lung disorders discussing the pathophysiologic bases of platelet involvement in these conditions and the experimental and clinical evidence for a role of platelets in lung diseases.

Platelets have a well-established role in haemostasis and thrombosis, but there is now considerable evidence that they also play an important role in a number of inflammatory diseases (see Ware and Post 2017), including respiratory diseases such as asthma (Pitchford and Page, Clin Exp Allergy 36: 399–401, 2006) and chronic obstructive pulmonary disease (COPD) (Ferroni et al. J Investig Med 48:21–27, 2000). There is a relevant amount of information on the involvement of platelets in allergic inflammatory diseases, and platelet abnormalities in patients with allergy have been reported for more than 40 years following the seminal observation by Benveniste et al. in 1972 that leukocyte-dependent histamine release from platelets involved IgE-mediated activation (Benveniste et al. J Exp Med. 136:1356–77, 1972). This work led to the discovery of the lipid mediator platelet-activating factor (PAF) capable of inducing eosinophilia (Arnoux et al. Am Rev Resp Dis 137: 855–860, 1988). It is becoming increasingly apparent that platelets are central to inflammatory diseases of the airways, being a source of inflammatory mediators (see Table 1) and spasmogens per se and being critical for the recruitment of leukocytes into tissues.

Platelets in Asthma

Pathophysiologic Observations: Altered Platelet Functionality

- Platelets accumulate into the lungs upon allergen exposure.
- Platelet activation by allergen via an IgE-mediated process reveals an important causal involvement of platelets in the inflammatory response.
- Studies in animals reveal platelets are necessary for pulmonary leukocyte recruitment, chronic inflammatory events leading to airway remodelling, and the release of spasmogens to cause bronchoconstriction. Emerging reports suggest platelets are involved in initial allergen processing with antigen-presenting cells.
- Many of these processes can be attributable to a direct effect of platelets, in their capacity to migrate through lung tissue and be present in the localised environment.

In 1978, Gallagher and colleagues observed that platelets isolated from the peripheral blood of allergic patients during the allergy season often showed reduced secondary wave platelet aggregation, and it was suggested that they behaved like 'exhausted' platelets (Gallagher et al. 1978). Since this early observation, there have been many other reports of altered platelet behaviour in patients with allergic disease, ranging from altered arachidonic acid metabolism to greater turnover of intra-cellular signalling pathways (Audera et al. 1988; Block et al. 1990). Indeed, these platelet abnormalities may well account for the observation that patients with allergic asthma have a mild haemostatic defect and delayed thrombin generation detected using the template bleeding time (Szczeklik et al. 1986). This 'exhausted platelet' syndrome may be the consequence of continuous platelet activation in vivo and is compatible with the observation that allergic patients undergoing allergen provocation have a mild thrombocytopenia (Kowal et al. 2006; Sullivan et al. 2000; Maestrelli et al. 1990) with increased numbers of platelet–leukocyte aggregates in their peripheral blood. Such observations clearly support the conclusion that platelet activation accompanies allergic exposure in such patients (Gresele et al. 1982, 1993; Pitchford et al. 2003; Sladek et al. 1990). This may explain recent observations suggesting that patients with asthma often have co-morbidities, including cardiovascular disease (Cazzola et al. 2013) and an increased risk of pulmonary embolism (Majoor et al. 2013), particularly patients with more severe asthma possibly associated with use of glucocorticosteroids (Varas-Lorenzo et al. 2007). This hypothesis is further supported by a growing number of clinical observations showing increased markers of platelet activation in allergic asthmatics. These include RANTES (CCLS), platelet factor 4 (PF4), CXCL4 and β-thromboglobulin (β-TG, CXCL7) in the peripheral blood of patients with asthma (Maccia et al. 1977; Kowal et al. 2006; Yasuba et al. 1991; Knauer et al. 1981), as well the demonstration of increases in some of these platelet markers in bronchoalveolar lavage (BAL) fluid obtained from such patients (Jeffery et al. 1989; Metzger et al. 1987) (Table 1). Furthermore, there are other observations demonstrating extravascular platelets in the airways of both experimental animals (Pitchford et al. 2008) and in patients with asthma (Jeffery et al. 1989; Metzger et al. 1987) (see Petito et al. 2017).

In the context of respiratory diseases, it is of interest that platelets have long been recognised as a rich source of spasmogens (Arnoux et al. 1988; Yoshimi et al. 2001) that can lead to both contraction of airway smooth muscle in vitro (Inoue and Kannan 1989) and bronchoconstriction in vivo (Robertson and Page 1987; Yoshimi et al. 2001). Indeed, we have recently reported that a range of inflammatory mediators, exemplified by bradykinin, elicit airway obstruction in vivo that is platelet dependent, building on earlier observations of platelet involvement in airway obstruction (Keir et al. 2015; Coyle et al. 1993). However, perhaps of greater interest for respiratory diseases are the increasing numbers of observations demonstrating a crucial role for platelets in the recruitment of leukocytes into various tissues, including the lung (Pitchford et al. 2003, 2005; Kornerup et al. 2010). Platelet-derived mediators are known to be able to induce leukocyte activation and recruitment (Page and Pitchford 2013), as well as the release of substances that contribute to the remodelling and repair of tissues after injury, making them well placed to contribute to some of the important features of asthma (Fig. 1). Furthermore, it is now recognised that platelets from allergic asthma patients express both the high- and the low-affinity IgE receptors on their surface and that exposure to sensitising antigens can lead to the generation of inflammatory mediators, such as oxygen free radical species, 5-HT and RANTES (Joseph et al. 1983, 1997; Hasegawa et al. 2001; Klouche et al. 1997). Interestingly, activation of the high-affinity IgE receptor can cause platelets to undergo chemotaxis (Pitchford et al. 2008), confirming other observations that suggest that platelets behave like primitive leukocytes and demonstrate directional movement in response to certain stimuli (Czapiga et al. 2005; Kraemer et al. 2010), stimuli that tend to be distinct from those that elicit platelet aggregation (Abi-Younes et al. 2001; Kowalska et al. 2000; Clemetson et al. 2000).

Platelets have long been recognised to contain high concentrations of 5-hydroxytryptamine (5-HT or serotonin) in their dense granules, and several clinical observations

Table 1 Principal platelet-derived inflammatory mediators and their involvement in airway diseases

Mediator	Action
αvβ3	NF-κB activation and induction of inflammatory cell responses (cell adhesion and transmigration into the lung)
CD40L	TNF superfamily: antigen-presenting cell activation, B-cell responses, endothelial cell activation
P-selectin	Selectin: leukocyte adhesion, complement activation
IL-1β	Cytokine: acute phase response, leukocyte and endothelial activation
TXA2	Eicosanoid: T-cell differentiation, monocyte activation, smooth muscle proliferation
Nitric Oxide (NO)	Reactive oxygen species: anti-inflammatory and antithrombotic
ADP	Platelet, leukocyte, endothelial cell activation
TNFα	Modulate air wall remodelling
LTB4	Modulate leukocyte recruitment
CXCL-7/β-TG	Modulate leukocyte recruitment, bronchospasm
CCL5/RANTES	Monocyte adhesion on the endothelium and recruitment
CXCL4/PF-4	Chemokine: monocyte, neutrophil and T-cell recruitment, Th differentiation, bronchospasm
TGFβ	Cytokine: cell proliferation, T-cell differentiation, B-cell and macrophage phenotype regulation
PDGF	Growth factor: cell growth and differentiation, monocyte/macrophage differentiation
VWF	Platelet adhesion, PMN extravasation
SDF-1	Chemokine: T cell, monocyte and PMN chemotaxis
VEGF	Growth factor: angiogenesis, adhesion molecule expression
5-HT	Dendritic cell activation, bronchospasm

have shown altered levels of this vasoactive amine in patients with asthma (Maccia et al. 1977; Malmgren et al. 1982; Ring et al. 1980). Furthermore, some studies have shown a beneficial effect of the 5-HT antagonist ketanserin in asthma (Cazzola et al. 1990, 1992). Tryptophan hydroxylase (THP)-1 is a critical enzyme for the biosynthesis of 5-HT outside of the central nervous system (CNS), and it is of interest that Durk et al. have utilised mice genetically deficient in THP-1, as well as mast cell-deficient mice, to demonstrate that platelets, rather than mast cells, are the main source of 5-HT released during an allergic inflammatory response (Dürk et al. 2013). Unlike mice, human mast cells are not a major source of 5-HT and so it is of even more interest that Idzko and colleagues have found elevated 5-HT levels in BAL fluid following segmental bronchial allergen challenge in allergic asthmatics, as their results suggest that the 5-HT found in the lung likely comes from activated platelets (Dürk et al. 2013). These results provide further support to other clinical observations reporting platelet activation in patients with allergic asthma (Maccia et al. 1977; Kowal et al. 2006; Pitchford et al. 2003; Johansson et al. 2012). It is of particular interest that platelets have now been found extravascularly in a number of inflammatory situations (Feng et al. 1998), including in the lungs of experimental animals (Pitchford et al. 2008) and patients with asthma (Jeffery et al. 1989). It becomes intriguing to know whether the elevated 5-HT found in BAL of allergic asthmatics is derived from circulating platelets and/or from platelets that have undergone diapedesis into lung tissue. Either way the results presented by Durk et al. are of further interest as they have reported that allergic mice deficient in THP-1 or treated with an inhibitor of THP-1, PCPA, exhibit reduced leukocyte infiltration into the lung and inhibition of the bronchial hyperresponsiveness (BHR) that normally accompanies allergen challenge, suggesting that the platelet-derived 5-HT is playing a central role in allergic inflammation in the lung. Given that there are some encouraging early clinical observations in patients with asthma administered drugs either affecting 5-HT uptake (Lechin et al. 1998) or antagonising 5-HT2 receptors (Lima et al. 2007), it would seem timely to consider large trials of such agents in patients with allergic airways disease.

Studies in Experimental Animal Models: Leukocyte Recruitment

There is now a growing body of literature that suggests that platelets play a central role in both allergic (Pitchford et al. 2003, 2005) and non-allergic (Kornerup et al. 2010) leukocyte recruitment into the lung, as well as a critical role in other manifestations of allergic asthma such as airway remodelling (Pitchford et al. 2004). The mechanisms by which platelets influence these processes are discussed below and open up the possibility of identifying a number of potential new targets for the treatment of inflammatory diseases such as asthma and COPD.

Investigation of the mechanics of blood flow (haemorheology) has uncovered interesting phenomena that have fundamental implications related to how platelets are required to initiate the ‘adhesion cascade’ that results in leukocyte recruitment into tissues associated with inflammatory airway diseases. In laminar flow in blood vessels, a shearing motion occurs due to the influence of wall friction that results in a

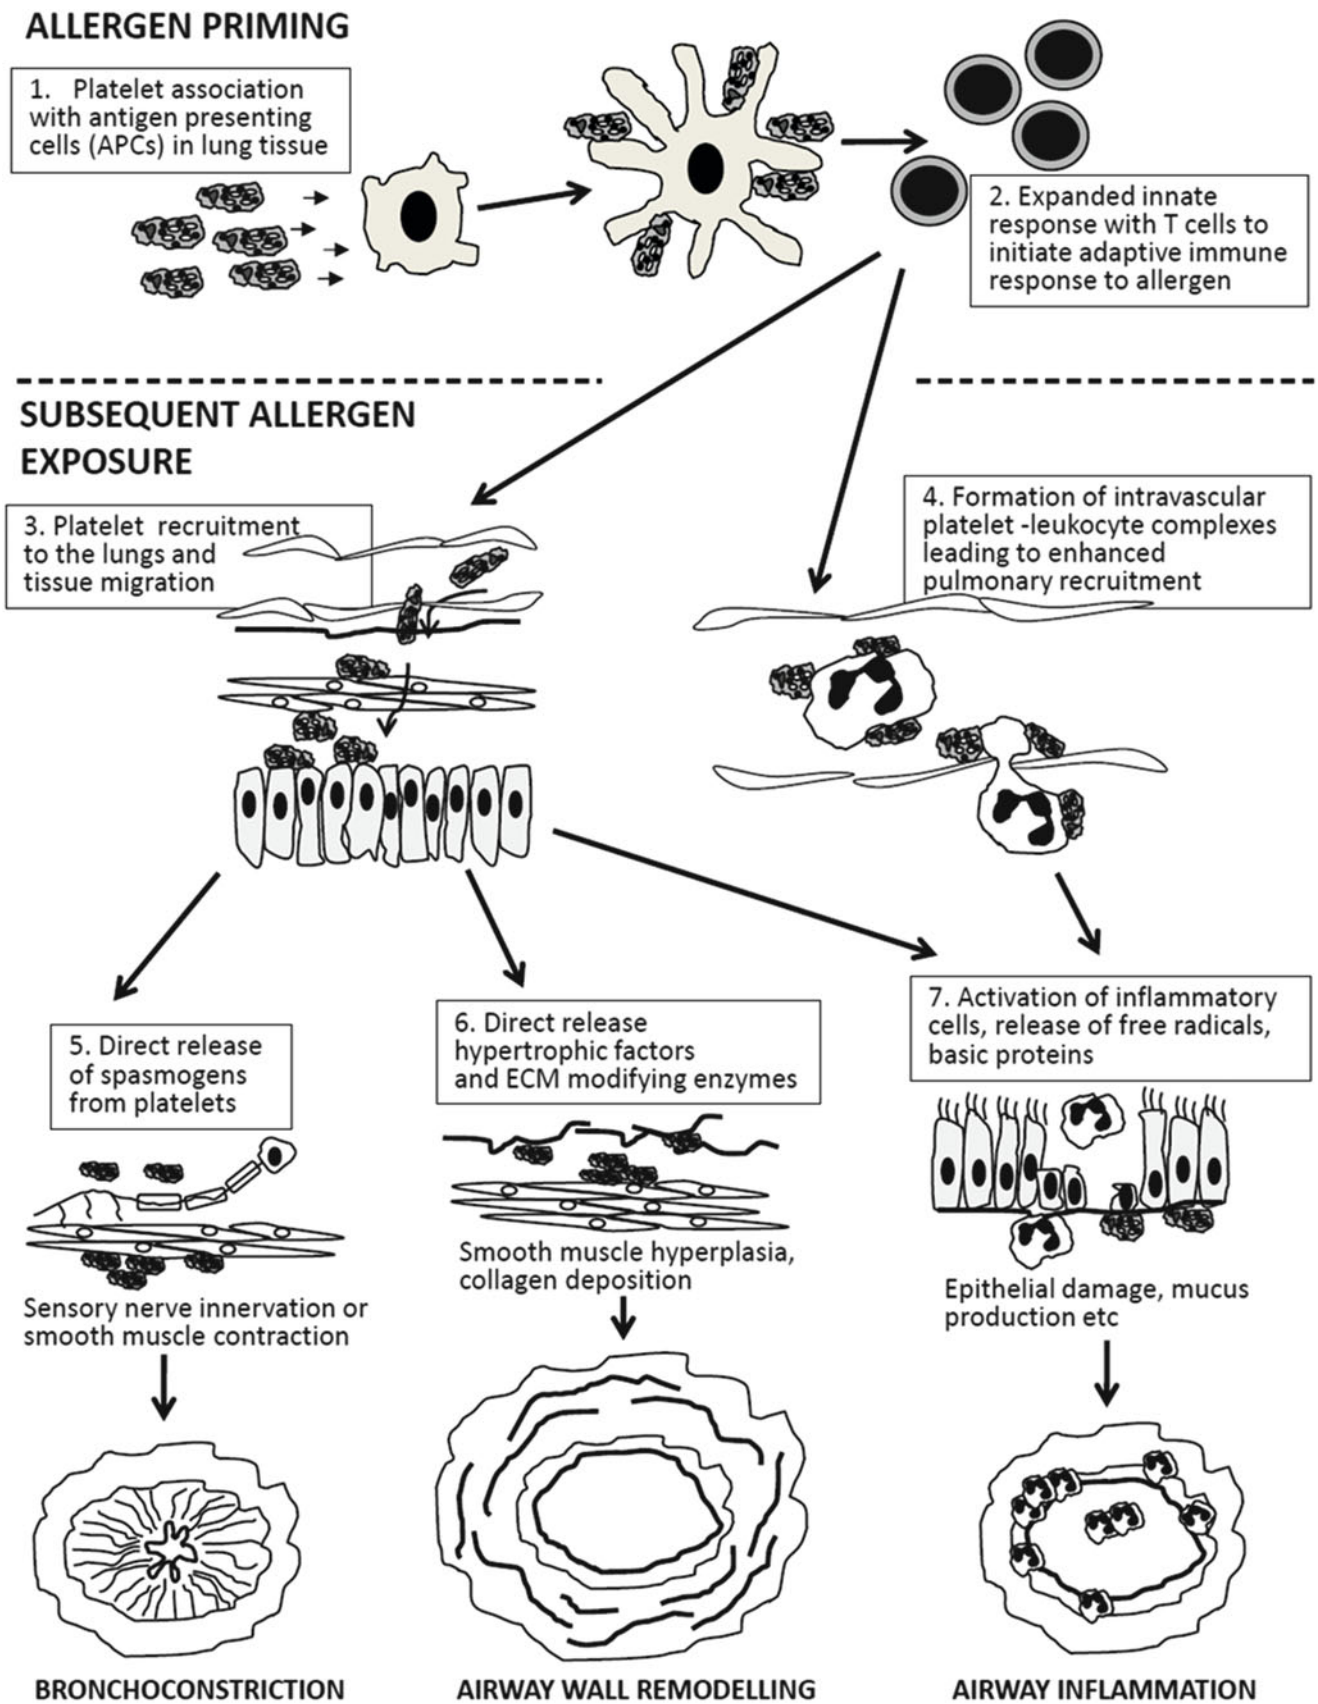

Fig. 1 There is evidence for platelet participation in both innate immune surveillance and the adaptive response to allergen and inflammatory events that occur after subsequent secondary exposure. This picture was originally published in Idzko, Pitchford, and Page J Allergy Clin Immunol (2015) 135: 1416-1423

parabolic velocity profile of the fluid (Hagan–Poiseuille Law); because blood is a non-Newtonian fluid, the viscosity of blood decreases with increasing shear rate and thus red blood cells actually aggregate to form reversible rouleaux under conditions of low shear and move inwardly (due to their relative deformability compared to platelets and leukocytes) into the inner part of the vessel (Goldsmith and Spain 1984a, b; Goldsmith et al. 1981, 1999). This phenomenon is known as the Fahraeus effect, the consequence of which is a redistribution of the blood elements, with the density of platelets and leukocytes increasing around the vessel periphery. The region of the vessel where the velocity gradient is highest is around the vessel wall; thus cells travelling at different velocities along adjacent streamlines have increased probability of cellular collisions. This peripheral zone therefore 'traps' leukocytes into an environment rich in platelets, greatly enhancing collisions between platelets and leukocytes (Goldsmith and Spain 1984a, b; Goldsmith et al. 1981, 1999) and leading to the tethering of platelets to leukocytes to form rosettes through P-selectin recognition steps, to the subsequent upregulation of integrin expression and to the firm adhesion to endothelium as platelet-bound leukocytes enter the capillary network. High-resolution video microscopy has revealed the existence of membrane tethers involving P-selectin/PSGL-1 bonds that regulate leukocyte rolling on platelets and P-selectin with changes in tether length and lifetime dependent on increasing shear force (Schmidtke and Diamond 2000). The biomechanics of the complex formation of activated platelets with leukocytes reveals that the high tensile strength of P-selectin/PSGL-1 interactions enables P-selectin-dependent tethering at high shear rates, whereas integrin activation may mediate platelet–leukocyte complex formation at low shear rates. Nevertheless, unstimulated leukocytes (which constitutively express PSGL-1/L-selectin) may also bind to activated platelets in an integrin-independent manner, suggesting that cell adhesion that is not purely selectin dependent may create platelet–leukocyte complexes (Xiao et al. 2006).

These events occur in the circulation of patients with asthma upon allergen challenge. Thus, circulating platelet–leukocyte complexes are found in allergic asthmatic patients after both spontaneous asthma attacks and after allergen challenge, in a biphasic manner (Gresele et al. 1993; Pitchford et al. 2003). The possible significance of these platelet–leukocyte complexes is to act as a 'priming' step for further leukocyte adhesion, since leukocytes attached to platelets display enhanced expression of the β1 integrin MAC-1 (Pitchford et al. 2003, 2005; Johansson et al. 2012). It is therefore of considerable interest that recent research has correlated platelet activation with eosinophil inflammation in patients with asthma (Benton et al. 2010). Furthermore, in patients with asthma, β1 integrin expression on eosinophils correlated with eosinophil-bound platelets expressing P-selectin and antigen challenge leads to the disappearance from the circulation of eosinophils bearing platelet P-selectin, presumably because these complexes are sequestered in the lungs (Johansson et al. 2012). The mechanistic significance of these platelet/eosinophil interactions is that this leads to increased eosinophil adhesion to the vascular endothelium via a platelet-P-selectin-dependent mechanism (Jawień et al. 2002; Ulfman et al. 2003).

The importance of platelets in pulmonary leukocyte recruitment after allergen challenge has now been extensively proven using in vivo models of platelet depletion. In fact platelet depletion, either via immunological or non-immunological methods, strongly reduces pulmonary eosinophil and lymphocyte recruitment in rabbits, guinea pigs and mice (Pitchford et al. 2003, 2005; Coyle et al. 1990; Lellouch-Tubiana et al. 1988) and the recruitment of effector T cells in murine models of contact hypersensitivity (Ludwig et al. 2004; Tamagawa-Mineoka et al. 2007). This process required intact platelets, since the reinfusion of lysed platelet products was insufficient to restore leukocyte recruitment, whereas the reinfusion of intact activated platelets expressing selectins on the cell surface restored leukocyte recruitment (Pitchford et al. 2005; Tamagawa-Mineoka et al. 2007). With similarities to allergic asthmatic patients undergoing allergen challenge, mice sensitised to allergen have circulating leukocytes attached to platelets displaying significantly increased CD11b (integrin αM) and VLA-4 (very late antigen-4) in comparison with leukocytes not attached to platelets (Pitchford et al. 2003, 2005). Contact with platelets therefore induces activation of leukocytes, thus enhancing the expression of integrins, presumably for firm adhesion. This has been confirmed by the experimental use of antibodies blocking P-selectin which results in the suppression of platelet–leukocyte complexes, integrin expression and subsequent tissue recruitment in models of asthma and chronic contact hypersensitivity (Pitchford et al. 2005; Ludwig et al. 2004; Tamagawa-Mineoka et al. 2007; Symon et al. 1999; Mayadas et al. 1993; Lukacs et al. 2002; De Sanctis et al. 1997; Broide et al. 1998). Indeed, the targeting of P-selectin or PSGL-1 as a novel therapeutic option is currently progressing in phase II clinical trials in patients with asthma (Bedard and Kaila 2010).

Nevertheless, many other studies also reveal that other mediators released, or expressed, by platelets can modulate leukocyte recruitment. Examples are the platelet-specific chemokines PF-4 (CXCL4), β-TG (CXCL-7) and RANTES (CCL5) and pleiotropic mediators such as leukotrienes, 5-HT and sphingolipids (Page and Pitchford 2013; Brandt et al. 2000; Duerschmied et al. 2013; Florey and Haskard 2009). Thus, whilst there is a requirement for platelets expressing adhesion molecules on their surface for leukocyte recruitment, this must also be sequential to the release or expression of other platelet-derived factors. However, it is not yet understood from a physiological perspective why

the process of leukocyte activation and adhesion to post-capillary venules is so inefficient and actually requires platelet activation. Perhaps the rapidity of platelet activation to danger signals combined with a higher surface area/volume ratio, allowing a critical density of adhesion molecules to be expressed compared to larger leukocytes, has resulted in an evolutionary requirement for platelets in the rheological processes that trigger the leukocyte adhesion cascade.

Pathophysiologic Observations: The Extravascular Presence of Platelets

Current perceptions concerning platelet function in inflammation are heavily influenced by the knowledge of the intravascular role of platelets in haemostasis and thrombosis. Thus, dogma suggests that the participation of platelets in inflammation is also confined to intravascular events and therefore that it is indirect and totally dependent on the ability of platelets to influence leukocyte recruitment. However, accumulating evidence details a novel function of platelets in being able to respond to chemotactic signals and migrate extravascularly through inflamed tissue (see Petito et al. 2017) (Fig. 2).

Platelets have been observed to undergo diapedesis in sections of the lungs obtained from patients with asthma and the lungs (and BAL fluid) from allergen-sensitised and allergen-exposed mice, rabbits and guinea pigs (Jeffery et al. 1989; Metzger et al. 1987; Pitchford et al. 2008; Lellouch-Tubiana et al. 1988; Beasley et al. 1989). Using quantitative histology, we have recently reported that the migration of platelets into lung tissue and the localisation of platelets around the airway wall in allergen-sensitised and allergen-exposed mice was an IgE-mediated process and that platelets from such mice could also undergo chemotaxis to the sensitising allergen in vitro (Pitchford et al. 2008). Interestingly, the migratory response of platelets in the lungs in vivo commenced before significant leukocyte recruitment, whilst at later time points, when leukocytes had also entered lung tissue, around 50 % of platelets were still not complexed to leukocytes (Pitchford et al. 2008). The rapidity of this response highlights that platelet activation by allergen is direct and independent of activation of other cells, like mast cells (Yoshida et al. 2002). It is interesting to note that evidence is accumulating of platelet migration into tissues in other inflammatory diseases, such as into the synovial fluid in patients with rheumatoid arthritis, and transmigration across the vascular wall after long periods of ischaemia (see Ware and Post 2017) (Boilard et al. 2010; Kraemer et al. 2010). The mechanisms controlling this platelet function have not been elucidated, but platelets express a number of different chemokine receptors (CCR1, CCR3, CCR4 and CXCR4) which are functional,

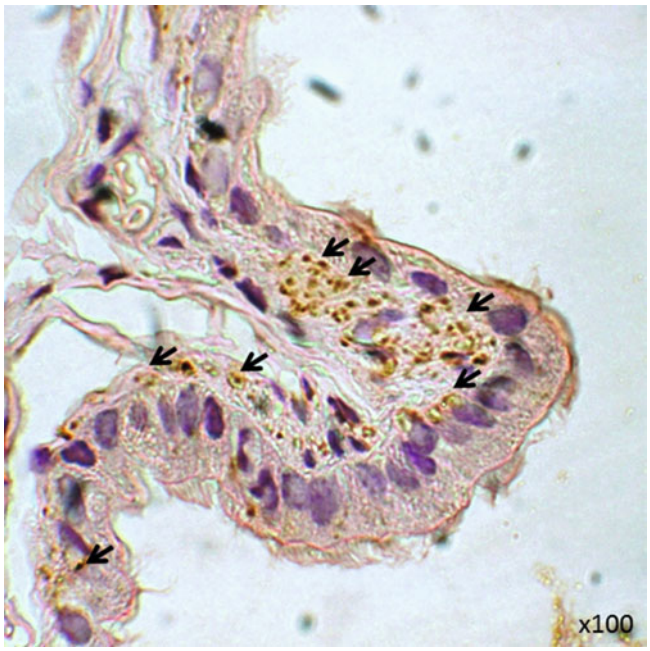

Fig. 2 Histological analysis of the lungs taken from ovalbumin (OVA)-sensitised mice after allergen inhalation. Section was stained for the platelet-specific antigen CD41 (integrin αIIb). Platelets (*brown*) can be observed throughout the airway wall. Image originally published in Page & Pitchford (2014) Clin Exp Allergy 44: 901–913

since the ligands SDF-1 α, MDC and TARC can activate platelets (Abi-Younes et al. 2001; Kowalska et al. 2000; Clemetson et al. 2000). Platelets have also been shown to undergo chemotaxis to f-MLP and SDF-1α and can therefore be considered as motile cells (Czapiga et al. 2005; Kraemer et al. 2010). Therefore, platelets can migrate through lung tissue and localise to specific resident cells/structures in a highly regulated process, as it is for leukocytes. Whilst the significance of platelet migration into lung tissue has not yet been fully characterised, platelets may directly influence the development of sensitisation towards allergen, BHR, bronchospasm, tissue damage and chronic inflammation leading to airway wall remodelling.

Studies in Experimental Animal Models: Involvement with Antigen-Presenting Cells and Contact with Allergen

Platelets express both the high-affinity (FcεRI) and low-affinity (CD23) receptors for IgE, as well as functional receptors for other immunoglobulins. Platelets can be activated by specific allergen via IgE-dependent processes, as revealed when platelets are taken from patients allergic to *Dermatophagoides pteronyssinus* (Der p1) and exposed to synthetic peptides derived from the allergen Der p1 ex vivo (Cardot et al. 1992). We have shown that platelets from

patients with asthma will undergo chemotaxis specifically towards the known allergen (rather than allergens to which individual patients are not allergic too) (Pitchford et al. 2008). The implications of direct platelet activation and motility by allergen are not yet known, but it is interesting to note that platelets activate dendritic cells (DCs) in the airways (Dürk et al. 2013). Both CD40 and CD40L have been identified on activated platelets and might be responsible for this cellular interaction (Semple et al. 2011; Henn et al. 1998). Platelet CD40L has been described in other situations as an important link between the innate and adaptive immune response to induce DC maturation, for example, the expression of CD80 and CD83, and immunoglobulin class switching (Elzey et al. 2003; Czapiga et al. 2004; Sprague et al. 2008). Platelet CD40L has recently been reported to be involved in the promotion of allergic airway inflammation by polarising Th2 responses after allergen exposure (Tian et al. 2015). Despite this evidence, it remains to be understood whether platelets are involved in the initial allergen sensitisation process per se.

Studies in Experimental Animal Models: Lung Function

The observation that platelets migrate into the lung tissue of patients with asthma, and into the lungs of allergen-challenged sensitised animals, opens the possibility that platelets may contribute directly to alterations in lung function in patients with asthma. For example, platelet depletion in allergen-sensitised rabbits and guinea pigs abolishes bronchoconstriction and anaphylaxis induced by inhaled spasmogens or allergens, respectively (Coyle et al. 1990; Lellouch-Tubiana et al. 1988). There is now some understanding of the pathways and platelet mediators involved in these processes from the observations on the effects of intravenous platelet agonists on bronchospasm and platelet accumulation in the lung (Arnoux et al. 1988; Yoshimi et al. 2001; Lellouch-Tubiana et al. 1988; Robertson and Page 1987). We have recently observed that platelet depletion inhibits bronchospasm induced by 'indirect spasmogens', such as capsaicin and bradykinin, whilst it does not inhibit direct-acting spasmogens, such as histamine and methacholine (Keir et al. 2015), suggesting that platelet-derived mediators contribute to airway obstruction under certain circumstances. Furthermore, the inhibition of the release of bronchoactive agents from platelets abrogated the resulting changes in airway obstruction, confirming that platelet-derived mediators might also contribute to airway tone (Arnoux et al. 1988; Yoshimi et al. 2001). Indeed, a direct participation of platelets in allergy, independent of leukocyte responses, was highlighted by the intradermal injection of supernatants from activated human platelets (but not leukocytes) inducing delayed, sustained inflammatory responses in the skin of patients with atopic dermatitis (Matsuda et al. 1997). These effects on tissue suggest that platelets are very capable of directly inducing sustained inflammation. Human platelets synthesise and release a number of bronchoactive mediators, for example, histamine, 5-HT, TXA2, adenosine and 12-hydroxyeicosatetraenoic acid (12-HETE), contain cytotoxic compounds within their granules and generate substances capable of inducing tissue damage, such as reactive oxygen species (ROS), cationic proteins (PCPs), platelet basic proteins (PBPs) and matrix metalloproteinases (Saxena et al. 1989; Knauer et al. 1984; Busti et al. 2010). Yet it is not understood how these mediators interact, and with what (e.g. sensory nerves, airway smooth muscle, epithelium), to elicit bronchospasm and BHR.

Studies in Experimental Animal Models: Chronic Inflammation and Lung Remodelling

One consequence of persistent, chronic inflammation is the alteration of tissue structure and function. In bronchial asthma, chronic inflammation contributes to changes in airway architecture referred to as 'airway remodelling'. The observation that platelets migrate into lung tissue of patients with asthma and in experimental animals (Jeffery et al. 1989; Metzger et al. 1987; Pitchford et al. 2008; Lellouch-Tubiana et al. 1988; Beasley et al. 1989) suggests that platelets may contribute directly to changes in the airway architecture by releasing factors that control the synthetic phenotype of the airway epithelium and of fibroblasts and airway smooth muscle cells. Indeed, in murine models of chronic allergic inflammation, the depletion of platelets led to a comprehensive suppression of lung remodelling (smooth muscle hyperplasia, subepithelial fibrosis, collagen deposition, epithelial hyperplasia), an effect that chronic treatment with glucocorticosteroids did not attain, suggesting that platelet involvement in tissue remodelling may in some instances be independent of leukocyte-associated inflammation (Pitchford et al. 2004). In patients with asthma, platelet activation was shown to persist for some time after the late asthmatic response had occurred (Kowal et al. 2006), even though the increases in circulating platelet–leukocyte aggregates returned to basal levels 24 h after allergen exposure (Pitchford et al. 2003), thus implicating platelets in chronic inflammatory events and airway remodelling.

Platelets are a rich reservoir of mitogens and enzymes and therefore may contribute to generate an environment that induces synthetic responses in structural airway cells. Platelet mitogens include PDGF, EGF (epidermal growth factor), TGF-β (transforming growth factor-β), VEGF (vascular endothelial growth factor) and the major product of arachidonic acid metabolism in platelets, TXA2, which all have proliferative activity on structural cells of the airways (Pitchford and Page 2002; Rendu and Bohard-Bohn 2002).

Platelet-derived enzymes include matrix metalloproteinases, β-hexosaminidases and heparanases that are released following allergen challenge in asthmatic patients and following ozone challenge in guinea pigs and may alter the composition of the extracellular matrix (Falcinelli et al. 2005; Kelly et al. 2000). Disruption of the composition and integrity of cell membranes by degradation of glycoproteins, glycolipids and glycosaminoglycans may also release membrane-bound growth factors for wound repair (McKenzie 2007). Recent evidence shows that platelet membranes are required to induce synthetic responses in airway smooth muscle cells (Svensson Holm et al. 2011), and this function was controlled by platelet 5-lipoxygenase, 12-lipoxygenase and the production of reactive oxygen species (Svensson Holm et al. 2008, 2014). These effects may be supplemented by the ability of platelets to influence the survival, recruitment, proliferation and differentiation of circulating stem cells involved in (inappropriate) tissue regeneration (Stellos et al. 2010). It can be surmised therefore that platelets may influence lung regeneration as well as inappropriate remodelling of the airways after injury, although the interplay between platelets and different structural cells is likely to be extremely complex and involve a plethora of mediators.

Platelets in Infectious Pulmonary Disease

- Platelets have a broad repertoire of receptor molecules that enable them to sense invading pathogens and infection-induced inflammation.
- Consequently, platelets exert direct antimicrobial mechanisms and initiate an intense crosstalk with other cells of the innate and adaptive immunity, including neutrophils, monocyte/macrophages, dendritic cells and B and T lymphocytes, favouring antimicrobial activity.

In mammalians, platelets have retained key structures and functions of immune effector cells which are integral to antimicrobial host defence (Morrell et al. 2014). In the bloodstream they act as quiescent 'sentinels' of tissue injury and microbial threat. Platelets exert activities that span from acute inflammation to adaptive immune responses that confer to them an important role as immune regulators during sepsis (Semple et al. 2011). Platelets store antimicrobial peptides, such as β-defensins, thrombocidins, PF-4 (CXCL4), RANTES (CCL5), connective tissue-activating peptide-3, platelet basic protein, thymosin β-4, fibrinopeptide B and fibrinopeptide A, and contribute to the innate immune system (Tang et al. 2002; Kraemer et al. 2011). Inflammatory lung diseases and other pulmonary disorders cause accumulation of platelets in the lungs, and tissue injury and systemic conditions such as sepsis can activate platelets in the circulation and sequester them in the pulmonary vascular bed (Fig. 3).

Pathophysiologic Observations

Platelets participate in inflammatory and immune responses using a variety of molecular mechanisms, including the release of chemokines (β-TG, PF4, ENA-78, Gro-α, RANTES, SDF1α and others), cytokines (HMBG1) and growth factors (PDGF, VEGF, EGF, FGF, TGFbeta, and so on), and the synthesis of lipid mediators, like thromboxane A2 and PAF, but contribute also to the maintenance of the endothelial barrier. Key differences exist between the characteristics of endothelium in the pulmonary circulation and the systemic vasculature. Notably, ICAM-1 and integrin $\alpha_v\beta_3$ are highly expressed by the pulmonary circulation as compared to other vascular beads (Panes et al. 1995; Singh et al. 2000). It is thus possible that platelet retention in the lungs is mediated by the constitutive expression of these two adhesion molecules by pulmonary endothelial cells. Activation of platelets, which is a requirement for their firm adhesion to endothelial cells, results in a conformational change

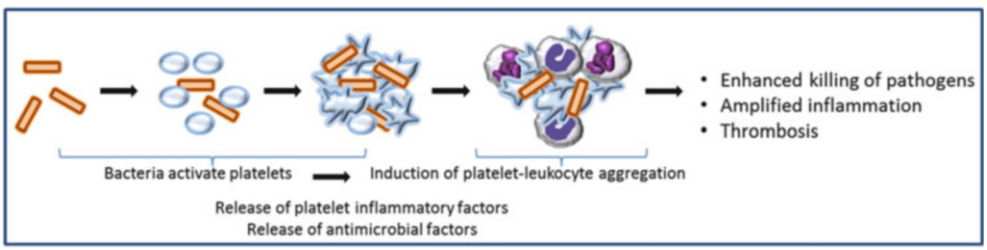

Fig. 3 Direct interaction of bacteria with platelets can lead to aggregation, release of antimicrobial factors and pro-inflammatory molecules and formation of platelet–leukocyte aggregates. Under some conditions, bacterial toxins of several classes can trigger these responses of human and murine platelets. Evidence suggests that these activities mediate immobilisation and killing of bacteria and other pathogens. In addition, however, each can contribute to local thrombosis and inflammation

in platelet $\alpha_{IIb}\beta_3$ that increases its affinity for fibronectin, which can then act as a bridge to endothelial cell $\alpha_v\beta_3$ in the low shear stress circulation of the pulmonary vascular bed (Goldenberg and Kuebler 2015). Moreover, platelets can induce inflammatory responses by expressing CD40L which is recognised by surface CD40 on endothelial cells which will then secrete adhesion molecules and TF (Freedman 2003). In addition, activated platelets display P-selectin which mediates their adhesion to PMN by binding to PSGL-1, favouring tethering and rolling on the endothelium, thereby guiding neutrophils to transmigrate (Weyrich et al. 2009) (Fig. 4).

Platelets express a ligand for triggering receptor expressed on myeloid cells (TREM)-1, a surface receptor that plays important roles in innate and adaptive immunity expressed by neutrophils and monocytes. Platelets bound to endothelium support the engagement of neutrophil TREM-1 and result in increased expression of pro-inflammatory chemokines and cytokines, thus amplifying the inflammatory response (Haselmayer et al. 2007). Platelets additionally function as a threshold switch for the release of neutrophil extracellular traps (NETs), web-like structures of DNA that can trap and kill microbes in the vasculature, by neutrophils (Brinkmann et al. 2004) (Rondina et al. 2017; Pryzdial et al. 2017; Foote et al. 2017). This occurs primarily in small vessels, like the liver sinusoids and pulmonary capillaries, where NETs, and particularly the histone components, are responsible for death of lung epithelial and endothelial cells, often with consequent tissue damage and organ dysfunction (Saffarzadeh et al. 2012).

Platelets also express Toll-like receptors (TLRs), a highly conserved family of pattern recognition receptors expressed from flies to mammals. TLRs bind pathogen-associated molecules that are broadly expressed by many infectious organisms. LPS is the most studied TLR ligand, and others include unmethylated cytosine guanine dinucleotide, double-stranded RNA and lipoproteins. Platelets express low levels of TLR2 (Aslam et al. 2006), TLR4 and TLR9 (Cognasse et al. 2005). In addition, additional TLRs and other secondary signalling molecules can become expressed following platelet activation. For example, high concentrations of thrombin induce the expression of TLR9 by platelets. TLR2 and TLR4 are functional in inflammatory responses such as sepsis, e.g. TLR4 triggers the expression of IL-6 and cyclooxygenase 2 (COX-2) in response to LPS (Scott and Owens 2008). LPS has been shown to induce thrombocytopenia and platelet accumulation in the lungs of wild-type but not TLR4-deficient mice. Moreover, LPS stimulation of platelet TLR4 induces platelet binding to and activation of adherent neutrophils. Indeed, stimulation of platelet TLR2 by synthetic bacterial lipopeptide directly activates the platelet's thrombotic and inflammatory response through the phosphoinositide 3-kinase (PI3-K) signalling pathway (Blair et al. 2009). In sepsis, neutrophils and

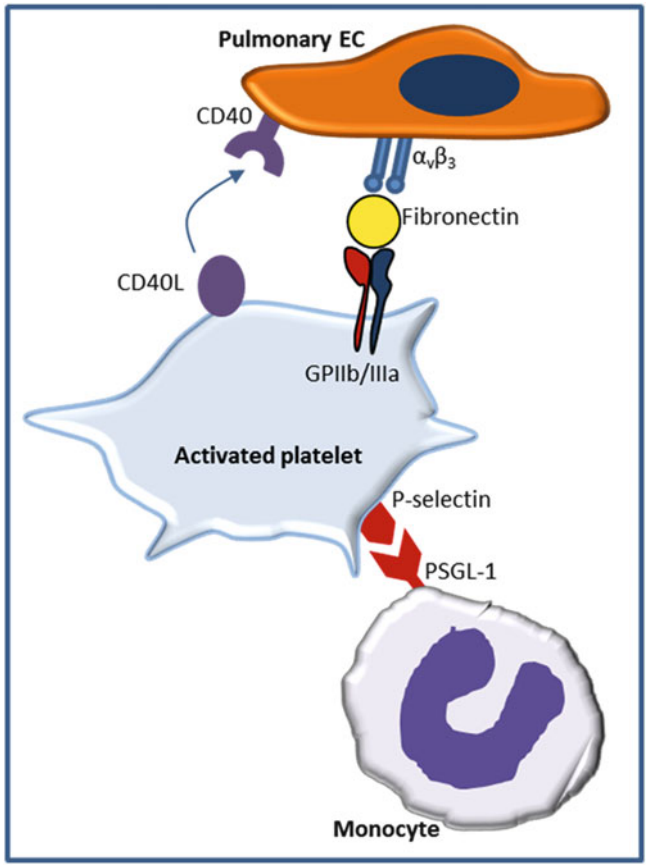

Fig. 4 Interactions between platelets and pulmonary ECs and monocytes in pulmonary infectious disease

platelets co-localise in several organs. Upon stimulation via TLR4, platelets induce neutrophil activation and the formation of NETs that display proteolytic activity, leading to the killing of microbes (Clark et al. 2007). Furthermore, platelets directly kill bacteria by releasing microbicidal peptides or by phagocyticing bacteria (Semple et al. 2011; Kraemer et al. 2011; Krijgsveld et al. 2000). Exposure of platelets to Gram-negative bacteria induces platelet aggregation, activation, P-selectin expression and formation of platelet/neutrophil aggregates via TLR2 (Beaulieu et al. 2011). Moreover, incubation of megakaryocytes with TLR2 leads to the generation of platelets with an enhanced pro-inflammatory gene and protein expression profile (Aslam et al. 2006).

In addition to their roles in innate immunity, platelets act as mediators between innate and adaptive immune response cells (Aslam et al. 2006; Elzey et al. 2003, 2005; Semple et al. 2011). Thus, platelets serve as early effectors of dendritic cells (DCs) activation in tissue injury through the release of CD40L and IL-1β and DCs are essential to link innate and adaptive immunity (Medzhitov and Janeway 2000; Banchereau and Steinman 1998). Platelet-mediated leukocyte adhesion to endothelium may also enhance lymphocyte trafficking during adaptive immunity and host

defence (Diacovo et al. 1996; von Hundelshausen and Weber 2007).

Studies in Experimental Animal Models

Platelets have a key role in immune surveillance by monitoring the surface of active macrophages (Wong et al. 2013). Platelets survey liver Kupffer cells through transient interactions via their GPIb with VWF constitutively expressed on Kupffer cells. When Kupffer cells capture blood-borne *S. aureus* or *Bacillus cereus*, they upregulate their VWF and the normally transient interaction with platelets becomes a sustained adhesion that actively encases the bacteria for eradication within the first minute of encounter. GPIb-deficient mice are significantly more susceptible to Kupffer cell damage and mortality in infections generated by the above-mentioned bacteria, ostensibly due to inefficient detection of Kupffer cell infection by platelets (Wong et al. 2013). Therefore, the targeting of infected macrophages by platelets seems to be an early and key host defence step to facilitate bacterial clearance and protection against disseminated infection (see Slaba and Kubes 2017).

The depletion of platelets in mice submitted to Klebsiella-induced pneumosepsis enhanced mortality in a way proportional to the extent of platelet depletion, by increasing the release of pro-inflammatory cytokines. Although Klebsiella sepsis did not directly enhance the expression of P-selectin on circulating platelets, the infection did increase the responsiveness of platelets to thrombin receptor stimulation (De Stoppelaar et al. 2014). In accordance, lipopolysaccharide (LPS) has been described to act as a platelet 'primer' (Gresele et al. 2008); in fact LPS induces platelet hypersensitivity to subthreshold concentrations of platelet agonists (Zhang et al. 2009).

During severe influenza A virus infection in mice, platelets massively infiltrated bronchoalveolar lavage fluid and were detected in ultrathin cryosections of the lungs staining positive for virus antihaemagglutinin, indicating that platelets actively incorporate influenza virus (Mazur et al. 2007).

Platelets in Cystic Fibrosis

- Platelets from cystic fibrosis (CF) patients have increased reactivity.
- A positive feedback loop of inflammation and platelet activation, which in turn lead to more inflammation and platelet activation, may exacerbate lung disease in patients with CF.

Cystic fibrosis (CF) is a multi-organ disease which affects the pancreas, the gastrointestinal tract, the male reproductive system and especially the respiratory tract. It is a lethal genetic disorder caused by a mutation in the gene, located in the long arm of chromosome 7, coding for the cystic fibrosis transmembrane conductance regulator (CFTR), a chloride ion channel belonging to the superfamily of the ATP-binding cassette (ABC) proteins (Riordan et al. 1989). Chronic lung inflammation, due to an impairment of mucociliary clearance and to the consequent bacterial colonisation, represents the main cause of mortality and morbidity in CF patients.

Pathophysiologic Observations

CF patients have an increase in circulating activated platelets and platelet reactivity, as determined by enhanced monocyte–platelet aggregates, neutrophil/platelet aggregates and platelet surface P-selectin (Sturm et al. 2010; O'Sullivan et al. 2005). Moreover, elevated concentrations of sCD40L and TXA2 metabolites, which correlate with decreased lung function, further implicate platelets in the pathophysiology of this lethal disorder (Ciabattoni et al. 2000; Falco et al. 2004).

CFTR was found to be expressed by neutrophils and platelets, where it is localised in the cytosol, cell membranes and α-granules, and when blocked a markedly decreased thrombin-induced AKT phosphorylation and an upregulation of TRAP-stimulated p38MAPK phosphorylation were observed (Mattoscio et al. 2010). p38 MAPK activation has been associated with platelet secretion of pro-inflammatory mediators; thus the CFTR-dependent increase in p38 MAPK phosphorylation is consistent with a pro-inflammatory profile of CF platelets.

Another abnormality reported in CF patients is the reduction of plasma levels of vitamin E, which may increase fatty acid oxidation and thus the production of isoprostanes, which in turn activate platelets (Ciabattoni et al. 2000). Moreover, reduced nitric oxide (NO) generation was also observed in patients with CF and found to be a negative prognostic index associated with bacterial colonisation of the lung and sustained inflammation (Balfour-Lynn et al. 1996; Grasemann and Ratjen 2012). Endothelial dysfunction may also contribute to reduce NO generation in CF

(Poore et al. 2013), and the reduction of NO may contribute to platelet hyperreactivity. Platelets also produce NO upon eNOS activation that may act as a negative feedback mechanism to limit platelet activation and platelet recruitment to a growing thrombus (Cozzi et al. 2015; Momi et al. 2014; Freedman et al. 1997). Furthermore, the blockade of CFTR blunted NO generation by platelets suggesting this as another mechanism of the platelet hyperfunction in CF (Mattoscio et al. 2010).

Platelet 12-lipoxygenase is a key enzyme in the biosynthesis of lipoxins (Romano et al. 1993), arachidonic acid (AA) metabolites with potent anti-inflammatory properties. Lipoxin formation occurs in vivo during platelet–PMN interactions (Gangemi et al. 2003) and represents a main stop signal of inflammation (Serhan et al. 2008). Of interest, CF patients display a defect in the biosynthesis of lipoxin A4 (Karp et al. 2004), whereby mutated CFTR downregulates lipoxin formation by selective inhibition of platelet 12-lipoxygenase activity.

Patients with CF have increased plasma levels of ATP, due to the dysfunction of CFTR which acts as an ATP transporter, as well as a chloride channel, that can contribute to platelet activation (Lader et al. 2000). ATP may in fact act as a platelet agonist in vivo under special circumstances, like under high shear stress conditions, and may thus also contribute to the hyperreactivity of CF platelets (Birk et al. 2002).

Altogether, these data suggest an involvement of platelets in the sustained inflammatory response of CF originating from increased pro-inflammatory platelet-activating mediators and reduced counter-regulatory signals (Mattoscio et al. 2010; O'Sullivan et al. 2005).

Patients with CF show thrombocytosis, increased expression of P-selectin on circulating platelets (O'Sullivan et al. 2005), increased platelet reactivity to ADP and TRAP (Stead et al. 1987) and increased release of platelet-derived mediators (e.g. TNFα, CD40L, LTB4 and interleukins) (Shoki et al. 2013). Moreover, patients with CF display increased circulating platelet–leukocyte and platelet–monocyte complexes (O'Sullivan et al. 2005) and enhanced NET formation in airway fluids correlating with impaired obstructive lung function. These phenomena are blocked by the intra-airway delivery of small-molecule antagonists of CXCR2, with inhibition of NET formation and improved lung function (Marcos et al. 2010). In CF, increased platelet number correlated with decreased PaO2 (Gross and Luckey 1969), increased urinary thromboxane metabolite excretion with decreased FEV1 (Davì et al. 1995; Ciabattoni et al. 2000) and increased plasma sCD40L with decreased pulmonary function (Falco et al. 2004). Taken together these studies suggest a link between platelet activation and progressive impairment of lung function in CF. Whether platelet abnormalities are the cause or consequence of lung inflammation in CF is unclear. However, platelet dysfunction in CF could be the result of platelet abnormalities intrinsic to CF, of the accumulation of plasma factors unique to CF and/or of generalised inflammation.

Studies in Experimental Animal Models

Mice carrying the F508del mutation of CFTR developed more severe thrombocytopenia, higher levels of plasma TxB2 and PAF levels and enhanced neutrophilic lung infiltration when challenged with LPS relative to wild-type controls (Zhao et al. 2013). Blockade of PSGL-1 (P-selectin glycoprotein ligand-1) or of P-selectin, PAF-receptor antagonism or correction of mutated CFTR trafficking by KM11060 (an analogue of sildenafil, which restores a function of the F508del-mutated CFTR chloride channel) all significantly increased plasma lipoxin A4 levels, whilst the depletion of platelets significantly decreased plasma lipoxin A4 and enhanced LPS-induced lung inflammation (Wu et al. 2014).

Therefore, a growing body of evidence suggests that platelets play a very important role in CF and along with evidence of platelet involvement in other inflammatory lung diseases suggests that they may represent a potential therapeutic target in CF. However, much work remains to be done before anti-platelet therapy can be recommended for patients with CF.

Platelets in Chronic Obstructive Pulmonary Disease (COPD)

Platelet activation represents a mechanism that may contribute to the increased cardiovascular risk associated with stable COPD and with exacerbations.

Chronic obstructive pulmonary disease (COPD) is a respiratory disorder characterised by progressive lung destruction with airflow limitation associated with an airway and systemic inflammatory response (Rabe et al. 2007). Low-grade, chronic systemic inflammation in COPD is frequently complicated by acute atherothrombotic events, independent of the smoking history or other cardiovascular risk factors (Malerba et al. 2013), and coronary artery disease is one of the leading causes of death in COPD (Hansell et al. 2003). Moreover, COPD patients have an increased risk of ischaemic stroke (Truelsen et al. 2001) and venous thromboembolism, particularly during acute exacerbations (Tillie-Leblond et al. 2006). Although the mechanisms responsible for the association between COPD and atherothrombosis are still largely unknown, platelet activation is one of the proven links.

Pathophysiologic Observations

A link between hypoxia and platelet activation has been suggested since hypoxia facilitates the activation of cyclooxygenase-1 and thus thromboxane formation (Ponicke et al. 1987). More recently, a significantly enhanced urinary 11-dehydro TxB2 excretion, the urinary metabolite of platelet-released TxA2, was reported in patients with COPD, irrespective of the smoking status, that inversely correlated with arterial oxygen tension (Davì et al. 1997). Increased in vivo platelet activation in hypoxaemic COPD patients with secondary pulmonary hypertension was also detected by a significant increase in circulating platelet aggregates and plasma β-TG (Cordova et al. 1985), suggesting that activation of platelets in the pulmonary blood vessels may be associated with the induction of pulmonary hypertension.

Moreover, an elevation in arginase activity in platelets, which is associated with a reduction of NO production, has been described in COPD patients, and this may also contribute to enhanced platelet reactivity (Guzman-Grenfell et al. 2011). Increased levels of circulating soluble P-selectin, most likely of platelet origin, have also been observed in COPD patients (Ferroni et al. 2000), and platelet P-selectin is crucial for the formation of platelet–leukocyte aggregates (Totani et al. 2016). It is therefore conceivable that neutrophil recruitment to the lungs, a feature of COPD patients, is favoured by interactions with activated platelets. Platelet–leukocyte interactions mediate the process of NETosis (see Evangelista et al. 2017) and NETs are a major contributor to chronic inflammation and lung tissue damage in COPD (Grabcanovic-Musija et al. 2015). NETs were found in COPD patients and are associated with other markers of activated innate immune response, including the expression of the pro-inflammatory cytokines IL-1β and CXCL8 and of the inflammasome component NLRP3. Consequently NETs may contribute, through a positive feedback and the stimulation of neutrophilic chemokines and cytokines, to the persistent airway neutrophilia observed in COPD (Wright et al. 2016). Further research is required to elucidate the participation of platelets in NETosis and the exact role that NETs are playing in COPD. Furthermore, the use of anti-platelet therapy in patients has been shown to improve survival in patients with oxygen-dependent COPD (Ekstrom et al. 2013).

Platelets in Acute Lung Injury and Acute Respiratory Distress Syndrome

- Platelet/neutrophil interactions may be major pathogenic contributors in ALI.
- The interaction between platelets and neutrophils is mediated by platelet P-selectin and neutrophil PSGL-1.
- Platelets contribute to NET formation that involves the expulsion of nuclear material embedded with histones, by neutrophils in ALI/ARDS. Histones were found in the bronchoalveolar lavage fluid in ARDS; in a transfusion-related acute lung injury model in mice, depletion of platelets was protective.

Acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) are life-threatening diseases occurring in critically ill patients. They are manifestations of an inflammatory response of the lung to direct and indirect insults and are characterised by severe hypoxaemia, hypercapnia, diffuse inflammatory lung infiltration and impairment of pulmonary compliance (Ragaller and Richter 2010). In particular, ALI is defined as an acute lung disease with bilateral pulmonary infiltrates in a chest radiogram consistent with the presence of oedema, and no evidence of pulmonary hypertension (Pepe et al. 1982). ALI is an important complication of sepsis.

Pathophysiologic Observations

Growing evidence suggests that platelets play a role in the pathogenesis of ALI (Zarbock et al. 2006). Intrapulmonary triggers, like acid aspiration and pneumonia, and systemic inflammatory stimuli activate the lung microvascular endothelium with upregulation of adhesion molecules, including ICAM-1 (Basit et al. 2006), release and presentation of chemokines (Belperio et al. 2006) and increase of lipid mediators (Zarbock et al. 2006; Kiefmann et al. 2004). During endotoxaemia platelets roll on and adhere to pulmonary capillary endothelial cells, as shown by intravital and electron microscopy (Kiefmann et al. 2006; Zarbock and Ley 2009), and release chemokines and lipid mediators that activate leukocytes and endothelial cells (Zarbock et al. 2006) (Fig. 5). Platelet microparticles (PMPs), small (50 nm to 1 μm) circulating cell-derived vesicles that break off from intact platelets upon activation and contain a variety of enzymes and proteins as well as mRNAs (McVey et al. 2012) (see Cointe et al. 2017), may play a role in ALI by promoting the inflammatory response of the lungs through the activation of neutrophil cell surface proteins (e.g. IL-8, MAC-1, PECAM-1, etc.) (Reutershan and Ley 2004; Bastarache et al. 2009; Shang and Yao 2014) and the production of cytokines and inflammatory mediators by endothelial cells (Eickmeier et al. 2013). A recent study showed that PMPs carry membrane-bound sCD40L, promote PMN-mediated HUVEC damage and may affect the

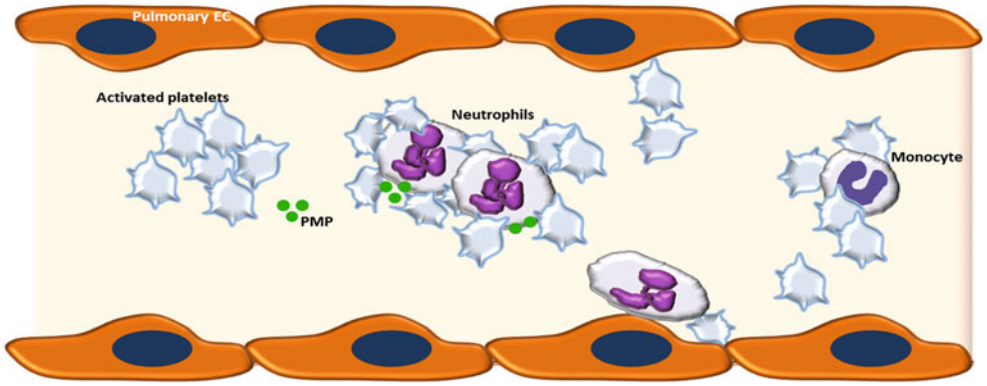

Fig. 5 Platelet–platelet, platelet–endothelial, platelet–PMN and platelet–endothelial cell–PMN interactions occur in pulmonary arterioles, capillaries and venules. These events can mediate acute lung injury. Different molecular interactions mediate adhesion of activated platelets to PMNs including P-selectin/PSGL-1, integrin MAC-1/integrin αIIbβ3 or ICAM-2, integrin MAC-1/GPIbα or JAM-3; ICAM-2/αLβ2 (LFA-1). Platelets also interact with monocytes under these conditions

development of ALI (Xie et al. 2015). Moreover, PMPs from LPS-stimulated platelets induce VCAM-1 production by cultured human endothelial cells (Levy and Serhan 2014).

Neutrophils and platelets are both key players in the pathophysiology of ALI. Thus, in a transfusion-related acute lung injury model in mice, depletion of either neutrophils or platelets was protective (Looney et al. 2009).

NETs are the product of a neutrophil death process that involves the expulsion of nuclear material embedded with histones, proteases, antimicrobial proteins and peptides. Histones have been found in the BAL fluid in acute respiratory distress syndrome (ARDS) (Bosmann et al. 2013). Platelets contribute to NET formation by neutrophils (see Slaba and Kubes 2017). Using an in vitro flow chamber system, it was shown that platelet-bound TLR4 detected TLR4 ligands in blood, activated neutrophils and facilitated the formation of NETs in the bloodstream. Moreover, using in vivo imaging in mice, it appeared that the lung capillaries where platelets bound neutrophils were hot spots for bacterial trapping and that the removal of platelets impaired bacterial clearance (Clark et al. 2007). Interestingly LPS, even at high concentrations, is not able to induce the formation of NETs in the absence of platelets, suggesting that platelets are not just facilitators in this process but essential mediators. On the other hand, the histone/DNA complexes of NETs activate platelets that in turn further promote NETosis, thrombosis and coagulation (Semeraro et al. 2011). Finally, extracellular histones, known to act as strong drivers of inflammation and tissue damage, activate TLRs resulting in pro-inflammatory cytokine production contributing to ALI development (Ward and Grailer 2014). All these observations point to an involvement of platelets in ARDS. One SNP within the LRRC16A gene (rs7766874), associated with variations in the platelet count, was involved in the pathophysiology of ARDS in a large series of 629 ARDS cases and 1,026 at-risk control subjects. However, it remained unclear whether the reduced platelet counts in patients with the LRRC16A SNP affected ARDS risk by a reduced platelet production, increased platelet activation/consumption or platelet sequestration in lung tissues (Wei et al. 2015).

Finally, another evidence has demonstrated that activated coagulation and impaired fibrinolysis are associated with ALI. During ALI, the coagulation system is activated, producing fibrin deposition in the lung (Idell et al. 1989) (Fig. 6). The newly produced thrombin, on the one hand, activates protease-activated receptors (PARs) on endothelial cells, inducing an inflammatory response with upregulation of cytokines as well as thrombin formation, whilst, on the other hand, it also activates platelets by binding to platelet PAR1 and 4 (Coughlin 2005). Thrombin also induces the conversion of fibrinogen to fibrin that, together with activated platelets, can induce the formation of microvascular thrombosis.

Studies in Animal Models

Inhibition of platelet/neutrophil aggregate formation resulted in reduced neutrophil recruitment, increased survival and lower levels of hypoxia in LPS-induced ALI in mice (Zarbock et al. 2006). In a ventilator-induced lung injury model in rats, increased levels of VWF were found on freshly isolated lung endothelial cells. The increased expression of VWF was inhibited by platelet removal from the lung perfusion and by a P-selectin-blocking antibody, and it was also drastically reduced in the lungs of mice perfused with blood from P-selectin knockout animals. These findings indicate that in ventilation-induced stress, platelets transfer VWF to endothelial cells and that platelet P-selectin plays a critical role in this

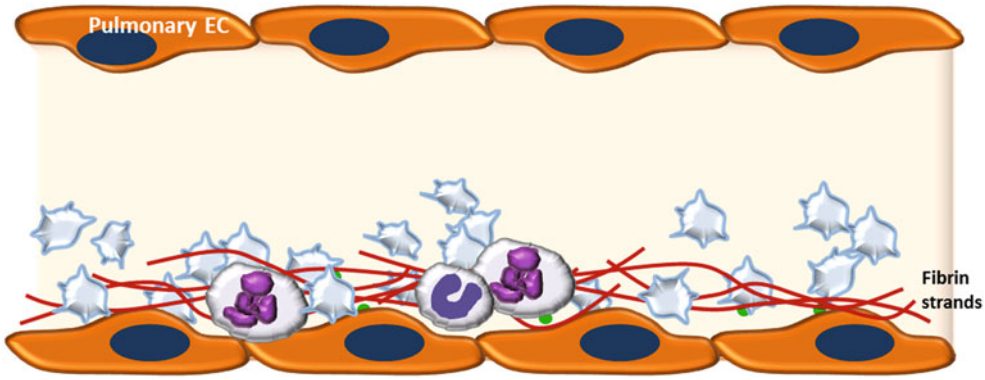

Fig. 6 Platelets and PMNs accumulate in macro- and microvessels in the lungs of patients with ALI/ARDS. Sequestration of platelets and PMNs is frequently associated with fibrin deposition and endothelial injury

transfer (Yiming et al. 2008). These data imply that during mechanical ventilation-induced lung injury, platelets deliver leukocyte-binding proteins to endothelial cells promoting leukocyte recruitment, thus playing a key role in generating a pro-inflammatory milieu.

Platelet depletion markedly reduced lung neutrophil infiltration in a murine model of lung injury induced by aerosolised LPS (Grommes et al. 2012). In the same model, antagonism of the CCL5-CXCL4 interaction reduced lung oedema, neutrophil infiltration and tissue damage, suggesting an important and causative role for platelet-derived chemokines in the development of lung injury (Grommes et al. 2012).

Moreover, in a mouse model of transfusion-associated lung injury (TRALI), platelet inhibition by aspirin or by a glycoprotein IIb/IIIa inhibitor reduced the degree of lung injury and the formation of NETs (Caudrillier et al. 2012). Therefore, platelet inhibition could reduce lung injury in ARDS by reducing the formation of NETs.

Take-Home Messages

A role for platelets in lung disorders has been revealed by studies in experimental animal models and in patients with different forms of acute and chronic lung injury with an inflammatory component, with platelets being critical for leukocyte recruitment, tissue damage and lung dysfunction. The complex web of cellular interactions that contribute to lung tissue damage, increasingly unravelled, includes now the humble platelet, and the improved understanding of the central pathophysiologic role of this cell may hold the key to improved treatments for these common conditions. It is becoming clear that the ability of platelets to act as inflammatory cells involves activation and signalling pathways distinct from those involved in haemostasis and thrombosis. This may provide new exciting opportunities for identifying new drug targets for the treatment of inflammatory lung disorders.

Hemostatic and Non-hemostatic Functions of Platelets in Patients with Liver Disease

Ton Lisman

Abstract

Chronic and acute liver diseases may be accompanied by substantial changes in primary hemostasis. Thrombocytopenia develops as a consequence of defective platelet production, increased consumption, and/or increased splenic sequestration. In addition, ill-defined platelet function defects may further impair primary hemostasis. However, defects in platelet number and function appear (partly) compensated for by increased levels of von Willebrand factor (VWF) and decreased circulating ADAMTS13. Consequently, patients with liver diseases may have a relatively well-functioning primary hemostatic system, which does not necessarily necessitate prophylactic transfusion of platelet concentrates, for example, prior to invasive procedures. Thrombopoietin receptor agonists are able to increase the platelet count, but normalization of the platelet count in patients with cirrhosis may lead to a thrombotic risk due to the high plasma levels of von Willebrand factor. The platelet count is a reasonable diagnostic and prognostic tool in patients with liver diseases. Platelets also have functions unrelated to cessation of bleeding in the context of liver disease. By incompletely understood mechanisms, platelets contribute to regeneration of the liver, for example, following a partial hepatectomy. In animal models of chronic or acute liver failure, platelets have been shown to exert both detrimental and beneficial effects. Whether platelets can both stimulate and inhibit progression of liver disease depending on the exact clinical context requires further study.

Introduction

Patients with liver diseases may acquire complex alterations in their hemostatic system including thrombocytopenia and platelet function defects, decreased plasma levels of coagulation factors, natural inhibitors of coagulation, and fibrinolytic factors (Lisman et al. 2002). In addition increased plasma levels of hemostatic proteins including von Willebrand factor, factor VIII, tissue-type plasminogen activator, and plasminogen activator inhibitor type 1 are frequently found. The causes for these complex hemostatic changes are multifactorial and include a decreased synthetic capacity of the liver, consumption of coagulation factors by disseminated or localized activation of coagulation, chronic endothelial cell activation, and portal hypertension-associated splenomegaly (Lisman and Porte 2010). Historically, patients with liver diseases were thought to have a bleeding disorder related to hemostatic failure. The notion of a bleeding tendency in patients with liver disease was supported by abnormalities in routine diagnostic tests of hemostasis (such as the platelet count and the prothrombin time) in a patient population characterized by frequent bleeding episodes and substantial blood loss during major surgery such as liver transplantation (Lewis et al. 1987). Extensive laboratory studies combined with careful clinical observations have substantially altered the concepts on

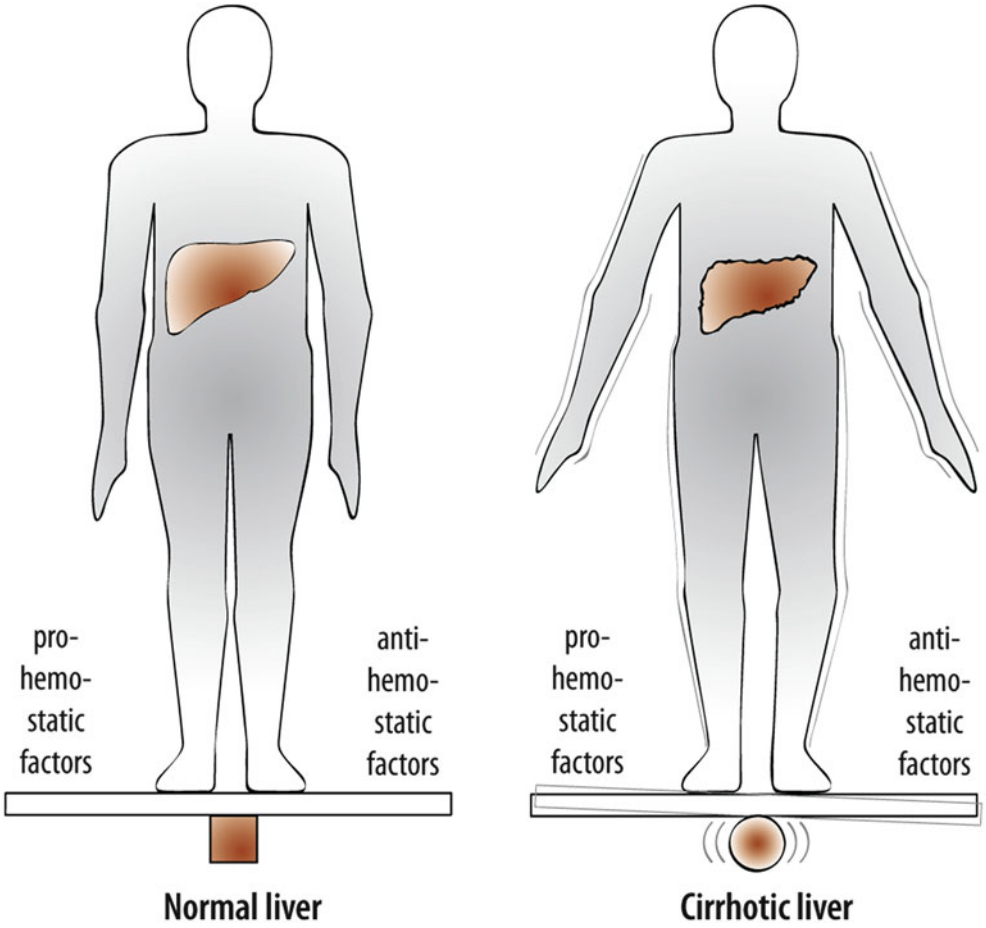

Fig. 1 The hemostatic balance in patients with liver disease as compared to that of healthy individuals. This cartoon depicts the stable hemostatic balance in healthy individuals and shows that although the hemostatic system in patients with liver disease is (re)balanced, the balance is fragile and may easily tip to either a hypo- or hypercoagulable status. Reprinted with permission from Lisman et al. (2013)

consequences of hemostatic disturbances in patients with liver diseases (Lisman and Porte 2010; Tripodi and Mannucci 2011; Northup and Caldwell 2013). The current belief is that the hemostatic balance in patients with liver diseases is relatively well preserved due to a concomitant decline in both pro- and antihemostatic pathways (Fig. 1). Clinical evidence for a "hemostatic rebalance" in liver diseases include developments in liver transplant surgery in which it has become clear that a proportion of patients can undergo this lengthy and invasive procedure without the requirements for any blood product transfusion (Massicotte et al. 2012), even in the presence of major laboratory abnormalities of hemostasis (Massicotte et al. 2008). In addition, it has become widely accepted that variceal bleeding, the prime bleeding complication of patients with chronic liver failure (i.e., cirrhosis), is a result of portal hypertension and local vascular abnormalities rather than a consequence of hemostatic failure (Garcia-Tsao and Bosch 2010). The hemostatic balance of patients with liver diseases, however, appears much more fragile compared to the hemostatic balance in individuals with competent liver function. This fragile hemostatic balance explains why patients with liver diseases may experience both hemostasis-related bleeding and thrombotic complications (Lisman et al. 2010).

This chapter will detail the abnormalities in primary hemostasis in patients with liver diseases and will provide guidance for clinical management of thrombocytopenia and platelet function defects in these patients. In addition, the prognostic value of the platelet count in chronic and acute liver diseases will be outlined. Finally, functions of platelets in liver diseases beyond cessation of bleeding will be discussed. These functions include stimulation of liver regeneration and roles in modulation of liver damage.

Part A: Alterations in Platelet Number and Function as a Consequence of Liver Disease

Thrombocytopenia of Liver Disease

Both cirrhosis and acute liver failure are frequently accompanied by thrombocytopenia. In more advanced cirrhosis, the majority of patients (50–75 %) have some degree of thrombocytopenia (a platelet count <150,000/μl), but

severe thrombocytopenia (<50,000/μl) is relatively rare at 1–11 % (Boyer and Habib 2015). The extent of thrombocytopenia increases with the severity of disease. Thrombocytopenia also frequently accompanies acute liver failure, although the proportion of patients with thrombocytopenia is lower and the extent of the platelet count reduction is milder in patients with acute liver failure compared to patients with cirrhosis, while the plasma levels of coagulation factors are much lower in acute liver failure compared to cirrhosis. In an analysis of 1598 patients from the US Acute Liver Failure Study Group, patients had a median platelet count of ~130,000 platelets/μl on admission, with 59 % of patients with a platelet count below 150,000/μl, 34 % of patients with a platelet count below 100,000/μl, and 9 % of patients with a platelet count below 50,000/μl (Lisman and Stravitz 2015). Platelet counts decline further after admission for ALF, reaching a nadir at day 4–5.

The thrombocytopenia of cirrhosis is multifactorial and may include defective synthesis of thrombopoietin (TPO) by the diseased liver (Peck-Radosavljevic et al. 2000), splenomegaly related to portal hypertension (Aster 1965), consumption as a result of disseminated or localized activation (Bakker et al. 1992; Kondo et al. 2013; Ikura et al. 2013), increased platelet destruction by autoantibodies directed to platelets (Kajihara et al. 2003), and direct bone marrow suppression by, for example, alcohol or the hepatitis C virus (Levine et al. 1986; Garcia-Suarez et al. 2000). Importantly, treatment of hepatitis C with interferon-based regimens causes a further decrease in platelet count, frequently necessitating dose adjustments or administration of thrombopoiesis-stimulating agents (Afdhal et al. 2008). The new generation antiviral agents do not appear to have this disadvantage (Pawlotsky et al. 2015). Although the liver is an important site of synthesis of TPO, decreased TPO synthesis does not appear to explain the thrombocytopenia of acute liver failure. In fact, TPO levels are normal-to-increased in most patients with acute liver failure, and levels further increase during the course of the disease, despite decreasing platelet counts (Schiodt et al. 2003). These observations are in contrast to the low plasma TPO levels in patients with cirrhosis (Peck-Radosavljevic et al. 2000). Whether TPO-mediated platelet production is intact in patients with acute liver failure, or whether thrombopoiesis is disturbed by mechanisms other than TPO deficiency, is unknown. Recent data suggest that platelet activation/consumption is an important cause for the thrombocytopenia of acute liver failure (Stravitz et al. 2016). In an analysis of platelet count over time in patients within the acute liver failure study group from the United States, the drop in platelet count over time increased in proportion to the extent of the systemic inflammatory response syndrome which is common in these patients. In addition, the drop in platelet count is accompanied by an increase in platelet-derived microparticles (Stravitz et al. 2013b, 2016). A similar mechanism has also been proposed to contribute to the thrombocytopenia of cirrhosis, but the presence of elevated levels of platelet microparticles in cirrhosis is controversial (Rautou et al. 2013; Tapper et al. 2013).

Platelet Function Defects

Already in the 1960s, it was shown that platelets from patients with cirrhosis have defective in vitro aggregability (Thomas et al. 1967). The decreased capacity to activate platelets from patients with cirrhosis in vitro has been confirmed by many laboratories (Desai et al. 1989; Ingeberg et al. 1985; Laffi et al. 1987; Alkozai et al. 2015). In addition, it has been shown that many patients with cirrhosis have a prolonged bleeding time that correlates poorly with the platelet count, which is indicative of a platelet function defect (Blake et al. 1990). Platelet function defects in cirrhosis have been ascribed to both intrinsic and plasma-derived factors. The intrinsic platelet defects include an acquired storage pool deficiency (Laffi et al. 1992), defective transmembrane signaling (Laffi et al. 1993) with defective synthesis of arachidonic acid (Laffi et al. 1987), and upregulation of cyclic AMP and GMP (Laffi et al. 1993) possibly as a result of an increased production of nitric oxide and prostacyclin in vivo (Cahill et al. 2001). Plasma-derived factors that inhibit platelet function in cirrhosis include abnormal high-density lipoprotein and bile salts (Desai et al. 1989; Baele et al. 1980). Platelet function in patients with acute liver failure has been poorly studied, but decreased platelet function has been shown in older studies (Rubin et al. 1977; Weston et al. 1977)

Hemostatic Status of Primary Hemostasis in Liver Diseases

Although platelet aggregation tests and other static in vitro tests of platelet function clearly suggest platelet hypofunction in patients with cirrhosis, there is no consensus that the thrombocytopenia and platelet function defects in cirrhosis translate to a defective primary hemostatic function. First, there is in vivo evidence of platelet hyperactivity including increased urinary excretion of the thromboxane A2 metabolite 11-dehydro-thromboxane B2 and increased plasma levels of platelet activation markers such as soluble P-selectin or platelet factor 4 (Davi et al. 1998; Panasiuk et al. 2001). Second, there is evidence for in vivo platelet activation including increased P-selectin expression on resting platelets and increased numbers of platelet-monocyte aggregates (Panasiuk et al. 2001; Sayed et al. 2010). This enhanced in vivo platelet activation may be related to

continuous endothelial activation. Alternatively, platelets may be activated during infection or as a result of systemic low-grade inflammation. Third, flow-based assays of platelet function including the PFA-100 and flow-based adhesion and aggregation studies used in research settings have suggested that platelet defects are explained by anemia and thrombocytopenia, but not by platelet function defects (Escolar et al. 1999; Lisman et al. 2006a). Finally, it has been proposed that highly elevated levels of von Willebrand factor (VWF) found in liver diseases compensate for the low platelet count in patients with liver disease (Lisman et al. 2006b). VWF levels are substantially elevated in both chronic (Lisman et al. 2006b) and acute (Hugenholtz et al. 2013) liver disease which is likely related to chronic endothelial cell activation, possibly in combination with decreased VWF clearance by the diseased liver. In addition, VWF synthesis may be increased, as liver disease is associated with induction of VWF expression in the liver (Hollestelle et al. 2004). Alternatively, VWF synthesis may be increased due to the substantially enhanced endothelial surface in patients with cirrhosis as a consequence of extensive collateral formation. VWF functionality is partially impaired, possibly due to proteolysis by proteases such as plasmin or elastase (Federici et al. 1993). Nevertheless, in flow-based in vitro assays, the quantitative increase by far overrules the qualitative defects resulting in a substantially increased adhesion of platelets to thrombogenic surfaces in the presence of cirrhotic plasma containing high VWF levels (Lisman et al. 2006b; Hugenholtz et al. 2013). Also, decreased levels of ADAMTS13 that are frequently present in patients with liver diseases (Uemura et al. 2008) may promote platelet function as ADAMTS13 not only processes freshly released VWF but also cleaves VWF in a growing platelet thrombus (Shida et al. 2008).

Not all these lines of evidence are conclusive. Elevated plasma levels of soluble P-selectin and PF4 may reflect decreased clearance of these markers rather than increased production. In addition, the net effect of thrombocytopenia, anemia, and high VWF on platelet function has been poorly studied. Nevertheless, several clinical observations are consistent with a relatively well-preserved function of primary hemostasis in liver diseases. First, patients with liver diseases are not protected from arterial thrombosis (Marchesini et al. 1999), which may be expected when platelet function would be substantially inhibited. Second, normalization of the platelet count in patients with cirrhosis by thrombopoietin appears to increase the risk of thrombosis (Afdhal et al. 2012), which may be related to a normal platelet count in the context of a substantial VWF/ADAMTS13 unbalance (Lisman and Porte 2012). Third, large invasive procedures in patients with cirrhosis, notably liver transplant surgery, are possible without preoperative correction of the platelet count and without perioperative administration of platelet concentrates (Massicotte et al. 2012). Nevertheless, one study has shown that severe thrombocytopenia (defined as a platelet count $<75{,}000/\mu l$) is a risk factor for procedural bleeding (Giannini et al. 2010). In addition, an in vitro study demonstrated that the thrombin-generating capacity of platelet-rich plasma from patients with cirrhosis only decreases compared to that of healthy controls when the platelet count falls below 60,000/μl. This study has been used by clinicians to advocate platelet transfusions prior to invasive procedures in patients with a platelet count $<60{,}000/\mu l$ (Northup and Caldwell 2013), thereby ignoring the fact that the function of platelets in cessation of bleeding is much more than providing a surface to support thrombin generation.

In aggregate, although platelet function defects in cirrhosis have been very well established using classical aggregometry and other static assays, accumulating evidence suggests that the primary hemostatic system in cirrhosis is relatively balanced (Violi et al. 2011) as the relatively mild thrombocytopenia is counteracted by a VWF/ADAMTS13 unbalance (Table 1). Furthermore, flow-based assays do not confirm the platelet function defects as detected in static assays, and in vivo evidence of platelet hyperactivation exists. Nevertheless, there is some clinical evidence that thrombocytopenia is related to an increased risk of procedure-related bleeding (Giannini et al. 2010). Importantly, coagulopathy, as defined by an increased international normalized ratio, appears not to be related to procedural bleeding risk (Giannini et al. 2010). Whether the bleeding risk in patients with thrombocytopenia and preserved coagulation is lower than in patients with

Table 1 Factors determining the balance in primary hemostasis in patients with cirrhosis

Factors impairing primary hemostasis	Factors supporting primary hemostasis
• Thrombocytopenia • Anemia • Platelet function defects • Reduced functional capacity of VWF • Increased production of nitric oxide and prostacyclin in vivo • Abnormal high-density lipoprotein • Increased plasma bile salts	• Substantially elevated levels of VWF • Decreased plasma levels of ADAMTS13 • Low-grade in vivo activation of platelets by activated endothelium or during infection/inflammation

thrombocytopenia and coagulopathy is uncertain and requires further study.

Management of Primary Hemostasis in Liver Diseases

The new insights in the balance of the primary hemostatic system may have consequences for management of bleeding. It has long been common practice to prophylactically correct a reduced platelet count prior to invasive procedures by infusion of platelet concentrates. More recently, thrombopoietin receptor agonists have been shown to successfully increase the platelet count in patients with cirrhosis (McHutchison et al. 2007; Afdhal et al. 2012). Given the potential compensation of the thrombocytopenia of liver diseases by elevated VWF and decreased ADAMTS13, the lack of evidence for a beneficial effect of prophylactic platelet transfusions in this setting (Tripodi et al. 2013; Yates and Sarode 2014), and the clear side effects of platelet concentrates, a restrictive approach toward prophylactic platelet transfusion in these patients appears justified. Both in the setting of liver transplantation in patients with cirrhosis and in patients with acute liver failure, it has been shown that administration of platelet concentrates was associated with poor outcome (de Boer et al. 2008; Pereboom et al. 2009; Stravitz et al. 2013a), and in liver transplantation this association appeared independent of severity of disease and other potential confounders. These potential effects of prophylactic platelet transfusion on outcome may relate to general transfusion reactions, volume overload, and transfusion-associated acute lung injury. Prophylactic administration of thrombopoietin receptor agonists should also be performed cautiously due to the potential thrombotic risk (Afdhal et al. 2012). Importantly, thrombopoietin receptor agonists were, in a randomized trial on preprocedural correction of platelet counts, associated with an increased risk of portal vein thrombosis but were not effective in reducing bleeding risk despite marked improvements in platelet count (Afdhal et al. 2012). Although some authors and guidelines advise to prophylactically administer platelet concentrates for high (er)-risk procedures (Northup and Caldwell 2013; Patel et al. 2012), a cautious use of this approach and a careful assessment of risks and benefits appear warranted. Our center promotes a wait-and-see approach for most invasive procedures, except those procedures during which bleeding can lead to irreversible damage (Weeder et al. 2014). In other words, only in case of active bleeding, blood product transfusion will be initiated. Nevertheless, although this approach is supported by an increasing number of centers that will start a liver transplant procedure without prophylactic correction of abnormal routine indices of hemostasis, clinical studies on the safety and efficacy of a restrictive strategy toward platelet transfusion in other settings are recommended (Lisman and Porte 2010).

1-Deamino-8-D-arginine vasopressin (DDAVP) is used in some centers to improve primary hemostasis in patients with cirrhosis. Although DDAVP has been shown to correct the skin bleeding time in patients with cirrhosis (Mannucci et al. 1986; Cattaneo et al. 1990; Burroughs et al. 1985), there is little evidence for clinical efficacy. DDAVP did not reduce blood loss during liver transplantation (Pivalizza et al. 2003) and had no effect on acute variceal bleeding (de Franchis et al. 1993). A randomized controlled study suggested that DDAVP is as effective as transfusion of blood products in preventing bleeding in patients (Stanca et al. 2010). However, a drawback of this study was the absence of a nontreated control group, which makes it impossible to determine whether DDAVP and blood products are equally effective in preventing blood loss or that neither intervention is effective. It is difficult to conceptualize how DDAVP could be hemostatically active in patients that already have substantially elevated VWF levels. Indeed, DDAVP infusion showed very little effect on laboratory indices of primary hemostasis including flow-based platelet adhesion studies (Arshad et al. 2015), although there is no consensus in literature on whether DDAVP actually increases VWF levels in patients with cirrhosis.

Part B: Platelets as Diagnostic Aid and Prognostic Indicator in Liver Diseases

The platelet count has been used to score various aspects of liver disease and has some prognostic value in various settings. Due to its wide availability and its low cost, the platelet count has been extensively studied in the context of disease staging and prognosis. Recent data in chronic or acute liver failure will be reviewed below.

Fibrosis and Cirrhosis

Staging of advanced fibrosis and cirrhosis is key in patients with chronic liver disease to identify those patients that require treatment. Although liver biopsy is the gold standard for disease staging, the procedure is invasive, expensive, not without risk, and may be biased by sampling errors and subjective interpretation. Noninvasive tests as an alternative for liver biopsy have been extensively studied. Both imaging techniques and clinical scores based on laboratory values have been explored (Sharma et al. 2014). A number of clinical scores include the platelet count. For example, the AST-platelet ratio index (APRI) has been extensively validated in chronic hepatitis and is useful in predicting the presence of cirrhosis in these patients (Xiao et al. 2015;

Chou and Wasson 2013). The World Health Organization has recently recommended the use of APRI to detect cirrhosis and advanced fibrosis in resource-limited settings (http://www.who.int/hepatitis/publications/hepatitis-b-guidelines-policy/en/). The APRI, however, has not been properly validated in patients with other etiologies of chronic liver disease and appears to have lower diagnostic value than other biochemical indices, particularly in alcoholic liver disease (Naveau et al. 2009). The FIB4 score consists of age, AST, ALT, and platelet count and has been proven useful in predicting fibrosis in hepatitis C and nonalcoholic fatty liver disease (Sterling et al. 2006; Shah et al. 2009). Again, the FIB4 score appears less useful in alcoholic liver disease.

The platelet count on its own has also merit in predicting whether a patient with liver disease is likely to have cirrhosis (Udell et al. 2012) or to assess severity of fibrosis (Giannini et al. 2006). In patients with established cirrhosis, the platelet count to spleen diameter ratio is potentially useful to identify those patients with esophageal varices (Chawla et al. 2012). The platelet count is also associated with the outcome of cirrhosis (decompensation or death) (D'Amico et al. 2006; Qamar et al. 2009), and it has been demonstrated that the degree of thrombocytopenia correlates to the extent of liver atrophy (Bleibel et al. 2013).

Acute Liver Failure

Recent analyses of data from the acute liver failure study group from the United States have demonstrated that patients with a poor outcome of their disease develop a more profound thrombocytopenia in the first week after admission (Stravitz et al. 2016). Specifically, platelet counts were lower in patients that died or underwent liver transplantation compared to those who spontaneously recovered. In addition, platelet counts in the first week of admission were lower in patients who developed the systemic inflammatory response syndrome, in patients who required vasopressors or renal replacement therapy, and in patients that developed hepatic encephalopathy. Interestingly, the PT/INR was not predictive of development of the systemic inflammatory response syndrome, requirement for vasopressors or renal replacement therapy, or development of hepatic encephalopathy, although it was associated with poor outcome. A possible mechanism explaining the association between thrombocytopenia and poor outcome involves platelet activation, likely initiated by the systemic inflammatory response syndrome. It has been demonstrated that exceptionally high levels of highly procoagulant microparticles are found in circulation in patients with acute liver failure, in particular in those with systemic inflammation (Stravitz et al. 2013b). From these data it has been proposed that inflammation-mediated platelet activation with subsequent platelet fragmentation to microparticles explains the relation between thrombocytopenia and outcome. In addition, the procoagulant microparticles have been proposed do drive progression of disease by enhancing intrahepatic activation of coagulation (see part D of this chapter).

Part C: Platelets as Stimulators of Liver Regeneration

Unlike other bodily organs such as the heart or kidneys, the liver has a unique regenerative capacity (Michalopoulos and DeFrances 1997). In most adult solid organs, injury tends to result in scarring and functional impairment rather than regeneration and repair. The liver is an exception to this rule, and full restoration of functional liver mass can occur even after substantial injury. The ultimate regenerative response of the liver occurs after a partial liver resection. Up to 70 % of liver tissue can be safely removed in patients that require a partial liver resection for removal of a liver tumor (Clavien et al. 2007). Following a resection, the liver eventually regenerates to its original size. In humans, substantial regeneration has already taken place after one week, with regeneration virtually complete after three to six months (Kele et al. 2012). In rodents, liver regeneration following a partial liver resection is even faster, with complete regeneration in mice after ~5 days. The liver not only regenerates following physical removal of liver tissue, but regenerative responses occur also when liver tissue is damaged by chronic or acute liver injury or by ischemia/reperfusion injury. In the context of liver transplantation, livers also suffer from acute hepatocellular injury as a consequence of combined warm and cold ischemia and the consequent reperfusion injury. The regenerative capacity of the liver following damage from either a chronic or acute insult is remarkable. Patients with acute liver failure can spontaneously recover from their disease, showing little or no evidence of histological abnormalities within months after the disease. Livers that have suffered substantial damage in the process of transplantation can also fully recover (Brenner 2009). Animal experiments and biopsy studies in humans have demonstrated that moderate fibrosis can resolve when the trigger is removed or when successful treatment is given.

Multiple laboratories have shown that platelets are vital for liver regeneration after a partial liver resection in small animal models (Lesurtel et al. 2006; Murata et al. 2008; Myronovych et al. 2008; Shimabukuro et al. 2009). Significantly, liver regeneration after partial liver resection was shown to be substantially delayed in mice that were treated with drugs that inhibit platelet function or mice that were treated with chemotherapeutic drugs or platelet-depleting

antibodies, causing almost complete thrombocytopenia. Conversely, in mice which the platelet count was increased by treatment with thrombopoietin receptor agonists, liver regeneration was accelerated (Shimabukuro et al. 2009; Lesurtel et al. 2006). Platelets appear also relevant for liver regeneration in humans as a low platelet count following a liver resection or liver transplantation is associated with postoperative liver dysfunction and mortality, which may be related to a failed regeneration (Alkozai et al. 2010). In addition to the role of platelets in regeneration following a liver resection, it has been established that platelets delay fibrosis in models of chronic intoxication (Watanabe et al. 2009) and that platelets facilitate repair after ischemia/reperfusion injury (Nocito et al. 2007). However, not all studies agree, and there is in fact also evidence that platelets are harmful in various models of liver disease, which will be discussed in part D of this chapter.

The mechanisms underlying platelet-mediated liver regeneration are poorly understood, and some of the theories discussed in literature are based on circumstantial evidence. Plausible theories and the experimental deficits will be discussed below and are depicted in Fig. 2.

Delivery of Growth Factors

It has long been assumed that the role of platelets in stimulating liver regeneration hinges strongly on growth factors stored within platelet granules. Following a partial liver resection in small animal models, a rapid influx of platelets in the liver sinusoids has been observed (Murata et al. 2007). Platelets also cross the endothelial lining within the liver and end up in the space of Disse or even within hepatocytes (Kirschbaum et al. 2015). This rapid platelet accumulation in the liver has been postulated to result in excretion of growth factors which enhance the regenerative response. Such growth factors include hepatocyte growth factor, vascular endothelial growth factor, insulin-like growth factor, and serotonin. Indeed, these mitogens have been shown to enhance proliferation of cultured hepatocytes in vitro (Matsuo et al. 2008; Balasubramanian and Paulose 1998). Compelling evidence for a role of serotonin in mediating platelet-mediated liver regeneration was provided by experiments using mice deficient in circulating serotonin (Lesurtel et al. 2006). However, the defective regeneration in these mice may also be explained by a defect in secondary

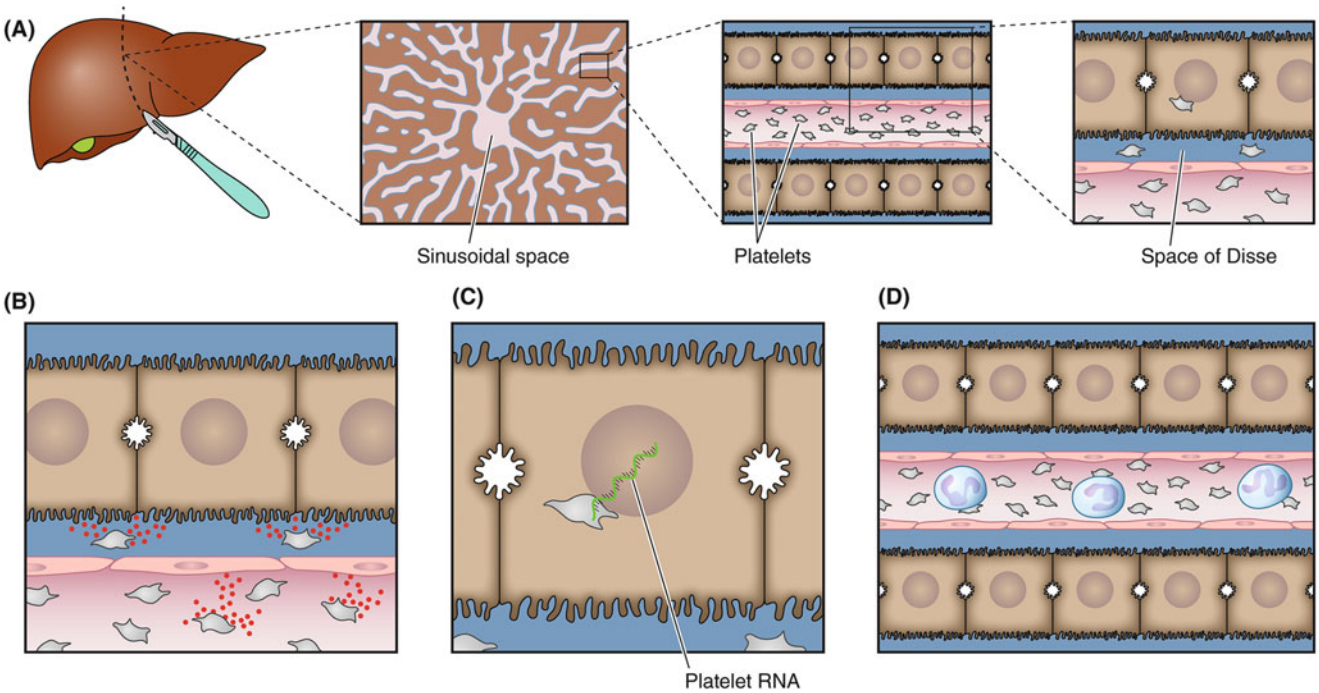

Fig. 2 Potential mechanisms underlying platelet-mediated liver regeneration. (**a**) Platelets accumulate in the sinusoidal space of injured livers or livers that have been surgically reduced in size. From the sinusoidal space, some platelets migrate into the space of Disse, and some platelets are taken up by hepatocytes. These platelets have the potential to activate multiple pathways that may all contribute to platelet-mediated stimulation of liver regeneration. Which of these pathways occur in vivo has not been definitively established. (**b**) Platelets may release contents from their granules that either directly stimulate hepatocyte proliferation (serotonin, IGF, HGF) or stimulate endothelial cells to release HGF (VEGF). Alternatively, the direct interaction of platelets with endothelial cells promotes release of interleukin 6 and VEGF that promote liver regeneration. (**c**) Platelets may transfer their RNA to hepatocytes, which promotes hepatocyte proliferation either by translation of mRNA or by the action of regulatory RNAs. (**d**) Platelets attract inflammatory cells, which are known to directly stimulate liver regeneration. Professional illustration by Patrick Lane, ScEYEnce Studios. Reprinted with permission from Lisman and Porte (2016)

platelet activation, as serotonin is not only a liver-directed mitogen but also a relevant platelet activator. Indeed, inhibition of the $P2Y_{12}$ receptor, which also results in defective secondary platelet activation, had similar effects as circulating serotonin deficiency. A human study provided evidence for serotonin consumption following a partial liver resection and showed that a low preoperative platelet serotonin content was associated with poor outcome (Starlinger et al. 2014). In this study, however, it was not examined whether the serotonin consumption following resection was related to this specific procedure or a consequence of a major abdominal surgical procedure in general. Indeed, a subsequent study in which serotonin content was compared between patients undergoing partial liver and pancreas resection provided no evidence for liver resection-specific consumption of serotonin (Alkozai et al. 2015).

Delivery of Platelet-Derived RNA

Since platelets are taken up by hepatocytes following a partial liver resection, it may be that platelets do not only deliver growth factors to the hepatocyte plasma membrane but also release factors involved in proliferation within the hepatocyte. An in vitro study demonstrated transfer of platelet-derived RNA to hepatocytes after platelet internalization by the hepatocyte with subsequent translation of platelet RNA to protein by the hepatocyte (Kirschbaum et al. 2015). This "functional" transfer of RNA contributed substantially to platelet-mediated hepatocyte proliferation. However, whether platelet RNA transfer contributes to liver regeneration in vivo needs to be established. Both platelet mRNA and regulatory RNAs may play a role in platelet-mediated liver regeneration, and the exact RNA species involved remain to be studied.

Platelets as Initiators of the Inflammatory Response

Although it is widely assumed that platelets stimulate liver regeneration by delivery of mitogenic cargo to the liver, there is another potential explanation for the role of platelets in liver regeneration. It has been well established that liver regeneration is associated with a localized or generalized inflammatory response. Liver regeneration is impaired in mice lacking inflammatory cells or production of proinflammatory cytokines such as TNF-α (Selzner et al. 2003; Yamada et al. 1997). Since platelets are well known to attract inflammatory cells (Stokes and Granger 2012), it is not unlikely that the role of platelet in liver regeneration is not mediated by platelets directly but indirectly by facilitation of the inflammatory response. Indeed, recent work has demonstrated that platelets are key in facilitating influx of neutrophils and repair following a sterile inflammation induced by thermal injury in a mouse model (Slaba et al. 2015).

Part D: Platelets as Modulators of Liver Disease Progression

Platelets as Drivers of Disease Progression

It has been well established that intrahepatic activation of coagulation occurs in animal models of acute and chronic liver disease (Anstee et al. 2008; Ganey et al. 2007). Activation of hemostasis might occur by apoptotic cells or may be initiated by platelet interactions with collagen, the deposition of which is the hallmark of fibrogenesis. Alternatively, decryption of hepatic tissue factor may initiate intrahepatic thrombus formation (Sullivan et al. 2013). Regardless of the initiating trigger, the hypercoagulable features of patients with cirrhosis likely stimulate the progression of the formation of such intrahepatic clots. There is accumulating evidence that intrahepatic thrombus formation is not just a consequence of the disease but rather an active player in disease progression. Initially, it was proposed that intrahepatic thrombi drive disease progression via a mechanism involving local ischemia (a phenomenon referred to as "parenchymal extinction") (Wanless et al. 1995). Later, it was proposed that cellular activation by coagulation proteases such as factor Xa (FXa) and thrombin is responsible for accelerating disease progression (Anstee et al. 2009). A randomized clinical trial has shown that anticoagulant treatment of patients with moderate to severe cirrhosis delays decompensation and death, indicating that prevention of intrahepatic activation of hemostasis may have clinical benefit (Villa et al. 2012). This single clinical study is in dire need of replication. Inhibition of platelet function or induction of thrombocytopenia has been demonstrated to delay disease progression in models of cholestatic (Sullivan et al. 2010) and non-cholestatic fibrosis (Assy et al. 2007), nonalcoholic fatty liver disease (Fujita et al. 2008), and acute liver failure (Miyakawa et al. 2015). In line with these results, a retrospective clinical study showed that the use of aspirin was associated with a decreased fibrosis progression in patients that underwent liver transplantation for hepatitis C (in whom fibrosis frequently recurs following transplantation) (Poujol-Robert et al. 2014).

Platelets have also been shown to facilitate $CD8^+$ T cell-induced liver damage in mouse models of hepatitis (Iannacone et al. 2005). Importantly, antiplatelet therapy was shown to decrease the severity of fibrosis, the development of hepatocellular carcinoma, and death in a mouse model (Sitia et al. 2012). It has been proposed that a clinical trial on the effect of aspirin on hepatocellular carcinoma

prevention may be realistic in high-risk patients (Carrat 2014). In those patients with advanced cirrhosis, however, there may be a potential bleeding risk due to the alterations in primary hemostasis (see part A of this chapter).

Platelets as Attenuators of Disease Progression

Confusingly, multiple studies have convincingly shown that platelets exert protective effects in animal models of liver disease. Part of these protective effects may be mediated by the capacity of platelets to stimulate liver regeneration, although this has been incompletely studied. Platelets have been shown to protect against cholestatic (Joshi et al. 2015; Jang et al. 2012; Kodama et al. 2010) and non-cholestatic liver disease (Watanabe et al. 2009) and also protect against other liver insults such as ischemia/reperfusion injury (Nocito et al. 2007). It has not yet been studied whether the different outcomes of experimental studies on platelets and liver disease progression depend on the model (e.g., hepatocyte vs cholangiocyte damage) or on the timing or mode of intervention (i.e., thrombocytopenia vs platelet inhibitors). In addition, the type, dose, and duration of pharmacological interventions may affect the ultimate outcome of the experiment. The potential efficacy of antiplatelet drugs in the prevention of progression of disease in humans may likewise be dependent on the severity of disease at onset of therapy, the underlying disease, and the type and dosing regimen of the drug, and these caveats should be considered in future clinical studies (Lisman 2015).

Take Home Messages

A Rational Approach to Management of Primary Hemostasis in Cirrhosis

- Patients with cirrhosis and thrombocytopenia can undergo major surgery (e.g., liver transplantation) without the requirement for any blood transfusion (Massicotte et al. 2015) as they are in hemostatic balance (Lisman and Porte 2010).
- Therefore, prophylactic transfusion of platelet concentrates is generally not indicated.
- Exceptions are severe thrombocytopenia and procedures during which bleeding can lead to irreversible damage.
- Thrombopoietin receptor agonists increase platelet count, do not reduce procedural bleeding, but increase risk of thrombosis.
- Therefore, thrombopoietin receptor agonists are likely not indicated in hemostatic management of patients with cirrhosis.
- DDAVP has little effect on laboratory indices of primary hemostasis in patients with cirrhosis and is likely not indicated.

Knowns and Unknowns on Platelet-Mediated Liver Regeneration

- Platelets stimulate liver regeneration after partial hepatectomy in rodent models.
- There is accumulating evidence of an association between a low postoperative platelet count and liver function recovery following partial hepatectomy in humans.
- Although release of platelet-derived growth factors is widely assumed to mediate platelet-dependent liver regeneration, no direct evidence in support of this mechanism exists.
- It also remains to be established whether platelet exert proliferative effects directly or indirectly via facilitating influx of inflammatory cells in the regenerating liver.

Platelets in Progression of Liver Diseases, Friends or Foes?

- Platelets contribute to progression of chronic and acute liver disease in multiple experimental animal models.
- Platelets have also been reported to attenuate disease progression in experimental animal models.
- Although antiplatelet therapy would be an attractive clinical strategy to reduce disease progression (as no alternatives are currently available), the relevance of the conflicting results in animal studies should be explored.

Platelets and Renal Disorders

Jens Lutz and Kerstin Jurk

Abstract

Patients with chronic kidney disease (CKD) have an increased risk of thrombosis as well as bleeding episodes. Platelet activation, platelet–leukocyte conjugates and platelet-derived microparticles together with an activation of endothelial cells can all confer pro-thrombotic effects in platelets. Furthermore, platelets can contribute to the inflammatory state in patients with CKD and thus together with their thrombosis promoting effect can also contribute to the increased cardiovascular risk of these patients. The bleeding risk in patients with CKD can be augmented by increased concentrations of uraemic toxins, anaemia and altered endothelial cell function all contributing to an impaired platelet function. However, platelets can also be directly involved in the pathogenesis of renal diseases such as thrombotic microangiopathy, immune complex-mediated renal disease, anti-GBM glomerulonephritis and antibody-mediated rejection after kidney transplantation as they can promote inflammatory responses after their activation. The following chapter gives an overview about the mechanisms involved in thrombosis and bleeding promoting effects of platelets in patients with CKD as well as the mechanisms behind the direct pathogenic effects of platelets in several renal diseases.

Platelets in Chronic Kidney Disease

Patients with deteriorating chronic kidney disease (CKD) and particularly those with end-stage renal disease (ESRD) and uraemia develop disturbances of the haemostatic system. Both thrombosis and bleeding can occur in patients with CKD. During early CKD stages, the thrombotic risk is likely to be increased, while during late stages and in uraemia also, the bleeding tendency is augmented. The bleeding risk is related to disturbances of the coagulation system, but also to distinct defects of the platelets, such as impaired platelet interaction with the vessel wall, platelet aggregation and platelet-dependent coagulation. Furthermore, interactions with drugs affecting the haemostatic system during haemodialysis sessions further impair platelet function in patients with end-stage renal disease. Dialysis patients may also present with hyperreactive platelets and an increased risk of thrombosis or hyporeactive platelets and an increased risk of bleeding.

Platelets are also directly involved in the pathogenesis of glomerular diseases as they can attract other inflammatory cells to the site of tissue damage, interact with renal cells (i.e. mesangial cells) or release pro-inflammatory chemokines, cytokines and growth factors. Here, the platelet secretome and transcriptome play an important role.

Platelet Dysfunction and Risk of Thrombosis

Patients with uraemia can present with thrombotic events such as deep venous thrombosis, pulmonary embolism, vascular access thrombosis in haemodialysis patients, central

vein thrombosis, right atrial thrombus, acute coronary syndrome, cerebrovascular event or peripheral artery occlusion (Ando et al. 2002; Lutz et al. 2014). CKD is characterized by inflammation, endothelial dysfunction and platelet activation. Increased levels of CRP, IL-1, IL-6 and TNF-α as well as of soluble adhesion molecules, such as soluble ICAM-1, VCAM-1 and P-selectin (Landray et al. 2004; Shlipak et al. 2003; Stenvinkel and Alvestrand 2002; Tripepi et al. 2005), are associated with CKD. It has been shown that endothelial cells exhibit decreased generation of vasoactive substances such as NO in patients with ESRD (Jankowski et al. 2003) which leads to less constitutive inhibition of circulating platelets via the cGMP/PKG pathway (Smolenski 2012; Walter and Gambaryan 2009). Hyperlipidaemia and hypertension represent important co-morbidities of CKD that have been shown to increase platelet reactivity via platelet scavenger receptors and CD40 ligand, respectively (Hausding et al. 2013; Zimman and Podrez 2010). However, how activated leukocytes and endothelial cells affect platelet function during the pathogenesis of CKD is poorly understood so far. Platelet hyperreactivity and activation affect primary haemostasis and coagulation, but also contribute to the inflammatory response via modulating the function of endothelial cells and leukocytes (Fig. 1). Particularly, hyperaggregability, the exposure of phosphatidylserine, shedding of platelet-derived microparticles and alteration in the platelet transcriptome and protein synthesis are implicated to contribute to the pro-thrombotic state.

Platelet–Platelet and Platelet–Leukocyte Interaction

Platelets of uraemic patients present normal concentrations of the glycoprotein (GP) IIb/IIIa ($\alpha_{IIb}\beta_3$ integrin) on their surface. These receptor complexes are responsible for the cross bridging of platelets via binding of fibrinogen or von Willebrand factor (VWF), resulting in platelet aggregation (Kaw and Malhotra 2006). Increased plasma levels of fibrinogen (Schoorl et al. 2013a) in patients with CKD may contribute to platelet hyperaggregability. In addition, plasma fibrinogen bridges activated platelets and leukocytes predominantly via the leukocyte αMβ2 integrin (Mac-1) to form hetero-cellular conjugates (Gawaz et al. 2005).

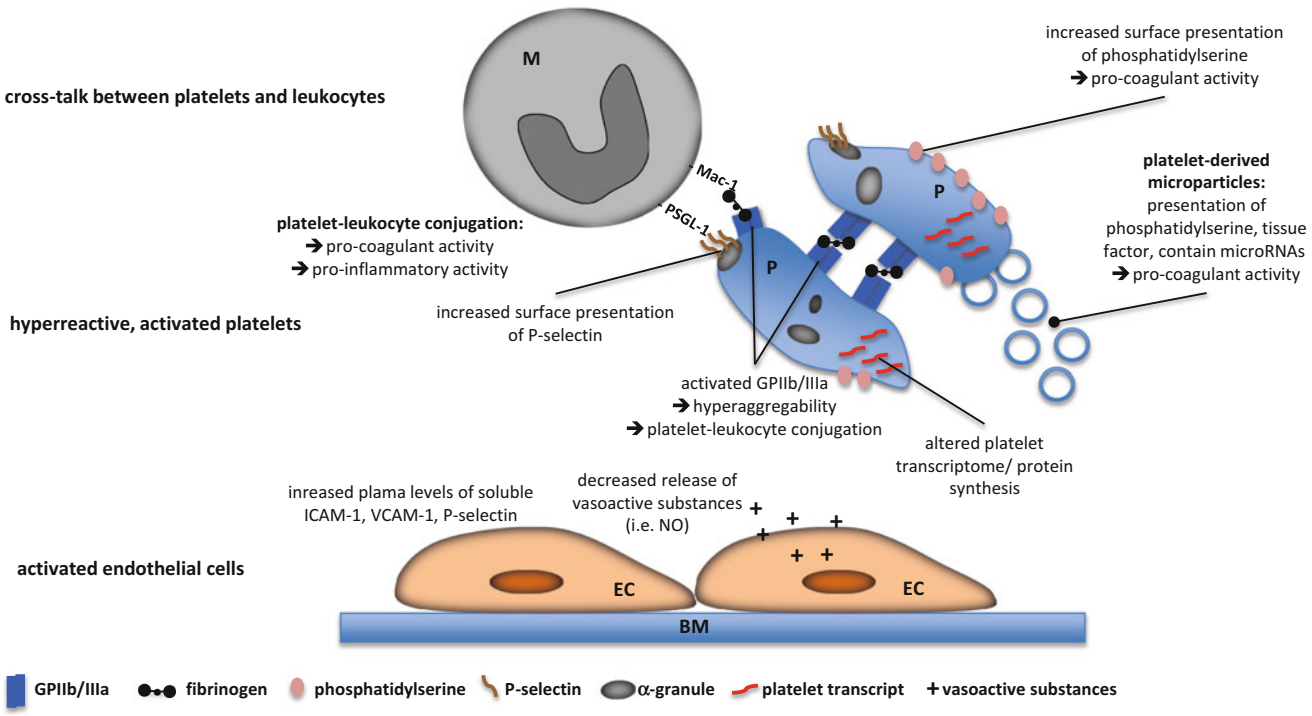

Fig. 1 Increased risk of thrombosis in patients with CKD/ESRD. Platelets from patients with CKD/ESRD especially under dialysis treatment are hyperreactive and activated. Platelet hyperaggregability, the exposure of phosphatidylserine, shedding of platelet-derived microparticles and alteration in the platelet transcriptome and protein synthesis are implicated to contribute to the pro-thrombotic state. Activated endothelial cells facilitate platelet hyperreactivity due to decreased release of NO. Activated platelets do not only interact with other platelets but also form hetero-cellular conjugates with leukocytes, such as monocytes via P-selectin/PSGL-1 and $\alpha_{IIb}\beta_3$/fibrinogen/Mac-1 adhesion axes. The crosstalk between platelets and leukocytes leads to functional interference of each other. *BM* basement membrane, *EC* endothelial cell, *M* monocyte, *P* platelet

The levels of VWF are normal in uraemic patients (Kaw and Malhotra 2006; Lee et al. 2010), but the binding to the platelets could be reduced (see below).

Platelets express increased levels of P-selectin on their surface, a marker of α-granule secretion (see also "platelet secretome") in uraemia. P-selectin-presenting platelets form conjugates with leukocytes, predominantly with monocytes and neutrophils, via the counter receptor P-selectin glycoprotein ligand-1 (PSGL-1) (Furie et al. 2001). Thereby, activated platelets modulate leukocyte function and vice versa via direct interaction supporting the pro-inflammatory and pro-thrombotic state. Soluble P-selectin shed from activated platelets or endothelial cells contributes to leukocyte recruitment to sites of vascular injury and therefore triggering the inflammatory response (Wagner 2005).

Platelet Procoagulant Activity and Exposure of Phosphatidylserine

Platelets expose increased levels of aminophospholipid phosphatidylserine (PS) on their surface that enables coordinated binding of distinct coagulation factors leading to enhanced coagulation due to amplified thrombin and subsequent fibrin formation and promoting a pro-thrombotic state in uraemia. Enhanced plasma levels of fibrinogen, VWF and FVIII, as well as decreased levels of protein C and S facilitate the generation of thrombin and fibrin generation (Galbusera et al. 2012). In addition, PS exposure on activated platelets serves as a clearance signal for macrophages (Bonomini et al. 2004, 2007) which shortens the life span of platelets in uraemia (Li et al. 2014). L-carnitine (LC) could reduce PS exposure in activated platelets in uraemia, possibly via inhibition of caspase activation (Bonomini et al. 2007). Whether uraemic patients might benefit from this effect of LC on platelet needs to be studied in the future.

Platelet Procoagulant Activity and Platelet-Derived Microparticles

Platelet-related thrombogenic factors in uraemic patients include platelet-derived microparticles (PMPs) (Goubran et al. 2015). The PMP surface is approximately 50- to 100-fold more procoagulant than the surface of activated platelets (Sinauridze et al. 2007).

PMPs are microvesicles with a diameter of 0.05–0.8 μm, a phospholipid bilayer and an increased PS exposure (Owens and Mackman 2011). They are released from the platelet membrane after activation by strong agonists, complement or shear stress as well as apoptosis. Interestingly, different activation patterns result in different PMP profiles. Strong agonists such as collagen or thrombin result in an increase of proteins which are related to platelet activation, while proteins related to platelet degranulation and the electron transport chain were reduced (Milioli et al. 2015). So far it is not clear how CKD influences platelet activation with different stimuli.

PMPs are also the result of platelet or megakaryocyte senescence as well as cytoskeletal abnormalities (Goubran et al. 2015). They influence the haemostatic balance under physiological conditions but can develop procoagulant activities resulting in thrombosis. PMPs can promote the expression of adhesion molecules, stimulate the release of cytokines, alter vascular reactivity and induce inflammation and angiogenesis as they contain growth factors, microRNA and different bioactive factors (Varon and Shai 2015). The release of tissue factor (TF) as well as coagulation factor binding to the negatively charged surface presenting PS belongs to the well-characterized procoagulant function of PMPs. In addition, PMPs promote healing and inflammatory responses. Thus, they contribute to the crosstalk and exchange of signals between cells and organs under pathological conditions (Varon and Shai 2015).

The PMPs bind factor Va and catalyse the formation of the prothrombinase complex, thus facilitating thrombosis (Sims et al. 1988, 1989). Elevated levels of PMPs were observed in cerebrovascular disease (Geiser et al. 1998) as well as acute myocardial ischaemia (Katopodis et al. 1997). Indeed, also patients with ESRD and patients on dialysis had elevated levels of PMPs, and no significant differences were observed between haemodialysis and peritoneal dialysis (Ando et al. 2002). Possibly, treatment with erythropoietin increases the release of PMPs (Ando et al. 2002). It is not clear so far what effects this has in terms of coagulation and the systemic inflammatory state of patients with ESRD.

Platelet Secretome

Platelets contain secretory granules, predominantly α-granules, δ-granules/dense bodies and lysosomes, and the release of granule cargoes is an important mechanism of platelet function and activation. Small biomolecules, such as ADP, ATP, polyphosphates, serotonin, histamine and Ca^{2+} and Mg^{2+} cations, are released from dense bodies upon platelet activation and act as important feedback and paracrine platelet agonists. Activated platelets release acid hydrolases, e.g. β-hexosaminidase, heparanase, elastase and cathepsins, from lysosomes which promote thrombus remodelling (Golebiewska and Poole 2015). However, the major cargo of platelet granules, e.g. multifunctional proteins and peptides, are stored in platelet α-granules. They contain adhesive proteins such as fibrinogen, VWF and thrombospondin-1 (TSP-1) promoting platelet

aggregation and coagulation. However, also coagulation factors, e.g. factor V and factor XIII, and anti-coagulation factors, e.g. antithrombin and proteins C and S, are stored in the α-granules. Moreover, different growth factors and chemokines such as vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), insulin-like growth factor 1, transforming growth factor β, platelet factor 4 (heparin-binding chemokine), fibroblast growth factor (FGF) and matrix metalloproteinases (MMPs) are stored in the α-granules of platelets (Pintucci et al. 2002; Sheu et al. 2004). Furthermore, angiostatin and endostatin, both inhibiting angiogenesis, have been located in α-granules. In addition, TSP-1 acts as an inhibitor of endothelial cell proliferation and capillary tube formation together with tissue inhibitors of matrix metalloproteinases (Golebiewska and Poole 2015). The α-granule membrane contains P-selectin but also additional receptors (e.g. $\alpha_{IIb}\beta_3$, GPIb-IX-V, GPVI) that are also constitutively expressed on the platelet surface. These are translocated to the platelet surface upon granule exocytosis and secretion mediating the crosstalk with leukocytes and the increase of receptor abundance on the platelet surface, respectively. Thus, the platelet secretome modulates not only primary and secondary haemostasis but also inflammation, cell growth and blood vessel development. So far, it is not clear how platelet secretion is affected by chronic renal failure.

Platelet Transcriptome and Protein Synthesis

Platelets do not contain a nucleus but contain cytoplasmic mRNAs as well as microRNAs derived from the megakaryocytes. This so-called platelet transcriptome influences platelet function and is altered in uraemia that seems to be at least partially correctable by dialysis (Ple et al. 2012). Moreover, it could be also a marker of disease progression (Clancy and Freedman 2015). Indeed protein synthesis can be initiated by platelet mRNAs (Schubert and Devine 2010; Schubert et al. 2014) such as the matrix metalloproteinase inhibitor TIMP 2 (Cecchetti et al. 2011). Blood clot retraction can be promoted by activated platelet-derived Bcl-3 (Weyrich et al. 2007). Interestingly the protein synthesis is altered in platelets of patients with CKD (Marques et al. 2010; Walkowiak et al. 2007). Platelet microRNAs could exert a regulatory role on platelet mRNAs. Phosphatidylcholine transfer protein (PCTP) and WD repeat-containing protein 1 (WDR1) are regulated by microRNAs. The microRNA hsa-miR-19b regulates WDR1, which is increased in platelets of uraemic patients and seems to be involved in platelet reactivity (Ple et al. 2012). It is not clear so far to what extent the platelet transcriptome influences platelet function in terms of bleeding episodes or thrombosis in patients with uraemia.

Haemodialysis

Platelet reactivity is increased in terms of fibrinogen binding in CKD patients undergoing haemodialysis (Aggarwal et al. 2002) and is associated with an increased risk of thrombosis (Kabbani et al. 2001; Thaulow et al. 1991; Trip et al. 1990) (Fig. 2). Further, increased shear stress, the surface of dialyzer membranes together with the biofilm and high- and low-molecular-weight heparin treatment may trigger platelet activation during haemodialysis (Gritters et al. 2008; Schoorl et al. 2013b). Haemodialysis results in platelet activation, characterized by granule cargo secretion with a release of platelet factor 4 as well as α- and β-thromboglobulin from α-granules together with ADP from dense bodies during dialysis with polysulfone membrane dialyzers (Elshamaa et al. 2009; Hoenich 1998). Furthermore, haemodialysis is associated with thromboxane A2 release (Hoenich 1998), platelet–monocyte and platelet–neutrophil conjugation (Bonomini et al. 1999; Gawaz et al. 1994a) and phosphatidylserine exposure of platelets (Schoorl et al. 2013b).

During haemodialysis the level of PMPs significantly increases (Daniel et al. 2006). Platelet degranulation has been shown to be associated with increased proendothelin-1 plasma concentrations from patients with end-stage CKD, a marker of endothelial cell activation (Schoorl et al. 2013a). It has been suggested that protein-bound uraemic toxins that

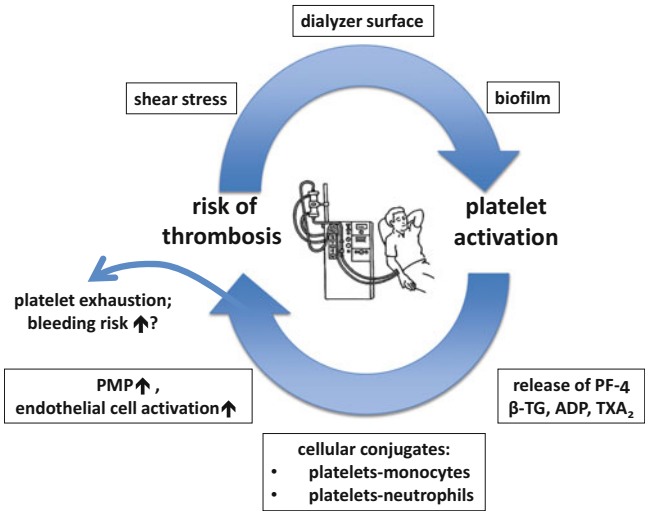

Fig. 2 Effect of haemodialysis on platelet function. Haemodialysis leads to platelet activation by an increased shear stress, the dialyzer membrane surface itself as well as the biofilm on the dialyzer membrane. Platelet activation is characterized by a release of platelet factor 4, β-thromboglobulin, ADP and thromboxane A2. Furthermore phosphatidylserine exposure on platelets increases, and platelet–monocyte and platelet–neutrophil conjugation occur. Furthermore, the level of PMPs increases. Platelet degranulation can participate in endothelial cell activation contributing to the inflammatory status in patients with ESRD

are poorly eliminated by haemodialysis cause activation of endothelial cells (Costa et al. 2008; Jourde-Chiche et al. 2009) contributing to the inflammatory status in patients with ESRD.

Platelet Dysfunction and Risk of Bleeding

Uraemic Toxins and Platelet Activation Defects in ESRD

Platelet function is substantially impaired in uraemic conditions especially in patients with ESRD (Boccardo et al. 2004; Glorieux et al. 2009) (Fig. 3). Uraemic toxins such as phenol, phenolic acid and guanidine succinic acid can mediate platelet hyporeactivity (Horowitz 1970; Horowitz et al. 1970; Rabiner and Molinas 1970). Phenolic acid can impair the primary aggregation in response to ADP, while guanidine succinic acid can inhibit the second wave of ADP-induced platelet aggregation. However, the bleeding time has not been described to correlate with the concentration of the dialyzable uraemic metabolites (Remuzzi et al. 1978a). Nevertheless, dialysis improves platelet function and reduces the bleeding risk (Benigni et al. 1993; Di Minno et al. 1985; Gawaz et al. 1994b; Sreedhara et al. 1995; Remuzzi et al. 1978b). This has been also recently demonstrated using closure time analysis for the evaluation of platelet function (Mekawy et al. 2015). Importantly, urea itself does not interfere with platelet function (Linthorst et al. 2010).

Platelets present frequently with a δ-storage pool defect characterized by a decreased content of ADP in δ-granules (Di Minno et al. 1985; Eknoyan and Brown 1981), an increased ATP/ADP ratio and a reduced content of serotonin. Platelets' ability to secrete the α-granule protein β-thromboglobulin is also diminished in patients with uraemia, all of them impairing haemostasis in these patients.

Furthermore, defective platelet release of ATP in response to thrombin together with an increased Ca^{2+} content and a reduced agonist-induced release of Ca^{2+} cations

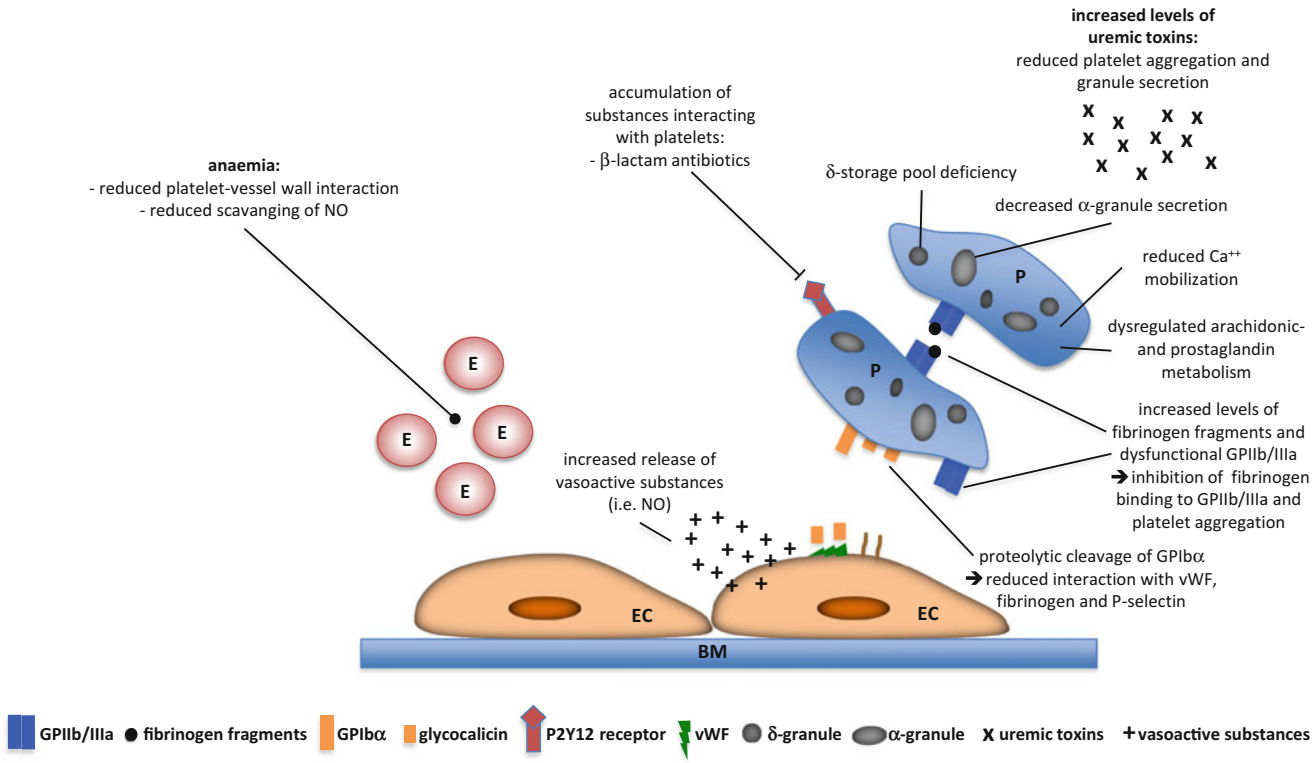

Fig. 3 Increased bleeding risk in patients with ESRD. Platelets from patients with ESRD may also present with hyporeactivity and an impaired functional response. Increased levels of uraemic toxins are predominantly responsible for decreased α-granule secretion, reduced Ca^{2+} mobilization, dysregulated arachidonic acid and prostaglandin metabolism. Platelet interaction with endothelial cells and platelet–platelet aggregation via fibrinogen binding are impaired caused by dysfunctional $\alpha_{IIb}\beta_3$ and competitive binding of fibrinogen fragments. Proteolytic cleavage of GPIbα, part of the GPIb-IX-V receptor complex, and release of the extracellular GPIbα fragment glycocalicin impair the interaction of platelets with VWF and endothelial cells. Endothelial cells especially under dialysis treatment release increased levels of NO which diminished platelet activation via the cGMP/PKG pathway. Increased NO levels are partly the result of insufficient scavenging by erythrocytes in anaemia. Further, anaemia reduces the rheological flow of platelets to the vessel wall. Platelet δ-storage pool deficiency and accumulation of β-lactam antibiotics impair platelet feedback activation through ADP-mediated signalling via the platelet ADP-receptor $P2Y_{12}$. *BM* basement membrane, *E* erythrocyte, *EC* endothelial cell, *P* platelet

from the platelets (Boccardo et al. 2004; Ware et al. 1989) could contribute to impaired platelet function in uraemia (Di Minno et al. 1985). The platelet Ca^{2+} content is also influenced by the arterial pressure, whereas lowering of arterial pressure reduces the Ca^{2+} content of platelets in patients with end-stage renal disease (Schiffl 1990). Interestingly, the release of Ca^{2+} from intracellular stores could be improved by erythropoietin (Zhou and Vaziri 2002) and in an experimental model by washing and resuspending of the platelets in non-uraemic plasma (Ware et al. 1989).

A disturbed arachidonic acid and prostaglandin metabolism associated with decreased synthesis and/or release of thromboxane A2 leads to reduced adhesion and aggregation capacity of platelets which may contribute to bleeding episodes (Di Minno et al. 1985; Smith and Dunn 1981) and could be reversed through dialysis (Bloom et al. 1986).

Clopidogrel is a potent antithrombotic drug by targeting the platelet Gi protein-coupled purinergic ADP-receptor $P2Y_{12}$ which amplifies the platelet aggregation response (Cattaneo 2015). However, it has been shown that renal dysfunction does not interfere with or aggravate the antithrombotic effect of clopidogrel (Mangiacapra et al. 2014).

Under distinct inflammatory conditions, platelets adhere through GPIbα of the GPIb-IX-V receptor complex to activated endothelial cells via binding to endothelial P-selectin (Frenette et al. 1995) or VWF (Andre et al. 2000). In addition, the major platelet fibrinogen receptor $\alpha_{IIb}\beta_3$ mediates binding of thrombin-activated platelets to unstimulated endothelial cells via platelet-bound adhesion proteins, such as fibrinogen, and endothelial ICAM-1 (Bombeli et al. 1998). During uraemia antibody detection of platelet surface, expressed GPIbα is reduced, which could be related to its proteolytic cleavage, for example, by plasmin whose level is elevated in uraemia (Mezzano et al. 1996; Salvati and Liani 2001; Sloand et al. 1991). Further, the resulting extracellular cleavage product glycocalicin may inhibit platelet adhesion through competitive binding to VWF (Himmelfarb et al. 1998). Moreover, a functional defect in platelet–VWF interaction can be related to an increased bleeding tendency in uraemic patients (Diaz-Ricart et al. 2000; Janson et al. 1980). Platelets exhibit reduced surface expression (Moal et al. 2003) and disturbed conformational change (Gawaz et al. 1994b) of $\alpha_{IIb}\beta_3$ upon platelet activation in uraemia. A reduced binding of VWF and/or fibrinogen to $\alpha_{IIb}\beta_3$ in uraemic patients could contribute to an impaired platelet adhesion and bleeding tendency (Benigni et al. 1993). While GPIb-IX-V acts as major VWF receptor to mediate mainly platelet adhesion, $\alpha_{IIb}\beta_3$ is the major receptor for fibrinogen to mediate predominantly platelet aggregation (Jurk and Kehrel 2005). Circulating fibrinogen fragments have been demonstrated to interfere with haemostasis as they competitively bind to $\alpha_{IIb}\beta_3$ resulting in a decreased fibrinogen-mediated platelet aggregation (Wratten et al. 1999; Sreedhara et al. 1996). Therefore, decreased platelet binding of VWF and fibrinogen has central impact on the development of platelet function defects in uraemic patients. This could be related to uraemic toxins (Benigni et al. 1993; Gawaz et al. 1994b) as it can be improved by dialysis.

Platelet function as assessed by in vitro bleeding time measurement using the PFA-100 device could be restored by haemodialysis (Mekawy et al. 2015). Although shedding of GPIbα could not be influenced by dialysis, impaired agonist-induced surface expression of $\alpha_{IIb}\beta_3$ could be reversed by peritoneal dialysis as compared to haemodialysis (Salvati and Liani 2001). This points to uraemic toxins being responsible for distinct platelet functional defects. The responsible uraemic toxins include methylguanidine, guanidine succinic acid, phenols and hydroxyphenyl acetic acid (Sohal et al. 2006).

However, haemodialysis could also contribute to impaired platelet function by promoting abnormal platelet cytoskeletal assembly (Diaz-Ricart et al. 2000). This can result in deficient tyrosine phosphorylation signalling which was more prominent in HD patients as compared to CAPD patients. Interestingly CAPD even restored this phenomenon partially. In addition, recurrent platelet activation due to regular dialysis treatment causes platelet exhaustion and refractoriness leading to increased bleeding risk (Fig. 2). However, it is not clear what clinical impact these observations have in relation to the beneficial effect of HD on platelet function.

Moreover, vasoactive substances such as nitric oxide (NO), inhibiting platelet aggregation through the formation of cGMP (Noris et al. 1993), or endothelium-derived prostacyclin (PGI_2) that modulates vascular tone also inhibit platelet function in uraemia, where increased levels have been detected (Kyrle et al. 1988). Thus, elevated levels of NO and prostacyclin contribute to platelet dysfunction with an increased bleeding risk in these patients (Kyrle et al. 1988; Defreyn et al. 1980; Radomski et al. 1990; Yokokawa et al. 1995). In congruence with these findings, inhibition of NOS by L-NMMA restores also platelet activity in uraemia (Remuzzi et al. 1990; Simon et al. 1995). Moreover, renal anaemia could also contribute to higher NO levels by a reduced scavenging capacity (Noris et al. 1993), thus contributing to decreased platelet activity (Kaw and Malhotra 2006).

Anaemia

Anaemia is often present in patients with end-stage kidney disease as a result of erythropoietin deficiency. Decreased levels of erythrocytes affect indirectly platelet activity and thus can promote bleeding episodes in uraemic patients (Fernandez et al. 1985; Galbusera et al. 2009; Howard et al. 1989). In anaemia platelets flow in the middle of the bloodstream due to the lower number of erythrocytes, which

impairs the interaction between platelets and the vessel wall resulting in a prolonged bleeding time. Furthermore, the low number of erythrocytes with a reduced haemoglobin amount lead to a reduced scavenging of NO (Martin et al. 1985) thus decreasing ADP and thromboxane A2 release via an enhanced activation of guanylyl cyclase (Noris et al. 1993) with increased cGMP levels thus inhibiting platelet aggregation (Kaw and Malhotra 2006).

However, erythropoietin can also directly influence platelets (Cases et al. 1992; Farag et al. 2012). This is of particular interest as it could at least partly explain why EPO therapy aiming at normal Hb levels increases the risk of cardiovascular events and mortality in patients with chronic kidney disease (CKD). Anaemic CKD patients on ESAs demonstrated increased levels of markers of platelet activation in terms of soluble P-selectin, soluble CD40L as well as platelet microparticles (PMPs).

Drugs

Drug–platelet interactions have fundamental effects on platelet function and thus may result in bleeding tendency, which is also the case in patients with uraemia. Antibiotics such as third-generation cephalosporins and β-lactam antibiotics play a role under these circumstances (Fass et al. 1987; Shattil et al. 1980). β-Lactam antibiotics interact with platelets through an interference with $P2Y_{12}$ receptors for ADP. These effects are related to dose and duration of the therapy.

Platelet-Induced Mechanisms of Renal Disease

Platelets and Renal Damage

The vasculature, particularly the microvasculature, plays an important role in renal diseases as it can mediate tissue damage through a direct interaction with inflammatory cells but also by secreting inflammatory mediators and growth factors into the surrounding tissue. Finally, it can influence tissue homeostasis through chronic changes of the vessel wall in terms of stenosis or obstruction with resulting tissue scarring due to chronic hypoxia and malnutrition of the dependent tissue area (Couser 1994, 1998). Platelets also contribute to the disease progress as in some studies of experimental glomerulonephritis they have been shown to produce and secrete inflammatory molecules and can represent pro-inflammatory effector cells, while in other models, platelet inhibition is not effective in reducing inflammatory reactions (Barnes 1997; Barnes and Venkatachalam 1985; Johnson 1994; Johnson et al. 1991). Thrombotic microangiopathy is a classical disease where an important pathophysiologic contribution of platelets has been demonstrated. Interestingly in the concanavalin A/anti-concanavalin A mouse model of endothelial cell damage blocking the platelet $P2Y_{12}$ receptor with clopidogrel reduced platelet activation and subsequently also endothelial damage (Schwarzenberger et al. 2015). Whether this is also effective under conditions of renal failure needs further investigation. Interestingly, mice lacking the $P2Y_{12}$ receptor are also protected from capillary rarefaction as well as progression of crescentic glomerulonephritis (Hohenstein et al. 2007). Thus, platelets may be relevant mediators of renal damage.

Furthermore, platelets have also been linked to the pathogenesis of different forms of glomerulonephritis (Zoja and Remuzzi 1995). Platelets together with their degradation products have been observed within the glomeruli and other compartments of the renal tissue in patients with lupus nephritis, mesangioproliferative, membranous, or IgA nephropathy. Platelet survival is also shortened in patients with glomerular diseases that could be related to platelet consumption in some forms of glomerulonephritis (i.e. lupus nephritis) (Clark et al. 1976; Parbtani and Cameron 1980). Activated platelets may release vasoactive, chemotactic and mitogenic substances within the glomerulus that interact with resident or inflammatory cells within the kidney thus promoting glomerular injury. It has been shown that polycationic macromolecules, platelet factor 4 and β-thromboglobulin released from platelet α-granules modulate glomerular permeability and increase immune-mediated glomerular injury (Zoja and Remuzzi 1995). Platelet-derived growth factor (PDGF) (Johnson et al. 1992a) mediates renal disease progression. In an experimental glomerulonephritis model, mesangial cell proliferation and matrix expansion could be effectively suppressed by an antibody against PDGF (Johnson et al. 1992b).

Platelets can also interact with mesangial cells as has been demonstrated with activated platelets from patients with SLE (Delmas et al. 2005). The platelets induced an increased expression of CD40 on mesangial cells together with a release of soluble CD40. This was dependent from a direct contact between the platelets and the mesangial cells as well as upon platelet-associated CD40 ligand (CD40L, CD154) expression. This resulted in a proliferation of mesangial cells and an increased release of TGF-β1. Thus, platelets from patients with SLE can activate mesangial cells through CD40/CD40L signalling, leading to a proliferation of mesangial cells together with an increased production of TGF-β1. On the other hand, platelet inhibition was inferior as compared to RAS blockade in terms of reducing TGF-β expression and matrix accumulation, while it effectively reduced glomerular thrombosis in an anti-thy-1 glomerulonephritis model (Peters et al. 2004).

Inhibitors of platelet function did not clearly demonstrate positive effects in terms of reducing disease progression in clinical studies. Dipyridamole (Donadio et al. 1984;

Zimmerman et al. 1983), ticlopidin (Izumino et al. 1986; Zoja et al. 1990) and aspirin in some, partly experimental, studies in conjunction with warfarin did not show clear benefits.

Immune Complexes and Platelet Activation

IgG immune complexes can also be involved in platelet-mediated thrombotic complications that can occur during heparin-induced thrombocytopenia, systemic lupus erythematodes, rheumatoid- and collagen-induced arthritis or some forms of chronic glomerulonephritis (Zhi et al. 2015). This is related to the capability of the Fc receptor, FcγRIIa, to initiate platelet activation. On the other hand, also the major platelet adhesion receptor, integrin $\alpha_{IIb}\beta_3$, could be involved resulting in mediating adhesion and aggregation after binding to IgG immune complexes. Interestingly binding of IgG immune complexes to FcγRIIa leads to platelet adhesion and initial signal transduction; thrombus formation requires $\alpha_{IIb}\beta_3$ receptor. Furthermore, the tyrosine kinases Lyn and Syk seem to be important signal transduction molecules in IgG complex-induced platelet activation. Whether a specific inhibition improves outcomes in immune complex-mediated diseases and the impact of renal function is not known so far.

Anti-GBM Glomerulonephritis

Experiments in anti-glomerular basement membrane antibody-mediated nephritis revealed an increased expression of P-selectin on platelets (Kuligowski et al. 2006). However, their accumulation was P-selectin independent. Interestingly, platelet depletion prevented the increase in glomerular P-selectin expression as well as the leukocyte recruitment. Depletion of both neutrophils and platelets also prevented urinary protein excretion in this model of glomerular disease indicating that platelet accumulation participates in the pathogenesis of renal injury in the anti-GBM nephritis. Finally, infusion of wild-type platelets into P-selectin deficient mice restored the ability of glomeruli in these mice to support leukocyte adhesion. Thus, leukocyte adhesion in glomeruli can occur through a non-rolling interaction of leukocytes with the endothelium mediated by platelet-derived P-selectin.

Antibody-Mediated Rejection After Kidney Transplantation

Antibody-mediated rejection substantially contributes to late allograft loss (Kuo et al. 2015; Sellares et al. 2012). In an experimental model of antibody-mediated kidney graft rejection in mice administration of donor specific antibodies (DSA) resulted in C4d deposition along the capillaries and VWF release from endothelial cells coated with platelet aggregates. Platelet-derived platelet factor 4 and serotonin accumulated in the graft. Furthermore, activated platelets expressing P-selectin attached to endothelium as well as macrophages. This was associated with endothelial damage. On the other hand, platelet depletion reduced platelet-derived factors as well as the accumulation of macrophages. Thus, platelets promote inflammation in response to DSAs and could play an important role in the development of antibody-mediated allograft rejection.

Take-Home Messages

- Platelet homeostasis is substantially disturbed in patients with advanced CKD and contributes to bleeding episodes as well as to thrombosis.
- The increased risk of thrombosis is related to platelet activation, platelet–leukocyte conjugates, platelet-derived microparticles and activation of endothelial cells.
- Uraemic toxins, anaemia and altered endothelial cell function can lead to bleeding episodes.
- Platelets are involved in the pathogenesis of renal diseases such as thrombotic microangiopathy, immune complex-mediated renal disease, anti-GBM glomerulonephritis and antibody-mediated rejection after kidney transplantation.

Platelets in Inflammatory Bowel Disease

Felix Becker and Thorsten Vowinkel

Abstract

Inflammatory bowel diseases (IBD) are chronic relapsing inflammatory disorders of the gastrointestinal tract, which encompass two main entities: ulcerative colitis (UC) and Crohn's disease (CD). While thrombotic events have long been recognized as characteristic extraintestinal features of CD and UC, growing evidence suggests that in particular platelets play a crucial part in the integration of the interdependent processes, inflammation and thrombosis/coagulation, that are important features of these diseases. As such, platelets are suggested to be involved in modulating the intestinal inflammatory phenotype by amplifying inflammation-induced trans-endothelial leukocyte recruitment and activation. The aim of this chapter is to summarize the importance of platelet abnormalities in IBD, their relevance for extraintestinal thrombotic complications, as well as the intestinal inflammatory phenotype, and to further review recent developments in targeting platelets as a therapeutic option in treatment of patients with IBD.

Introduction

Inflammatory bowel diseases (IBD) are chronic relapsing inflammatory disorders of the gastrointestinal tract, which encompass two main entities: ulcerative colitis (UC) and Crohn's disease (CD). While thrombotic events have long been recognized as characteristic extraintestinal features of CD and UC, growing evidence suggests that in particular platelets play a crucial part in the integration of the interdependent processes, inflammation and thrombosis/coagulation, that are important features of these diseases. As such, platelets are suggested to be involved in modulating the intestinal inflammatory phenotype by amplifying inflammation-induced trans-endothelial leukocyte recruitment and activation. The aim of this chapter is to summarize the importance of platelet abnormalities in IBD, their relevance for extraintestinal thrombotic complications, as well as the intestinal inflammatory phenotype and to further review recent developments in targeting platelets as a therapeutic option in treatment of patients with IBD.

IBD

IBD are idiopathic inflammatory conditions that represent an increasing global health issue with rising incidence in Westernized and developing countries (Molodecky et al. 2012). The principle types of IBD are UC and CD and are defined as chronic relapsing intestinal disorders, with a shared cardinal symptom of intestinal inflammation. UC is restricted to the colon and causes mucosal inflammation, whereas CD can occur along the entire gastrointestinal tract and affects all layers, termed "transmural" inflammation (Ordas et al. 2012; Baumgart and Sandborn 2012). Although the precise etiology of IBD has not yet been unraveled, it is commonly accepted that complex alterations in the mucosal immune system in genetically susceptible individuals lead to an inappropriate intestinal host response to unspecified environmental factors (Xavier and Podolsky 2007). Mounting

evidence suggests that IBD do not just involve dysregulated immune cells but also involve complex interactions and active participation of other cellular systems, including platelet aggregates, which are frequently found within mucosal microthrombi, and contribute to the complex alterations in the mucosal immune system (Danese et al. 2004).

Platelet Abnormalities in IBD

CD and UC are both accompanied by distinct quantitative, morphological, and functional changes in platelet characteristics including increased cell number, decreased volume, enhanced activation, and elevated aggregation (Table 1). While platelet abnormalities are now a well-established feature in IBD, recent work has focused not only on unraveling a possible pathogenic role of platelets in the initiation and perpetuation of the intestinal inflammation in IBD but also on using platelets and their abnormal activity to monitor disease progression and activity in UC and CD.

Reactive Thrombocytosis in IBD

As early as 1968, Morowitz et al. first described that active IBD was associated with an increase in platelet number, a term defined as reactive thrombocytosis, and defined as a platelet count of $>450 \times 10^9$/L (Morowitz et al. 1968). Soon after that it was further demonstrated that the number of platelets correlated with recognized serological disease activity indices, including hypoalbuminemia (low albumin levels), increased erythrocyte sedimentation rate (ESR), and serum orosomucoid (an acute-phase alpha-globulin glycoprotein) concentration. These findings established platelet count as a measure of disease activity in IBD (Talstad et al. 1973; Harries et al. 1983). The unique feature of reactive thrombocytosis was also used to distinguish diarrhea, due to IBD, from infectious diarrhea, both of which can present themselves with the cardinal clinical features of diarrhea, abdominal pain, and cramping, while reactive thrombocytosis is present in IBD only (Harries et al. 1991). In addition, platelet count can even be used to discriminate between active forms of CD and UC and its inactive counterparts, as well between diseased and healthy individuals (Kapsoritakis et al. 2001). Since platelet count was positively correlated with an active state of disease in UC and CD, which predominantly represents the extent and severity of intestinal inflammation, a recent study was performed and aimed at finding an association between increased platelet numbers and colorectal neoplasia (CRN) in UC patients, as a possible consequence of exacerbated colonic inflammation. Patients with CRN had a significantly higher platelet count, a relationship that was confirmed in the corresponding univariate logistic regression analysis. Although platelet count did not reach the significance level in the subsequent multivariate logistic regression analysis, it shows the potential of platelet markers as short- and long-term serologic biomarkers in IBD (Koutroubakis et al. 2015).

Mechanisms and Consequences of Reactive Thrombocytosis

The exact mechanism behind reactive thrombocytosis in IBD is not completely understood. In human IBD, as well as experimental models of colitis, it has been shown that platelets have a normal life span, suggesting that an increased production (thrombopoiesis), rather than an accelerated activation and consumption in the inflamed microvasculature, is responsible for the elevated platelet count (Webberley et al. 1993; Senchenkova et al. 2013). In line with these findings, IBD patients with reactive thrombocytosis have increased levels of thrombopoietin (TPO), which is a crucial promoter of thrombopoiesis, as well as increased levels of interleukin 6 (IL-6), which induces hepatic TPO production. Furthermore, data obtained from a model of experimental colitis has demonstrated a connection between IL-6 and platelet activation, reactive thrombocytosis, and platelet–leukocyte aggregate (PLA) formation, with IL-6 found at least in human CD to be elevated (Yan et al. 2014; Heits et al. 1999; Senchenkova et al. 2013; Mahida et al. 1991). However, a direct correlation between serum levels of TPO and platelet count during active IBD could not be detected, which suggests that other factors might be responsible for the reactive thrombocytosis (Papa et al. 2003). While an elevated platelet count in IBD has now been well established to be

related to disease activity, thrombocytosis is not an independent risk factor for thromboembolism, as it has been found in other diseases, such as cancer (Voudoukis et al. 2014).

Morphological Platelet Changes

Although the exact mechanisms responsible for the alterations in thrombopoiesis during the active phases of disease in UC and CD patients remain unknown, one distinct feature of this process is well established in IBD, and that is the smaller mean platelet volume (MPV). Platelet number and volume are normally inversely related, and as such, studies have comprehensively shown a decreased MPV to be associated with the increased platelet count in IBD (Jaremo and Sandberg-Gertzen 1996; Chakraborty et al. 2011). Moreover, since the average size of a platelet correlates with its function and activation, efforts have been made to use MPV as an additional serologic inflammatory biomarker for the detection and activity surveillance in patients with UC and CD (Martin et al. 1983; Thompson et al. 1982; Gasparyan et al. 2011). While the feature of a reduced MPV has been uniformly described in early IBD studies, subsequent reports correlated this feature with disease activity and severity. It was reported that active CD and UC were associated with a decreased platelet volume, which was inversely correlated with traditional serologic inflammatory markers such as C-reactive protein (CRP), white blood cell count (WBC), and ESR (Kapsoritakis et al. 2001; Ozturk et al. 2013; Shen et al. 2009). An additional correlation with an endoscopic activity index was later described for UC (Yuksel et al. 2009). Similar to reactive thrombocytosis, the exact mechanism(s) responsible for the decrease in MPV in IBD remain uncertain. Early studies suggested an enhanced thrombopoiesis as a result of an increased consumption of larger platelets and the subsequent release of immature and smaller platelets (Voudoukis et al. 2014). It has also been suggested that younger platelets (with a higher MPV) are more prone to form platelet aggregates, which in turn would increase the relative appearance of older platelets with a smaller MPV (Vizioli et al. 2009; Giannotta et al. 2015). However the abovementioned studies demonstrating a normal platelet life span in IBD challenged this explanation (Webberley et al. 1993). In addition, the lower MPV in IBD patients was not correlated with levels of pro-thrombopoiesis molecule TPO but rather negatively correlated with the platelet-specific activation markers: beta-thromboglobulin (ß-TG) and platelet factor 4 (PF4) (Kapsoritakis et al. 2001). This further demonstrated the need for platelet kinetic studies in the specific setting of IBD, which take into account platelet activation, possible platelet consumption, and an altered thrombopoiesis due to the chronic inflammatory state.

Platelet Activation in IBD

In IBD, growing evidence suggests that platelets circulate in an active state, with the inflamed intestinal microcirculation being the likely origin of activation. This notion is further supported by findings that platelet activation and aggregation are increased in capillaries compared to peripheral venous blood (Tschoepe et al. 1993; Collins et al. 1997; Irving and Rampton 2007). In UC and CD, the mesenteric microvasculature is chronically inflamed, leading to continuous endothelial cell damage, indicated by increased serum levels of von Willebrand factor (vWF), endothelial protein C receptor (EPCR), and thrombomodulin (TM) (Stevens et al. 1992; Boehme et al. 1997; Meucci et al. 1999). Endothelial cell damage results in the exposure of basement membrane collagen and tissue factor (TF), which are both potent stimulants for platelet activation. The characteristic chronic intestinal inflammation in CD and UC also results in microvascular dysfunction with endothelial cell activation as well as leukocyte recruitment and transmigration. As outlined below, platelets can be directly activated by the receptor-mediated contact to stimulated endothelial cells or to leukocytes adhering to the endothelial cell layer. In addition, a variety of soluble mediators including lipid mediators (e.g., platelet-activating factor [PAF]), cytokines (e.g., interferon-γ), or chemokines (e.g., CCL22), which are released by resident or recruited immune cells and are all able to activate platelets (Stokes and Granger 2012).

Assessment of Platelet Activation

The activated state can be accessed by serum measurements of platelet-derived molecules (such as ß-TG and PF4) or by directly assessing membrane-bound activation-dependent antigens (e.g., glycoproteins $\alpha_{IIb}\beta_3$, P-selectin, CD40, and GP53) on platelets. Once activated, platelets release a broad variety of activation products and undergo distinct changes in the character and formation of their membrane-bound receptors. These effects will now be discussed in more detail.

Soluble Markers of Platelet Activation

In the context of IBD, ß-TG and PF4, both released from the platelet α-granules, have gained interest as markers of platelet activation. Since PF4 and ß-TG are also potent chemoattractants for neutrophils, monocytes, eosinophils, and fibroblasts, it was suggested that the inflammatory response in UC and CD could be modulated by the degree and endurance of platelet activation; thus efforts were made to correlate levels of PF4 and ß-TG with disease activity (Collins and Rampton 1997). While it was uniformly described that both PF4 and ß-TG were markedly raised in CD and UC, conflicting results were obtained when describing a correlation between these factors and IBD disease activity. Collins et al. and Webberley et al. found no association between platelet

activation and disease status in UC and CD, while Vrij et al. were able to correlate PF4 and ß-TG levels with biochemical and endoscopic indices of disease activity (Collins et al. 1994; Webberley et al. 1993; Vrij et al. 2000).

An additional serological marker for heightened platelet activation in IBD was introduced by Danese et al. who showed that soluble CD40 ligand (sCD40L), which is exclusively shed by activated platelets, is elevated in UC and CD. Of interest, concentrations of sCD40L in UC and CD have been described to be positively correlated with the extent of mucosal inflammation, suggesting that this platelet-derived activation marker might be a suitable serologic marker of disease activity in IBD (Danese et al. 2003a, b; Ludwiczek et al. 2003).

Recently, platelet-derived microparticles (PDMP) have been accessed as markers of platelet activation during inflammation. Evidence suggests that activated platelets in IBD shed these microparticles, and in UC and CD, PDMP formation is significantly increased. Furthermore, PDMP levels have also been shown to be both correlated with disease activity and with soluble P-selectin (a classical marker of platelet activation) (Andoh et al. 2005). Thus, these findings suggest PDMP to be promising serologic markers to measure platelet activation and disease activity in patients with IBD.

Membrane-Bound Markers of Platelet Activation

Among the platelet surface markers, growing evidence suggests GPIIb/GPIIIa, P-selectin, CD40, and GP53 to be not only selective markers for platelet activation but also functionally crucial for the inflammatory and hemostatic properties of activated platelets in IBD. We discuss each marker in more detail below.

GPIIb/GPIIIa The platelet-specific glycoproteins IIb (CD41) and IIIa (CD61), also known as integrin $\alpha_{IIb}\beta_3$ complex, undergo specific conformational changes upon platelet activation, which enables the complex to bind its respective ligands, primarily fibrinogen. GPIIb/GPIIIa is essential for platelet aggregation and endothelial adherence and especially important for the cross-linking of thrombin-activated platelets in the process of clot building, where soluble fibrinogen bridges activated platelets via GPIIb/GPIIIa binding. The importance of thrombin activation in CD has recently been defined by showing that responsiveness to thrombin was higher in patients with active CD compared to patients in remission and healthy controls (Schmid et al. 2014). An increase in GPIIb/GPIIIa-positive platelet area was found in the colonic mucosa of UC patients with active disease, which was not only significantly greater when compared to healthy controls, but also higher compared to patients with inactive UC (Kayo et al. 2006).

P-selectin P-selectin is a member of the cell adhesion molecule (CAM) family and expressed on the surface of activated platelets and endothelial cells. Its respective ligand is P-selectin glycoprotein ligand-1 (PSGL-1), which is constitutively expressed on the surface of leukocytes. Thus, P-selectin–PSGL-1 binding is necessary for platelet–leukocyte aggregates. In IBD, the expression of P-selectin is significantly increased when compared to platelets from healthy controls, although independent of disease activity (Collins et al. 1994).

CD40/CD40L The CD40/CD40L system (a member of the TNF superfamily) is one of the key pathways in IBD, since it enables the cross talk between classic immune and nonimmune cells in the initiation and perpetuation of inflammation. While CD40 is expressed on a variety of cells, the membrane glycoprotein CD40L is primarily found on the surface of activated platelets and CD4+ T cells. Functionally, platelet CD40L and platelet-derived sCD40L are crucially involved in inflammatory as well as thrombotic cascades (see below) as they are the central ligand/receptor pair for platelet–leukocyte, platelet–platelet, and platelet–endothelial cell interactions and co-stimulations (Vowinkel et al. 2007; Andre et al. 2002a, b; Danese et al. 2003a, b). Platelets from UC and CD patients have a significantly greater expression of CD40L and are in addition the exclusive source of sCD40L, which is also significantly increased in the plasma of IBD patients (Danese et al. 2003a, b).

GP53 GP53 is another surface glycoprotein, which is exclusively found on activated platelets, and whose surface appearance indicates the degranulation of lysosomes. GP53 has been described to be significantly upregulated on platelets from both CD and UC patients compared to healthy controls, while no correlation with disease activity or extent of inflammation was reported when comparing active with inactive disease (Collins et al. 1994).

Platelet Aggregation

Activated platelets can form two distinct forms of aggregates: homotypic platelet–platelet and heterotypic platelet–leukocyte aggregates (PLA). As such, platelet aggregates are involved in thrombotic as well as in inflammatory processes. Since homotypic platelet adhesion is required for the sequence of thrombus development, platelet–platelet aggregates are most likely prone to be involved in intestinal thrombus formation. On the other hand, it has been shown that leukocytes, which form a complex with activated platelets, are more intensely activated than free circulating ones (Peters et al. 1999). As a consequence of this enhanced activation complex, leukocytes display increased inflammatory properties and are more likely to adhere and subsequently migrate into inflamed tissues. While the formation of platelet–platelet aggregates is mediated by fibrinogen or vWF cross-linking via the GPIIb/GPIIIa

receptor complex on activated platelets, the formation of PLA is mostly established via binding of P-selectin (expressed on platelets and endothelial cells) and PSGL-1 (constitutively expressed on leukocytes). In addition, participation of CD40L (expressed on platelets), Mac-1 (expressed on leukocytes), as well as GPIIb/GPIIIa–fibrinogen–GPIIb/GPIIIa cross talk has also been described to be involved in the formation of PLA.

Mechanism Consequences of Platelet Aggregation in IBD

There are several lines of evidence that are consistent with platelet hyper-aggregation in IBD patients. Webberly et al. described spontaneous in vitro aggregation of platelets isolated from 30 % of IBD patients, an observation that was absent in healthy controls. In addition, platelets obtained from UC and CD patients were hypersensitive in response to aggregating agents such as adenosine diphosphate, collagen, and arachidonic acid (AA) (Webberley et al. 1993). Collins et al. described an enhanced in vitro platelet aggregation in response to AA in CD and UC patients, which was IBD specific since it was not found in patients with rheumatoid arthritis (Collins et al. 1994). It was also further shown that the enhanced hyper-aggregation of platelets in IBD continued even during inactive states of disease, suggesting a possible involvement of activated platelets in relapsing flares of IBD patients (Andoh et al. 2006). When platelet aggregates were studied in vivo, patients with active IBD exhibited more circulating aggregates than healthy controls or rheumatoid arthritis patients (Collins et al. 1994). These results suggest that the hyper-aggregation of platelets in IBD cannot be seen as a general common consequence of chronic inflammation but rather as a specific characteristic feature of CD and UC. This phenomenon was further defined by showing that IBD patients had more circulating aggregates in the mesenteric venous circulation than in the supplying arterial system, as well as intracapillary platelet aggregates in rectal biopsies, suggesting the microcirculation within the inflamed intestine as the origin of platelet activation and aggregation (Collins et al. 1997; Dhillon et al. 1992). Compared to healthy individuals as well as inflammatory controls (rheumatoid arthritis), IBD patients exhibit an increased appearance of PLA. Using peripheral whole blood samples, Irving et al. showed that formation of circulating PLA was higher in IBD patients than it was in healthy and inflammatory controls (Irving et al. 2004). Furthermore, they identified that the mesenteric vasculature was the origin of PLA formation in patients with UC (Irving and Rampton 2007). One common finding in these studies was that the formation of PLA was not correlated with disease activity, which was confirmed when specifically analyzing platelet–monocyte and platelet–neutrophil aggregates in UC patients. This dissociation between disease activity and heterotypic platelet aggregation suggests that PLA formation might be pathogenic in IBD rather than just caused by chronic inflammation.

Although platelets might represent the crucial link between the characteristic interaction between thrombosis/coagulation and inflammation in IBD, it is worth mentioning that other hemostatic parameters involved in the coagulation cascade are also altered. While some of the changes in platelet activation and aggregation are found to be IBD specific, chronic inflammation in general activates coagulants, reduces anticoagulants, and inhibits fibrinolysis, all of which most likely participate in the pro-thrombotic state associated with IBD (Senchenkova et al. 2015; Giannotta et al. 2015).

- CD and UC are accompanied by distinct quantitative morphological and functional changes in platelet characteristics, including increased cell number and decreased volume.
- Platelets in IBD are characterized by an enhanced activation and elevated aggregation.

Platelets in Extraintestinal Disease

While UC and CD primarily affect the gastrointestinal tract, a variety of extraintestinal manifestations have been described in IBD patients. Besides solid organ manifestations such as dermatologic, musculoskeletal, or ocular disease, the vascular and hemostatic systems are commonly affected, resulting in thromboembolic disease, in which platelets have shown to play a crucial role. While a variety of diseases (such as cancer) are linked to an increased risk for the development of thrombosis, neither other chronic inflammatory disorders, which are similar to IBD (e.g., rheumatoid arthritis), nor other chronic bowel diseases (e.g., celiac disease) have been shown to enhance the risk for systemic thromboembolic events, suggesting this feature to be unique for IBD (Miehsler et al. 2004).

Thromboembolic Events

Although the precise etiology of IBD-related thrombotic events is multifactorial and remains poorly understood, growing evidence suggested that the procoagulant tendency in CD and UC is most likely a result of complex abnormalities in the coagulation and fibrinolysis system, in particular alterations in the character and function of platelets (Yoshida and Granger 2009). In addition, platelet activation and aggregation are unique to IBD while not present in other inflammatory diseases; thus platelets have been implicated as cellular mediators of the distant organ thrombosis response to the intestinal inflammation in IBD (Collins et al. 1994). As described above, in patients with

UC and CD, platelets are primed to form homotypic platelet–platelet and heterotypic platelet–leukocyte aggregates in the microvasculature of the inflamed intestine and circulate in an enhanced state of activation. Therefore, formation of activated hyperaggregable platelets have been suggested to be a key event for the enhanced thrombogenic potential observed in CD and UC patients, as they are crucial for the onset and stabilization in the sequence of thrombus formation (Fig. 1) (Senchenkova et al. 2015).

The association between thromboembolic (TE) events and chronic intestinal inflammation was first described in 1936 by Bargen et al. who reported venous and arterial thrombosis as a serious complication in patients with UC (Bargen and Barker 1936). Since then, a mounting body of evidence has established IBD patients to have a greater risk for TE events, with reported incidences in clinical studies ranging from 1.2 to 7.5 % (Talbot et al. 1986; Webberley et al. 1993). These numbers even rise up to 41 % when postmortem autopsy studies are analyzed (Sloan et al. 1950). In recent years, cohort studies from Austria and Canada have also shown that the overall incidence of TE events is around 6.5 % in both UC and CD patients, with a threefold increase in the risk of systemic TE events compared to the general population and matched inflammatory diseases (Miehsler et al. 2004; Bernstein et al. 2001). In IBD, both the arterial and venous segments of the vascular tree are affected by thromboembolic complications, although thrombus formation in the venous system is more frequent. Most TE events become manifested as deep venous thrombosis (DVT) or pulmonary embolism (PE); however, less frequently affected sites include mesenteric, portal, or retinal veins; the cerebrovascular system; as well as arteries of the lower and upper extremities, renal or coronary arteries. TE events are among the leading causes for morbidity and mortality amid UC and CD, and in the case of TE events associated with IBD patients, their mortality is twofold higher than in non-IBD patients (Nguyen and Sam 2008).

Mechanisms of Thromboembolic Events

While the enhanced thrombus formation in IBD patients within the inflamed intestinal microvasculature can be in part explained by direct inflammation-induced disturbances to the vascular endothelial cell layer, such as a loss of EPCR and TM, these factors cannot account for thrombotic events observed in distant vascular beds (Scaldaferri et al. 2007). Thus, mechanistically, it has been suggested that platelets are primed for activation and aggregation in the inflamed intestinal

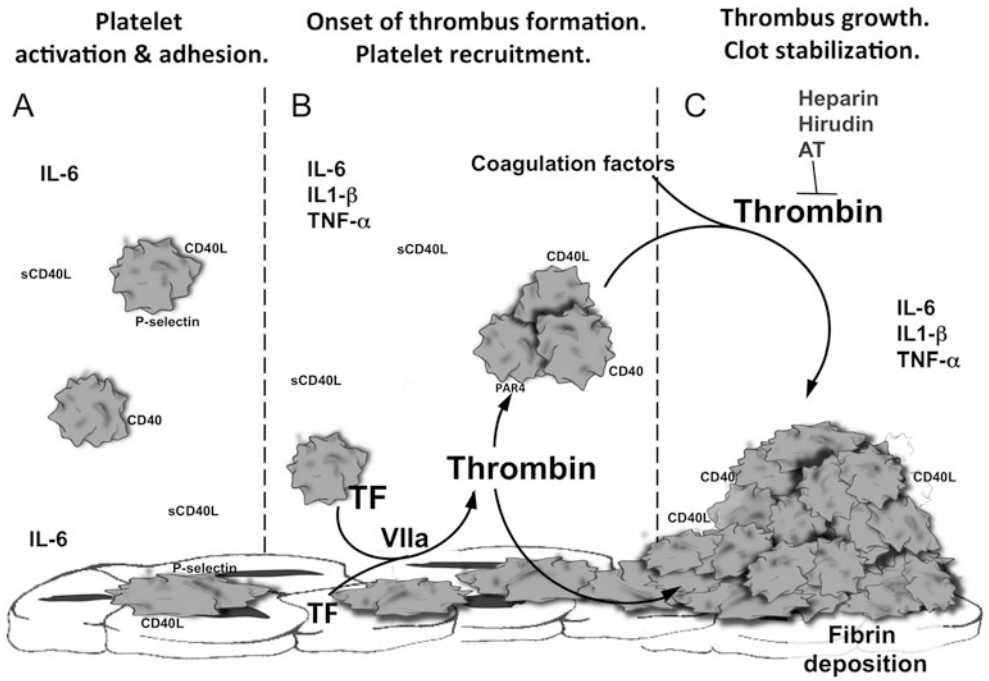

Fig. 1 Sequential changes in platelet and endothelial cell function that lead to thrombus formation in the vasculature during colitis. (Panel A) Different mediators released from the inflamed bowel elicit the activation of platelets, which promotes their adhesion to vascular endothelium via a CD40L and P-selectin-dependent mechanism. (Panel B) The accumulation of inflammatory cytokines (IL-6, IL-1β, TNF-α) results in the expression of TF and the subsequent generation of factor VIIa and thrombin, which promotes the recruitment of additional adherent platelets and the onset of thrombus formation. (Panel C) The rapid accumulation of platelets and deposition of fibrin result in thrombus growth and stabilization on the vessel wall. The transition from B to C is impeded by the antithrombin agents, heparin, hirudin, and antithrombin. *IL* interleukin, *TF* tissue factor, *TNF-α* tumor necrosis factor-α [Reproduced with kind permission of *Seminars in Thrombosis and Hemostasis* and the author (Senchenkova et al. 2015)]

microcirculation and then form thrombi in remote vascular beds. In line with this idea are observations from recent clinical studies with IBD patients, which suggest that TE events are more frequent during active disease state and that their incidence correlates with the extent of disease, with a shift toward TE events in CD during colonic involvement and in UC with pancolotic involvement (Solem et al. 2004; Miehsler et al. 2004; Spina et al. 2005; Oldenburg et al. 2000, 2005). It is however notable that approximately a third of all TE events in IBD occur while the disease is quiescent (Talbot et al. 1986).

A similar mechanism for an intestinal release and distant pro-thrombotic effects has been shown in experimental models of colitis for common soluble inflammatory mediators such as IL-1ß, TNF-α, and IL-6. All three cytokines were elevated during murine colitis and were able to mimic IBD-related extraintestinal thrombosis when administered to WT mice (Yoshida et al. 2010, 2011; Yan et al. 2014; Senchenkova et al. 2013). These observations indicate that intestinal inflammation and extraintestinal thrombosis are intrinsically linked. Following on from these findings, recent studies have provided further evidence for the role of platelets and specifically the CD40/CD40L signaling pathway as the key biological mediators involved in this cascade. Soluble or cell membrane-bound CD40L is expressed and shed by platelets activated in the inflamed mucosa, increased in UC and CD patients, and involved in the linkage between inflammation and thrombosis/coagulation in IBD (Danese et al. 2003a, b; Koutroubakis et al. 2004; Vowinkel et al. 2007). Elevated CD40L is a risk factor for vascular events, can bind to GPIIb/GPIIIa, and elicits pro-thrombotic capacity by stabilizing arterial thrombi and stimulating vascular endothelial cells to induce the upregulation of TF, which is an important initiator of IBD-related thrombus development (Anthoni et al. 2007; Andre et al. 2002a, b; Slupsky et al. 1998; Prasad et al. 2003). In addition, Gavins et al. suggested that activated and adherent platelets within the inflamed microvasculature of experimental colitis are the source of heightened levels of sCD40L, which then subsequently contribute to the enhanced incidence of thrombotic events in distant organs, as their work revealed that CD40L and sCD40L are crucial for intestinal inflammation-enhanced thrombosis in remote microvascular beds (Gavins et al. 2011).

- In patients with UC and CD, platelets are primed to form homotypic platelet–platelet and heterotypic platelet–leukocyte aggregates in the microvasculature of the inflamed intestine and circulate in an enhanced state of activation.
- As a consequence, IBD patients are prone to develop thromboembolic events

Platelets in Intestinal Disease

Initially platelets were recognized to be engaged solely in coagulation and hemostasis. However, a growing body of evidence has demonstrated their direct involvement in the mucosal immune response and inflammatory cascade in IBD. The suggested function of platelets within the complex mucosal immune system has been derived from their capacity to liberate a broad range of pro-inflammatory molecules, which can activate leukocytes and vascular endothelial cells. On the other hand however, platelet activation can also be elicited by substances released from both inflammatory cells and endothelial cells themselves (Fig. 2).

Platelet–Platelet Interactions

Convincing results have recently expanded the role for platelet activation and aggregation in IBD and even identified the diseased intestine as origin of such activity. Although the precise molecular mechanism(s) remain poorly understood, several pathways have been suggested to be involved in the activation of platelets and the cross talk to immune and other nonimmune cells within the inflamed microvasculature in IBD. Platelets and their activation products (e.g., histamine, thromboxane A_2 [TXA_2], PF-4, ß-TG) stimulate vascular endothelial cells and leukocytes in the inflamed microvasculature and therefore are able to locally intensify acute and chronic inflammatory conditions. In addition, intestinal micro-infarction, as the result of enhanced platelet aggregation, has been suggested to be involved, at least in part, in the pathogenic process associated with CD.

The initial recognition for an involvement of activated platelets in the mucosal pathology in IBD has arisen from histological studies, which revealed the presence of mucosal thrombi in rectal biopsies of CD and UC patients. Although not directly related to disease activity, this specific feature of capillary thrombi was not found in control biopsies (Dhillon et al. 1992). These intravascular thrombi within mucosal capillaries are formed of activated platelets, which are connected via GPIIb/GPIIIa–fibrinogen cross-linking and thought to be responsible for the observed multifocal mesenteric micro-infarction in CD (Sankey et al. 1993). This notion was further supported when it was discovered that patients with CD exhibit an increase in the procoagulant molecule TF, which correlates with the extent of thrombosis in the mucosal vascular bed (More et al. 1993). The increase of TF levels was due to an upregulation of production by monocytes, macrophages, and vascular endothelial cells, an effect which was later found to be dependent on CD40L binding (Slupsky et al. 1998). A direct functional consequence of this intestinal micro-infarction is the impaired mucosal perfusion, which has

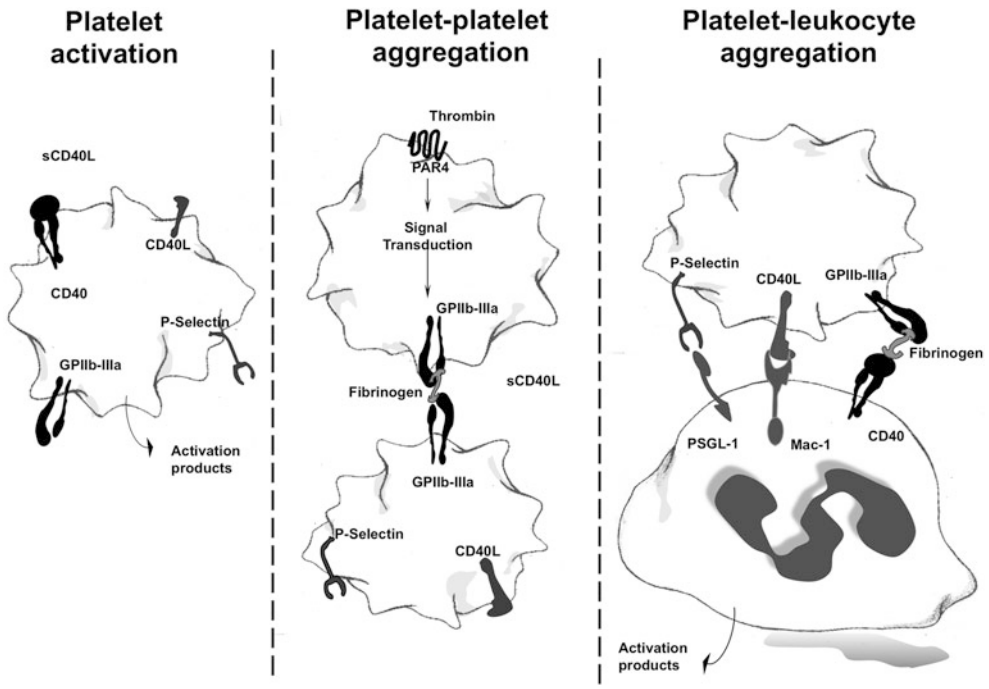

Fig. 2 The diverse platelet responses that accompany human and experimental colitis. Mediators released from the inflamed bowel predispose platelets to activation, platelet–platelet aggregation, and platelet–leukocyte aggregation. Platelet–platelet aggregation results from the bridging of GPIIb/GPIIIa on thrombin-activated platelets via fibrinogen. The heterotypic aggregation of platelets with leukocytes is mediated by three types of platelet–leukocyte adhesive interactions, that is, P-selectin–PSGL-1, CD40–Mac-1, and GPIIb/GPIIIa–fibrinogen–GPIIb/GPIIIa [Reproduced with kind permission of *Seminars in Thrombosis and Hemostasis* and the author (Senchenkova et al. 2015)]

been suggested to be involved in the pathogenesis of the progressive destructive inflammation associated with IBD (Hatoum et al. 2003; Wakefield et al. 1989).

Platelet–Endothelial Cell Interactions

Endothelial cells are the origin of platelet activation at the tissue level but are also the target of a variety of platelet-released activation products. Thus, on the one hand, the endothelium activates platelets, but on the other hand, endothelial cells can be stimulated by activated platelets. As described above, early in vivo evidence suggested that platelet activation in IBD takes place in the vast intestinal microvascular bed of the inflamed mesenteric endothelium (Collins et al. 1997). This concept was further supported recently in an in vitro study in which human intestinal microvascular endothelial cells (HIMEC) were co-cultured with the inflammatory cytokine IL-1ß to mimic the inflamed mucosa conditions in IBD. Once exposed to that inflammatory milieu, activated HIMEC triggered platelet activation, as observed by an increased CD40L and P-selectin surface expression, as well as a significantly increased release of sCD40L. In addition, in the clinical setting, it was shown that the sCD40L levels in UC and CD were proportional to the anatomical extent of mucosal inflammation, which reflects the size of the activated endothelial cell surface area encountered by platelets (Danese et al. 2003a, b). While these results demonstrated that endothelial cells are able to activate platelets to express and release CD40L, the same pathway has been shown to be involved in the stimulation of endothelial cells by activated platelets. Clinical findings have demonstrated that CD40L+ platelets adhere to the intestinal microvascular endothelium in IBD patients, forming intravascular platelet aggregates. Downstream effects of this cross talk have been shown in vitro, where activated CD40L+ platelets from IBD patients induced an upregulation of intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1), as well as production of IL-8 by HIMEC in a CD40-dependent fashion (Danese et al. 2003a, b). The upregulation of ICAM-1, VCAM-1, and IL-8 is a key step in the pathophysiology of IBD, since IL-8 is one of the main neutrophil chemoattractants, and CAMs are necessary for the hallmark events of leukocyte adhesion and trans-endothelial transmigration in the inflamed mucosa. Additionally, on binding to HIMEC, platelets are also able to release large amounts of RANTES, which in turn binds to glycosaminoglycans and is then presented on the surface of HIMEC, increasing their adhesiveness for T cells. Furthermore, this release of RANTES is further exacerbated in activated platelets from UC and CD patients (Danese et al. 2003a, b). Data from experimental colitis models also suggests that activation-specific platelet-derived factors such as histamine, PAF, and cationic proteins directly

contribute to endothelial cell dysfunction (e.g., increased vascular permeability) (Mori et al. 2005a, b).

Platelet–Leukocyte Interactions

Besides the abovementioned capacity to prone endothelial cells for an enhanced leukocyte recruitment, adhesion, and chemotaxis, activated platelets in IBD can also directly interact with immune cells to induce a pro-inflammatory phenotype and stimulate their adhesiveness. Such a pro-inflammatory stimulation was shown in UC patients, where activated platelets enhanced the production of reactive oxygen species (ROS) in neutrophils, which at least in part may be partially responsible for the well-established neutrophil-mediated mucosal damage in UC (Suzuki et al. 2001). On the other hand, when leukocytes are recruited to sites of injury in the intestinal microcirculation, they in turn can activate platelets by releasing PAF followed by the release of TXA_2 and subsequent platelet activation and aggregation (Eliakim et al. 1988; Webberley et al. 1993). The co-dependence of leukocyte recruitment and platelet activation in IBD was demonstrated by Vowinkel et al. in an experimental model of colitis. In this study, they showed that in the inflamed colonic microvasculature, the majority of leukocytes that were adherent to endothelial cells were attached to platelets. The importance of the P-selectin–PSGL-1-mediated binding and co-stimulation was further shown when platelet depletion diminished the recruitment of leukocytes in this in vivo model (Vowinkel et al. 2007).

- In IBD, platelets are directly involved in the mucosal immune response and inflammatory cascade.
- As such, it has been suggested that platelets play a role in modulating the intestinal inflammatory phenotype by amplifying inflammation-induced transendothelial leukocyte recruitment and activation.

Platelet-Directed Therapies in IBD

It has become evident that platelets are a crucial link between the two interdependent cascades, thrombosis/coagulation and inflammation, in IBD. Growing evidence suggests that the cross talk between platelets and other nonimmune cells, as well as classic immune cells, is in part responsible for the development of the vicious cycle in IBD patients wherein inflammation and thrombosis/coagulation stimulate and intensify each other. It is already established that there is a cross talk between inflammation and thrombosis, in that inflammation can beget thrombosis and thrombosis can beget inflammation. Therefore, platelets offer the unique opportunity to be the target for novel therapeutic strategies in UC and CD, both of which are chronic inflammatory disorders, associated with an increased risk for thrombosis. The overall aim for an anti-inflammatory platelet-based therapy in IBD would be to attenuate platelet activity to limit platelet interactions with leukocytes and endothelial cells, thus reducing the intestinal inflammation and the subsequent risk for thrombosis in distant vascular beds. However, at the same time, it is crucial to preserve the significant role of platelet aggregates as effector cells in the physiological thrombus formation to prevent bleeding complications. Overall, this has lead to the concept that platelet aggregation and platelet activation should be functionally and therapeutically dissociated, with the latter being the desired therapeutic avenue (Danese et al. 2004; Pitchford 2007). Although this seems to be worthwhile, there are multifaceted interferences between platelet activation and aggregation that often complicate this concept.

Current IBD Therapies

There is growing evidence that established IBD drugs might at least in part be therapeutically active by interfering with inflammation-elicited platelet activation and aggregation. The thiol 6-mercaptopurine (and its prodrug azathioprine) has been shown to inhibit human platelet aggregation, and 5-aminosalicylic acid (5-ASA) reduces platelet activation (Thomas et al. 1986; Carty et al. 2000). In addition, the human/mouse chimeric anti-TNF antibody cA2 has been demonstrated to reduce thrombin generation in CD patients, suggesting a possible indirect effect on platelet function (Hommes et al. 1997).

Potential Future Platelet-Specific IBD Therapies

Recent advantages in our understanding of current platelet physiology and their role in UC and CD pathophysiology have led to a variety of novel antiplatelet therapies in human and experimental IBD. Some of these therapies will be discussed in more detail here.

Purinergic Receptors Platelets express three purinergic receptors on their surface: $P2X_1$ (activated by ATP), $P2Y_1$, and $P2Y_{12}$ (both activated by ADP), of which especially the ADP receptors are involved in platelet activation (e.g., P-selectin expression) and aggregation (e.g., PLA formation) (Leon et al. 2003). Clopidogrel and its predecessor, ticlopidine, are the most commonly used platelet purinergic receptor antagonists and are routinely used to inhibit platelet aggregation, especially in the prevention of stroke and myocardial infarction (CAPRIE Steering Committee 1996). In both human and murine models, clopidogrel (a $P2Y_{12}$ antagonist) has shown a promising reduction of platelet-

dependent inflammatory cascades, such as an inhibition of platelet P-selectin expression, a reduction in platelet–leukocyte adhesion, and an attenuated platelet-dependent production of ROS by leukocytes (Evangelista et al. 2005). In addition, clopidogrel has even been successfully tested in a murine model of colitis (Patel et al. 2012). However, its efficacy in human IBD has yet not been proven. In fact, a recent retrospective chart review found no difference in disease progression between IBD patients receiving clopidogrel and a matched IBD control group (Vinod et al. 2012).

P-selectin As mentioned above, P-selectin is expressed on activated platelets as well as endothelial cells and required for aggregation with leukocytes via binding of PSGL-1. Blocking P-selectin or PSGL-1 seems to be desirable in IBD therapy, since it would attenuate the hallmark event of intestinal inflammation-induced trans-endothelial leukocyte recruitment and activation. Using blocking antibodies against P-selectin and PSGL-1, as well as genetically deficient mice, Mori et al. confirmed this concept by showing a profoundly reduced platelet and leukocyte adhesion within the colonic microvasculature in an experimental murine model of colitis following blockade of P-selectin and PSGL-1 (Mori et al. 2005a, b). In human IBD, Ji et al. showed that dermatan sulfate was able to inhibit P-selectin expression on platelets in UC and CD patients (Ji et al. 2004). However, although mechanistically P-selectin seems to be a potential target in IBD therapy, clinical studies testing this hypothesis are still awaiting.

CD40/CD40L The CD40/CD40L signaling pathway is one of the key pathways for the platelet-dependent amplification of inflammation and thrombosis/coagulation and vice versa. Thus, especially CD40L has become a target of interest in modern IBD therapy. In models of experimental colitis, Vowinkel et al. (using the CD40–CD40L pathway inhibitor trapidil), Liu et al. (using an anti-CD40L neutralizing monoclonal antibody), and Gao et al. (using a CD40 antisense oligonucleotide) have established the promising mechanism of blocking CD40–CD40L interactions in intestinal inflammation (Vowinkel et al. 2007; Liu et al. 2000; Gao et al. 2005). In addition, the monoclonal antihuman CD40 antibody ch5D12 has been successfully used in an IBD and shown to be safe and effective for the induction of remission patients with CD (Kasran et al. 2005). Recently, the established IBD drug infliximab (a chimeric monoclonal TNF-α antibody) has been found to reduce circulating plasma levels of platelet-shed sCD40L and prevented CD40 and VCAM-1 upregulation by endothelial cells (Danese et al. 2006).

Thromboxane A_2 TXA_2 is a classical inflammatory mediator of platelet activation. It is predominantly released by activated platelets and is able to further stimulate platelet activation and aggregation. In a murine model of colitis, selective thromboxane synthetase inhibition showed promising results since it reduced inflammatory colonic lesions (Vilaseca et al. 1990). These early experimental results were followed up in human UC and CD patients, as well as in smaller human IBD pilot studies, which confirmed a possible beneficial therapeutic potential (Casellas et al. 1995; Collins and Rampton 1997; Collins et al. 1996; Carty et al. 2000). However, ridogrel (a combined thromboxane synthesis inhibitor and receptor blocker) showed a lack of efficiency when tested in larger independent, randomized, parallel-group trials for UC and CD (Tytgat et al. 2002; Carty et al. 2001). Overall, these results suggest that further investigations into inhibiting TXA_2 as a potential therapeutic target for the treatment of IBD are needed.

Concluding Remarks

Within the last two decades, we have seen a tremendous development in our understanding of the multifaceted roles that platelets play in the pathophysiology of IBD. However, it is also notable that these findings have not yet been fully translated into novel diagnostic or therapeutic tools in the clinical treatment and modern management of IBD. Ongoing research is needed to fully characterize the pro-inflammatory and pro-thrombotic character of platelets in order to be able to target their specific interactions within the mucosal immune system for the treatment of IBD. When we can inhibit the platelet-derived amplification of the chronic intestinal inflammation in UC and CD, we might also be able to shift the balance in the thrombosis/coagulation system to favor a physiological hemostasis, to avoid bleeding complications, and to prevent thrombotic events in remote vascular beds, which until today threatens IBD patients.

Take-Home Messages

- IBD is accompanied a reactive thrombocytosis and platelets in IBD are characterized by an enhanced activation and elevated aggregation.
- Platelets in IBD are primed to form homotypic platelet-platelet and heterotypic platelet-leukocyte aggregates with IBD patients being prone to develop thromboembolic events.
- In IBD, platelets are directly involved in the mucosal immune response and inflammatory cascade.
- Platelets play a role in modulating the intestinal inflammatory phenotype by amplifying inflammation-induced trans-endothelial leukocyte recruitment and activation.

Platelets and Neurodegenerative Diseases

Lili Donner and Margitta Elvers

Abstract

For decades, platelets have been thought to be an adequate tool for the diagnosis and analysis of neurodegenerative disorders. Although the impact of platelets in Alzheimer's disease (AD) has been extensively studied for many years, the contribution of platelets in other neurological disorders remains an open question. AD is the most common form of senile dementia and is characterized by neurotoxic amyloid-β (Aβ) plaque formation in the brain parenchyma and cerebral blood vessels. However, AD is related to vascular diseases such as stroke and atherosclerosis. Vascular risk factors increase the risk of AD. Moreover, AD patients suffer from cerebrovascular dysfunction with altered blood flow. Platelets are major players in vascular diseases but are also involved in neuroinflammatory diseases such as AD. Platelets express the amyloid precursor protein (APP) and display the complete enzymatic machinery to process APP into Aβ peptides through a signaling pathway known in the brain. Aβ stimulates platelet activation and adhesion, as well as formation of platelet aggregates. AD patients and AD transgenic mice display modified platelet structure and function with alterations in platelet membrane fluidity, generation of reactive oxygen species, altered APP processing, and abnormal platelet activation. Thus, platelets were considered to be an easily accessible biomarker for quick and safe diagnosis of AD. Furthermore, anti-platelet therapy was thought to be effective in the inhibition of AD progression. Clinical trials of the last few years have provided evidence that aspirin, at least, has no beneficial effect on the progression of AD. However, different studies in mice and humans support the hypothesis that platelets not only mirror the disease but actively contribute to the progression of AD.

Introduction

Alzheimer's disease is an age-related neurodegenerative disorder affecting more than 45 million people worldwide (Canobbio et al. 2015). The crucial event in AD is the misfolding and aggregation of amyloid-β (Aβ), leading to the formation of Aβ deposits in brain parenchyma and cerebral vessels (Glenner and Wong 1984; Masters et al. 1985). Recently, it has become evident that AD is a more intriguing disorder that also affects peripheral tissue outside the brain. Alterations in AD patients occur not only in the central nervous system but also in blood vessels and blood cells, with Aβ deposits in cerebral vessels (Thal et al. 2008). Furthermore, AD is strongly related to the vascular system. Vascular risk factors for AD and cerebrovascular dysfunction are observed in AD patients with abnormal blood flow (Iadecola 2004; Luchsinger et al. 2005).

Alzheimers' Disease: A Neurodegenerative Disorder with High Prevalence

APP Structure and Function

AD is characterized by the accumulation of extracellular plaques containing mostly self-aggregating 40–43 amino acid residue peptides of Aβ and intracellular neurofibrillary tangles (Glenner and Wong 1984; Masters et al. 1985). The Aβ peptides are generated from amyloid precursor protein (APP) (Fig. 1). Human APP belongs to an evolutionarily conserved family of type 1 transmembrane glycoproteins, which also includes the amyloid precursor-like proteins 1 and 2 (APLP1 and APLP2) (Goldgaber et al. 1987; Wasco et al. 1993). APP contains a large extracellular N-terminal domain, a transmembrane domain, and a short intracellular cytoplasmic C-terminal domain (Fig. 1). In humans, several alternatively spliced isoforms of APP have been identified (Beyreuther et al. 1993). Whereas the 695 amino acid form is expressed predominantly in neurons, the 751 and 770 amino acid forms containing a Kunitz protease inhibitor domain are ubiquitously expressed in non-neuronal cells (Bayer et al. 1999; Mattson 1997), including platelets (Li et al. 1994). APP is synthesized in the endoplasmic reticulum (ER) and then trafficked through the Golgi apparatus to the trans-Golgi network (TGN) (Xu et al. 1997). The post-translational modifications of APP such as N- and O-linked glycosylation, tyrosine sulfation, and phosphorylation occur in the ER and Golgi/TGN. The modified, mature APP protein can be then shuttled in TGN-derived secretory vesicles to the cell membrane, where most of its cleavage occurs. Afterwards, a small fraction of APP is endocytosed and processed by the endosomal lysosomal pathway (Haass et al. 2012).

The C-terminus of APP can interact with different adaptor proteins, including the G_0 protein (Brouillet et al. 1999), brain proteins Fe65 and X11 (Tomita et al. 1999; Zambrano et al. 1997), JIP (c-Jun N-terminal kinase [Jnk]-interacting protein) protein families (Inomata et al. 2003), and disabled-1 (Dab1) protein (Homayouni et al. 1999). Phosphorylation of APP facilitates interactions with other adaptor proteins such as ShcA and Grb2 via the PTB (phosphotyrosine binding) or SH2 (Src homology 2) domains (Russo et al. 2005). APP can also act as a receptor involved in cell–cell or cell–matrix adhesion processes and can bind to sulfated proteoglycans, laminin, collagen, and integrins (Beher et al. 1996; Ghiso et al. 1992; Small et al. 1992; Williamson et al. 1996).

APP has mainly been studied in relation to AD, but the physiological function of APP is unknown. A number of studies indicate that APP plays an important role in cell growth and proliferation. Moreover, APP influences cell migration, cell adhesion, axonal transport, dendritic outgrowth, and synapse formation (Haass et al. 2012). Studies with mice have shown that APP knockout mice have reduced brain weight, deficient long-term potentiation, and impaired spatial navigation in behavioral tests (Ring et al. 2007). Mice overexpressing APP have enlarged cortical neurons, suggestive of a neurotropic effect (Oh et al. 2009).

APP Processing and Aβ Production

APP can undergo amyloidogenic processing, which occurs mainly at the cell surface, leading to Aβ generation and non-amyloidogenic processing, which takes place in intracellular compartments (Beyreuther et al. 1993; Vetrivel and Thinakaran 2006; Yu et al. 2005; Ling et al. 2003) (Fig. 1). In amyloidogenic processing, cleavage of APP by β-secretase, known as membrane-anchored aspartyl protease BACE (Vassar and Citron 2000), generates the soluble N-terminal fragment APPβ (sAPPβ) and the C-terminal fragment βAPP-CTF. Subsequent cleavage of βAPP-CTF within its transmembrane region by γ-secretase generates Aβ(1-40), Aβ(1-42/43), and APP intracellular domain (AICD) (Haass et al. 2012). In non-amyloidogenic processing, generation of Aβ is precluded because APP is cleaved within the Aβ sequence by α-secretase, which belongs to the metalloproteinase family of Adamlysins including ADAM 10 (Lammich et al. 1999) and ADAM 17 (Buxbaum et al. 1998). Cleavage leads to generation of the soluble, secreted APPα (sAPPα) fragment and the membrane-tethered αAPP-CTF. The remaining αAPP-CTF fragment can be processed by γ-secretase, giving rise to peptide P3 and the APP intracellular domain AICD (Haass et al. 2012) (Fig. 1). The release of AICD into the cytosol may play a role in nuclear signaling (Haass et al. 2012).

Aβ is generated ubiquitously, but clinically relevant Aβ deposition takes place only in the brain. To date, the factors that promote Aβ deposition or prevent its clearance in the brain are not known. Approximately 90 % of secreted Aβ consists of the Aβ(1-40) peptide, whereas only 10 % is Aβ (1-42) under normal conditions. Aβ(1-42) peptides are more amyloidogenic in vitro (Jarrett et al. 1993) and initiate Aβ deposition and plaque formation in vivo because Aβ(1-42) is

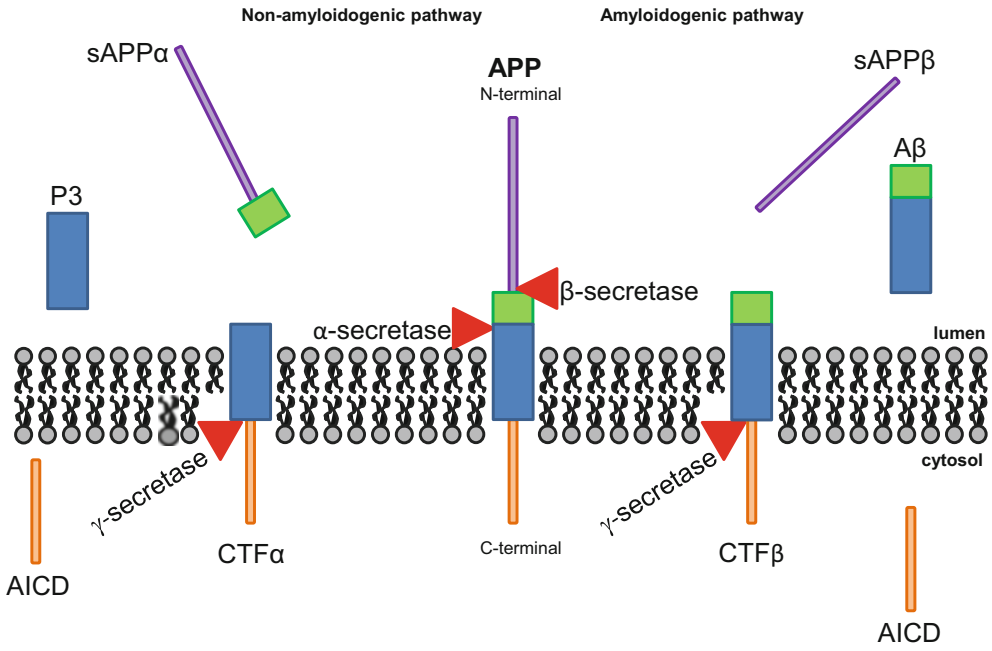

Fig. 1 Proteolytic processing of amyloid precursor protein (APP). APP can undergo non-amyloidogenic (*left*) or amyloidogenic (*right*) processing. Amyloidogenic pathway: APP is first cleaved by β-secretase, resulting in soluble β-APPβ (sAPPβ) and C-terminal β fragment (CTFβ). The cleavage of CTFβ by γ-secretase generates APP intracellular domain (AICD) and Aβ. Non-amyloidogenic pathway: α-Secretase cleaves within the Aβ-domain, generating soluble α-APP fragments (sAPPα) and the C-terminal fragment α (CTFα). The cleavage of CTFα by γ-secretase leads to release of the P3 peptide and AICD

selectively deposited in amyloid plaques (Gravina et al. 1995). Thus, the level of Aβ(1-42) in the brain might play a substantial role in the origin of Aβ deposition.

Cerebral Amyloid Angiopathy

Cerebral amyloid angiopathy (CAA) is characterized by the extracellular deposition of Aβ peptides, mainly Aβ(1-40) (Gravina et al. 1995), in the walls of cortical and leptomeningeal arteries (Glenner and Wong 1984). The incidence of CAA increases with age and occurs sporadically or as a result of genetic mutations (Thal et al. 2008). Risk factors for CAA include mutations of *APP*, presenilin 1 (*PSEN1*, also known as *PS1*) , and presenilin 2 (*PSEN2*, also known as *PS2*) genes and possession of the epsilon 4 allele of apolipoprotein E (Thal et al. 2008). Pathological examination of blood vessels shows loss of smooth muscle cells, luminal narrowing, vessel wall thickening, microaneurysm formation, and intracerebral microhemorrhage (Mandybur 1986; Vinters et al. 1998). CAA is present in over 95 % of AD patients (Jellinger and Attems 2007) and could contribute to neurodegeneration and, thus, to cognitive decline in AD.

Mutation as Risk Factor for Familial AD

About 95 % of AD cases are late onset and sporadic without defined causes, whereas less than 5 % are familial AD, caused by mutations and having an age of onset before 65 years (Zekanowski et al. 2004). Three dominant genes have been identified in cases of familial AD: *APP* on chromosome 21 (Goldgaber et al. 1987; Kang et al. 1987; Tanzi et al. 1987), *PSEN1* on chromosome 14 (Li et al. 1995; Schellenberg and Montine 2012; Tanzi et al. 1987), and *PSEN2* on chromosome 1 (Levy-Lahad et al. 1995). All these mutations have been shown to somehow affect the metabolism of Aβ. Mutations in APP have been identified in a 54 amino acid segment in and around the Aβ peptide sequence, leading to an increase in Aβ formation (Schellenberg and Montine 2012). For example, the Swedish mutation at the N-terminus of the Aβ domain of APP (Mullan et al. 1992) favors β-secretase cleavage (Cai et al. 1993) and is associated with an increase in Aβ peptides in the brain of AD patients. APP23 transgenic mice, which express human APP with only the Swedish mutation, develop parenchymal and cerebrovascular Aβ deposits and have often been used to study CAA pathogenesis (Sturchler-Pierrat et al. 1997). Mutations in the subunits of the γ-secretase enzymatic complex (presenilin 1 or presenilin 2) display alterations in the amino acid sequence of the transmembrane domain that affects the enzymatic processing of APP. Moreover, enhanced production of the less-soluble and more toxic Aβ (1-42) peptide is observed (Schellenberg and Montine 2012).

Platelet APP, Processing and Release of Aβ, Coagulation

Role and Metabolism of APP in Platelets

Platelets contain large amounts of APP, which contributes to more than 90 % of the circulating APP (Chen et al. 1995; Li et al. 1994; Van Nostrand et al. 1990). The concentration of

APP isoforms in platelets is comparable to those in brain but with a different expression pattern. APP695 is the most abundant form in the brain whereas APP770 and APP751 are the predominant forms in platelets (Bush et al. 1990; Li et al. 1995; Selkoe et al. 1988). APP is found at the plasma membrane and in α-granules of platelets (Gowert et al. 2014; Van Nostrand et al. 1990). Full-length APP is expressed on the platelet membrane, encoded by platelet mRNA (Gardella et al. 1990), and may act as a platelet receptor (Li et al. 1994). Platelet activation leads to a threefold increase in surface APP (Li et al. 1994). The physiological role of APP and its metabolites is not yet well understood. Platelets express the complete enzymatic machinery responsible for the metabolism of APP. Under physiological conditions, APP is metabolized through the non-amyloidogenic pathway. α-Secretase is activated by Ca^{2+} and calmodulin (Canobbio et al. 2011) and releases soluble APP (sAPP). Soluble APP dose-dependently inhibits platelet aggregation and secretion in response to stimulation with ADP or adrenaline, suggesting that the release of APP is part of a negative feedback regulation of platelet activation (Henry et al. 1998). Secreted isoforms of APP exhibit the Kunitz proteinase inhibitor domain that is analogous to the cell-secreted proteinase inhibitor known as protease nexin-2. Overexpression of sAPP in circulating platelets of transgenic mice leads to inhibition of thrombosis because of its anticoagulant function, indicating that APP plays an important role in regulating hemostasis and thrombosis (Xu et al. 2009). In fact, sAPP isoforms potently inhibit the intrinsic coagulation factors XIa and IXa (Schmaier et al. 1995; Smith et al. 1990) and this inhibition is enhanced by heparin and zinc (Komiyama et al. 1992).

Processing of APP and Aβ Release

High levels of APP in platelets and the fact that platelets are the major repository of Aβ in blood suggests a direct contribution of platelets to the accumulation of Aβ in brain and in the vasculature (Chen et al. 1995). APP is a transmembrane glycoprotein with a large extracellular N-terminal domain and a short cytoplasmic C-terminal domain that is proteolytically processed in a complex way. Two alternative pathways have been described that involve either α-secretase in the non-amyloidogenic pathway or β-secretase in the amyloidogenic pathway, besides the γ-secretase complex (Kang et al. 1987). Platelets possess α-, β-, and γ-secretases and produce APP fragments comparable to those found in the brain: sAPPα and sAPPβ isoforms, CTFβ amyloidogenic fragment, and Aβ peptides (Li et al. 1998). The α-secretase ADAM-10, the β-secretase BACE1, and the γ-secretase catalytic subunit presenilin were found to be expressed in platelets (Colciaghi et al. 2004; Evin et al. 2003; Vidal et al. 1996). In contrast to neuronal cells, the predominant pathway for APP processing in platelets is cleavage by α-secretase, because high levels of sAPPα are detected but low levels of Aβ (Colciaghi et al. 2004). Moreover, high amounts of sAPPα are stored in platelet granules (Smith and Broze 1992). In contrast to neurons, which produce high amounts of Aβ(1-42) peptides, the Aβ(1-40) peptide is mainly released from platelets. This is in line with observations demonstrating that the circulating Aβ forms contribute to vascular amyloid deposition (CAA) composed mainly of Aβ(1-40), whereas the dominant form in parenchymal amyloid plaques in the brain is Aβ(1-42) (Herzig et al. 2004). In response to platelet activation, full-length APP is proteolytically cleaved by a Ca^{2+}-dependent cysteine protease, providing evidence for the participation of an amyloidogenic species of APP in the proteolytic processing platelets (Chen et al. 2000; Li et al. 1995). In addition, platelets release Aβ upon activation by thrombin, collagen, and synthetic Aβ(1-40), thereby contributing most of the Aβ present in the circulation (Gowert et al. 2014; Li et al. 1998). Different forms of Aβ peptides are processed and released from thrombin-activated and resting platelets with different kinetics, including the classical Aβ peptides, Aβ(1-40) and Aβ(1-42), and several shorter C-terminally truncated forms such as Aβ(1-39), Aβ(1-38), Aβ(1-37), and Aβ(1-34) (Smirnov et al. 2009). The origin of Aβ in blood has been extensively discussed and two major hypotheses have been proposed. Either circulating Aβ derives from the central nervous system via the blood–brain barrier and becomes absorbed by blood cells (mainly by platelets) or additional release of Aβ from non-neuronal cells such as platelets occurs (Di Luca et al. 2000; Prodan et al. 2006).

In atherosclerosis, processing of APP is a mechanism mediated by macrophage activation. The presence of APP, Aβ, and platelets together with inducible NO synthase (iNOS), a marker of macrophage activation, was confirmed in microvessels in advanced human carotid artery plaques (De Meyer et al. 2002). The incubation of human THP-1 macrophages and human platelets induced platelet phagocytosis and the formation of foam cells containing lipids, APP, and Aβ. In contrast, treatment with a protease inhibitor reduced APP processing and inhibited NO biosynthesis. Aβ was present in activated iNOS-expressing perivascular macrophages that had phagocytized platelets, suggesting that platelet-derived APP is proteolytically processed to Aβ, leading to iNOS induction and thus to macrophage activation (De Meyer et al. 2002). Consistently, Aβ peptides promote and synergize chronic inflammatory processes responsible for the degeneration and destruction of arterial vessel walls (Kokjohn et al. 2011). Thus, processing of APP could represent a biochemical link between atherosclerosis and AD; accordingly, nonsteroidal anti-inflammatory drugs (NSAIDs) have an impact in both diseases (Lathe et al. 2014). Interestingly, high levels of Aβ(1-42) were observed

in aged, non-demented individuals with cerebral atherosclerosis but no changes were detected in the β-secretase BACE1 (Sadleir et al. 2013).

Platelet Activation by Aβ

Different studies in the past have shown that Aβ is able to activate platelets, trigger platelet aggregation, and stimulate intracellular signaling pathways (Fig. 2a). Aβ interacts with platelets and supports platelet aggregation via specific platelet membrane receptors in vitro and in vivo (Gowert et al. 2014; Kowalska and Badellino 1994; Wolozin et al. 1998). Activation of platelets by Aβ is mediated at least in part by PLCγ2 and protein kinase C and triggers thrombus formation in vitro and in vivo in venules of mesenteric arterioles (Gowert et al. 2014; Shen et al. 2008a, b). Moreover, preincubation of platelets with Aβ induces activation of the p38 MAPK signaling pathway, including PAR1, PI3K, Akt, and cytosolic phospholipase A2 (cPLA2) activation and thromboxane production (Shen et al. 2008a, b). Platelet adhesion is also supported by Aβ (Barnham et al. 2004; Canobbio et al. 2013; Gowert et al. 2014; Kowalska and Badellino 1994). Immobilized Aβ peptides induce platelet adhesion and spreading and accelerate platelet spreading on collagen under static conditions (Canobbio et al. 2013; Gowert et al. 2014). Under flow conditions, Aβ stimulation enhances platelet adhesion to collagen and, in addition, platelets are able to adhere to immobilized Aβ. In mice, platelet adhesion to the injured carotid artery is enhanced by injection of Aβ-stimulated platelets (Gowert et al. 2014). Adhesion to Aβ peptides results in the activation of Akt, Erk, MLC, and p38 MAPK and induces Rap1b activation (Canobbio et al. 2013). Sonkar and coworkers have shown that Aβ stimulates RhoA activation, leading to modulation of actomyosin organization (Sonkar et al. 2014). Gowert and colleagues found that platelet stimulation with Aβ(1-40) alone does not lead to P-selectin exposure or integrin activation, as measured by flow cytometry. However, Aβ(1-40) increases ADP-stimulated platelet responses and induces phosphatidylserine exposure and platelet microparticle formation (Gowert et al. 2014). In line with these results, Canobbio and colleagues provided evidence for the requirement of ADP for the Aβ-induced signaling pathway, including phosphorylation of Akt, pleckstrin, Erk, p38 MAPK and MLC as well as Rap1b activation and aggregation (Canobbio et al. 2013).

Coagulation: Role of Fibrinogen

In the last few years, a prominent role for fibrin and fibrinolysis in the progression of Aβ pathology has been demonstrated by the group of Sidney Strickland. They observed age-dependent fibrin deposition and increased blood–brain barrier permeability in transgenic mouse models of AD (Paul et al. 2007). The analysis of different transgenic mouse models suggested a direct contribution of fibrin to the pathology of AD. AD mice with only one functional plasminogen gene showed reduced fibrinolysis and increased neurovascular damage compared with AD mice without plasminogen deficiency. Treatment of AD mice with

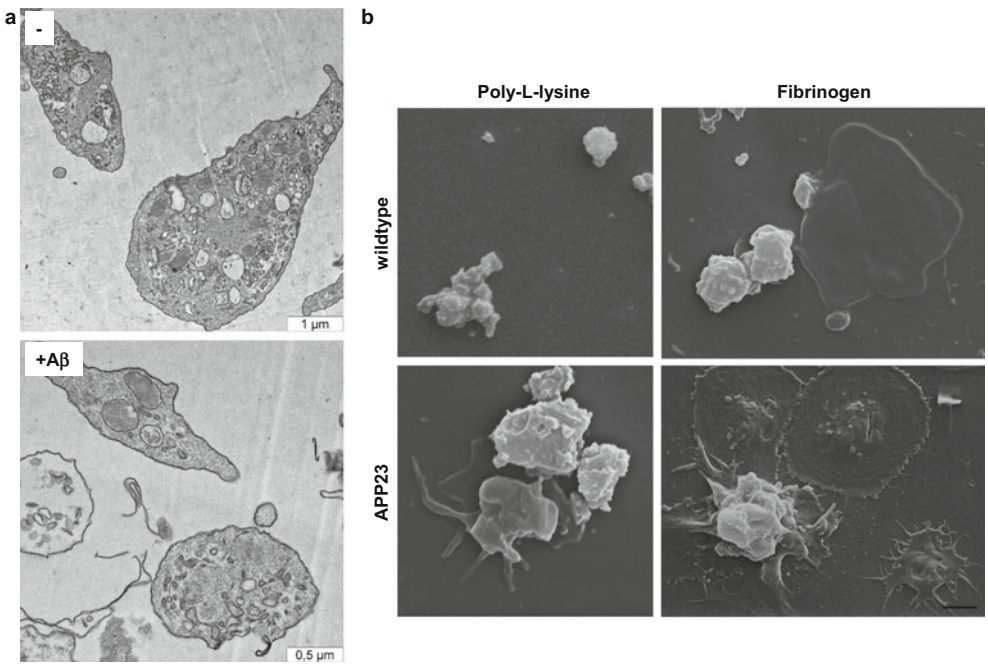

Fig. 2 Platelet activation in response to Aβ. (**a**) Stimulation of platelets with 50 ng/mL Aβ leads to platelet activation, as shown by TEM. Resting platelets (*upper panel*), Aβ stimulated platelets (*lower panel*). *Scale bar* as indicated. (**b**) Representative images show platelets from wild-type and APP23 mice under basal (poly-L-lysine, *left panel*) and stimulating conditions (fibrinogen, *right panel*) as analyzed by scanning electron microscopy (SEM). *Scale bar* 1 µm

the plasmin inhibitor tranexamic acid worsened pathology, and removal of fibrinogen from the circulation of AD mice by ancrod treatment attenuated neuroinflammation and vascular pathology (Paul et al. 2007). Aβ specifically interacts with fibrinogen, inducing its oligomerization (Ahn et al. 2010). The fact that Aβ modifies the structure of fibrinogen implies abnormal fibrin clot formation in AD. Further studies indicated an abnormal resistance to degradation of A-β-modified fibrin clots (Cortes-Canteli et al. 2010). In Aβ-positive blood vessels, fibrinogen was observed in mouse and human AD samples. Intravital brain imaging of clot formation provided evidence for abnormal thrombosis and fibrinolysis in AD mice (Cortes-Canteli et al. 2010). Interestingly, fibrin deposition was increased in AD brains and shown to correlate with the degree of AD pathology (Cortes-Canteli et al. 2015).

Platelets and AD

Altered Structure and Function of Platelets in AD

Data from patients and transgenic mouse models clearly indicate that platelet structure, function, and clearance are altered in AD compared with healthy controls. The most commonly used mouse models of AD are shown in Table 1.

Platelet Membrane Structure and Fluidity

APP processing and Aβ generation occurs within the membrane, therefore the structure and composition of the platelet membrane is important for Aβ production and the progression of AD. Abnormal platelet membrane fluidity in AD has been ascribed to alterations in internal membrane composition but not to differences in membrane phospholipid synthesis (Cohen et al. 1987; Kanof et al. 1991; Swiderek et al. 1997). These changes have never been described for other dementias, for example, multi-infarct dementia (Swiderek et al. 1997). Analysis of the cholesterol content of platelet membranes and red blood cells showed no significant alteration per se; however, a slight decrease in platelet membrane cholesterol was observed in a small group of AD patients. Increased membrane cholesterol was reported to result in increased β-secretase activity, which is important for the generation of Aβ(1-40) (Liu et al. 2009).

Oxidative Stress and Free Radical Generation

Oxidative stress has been implicated in the progression of AD (Barnham et al. 2004). In addition to Aβ-mediated effects on platelet activation, aggregation, adhesion, and thrombus formation, the stimulation of platelets with Aβ induces the generation of reactive oxygen species (ROS) and membrane scrambling (Gowert et al. 2014). ROS overproduction contributes to mitochondrial dysfunction and, thus, to the pathogenesis of AD (Sheehan et al. 1997). ROS levels increase with enhanced environmental stress to control cellular function, including apoptosis (Rada and Leto 2008). Stimulation of platelets with Aβ leads to increased ROS levels with enhanced expression of active caspase-3, which is known to play a central role in cell apoptosis. Caspases also play a role in platelet activation and senescence by promoting the removal of aged or activated platelets from the circulation, suggesting that contact of platelets with Aβ leads to platelet apoptosis (Gowert et al. 2014; Shcherbina and Remold-O'Donnell 1999). Cell shrinkage is another hallmark of cell apoptosis and was observed in platelets stimulated with Aβ, as measured by reduced cell volume, mitochondrial potential, and annexin V binding, thus supporting data showing that Aβ promotes apoptosis of platelets (Gowert et al. 2014).

In contrast to macrophages, platelets are not able to phagocyte synthetic Aβ fibrils or soluble Aβ (Yazawa et al. 2001). However, induction of apoptosis in platelets enables the uptake of pre-aggregated Aβ(1-42) into platelets. Thus, the uptake of Aβ fibrils by apoptotic platelets could be a novel mechanism for local accumulation of Aβ when platelets adhere to vascular amyloid plaques at cerebral vessels and undergo apoptosis (Gowert et al. 2014).

Altered APP Processing

It is well known that platelets of AD patients show AD-specific alterations in APP processing that might reflect abnormal APP metabolism in brain. Colciaghi and coworkers found significant modification of APP,

Table 1 Summary of the most commonly used genetic mouse models of AD

Line	APP23	APP/PS1	3 × Tg-AD	5 × FAD	Tg2576
Amyloid plaques	+	+	+	+	+
Tau-phosphorylation	+	+	+	–	–
Neurofibrillary tangles	–	–	+	–	–

ADAM10, and BACE1 involved in the amyloid cascade, as detected in the earliest clinically detectable state of AD (Colciaghi et al. 2004). This data provides evidence for early metabolic changes towards the amyloidogenic pathway. Abnormalities in the pattern of platelet APP in AD patients have been observed (Bush et al. 1992; Di Luca et al. 1998; Rosenberg et al. 1997). Rosenberg and colleagues measured the ratio between the 120–130 kDa APP isoform and the 110 kDa APP isoform and found that APP processing was affected as compared with healthy subjects (Rosenberg et al. 1997). A correlation between platelet APP isoform ratio and cognition was described by Liu and coworkers, suggesting that a reduction in this ratio could act as a marker of cognitive decline in AD patients (Baskin et al. 2000; Liu et al. 2007). Alterations in APP isoforms show a positive correlation with the progression of clinical symptoms, suggesting that this parameter could be a good marker for determining the progression of AD. Because alterations in APP processing are described as an early event in AD, the APP ratio could have a great diagnostic power and be a very important AD biomarker (Borroni et al. 2002; Di Luca et al. 1998). In contrast to observations with patients suffering from sporadic AD, patients that carry a *PSEN2* mutation have no alteration in the expression or concentration of APP isoforms, suggesting that the pathological effect of this mutation might occur upstream of the amyloid cascade (Pastorino et al. 2000).

Abnormal Platelet Activation

Different studies have provided evidence for altered platelet activation in AD patients and AD transgenic mice. As early as 1998, Sevush and colleagues measured the percentage of circulating platelet aggregates, expression of platelet P-selectin, formation of leukocyte–platelet complexes, and presence of platelet microparticles in AD patients (Sevush et al. 1998). They observed platelet activation under nonstimulating conditions, suggesting that damaged cerebral endothelial cells or membrane abnormalities might be responsible for nonstimulated platelet activation in patients with AD. Stellos and coworkers measured $\alpha_{IIb}\beta_3$ integrin activation and P-selectin exposure for platelets from AD patients under resting conditions. Higher baseline expression of these platelet activation markers were observed in patients with fast cognitive decline compared with patients with slow cognitive decline during a 1-year follow-up period (Stellos et al. 2010). The analysis of cognitive decline in patients with AD revealed that treatment with cilostazol (a phosphodiesterase-3 inhibitor) significantly inhibited changes in cognitive function test scores, whereas patients randomly assigned to clopidogrel or aspirin (platelet inhibitors) showed a statistically significant cognitive decline (Sakurai et al. 2013). Because therapy with platelet inhibitors did not delay cognitive decline, it was speculated that the effect of the phosphodiesterase-3 inhibitor was mediated by platelet inhibition via an increase in cAMP levels or via improvement in endothelial function (Sakurai et al. 2013). However, cilostazol is known for its profoundly unwanted cardiovascular and hemorrhagic properties and is therefore not a useful therapeutic tool for AD patients.
