Foreword

When I joined Marc Verstraete's laboratory as a medical student in 1959, the emphasis was on hemophilia, vitamin K antagonists as oral anticoagulants, and the development of thrombolysis. Platelet studies were limited to platelet count, bleeding time, and clot retraction. When an otherwise healthy patient with a bleeding disorder had a normal coagulation profile, a normal platelet count, a prolonged bleeding time, and an absent clot retraction, we diagnosed Glanzmann's thrombasthenia; if, however, in the same setting the clot retraction was normal, we considered von Willebrand's disease. How times have changed! In the 1960s, aggregometry allowed the first functional platelet studies; the inhibitory effect of some anti-inflammatory agents, in particular aspirin, was discovered, and the first speculations made about a possible antithrombotic potential of these agents. In the 1970s, there was in scientific meetings a strict divide between "clotters" (studying coagulation) and "clumpers" (studying platelet aggregation); fortunately, this gap gradually narrowed when it became obvious that platelets are closely involved in physiological coagulation and that coagulation induces platelet activation. The 1980s saw confirmation of aspirin as antithrombotic agent; it became a mainstay for the prevention and treatment of arterial vascular disease. At the same time, new developments in cell biology were being applied to megakaryocytes and platelets. Since then, new pathways and receptors have been continuously discovered; the molecular bases of numerous congenital thrombocytopenias have been defined; new platelet inhibitors have been developed and evaluated in clinical studies; platelet inhibition remains crucial despite the continuing progress with vascular stents to combat arterial disease. Platelets are now recognized to play an important role in inflammation, angiogenesis, cancer, etc.

So why, in this Internet age, a new book on platelets? Platelet studies are a typical area where cell biology and clinical practice meet. A book is an ideal site to bring these two separate worlds together. Cell biologists are interested in the potential clinical application of their findings; clinicians are interested in the biological basis of their treatments; this book provides all the answers in one place. It now has become impossible to possess the total knowledge on platelets; even experts will benefit from a book like this. For students entering the field, it provides them with a daunting but comprehensive "state of the art," to which they can hope to add new findings.

The first edition of this book dates from 2002. When comparing the Tables of Contents, I find, besides an update of previously covered topics, many new entries such as the platelet proteome and transcriptome, CLEC, a new emphasis on neutrophil–platelet interactions, platelets as carriers of genetic material for cell delivery, or platelets in regenerative medicine, among several others.

The book now contains 97 chapters. To identify and convince top scientists to contribute, to put this all together, to elaborate a useful index for search purposes, all this is

a formidable task. I wish to congratulate Paolo Gresele, with whom I shared an exciting research period and a continuing friendship, José Lopez, Neil Kleiman, and Clive Page for this hard work, but, above all, for a very useful achievement, which will bear many fruits in the years to come.

A Brief History of Blood Platelets: A Personal View

Michael C. Berndt, Pat Metharom, and Robert K. Andrews

Abstract

A search on 'platelets' in Pubmed yields more than 100,000 publications indicating both the depth and interest. Platelets are small anucleate cells that circulate freely in the vasculature. In haemostasis, they adhere rapidly, become activated, spread and coat the damaged vasculature. Our understanding of platelet structure and function has advanced in waves, dependent upon the development of the next cutting-edge technology. This brief chapter describes the key historical events leading to our current understanding of platelet structure and function.

Introduction

Platelets are small anucleate cells that circulate freely in the vasculature. In haemostasis, they adhere rapidly, become activated, spread and coat the damaged vasculature. The activated platelets become cohesive and release their dense body and alpha granule contents aiding in the recruitment of additional platelets and the formation of a platelet aggregate or thrombus that is stabilised by activation of coagulation and thrombin-dependent fibrin deposition (Andrews and Berndt 2004). Although haemostasis and thrombosis are now recognised not to be identical processes, a similar sequence of events also occurs in arterial thrombosis. Besides their pivotal functional role in haemostasis and thrombosis, platelets are now known to be essential in a wide variety of non-haemostatic functions, including their interface with inflammatory responses; in rheumatoid arthritis, cancer metastasis, tumour angiogenesis and lymphatic development; in the regulation of infection; and the killing of intra-erythrocytic malarial parasites, amongst others (Boilard et al. 2010; Erpenbeck and Schön 2010; Klement et al. 2009; Suzuki-Inoue et al. 2010; Clark et al. 2007; McMorran et al. 2009).

A definitive treatise on the history of platelet research, both from a basic and a clinical perspective, could easily be the subject of a multivolume series, rather than the subject of a brief chapter. At the time of writing, a search on 'platelets' in Pubmed yields more than 100,000 publications indicating both the depth and interest in the field. Those who are interested in a more structured and recent review on the history of platelet research, both from a basic and clinical viewpoint, and also from the perspective of where the field is leading, are referred to the excellent recent review by Coller (2011). I (MCB) started my career in platelet research in the laboratory of David Phillips in Memphis Tennessee in 1979. Like many fields of research, our understanding of platelet structure and function has advanced in waves, dependent upon the development of the next cutting edge technology. In David Phillips's laboratory, the interest was on the structure and function of platelet membrane glycoproteins. The

then breakthrough platform technology was the capacity to surface label human platelet membrane glycoproteins and analyse them on one- and two-dimensional SDS-polyacrylamide gels. It is this technology that led to the definition of the membrane glycoprotein defects in Bernard-Soulier syndrome (BSS) and Glanzmann's thrombasthenia (GT) and the fundamental understanding of the role of these glycoproteins in haemostasis and thrombosis.

The Discovery of Blood Platelets and Early Research

Spanning centuries, the discovery of blood platelets was fundamentally dependent on the invention of the compound microscope by Hans and Zacharias Janssen in the 1590s (see Table 1). Discovery of blood platelets as a distinct cellular entity in blood is attributed to Bizzozero in 1882, although their discovery and potential function are prefaced in earlier studies over the previous 40 years (Table 1). In particular, the studies of George Gulliver and William Addison in the 1840s predated the first identification of blood platelets and their function with respect to their association with the fibrin clot (Fig. 1) (Addison 1842; Gerber and Gulliver 1842). In 1906, James Wright described the bone marrow and megakaryocyte origin of platelets (Wright 1906). By the late 1950s, the ultrastructure of platelets along with their constituent intracellular organelles such as alpha granules and dense bodies had been described as had the fundamental role of blood platelets in bleeding and thrombosis and their pivotal and necessary contribution to coagulation (Hellem and Owren 1964; Berger 1970; Coller 2011). The field awaited the transition from the observational to the molecular age of research.

Table 1 Evolution of knowledge leading to platelet discovery and its origin

Timeline	Discoveries	References
1590s	Hans and Zacharias Jansen invent compound microscope	Spencer (1937)
1628	Publication of *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* (*Movement of the Heart and the Blood in Animals*) by William Harvey demonstrates the concept of blood circulation	Kilgour (1961), Harvey and Leake (1928)
1665	The best-seller *Micrographia* from Robert Hooke details his discovery of cells	Hooke (1665)
1674	Anton van Leeuwenhoek (or Leeuwenhoeck), using his handcrafted and most advanced microscope of the period, gives the first accurate description of red blood cells	Leeuwenhoeck (1674)
1771	Publication of William Hewson's *Experimental Inquiry into the Properties of the Blood.* Discovery of fibrinogen and anticoagulants (neutral salts)	Hewson (1771)
1827	Joseph Jackson Lister, a pioneer achromatic objective lenses for the compound microscope, publishes *Notice of some Microscopic Observations of the Blood and Animal Tissues* with Thomas Hodgkin. It is now possible to resolve objects accurately to '1/3000' in. (approx. 8 μm) and without spherical aberration	Hodgkin and Lister (1827)
1840s	George Gulliver publishes one of the first illustrations of platelets. He describes minute spherules sized at 1/10,000 of an inch (approx. 2.5 μm) that can become star-shaped, although no significance is attached to this observation	Gerber and Gulliver (1842)
	William Addison describes within blood minute granules 8–10 times smaller than 'colourless corpuscles' in relation to fibrin clot	Addison (1842)
	Alfred Donné defines three elements within blood, red and white cells and small globulins, less than 1/300 mm (approx. 3 μm) in size, that look like globulins of chyle	Donné (1842)
1864	Lionel S. Beale publishes the first clear illustration of platelets in *On the Germinal Matter of the Blood, with Remarks upon the Formation of Fibrin*, although these colourless corpuscles were considered by Beale to be early stage of blood cell development	Beale (1864)
1865	Max Schultze defines a group of colourless little spherules 6–8 times smaller than RBCs as a distinct and normal blood constituent population	Schultze (1865), Brewer (2006)
1874	William Osler describes pale, round discs in blood that can quickly coalesce in shed blood. Unfortunately, Osler thought them to be a type of bacteria	Stone (2003), Osler (1873)
1882	Giulio (or Julius) Bizzozero coins the terms 'piastrine', 'plaquettes' and 'Blutplattchen' (Italian, French and German, respectively) to describe platelets and demonstrates the importance of platelets in thrombosis and as the third component of the blood (together with RBCs and WBCs)	Brewer (2006), Bizzozero (1881), Wright (1906)
1906	James Homer Wright demonstrates the bone marrow and megakaryocyte origin of platelets	Wright (1906)

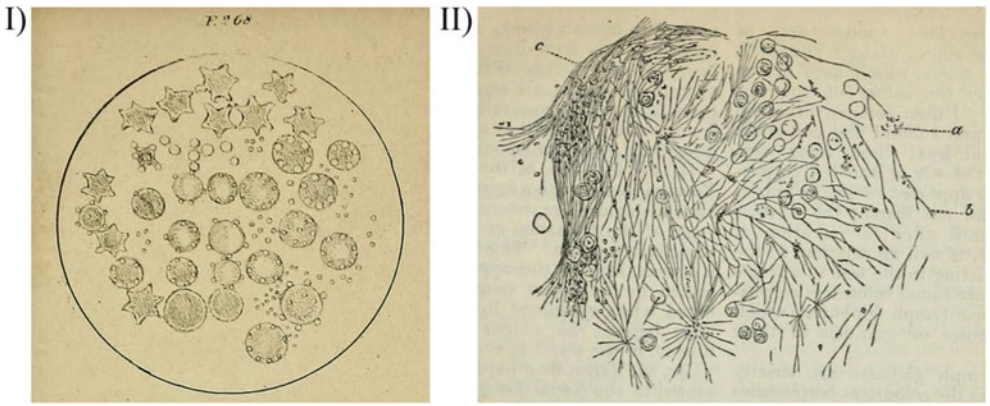

Fig. 1 (**a**) John Siddall's drawing of George Gulliver's minute spherules (Gerber and Gulliver 1842). (**b**) The illustration of William Addison's fibrin clot shows a delicate mesh of fibrin, blood cells and minute molecules or granules (*a*), filaments with molecules (*b*) and thick coagulated fibrin (*c*) (Addison 1842)

The 1960s

The 1960s was the decade in which most of our modern understanding of platelet function was initiated. This was launched on the basis of what was then a remarkable insight and innovation, the invention of the light transmission platelet aggregometer by Born in 1962 (Born 1962). This facilitated at this time or shortly afterwards the identification of what are now recognised as the primary physiologically relevant platelet agonists, ADP, collagen and thrombin (Born 1962; O'Brien 1962; Prentice et al. 1966; Zucker et al. 1966). By the end of the 1960s, the concept and mechanism for development of the platelet haemostatic plug were clearly identifiable in terms of modern concepts (Fig. 2) (Berger 1970).

The 1970s

The 1970s saw the discovery of the role of the regulatory arachidonic acid metabolites, thromboxane A2 and prostacyclin, as positive and negative regulators of platelet function, followed in the 1980s by the identification of nitric oxide as a negative regulator of platelet function (Hamberg et al. 1975; Moncada et al. 1976; Mellion et al. 1981; Palmer et al. 1987). The next historical advance in the understanding of platelet biology was the analysis of platelet–vessel wall interactions utilising new model systems developed by Baumgartner and colleagues as well as other investigators. Importantly, these studies took into account the effects of blood flows on platelet behaviour, with long-lasting consequences. When blood was flowed over rabbit aortas denuded of the endothelial lining by a balloon catheter, analysis by light or electron microscopy revealed a 'tight and continuous' layer of platelets within several minutes (Baumgartner and Haudenschild 1972; Baumgartner 1973). Further, this adhesion appeared to be independent of fibrin formation. These observations were in contrast to what was seen at lower blood flows in the same system where fibrin deposition was apparent at the subendothelial surface together with platelets and red blood cells. Together, this work pointed to a critical role for platelets in thrombus formation at elevated shear rates and independent of coagulation. However, specific platelet receptors and adhesive ligands relevant to high shear-dependent platelet adhesion were yet to be identified.

This detailed analysis of time-dependent morphometric changes of platelets interacting with subendothelium also showed a series of steps, from circulating platelets, to initial contact, adhesion and finally 'thrombus' formation (Baumgartner and Haudenschild 1972). The major platelet shape change associated with these stages was also notable. Further studies began to provide a foundation for subsequent identification of key platelet-specific receptors mediating these high-flow events. A highly negatively charged carbohydrate-rich layer (glycocalyx) on the surface of platelets containing factors critical to adhesion and aggregation was identified by electron microscopy and biochemical analysis of isolated platelet membrane fractions, notable both for the unique glycoprotein component and high-density sialic acid (Nurden 1974). Platelet aggregation induced by 'bovine FVIII' [now identified as bovine von Willebrand factor (VWF)] or by ristocetin and platelet adhesion to the subendothelial matrix were known to be defective in the rare congenital macrothrombocytopenia, Bernard-Soulier syndrome (BSS), whereas the response to other agonists was essentially normal. A 'gross abnormality in the 155,000-molecular weight glycoprotein seen in membrane fractions' of BSS platelets was identified as a key factor in the functional defect. This was supported using an acquired antiplatelet antibody isolated from a multiply transfused BSS patient (Nurden and Caen 1975; Tobelem et al. 1976). Treatment of normal platelets with this antibody in vitro resulted in a specific BSS-like aggregation defect. Subsequent detailed analyses by several groups identified the 155,000-molecular weight glycoprotein as GPIbα along with the absence of the other subunits of the GPIb-IX-V

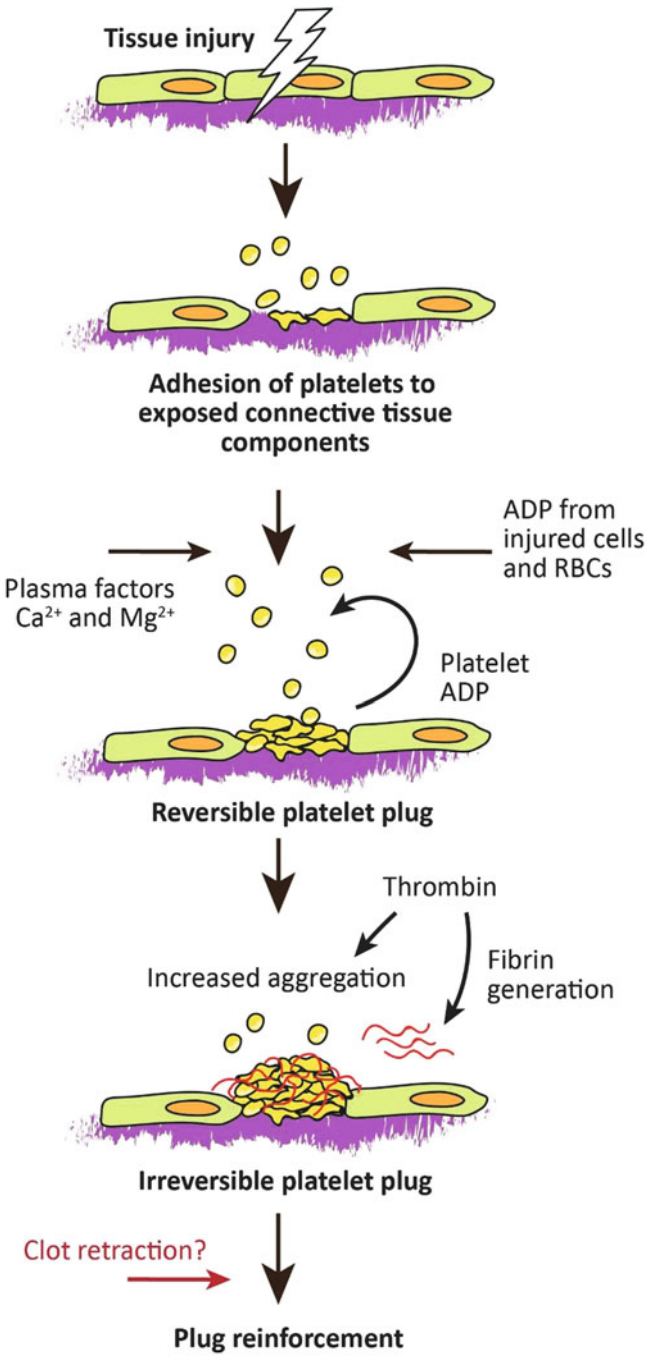

Fig. 2 The concept of the haemostatic plug circa 1960s (Hellem and Owren 1964; Berger 1970)

complex (Nurden et al. 1981; Clemetson et al. 1982; Berndt et al. 1983). These and other contemporary studies showing decreased adhesion of giant BSS platelets to subendothelium under flow conditions also further implicated a key role for VWF in platelet adhesion at elevated shear rates (Weiss et al. 1974, 1978). Importantly, an abnormal platelet glycoprotein pattern was also recognised in another inherited platelet disorder, Glanzmann's thrombasthenia (GT), where, unlike BSS, platelet aggregation was impaired to all agonists except ristocetin (Zucker et al. 1966; Nurden and Caen 1974). The analysis of platelets from healthy donors or patients with GT where membrane surface glycoproteins were labelled and separated by two-dimensional SDS-polyacrylamide gel electrophoresis revealed individual molecules and defects associated with two major glycoproteins in GT platelets ('IIb and III') (Phillips and Agin 1977). At this stage, specific platelet glycoprotein (GP) receptors were identified as functional, but biochemically were little more than spots on gels, with protein properties and regulatory mechanisms yet to be fully defined.

The 1980s and 1990s

The important role of specific platelet membrane glycoproteins as receptors for collagen, VWF and other adhesive ligands in platelet adhesion to subendothelium and in platelet function in general was further elucidated using improved in vitro perfusion systems (Baumgartner and Sakariassen 1985; Sakariassen et al. 1987; Fressinaud et al. 1988), by quantitative analysis of receptor–ligand interaction, by analysis of platelets deficient in particular receptors, by the generation of novel function blocking anti-GP antibodies and by specific inhibitors primarily isolated from snake venoms. For GPIIb-IIIa ($\alpha_{IIb}\beta_3$), the combination of these types of approaches identified fibrinogen, fibronectin and VWF as physiologically relevant ligands in platelet aggregation and the important role of the peptide sequence, Arg-Gly-Asp (RGD), in ligand recognition (Coller 1980; Peerschke et al. 1980; McEver et al. 1983; Coller 2015). For GPIb, analogous approaches defined the role of the N-terminus of the GPIbα chain of the GPIb-IX-V complex in binding von Willebrand factor and thrombin (Ruan et al. 1981; Coller et al. 1983; Fujimura et al. 1986; Andrews et al. 1989b; De Marco et al. 1994). A large family of RGD-containing venom proteins, termed disintegrins, were shown to act as potent inhibitors of platelet aggregation (Niewiarowski et al. 1994).

Indeed, snake toxins selectively targeting platelet glycoproteins and their ligands—both activating and inhibitory—played a central role in defining the function of platelet receptors. The ability of the C-type-like snake venom lectin, botrocetin, to induce VWF-dependent platelet aggregation had been investigated as a clinical laboratory test for assessing GPIb–VWF interaction since the early 1980s (Brinkhous et al. 1983; Howard et al. 1984). Botrocetin was subsequently purified (Andrews et al. 1989a; Fujimura et al. 1991) and contributed to new structure-function analysis of binding domains for VWF and GPIbα interaction (Sugimoto et al. 1991; Berndt et al. 1992). Isolation and identification of the primary platelet collagen receptor,

GPVI, was greatly facilitated by the snake venom toxin, convulxin, which induced potent collagen-like signalling/activation and bound p62/GPVI (Polgár et al. 1997). Toxins containing Lys-Gly-Asp (KGD) mimicking the RGD sequence in $\alpha_{IIb}\beta_3$ ligands were also intensively investigated as antithrombotic agents (Scarborough et al. 1991, 1993a, b, 1999), ultimately leading to the clinically used antiplatelet agent, eptifibatide (Integrilin), a cyclic heptapeptide. Other important snake venom toxins reported in the mid-1990s included mocarhagin, and subsequently Nk proteinase, metalloproteinases with exquisite selectivity for cleaving the sulphated anionic sequence of GPIbα, resulting in loss of binding of both VWF and thrombin. Mocarhagin also cleaved an analogous sequence of P-selectin glycoprotein ligand-1 (PSGL-1) and played an important role in mapping sites and defining specific functions of these receptors (De Luca et al. 1995; Ward et al. 1996; Wijeyewickrema et al. 2007; Ravanat et al. 2010; Carrim et al. 2015).

The functional analysis of platelet membrane glycoproteins was also greatly facilitated by the cloning of the individual receptors including GPIIb and GPIIIa, the GPIb α and β subunits, and GPVI (Poncz et al. 1987; Loftus et al. 1987; Fitzgerald et al. 1987; Lopez et al. 1987, 1988; Rosa et al. 1988; Clemetson et al. 1999), which, when expressed in cell lines, provided information on the regulation of surface expression and co-complexing with other receptors and signalling proteins. This included identification of additional binding partners beyond adhesive ligands involved in haemostasis and thrombosis, including GPIbα binding P-selectin and leukocyte $\alpha_M\beta_2$ (Romo et al. 1999; Simon et al. 2000). These approaches, together with the increased analysis of genetic models in mice, have helped characterise the pathophysiological roles of platelets not only in thrombosis and haemostasis but also in inflammation and other vascular processes (López et al. 2005) to where the field lies today.

Take-Home Messages

- A history of basic and clinical platelet research could be the subject of a multivolume series (>100,000 publications on 'platelets' in Pubmed).
- This brief chapter provides an individual investigator's perspective of key historical discoveries and developments in the platelet field.
- Advances in understanding have depended upon the ongoing development of new technologies.
- Over decades, the role of key platelet-specific glycoproteins in haemostasis and thrombosis has been defined, related to molecular defects in inherited platelet disorders.

Phylogeny of Blood Platelets

Stefania Momi and Viroj Wiwanitkit

Abstract

In biology, phylogenetics is the study of the evolutionary history and relationships among individuals or groups of organisms (e.g., species or populations). At present, molecular phylogenetics is the modern technique for helping with the classification of biological systems. This chapter briefly discusses the phylogeny of blood platelets.

Introduction

In biology, phylogeny indicates the development or evolution of a particular group of organisms and can help to classify biological materials based on evolutionary relationships (Rosen 1974). Phylogenic classifications are based on anatomical appearance, physiology, biochemistry, as well as genetics. With the great advancements in genetic knowledge, modern phylogeny is largely based on the similarity or differences of genetic traits, i.e., on DNA or RNA. At present, scientists rely mainly on genetic phylogeny for classifying living organisms, and indeed using genetic information for classification is better than using anatomical, physiological, or biochemical features since the phenotype may be similar despite there being a different genotype. The use of genetics to study phylogeny is called phylogenetics (Marks 1991; Thornton 2002) and is based on the study of the genome to find out similarities between organisms, similar to dichotomous keys in classical taxonomy, thus defining the phylogenetic tree. The living organisms that have close relationships in evolution will be placed at a near distance in the phylogenetic tree (Fig. 1).

In addition to the classification of living organisms, phylogenetics is applicable to the classification of the components of organisms, including proteins, cell types, or biological structures, and of molecules, through the use of molecular phylogenetics (Marks 1991; Pyron 2015; O'Brien 1994).

An important advance in molecular phylogenetics has come from the introduction of bioinformatics. In fact, after the completion of the human genome project, computational and engineering approaches for the manipulation of data derived from genetic analyses have become available (Watson 1990; Cantor 1990) allowing in silico approaches to the study of structural and comparative genomics, the latter also applicable to phylogenetic studies (Eisen 1998; Eisen and Wu 2002). Phylogenomics involves reconstruction analysis of gene function and evolutionary analysis of rates and patterns of gene evolution (Eisen and Wu 2002).

Phylogeny of Platelets

Although once primarily known for their role in hemostasis and thrombosis, platelets have been increasingly recognized as multipurpose cells. Indeed, they have the ability to influence a wide range of seemingly unrelated pathophysiological events, like hemostasis, lymphogenesis, tissue regeneration, infection, and immunity (Franco et al. 2015) (see current book).

The ability of platelets to exert a wide repertoire of complex functions likely dates back to an era in which innate host defenses were accomplished by one cell type, or at most by a small number of cells, instead than by the extensive and specialized cellular repertoire that has then developed in the blood of humans and other mammalian species (Fig. 2).

Invertebrate species generally possess an open circulatory system (the hemolymph) and lack differentiated formed elements in blood, such as neutrophils, erythrocytes, and platelets. Indeed, in many marine invertebrates (ascidians, mussels, decapod crustaceans, marine arthropods, etc.), only one type of cell circulates in blood or is present in the coelomic fluid, the fluid contained in the main body cavity in most multicellular invertebrates, and plays multiple roles in host defense, among which hemostasis. Such cells can aggregate and seal wounds (Levin 2002). One example is the amoebocyte of the arthropod horseshoe crab, *Limulus polyphemus*, that inhabits coastal waters of North America. In horseshoe crabs, one of the major defense systems is carried by the hemolymph which contains at least two types of hemocytes, granular and non-granular, based on cell morphology. However, there appears to be only one type of hemocyte in the systemic circulation of the adult animal, the so-called amoebocyte/granulocyte characterized by an oval, plate-shaped structure, 15–20 μm in its longest dimension that contains numerous dense granules since the population of the non-granular hemocytes is only 1 % of the total cells (Iwanaga and Kawabata 1998). These cells have primitive wound-sealing functions, aggregate in response to lipopolysaccharide (LPS), and release a cascade of antimicrobial substances (such as the anti-LPS factor), lectins, protease inhibitors (including trypsin inhibitor and α_2-macroglobulin), and also coagulation factors (factor C, factor B, factor G, proclotting enzymes, coagulogen) involved in the engulfing and killing of invading microbes and in preventing the leakage of hemolymph (Smith et al. 1995; Levin and Bang 1964; Takahashi et al. 1994; Goffinet and Grégoire 1975). The granular hemocytes of the horseshoe crab *Tachypleus tridentatus* have similar activities, although divergence of the two species appears to have occurred over 100 million years ago, suggesting that the granular hemocyte has

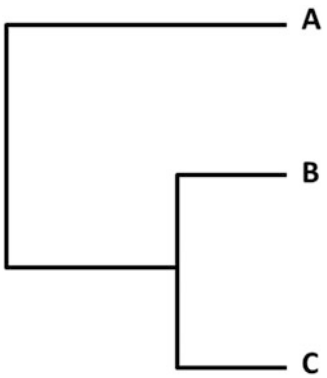

Fig. 1 Example of a phylogenetic tree. From this tree, C is closer in genetic evolution to B than A

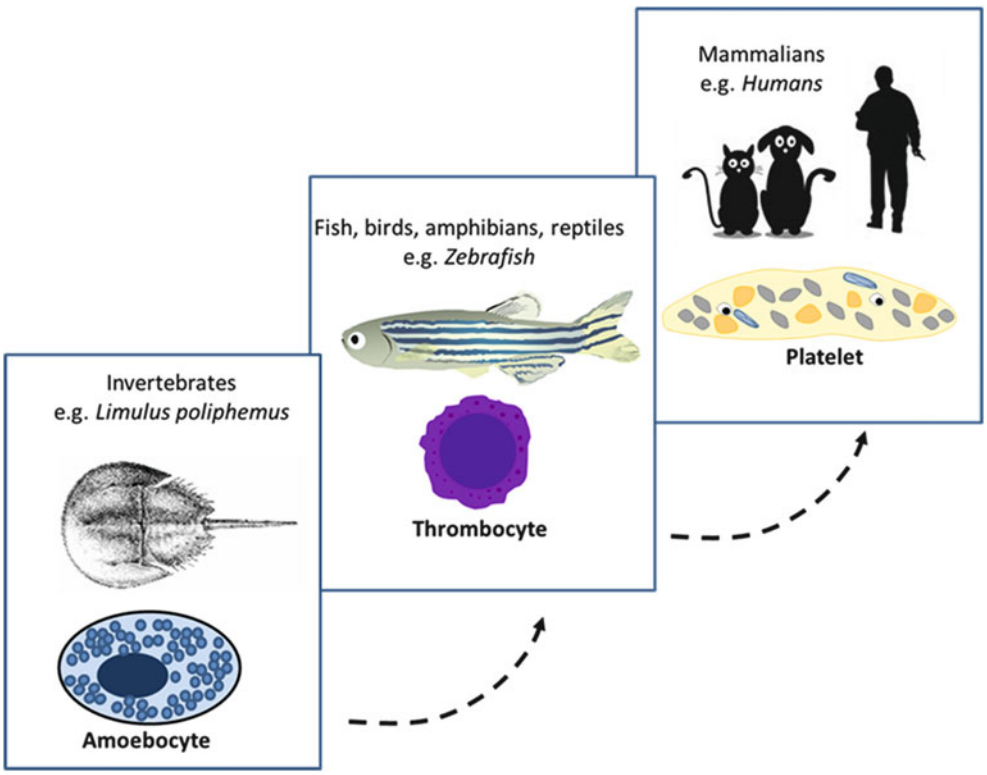

Fig. 2 Evolutionary links of platelets to multifunctional innate defensive cells provided with primitive multiple defensive roles

developed earlier than the divergence between the two species (Kawabata et al. 2003). Drosophila largely relies on innate immunity, encompassing both a humoral response of antimicrobial peptide expression and cellular responses for bacteria encapsulation and phagocytosis (Royet et al. 2003). At every developmental stage of *Drosophila*, aside from the early embryo, more than 90 % of all hemocytes are plasmatocytes (Rizki and Rizki 1984), which have important functions during animal development and in response to infection, tissue damage, and tumor growth. The mechanisms that coelomocytes employ to clear microbes from the coelom require shape change and therefore a cytoskeleton and include activities as motility, phagocytosis, secretion, degranulation, and clot formation (Smith et al. 1995). Sea urchin coelomocytes accumulate at sites of injury in response to chemotactic stimuli, generate sealing and encapsulating clots that are dependent on cell–cell adhesion, and have secretory and phagocytic functions (Rothenberg and Davidson 2003). Profilin is an important regulator of actin filament polymerization in sea urchins and becomes activated through the inositol triphosphate second messenger system.

Coelomocytes of earthworms have many similar functions (Cooper et al. 2002). These and other examples of invertebrate cellular responses provide key insights into the evolution of vertebrate innate and acquired host defenses (Salzet 2001).

Nonmammalian vertebrates have nucleated, often spindle-shaped, thrombocytes that represent the first cells that specialized in hemostasis during evolution (Ratnoff 1987). Zebrafish (*Danio rerio*) and other fish species have circulating mononuclear leukocytes, granulocytic leukocytes, and nucleated thrombocytes that have phenotypic features and functional characteristics similar to those of platelets (Rowley et al. 1997; Jagadeeswaran et al. 1999). However, in contrast to platelets, thrombocytes do not aggregate in response to adenosine diphosphate (ADP), nor to epinephrine (Belamarich et al. 1966; Ratnoff 1987), and, in contrast to mammalian platelets, they do not accumulate or produce serotonin.

However, Zebrafish thrombocytes play a role in the development of arterial thrombi (Thattaliyath et al. 2005). Thrombocyte aggregation in sharks is temperature reversible, a feature that is not seen with mammalian platelet aggregation (Rowley 1988). Shark thrombocyte aggregation is also independent of thrombin and ADP (Rowley 1988). Thrombocyte concentration and clotting time appear to be negatively affected by glucocorticoid excess in fish. Excessive levels of glucocorticoid tend to decrease the total thrombocyte count and increase the clotting time. Reptiles, birds, and amphibians also have nucleated thrombocytes (Levin 2002). Thrombocyte cytoplasmic granules have been described as numerous, scarce, or absent, depending on the vertebrate group or species (Lopez-Ruiz et al. 1992; Esteban et al. 2000). For example, only a single population of granules has been reported in fish granular thrombocytes and in amphibian thrombocytes. These granules show morphological and cytochemical features typical of lysosomes, although the presence of a variable number of cytoplasmic vesicles has led to the suggestion that subpopulations exist in fish (Pica et al. 1983). Occasional azurophilic granules have been described in reptile thrombocytes (Sypek and Borysenko 1988). Moreover, in the thrombocyte cytoplasm and lower vertebrate blood plasma, the presence of factors similar to those present in platelets has been shown (e.g., platelet factor 4, β-thromboglobulin, factor VIII-related antigen, etc.) (Spurling 1981; Pica 1990; Taffarel and Oliveira 1993; Hill and Rowley 1998). The cytoplasm in reptile thrombocytes is particularly delicate, viscous, and prone to rupture (Sypek and Borysenko 1988). Their perinuclear area contains actin-like filaments, and a smooth endoplasmic reticulum is sparsely distributed throughout the peripheral cytoplasm (Wood and Ebanks 1984). Concerning birds, an extensive ultrastructural study of six domestic species showed that thrombocytes are similar in size to lymphocytes, but have a denser nucleus and a very highly vacuolated cytoplasm. Moreover, they have a membrane surface-connected canalicular system similar to mammalian platelets (Levin 2002). Thrombocytes are the most common blood cell in the chicken after erythrocytes; they contain 5-hydroxytryptamine (Kuruma et al. 1970) and release protein materials containing a well-separated fraction which seems to correspond to β-thromboglobulin (Wachowicz and Krajewski 1979). Birds have more prolonged bleeding and do not form vaso-occlusive thrombi after arterial vessel wall injury in vivo (Schmaier et al. 2011). A recent study comparing a set of 5 representative mammals with 48 bird species across the avian phylogeny, 12 reptiles, 3 amphibian, and 3 fish species showed that the cytoplasmic domain of GPIbα is lacking in birds and this might help to explain why, unlike mammalian platelets, avian thrombocytes take longer to produce a clot to control bleeding (Ribeiro et al. 2015).

Some functions of mammalian platelets are vestiges of activities originally present in the primitive multicompetent cells from which mammalian blood cells have evolved. Nonnucleated platelets, and presumably their polyploid megakaryocyte progenitors in the bone marrow, are present only in mammals, suggesting that this unique mechanism producing an unprecedented, highly specialized anucleated cell from the cytoplasm of a larger cell allows to provide more evolved organisms with a highly efficient system supporting hemostasis. However, although the platelet is highly differentiated for *hemostatic* defensive functions, it maintains potent *inflammatory* activities and molecular mechanisms that link the hemostatic and immunologic/inflammatory systems, possibly as a rudimentary remnant from the more primitive multifunctional innate defensive cells. The evolutionary events that resulted in the appearance of mammalian megakaryocytes and platelets, as well as the potential biological advantage of this system, remain to be further clarified.

Phylogeny of Platelet Molecules and Receptors

One of the first molecules to be investigated phylogenetically has been platelet-derived growth factor (PDGF). The phylogenetic analysis of PDGF was first reported by Singh et al. (1982) who analyzed clotted blood sera from mammals, lower vertebrates, and marine invertebrates to screen for homologues of human PDGF by radioreceptor assay and found that the phylogenetic distribution of PDGF homologues does not correlate with distribution of platelets in evolution (Singh et al. 1982). It was suggested that the coincidental appearance on the vertebrate line of development of one anatomical feature, i.e., a pressurized circulatory system, and of PDGF supports the hypothesis that PDGF plays a role in the maintenance and repair of the vascular lining in vivo. Another related molecule that has been studied is platelet-derived endothelial cell growth factor (PD-ECGF) (Hagiwara et al. 1991). The gene for hPD-ECGF is localized to chromosome 22, and Southern blot analysis using genomic DNAs from several vertebrates suggested that the gene for PD-ECGF is conserved phylogenetically among vertebrates (Hagiwara et al. 1991). Thrombospondin (TSP) is a large, trimeric, modular glycoprotein contained in platelet α-granules (Bornstein 1992) with important roles in cell-extracellular matrix interactions, angiogenesis, synaptogenesis, and connective tissue organization. McKenzie et al. reported that the TSP-1, TSP-3, TSP-4, and TSP-5 genes lie within paralogous regions that provide insight into the ancestral genomic context of vertebrate TSPs. Precursors of the TSP-1 to TSP-5 genes were all present within corresponding ancestral genomic contexts in the last common ancestor of bony fish and tetrapods, and the authors concluded that the TSP-5/COMP protein sequence has evolved to its current state as an innovation of tetrapods and that, given the significant role of TSP-5/COMP in mammalian cartilage, the polypeptide sequence evolved rapidly in tetrapods possibly under the selection pressures imposed on the bony endoskeleton by the switch from aquatic swimming to terrestrial locomotion (McKenzie et al. 2006). Bentley and Adams studied the evolution of TSP and their ligand-binding activities and found that the trimer and pentamer subgroups of vertebrate TSPs represent the outcomes of very different evolutionary events and that the trimerizing coiled coil of TSP-1 and TSP-2 is a chordate innovation. They speculated that the evolution of stable oligomerization by a coiled-coil domain in combination with the increased ligand-binding avidity provided by a trimer was favored strongly under natural selection. The many activities of TSP-1 and TSP-2 that are mediated by their TSR domains in vivo (e.g., TGFβ binding/activation, CD36-dependent anti angiogenesis, and CD36-dependent regulation of nitric oxide-regulated vascular responses) demonstrate the extent to which the functional properties of TSPs were impacted by the evolution of TSP subgroup A (Bentley and Adams 2010). Human platelet antigens (HPAs) are polymorphisms localized on the main platelet receptors (integrin $\alpha_{IIb}\beta_3$, the GPIb-IX-V complex, integrin $\alpha_2\beta_1$) which can stimulate production of alloantibodies in case of transfusion of platelets with different HPAs (Landau and Rosenberg 2011). The HPAs involve single-nucleotide polymorphism at evolutionary variable positions located on the protein surface. These polymorphisms do not cause diseases, but may lead to immunological disorders. Interestingly, some HPAs might also affect the activation process of the protein. The integrins form heterodimers, whereas each subunit comprises multiple domains. This allows a regulation mechanism that involves multiple conformations of the protein on the cell surface (Landau and Rosenberg 2011). Hadhri et al. (2010) studied HPA-1 to HPA-6 and HPA-15 in Tunisian blood donors and found by phylogenetic analysis that Tunisians are more closely related to western (Europeans and North Africans) than to eastern Mediterranean populations. The relationships between North Africans and Mediterranean western Europeans may be explained by the northward Berber migration. It represents a baseline study for future research in the population movement of Maghrebians and may help to better understand the mechanism of platelet alloimmune syndromes.

The $\alpha_{IIb}\beta_3$ receptor is a member of a large family of receptors termed integrins that extend back in evolution to *Drosophila* that are involved in cell adhesion and aggregation, as well as in protein trafficking and bidirectional signaling (Poncz et al. 1987; Fitzgerald et al. 1987; Hynes 1987). Recently, the phylogenetic tree of nine human platelet glycoproteins was reported. Six members (i.e., GPIBA, GPIBB, GP9, GP5, ITGA2, GP2B) were identified as ancestors and showed a close genetic relationship, two (GP3A and GP3B) were close to one another being identified as common GP3, and the last one (CD151) was unique and unrelated to the others (Wiwanitkit 2005) (Fig. 3).

The group of Shaun Coughlin in 1998 compared the amino acid sequences of mouse, human, and *Xenopus* PARs using a computer-based "phylogenetic" analysis program (Pileup) to generate a PAR family tree (Fig. 4) (Kahn et al. 1998).

They speculated that the existence of a *Xenopus* homologue of the PAR1 gene suggests that *Par1g* and *Par2g* diverged before the existence of separate mammalian and amphibian lineages. Considering that all PARs function as thrombin receptors, it is presumable that the capacity to signal in response to thrombin preexisted the divergence of mammals and amphibians. It is possible either that this system played a hemostatic role by mediating platelet or thrombocyte activation in early vertebrates or that thrombin signaling plays a role in embryonic development independently of platelet activation (Connolly et al. 1999), raising the possibility that PARs and signaling in response to thrombin or thrombin-like proteases may have evolved initially to serve a function unrelated to hemostasis (Kahn et al. 1998).

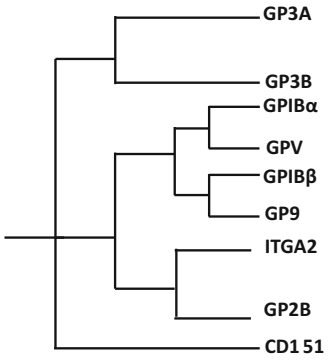

Fig. 3 Phylogenetic tree of human glycoproteins (modified from Wiwanitkit (2005))

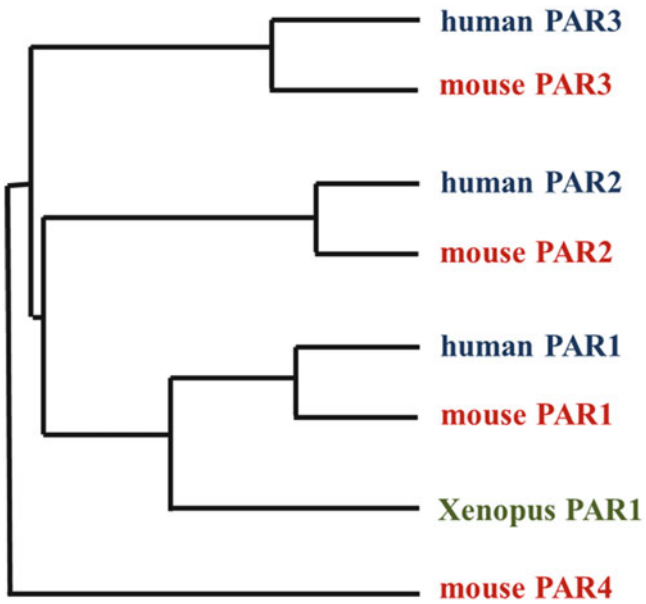

Fig. 4 PAR family tree. Human, mouse, and *Xenopus* genes are shown. Derived from data published on Kahn et al. (1998)

A recent study has compared human platelets and avian thrombocytes. Examination of the genes that are expressed selectively in avian thrombocytes has been carried out by the use of both quantitative PCR and microarray analysis and revealed orthologs for many of the genes known to be required for platelet synthesis and function, including those encoding the MPL receptor that stimulates platelet production; the protease-activated receptors that mediate thrombin activation of platelets; the β_3 and α_2 integrins that mediate platelet adhesion to fibrinogen and collagen, respectively; and the glycoprotein Ib/V/IX (GP9) receptor complex that binds von Willebrand factor (VWF) to mediate adhesion under shear. One notable exception was the lack of thrombocyte-specific upregulation of the gene encoding the ADP receptor P_2Y_{12} in avian thrombocytes, consistently with previous studies showing that they neither contain nor respond strongly to ADP (Schmaier et al. 2011). In addition, chicken thrombocytes spread less efficiently than mammalian platelets on collagen and express low levels of the $\alpha_{IIb}\beta_3$ integrin which is essential for aggregation. The authors suggested that platelets evolved in mammals to provide a hemostatic advantage that in modern humans has become a primary mechanism of cardiovascular disease (Schmaier et al. 2011).

The cyclooxygenase (COX) pathway, which generates prostanoids starting from arachidonic acid, was first reported in 1964 by two independent research teams (see Fries and Grosser 2017). In 1989, the purification of the TP receptor present in human platelets was reported, and in 1991 its cDNA cloned (Fries and Grosser 2017). The TP receptor was identified as a member of the G-protein-coupled rhodopsin-type receptor superfamily. The technique of amino acid sequence comparison has been used to infer the phylogeny of the prostanoid receptors. It was suggested that the ancestral prostanoid receptor responded to PGE2 generated by the COX pathway (Wise and Jones 2002) (Fig. 5). Alignments of all the prostaglandin receptors showed that the EP2 receptor is more similar to the prostacyclin (IP) and the PGD2 (DP) receptors than to the other three EP receptors. Phylogenetic analysis of receptor sequences led to the conclusion that the prostaglandin receptors evolved from a precursor EP receptor into two subfamilies that are characterized by different G-protein coupling. Thus, the IP and DP receptors evolved from the EP2 receptor, and the PGF2α (FP) receptor and thromboxane (TP) receptors evolved from EP3 and EP1 receptor (Fig. 5) (Gill et al. 1998).

Fish thrombocytes convert arachidonic acid to prostaglandins with little, if any, thromboxane formation, whereas thromboxane is a potent inducer of platelet aggregation in mammals (Rowley 1988). Considering the TXA_2/TP receptor relevance in the pathophysiology of the cardiovascular system, evolutionary forces may have favored regulatory mechanisms leading to low basal activity and selected against more highly active phenotypes.

Some distinctive characteristics of platelet function along the phylogenic tree are reported under Table 1.

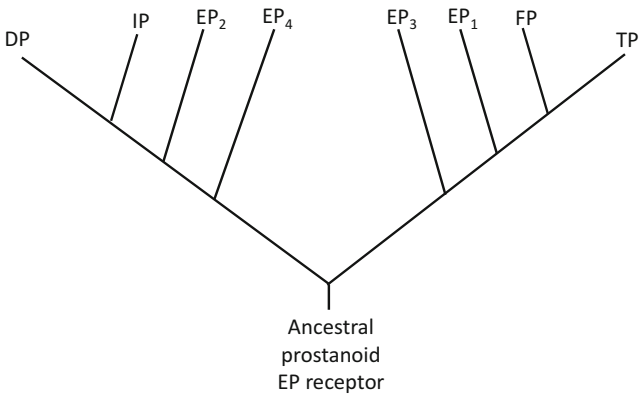

Fig. 5 Proposed evolution of the prostanoid receptors (modified from Wise and Jones (2002))

Table 1 Platelet function characteristics in nonmammalian and mammalians vertebrates as compared to human platelets

	Non mammalian vertebrates	Mammalians									
	Fish, birds, reptiles, amphibians	*Mirounga angustirostris*	*Orcinus orca*	*Equus caballus* (Horse)	*Sus scrofa domesticus* (Pig)	*Ovis aries* (Ovine)	*Canis lupus familiaris* (Dog)	*Rat norvegicus* (Rat)	*Mus musculus* (Mouse) (C57BL/6)	Non human primates

Take-Home Messages

Platelets are unique, highly specialized anucleate mammalian blood cells, with an exclusive molecular repertoire, that have evolved to fulfill crucial functions in host integrity, defense, and repair. However, although they are highly differentiated for hemostasis, platelets also display inflammatory and antimicrobial activities linking the clotting, innate, and adaptive immune responses. This diversity of functions suggests evolution from more primitive multifunctional innate defensive cells, the hemocytes, that mediate wound healing and can induce hemolymph coagulation and clotting at sites of tissue injury or exoskeletal disruption, but that are also involved in host defense against invading pathogens. These primordial hematological responses may point to an evolutionary link between innate immune responses and platelet function. These observations may explain why platelets share many immune-related and tissue-repairing functions, i.e., the functions of the early protective hemocytes that still persist as vestigia in the platelets of mammals. Perhaps, during evolution, the hemostatic and immune functions of hemocytes diverged, and platelets and leukocytes were generated. Studies on the evolution of some platelet proteins confirm a recent development of several platelet-associated molecules further characterizing platelets and their structures as relatively recent specialized actors in the field of host protection.

Platelet Morphology and Ultrastructure

Harry F.G. Heijnen and Suzanne J.A. Korporaal

Abstract

Platelets are key players in hemostasis, the process that is essential in the prevention of blood loss in response to injury of a blood vessel. When platelets encounter breaches in the vascular wall, they rapidly adhere to the site of injury and aggregate to form a platelet plug. Subsequently coagulation will be initiated resulting in a fibrin network that reinforces the plug. Failure to form an adequate plug leads to a bleeding tendency. On the other hand, excessive platelet reactivity leads to an increased risk of vascular occlusion and thrombosis. In order to better understand how platelets function, it is essential to have insight into their overall morphology and (ultra)structure. This chapter will contribute to this and present our current view of the platelet structure and physiology in health and disease and the recent techniques available to visualize this.

Overall Morphology and Function of Platelets

Blood platelets are small anucleate cell fragments that, together with the red blood cells, are the most abundant cells in the circulation. They derive from megakaryocytes (MKs) in the bone marrow that extend long pseudopodia-like extensions into the sinusoids (Behnke 1969; Italiano et al. 1999, 2007; Thon and Italiano 2010). These extensions, termed proplatelets, further grow due to shear rates of the vasculature and are then thought to fragment to release platelets into the microcirculation. Platelets have a typical discoid shape, a diameter of ~4 μm, and a thickness of ~1 μm. This lentiform shape is brought about by a bundle of peripherally oriented microtubules (White 1968; Italiano et al. 2003) and involves also a complex interplay between the plasma membrane and the underlying spectrin skeleton (Hartwig and DeSisto 1991; Hartwig et al. 1999; Patel-Hett et al. 2011). The discoid shape of the platelets, together with rheological parameters of the flowing blood and the red blood cell shape, ensures that the platelets circulate in a well-defined area in close proximity to the endothelial cell surface (Aarts et al. 1983). These factors are important as the endothelium is the area where the natural inhibitors of platelets (i.e., nitric oxide and prostacyclin) are present at highest concentrations, and it ensures that platelets are able to continuously monitor the endothelium for breaches. Upon endothelial injury, platelets rapidly adhere and interact with components of the subendothelium, i.e., collagen, von Willebrand factor (VWF), and fibronectin, to start restoration of the integrity of the vessel wall (Sixma et al. 1991; Sixma and de Groot 1994). Such interactions generate a series of activation signals in the platelets that result in a dramatic change of their shape, secretion of their granular contents, and the activation of the integrin $\alpha_{IIb}\beta_3$. The latter is the main receptor for fibrinogen and VWF and is responsible for building the hemostatic platelet plug that arrests bleeding after endothelial injury (Fig. 1). Actin-myosin-based platelet retraction finally stabilizes the plug (Hashimoto et al. 1994). Platelet adhesion, aggregation, and secretory responses are the result of a series of complex processes. The unraveling of these processes has been for decades an important goal for researchers in the field of

hemostasis and thrombosis. Analysis of the platelet ultrastructural changes is key for the understanding of the rapid membrane dynamics that occur during adhesion and activation and has contributed to our present understanding of platelet functioning. In addition, flow devices, real-time imaging, and new developments in light and electron microscopic imaging have offered new opportunities to dissect the relationship between platelet structure and function.

Visualization of Platelets

Platelets can be visualized by light microscopy (LM) on whole blood smears prepared from anticoagulated blood after staining with a May-Grünwaldt Giemsa or Wright stain. In such preparations, platelets appear as small red-bluish, oval and round structures with purple-red puncta as granules. Giant platelet characteristics for macrothrombocytopenia are readily recognized by LM (Zucker-Franklin 2003). This method is therefore suitable for the diagnosis of macrothrombocytopenia-associated platelet disorders and certain storage pool diseases. Platelet adhesive properties can be monitored ex vivo using static adhesion assays or flow devices (Sakariassen et al. 1983; Sixma et al. 1987; Kulkarni et al. 2004). Real-time video microscopy and high-speed CCD cameras coupled to specially developed perfusion devices, and image-processing software, have pushed up both the resolution and sensitivity, making "live" visualization possible of the various steps of platelet adhesion and thrombus building in naturally flowing blood (Fig. 2) and on different physiological surfaces (Fig. 3) (Maxwell et al. 2006; Nesbitt et al. 2013). Confocal microscopy and new super-resolution imaging platforms, such as structured illumination microscopy (SIM), direct stochastic optical reconstruction microscopy (dSTORM), reflection interference contrast microscopy (RICM), and total internal reflection fluorescence (TIRF) microscopy, have provided new ways for imaging of platelet adhesion (Reininger et al. 2006),

Ca(2+) dynamics (Nesbitt et al. 2003), cytoskeletal rearrangements (Poulter et al. 2015), as well as molecular localization and translocation events (secretion) (Fig. 2c, inset) (Kamykowski et al. 2011). In addition, fluorescently labeled phalloidin, organelle-specific fluorescent dyes (e.g., mepacrine or acridine orange), specific fluorescent calcium indicators, and cell surface and secretion markers are now widely used to study platelet adhesion dynamics (Fig. 2c, d).

Electron microscopy (EM) has always played an important role in the various branches of platelet research. Scanning electron microscope (SEM) has been widely used for obtaining images of the platelet surface topology at rest or after interaction with physiological substrates (Fig. 3a). Such SEM preparations provide information on functional alterations such as shape change, the size of thrombi, and the formation of fibrin. Whole-mount preparations of platelets adhered to physiological surfaces such as fibrinogen, VWF, or collagen can also be prepared on substrate-coated EM grids and studied by transmission electron microscopy (TEM) after uranyl staining and embedding in methylcellulose (Fig. 3b). Combined with immunogold labeling strategies, these techniques provide information on the topographical distribution of cell surface receptors and associated ligands (Lewis et al. 1990; Beumer et al. 1995).

Thin section TEM is the most widely used method to visualize platelet ultrastructure (Fig. 4). With TEM, the intracellular organization of organelles and to some extent

also cytoskeletal elements can be visualized. The classical method includes chemical fixation using aldehydes, dehydration in a series of graded dilutions of alcohol, and embedding in an epoxy resin. Ultrathin sections are prepared and visualized by TEM following heavy metal staining. Such TEM preparations provide only 2D images of the cellular ultrastructure and limited information within the Z-axis. In addition, the harsh fixation protocols involving OsO4, and embedding in epoxy resins, limit antibody access and thereby detection of the subcellular distribution of proteins. New technologies have been developed that overcome these limitations. These include the use of cryo-ultramicrotomy and immunogold labeling of frozen thin sections (i.e., the Tokuyasu method) (Fig. 4) (Tokuyasu 1973; Geuze et al. 1979; Morgenstern 1980) and the generation of new (3D) electron microscopic techniques to image larger cell volumes (Fig. 5) (van Nispen tot Pannerden et al. 2010; Eckly et al. 2014). Although chemical fixation does not arrest rapid membrane dynamics, it is still the most commonly used method to preserve platelets for ultrastructural analysis and immunogold cytochemistry. Immuno-electron microscopy is increasingly becoming a routine technique to precisely localize molecules within their subcellular context, enabling visualization of protein transport routes and molecular translocation events (Fig. 4c, d) (Heijnen et al. 1997, 1998). In addition, cryo-immobilization methods (high-pressure freezing (HPF)) and electron tomography approaches (dual-axis tomography, focused ion beam/scanning electron microscopy (FIB/SEM)) are more and more entering the field and provide the opportunity to visualize the spatial 3D organization of cellular structures (van Nispen tot Pannerden et al. 2010; Eckly et al. 2014).

The Resting Platelet Ultrastructure

Platelets contain a number of structural elements, most of which have been characterized by traditional TEM (Behnke 1967a, 1968a, 1970; White 1968, 1969; White and Clawson 1980; White and Krumwiede 2007). They include the plasma membrane (PM); the open canalicular system (OCS), an elaborate membrane system that is contiguous with the plasma membrane; the dense tubular system (DTS), a reticular membrane network, and remnant of the smooth endoplasmic reticulum (ER); a peripheral band of microtubules; a spectrin-based membrane skeleton; an actin-based cytoskeletal network; and a population of cytoplasmic organelles that include mitochondria, peroxisomes, and secretory alpha granules, dense granules, and lysosomes. Platelets are very vulnerable to activation. Contact activation during blood collection and handling steps during isolation and centrifugation may cause subtle pre-activation, resulting in premature loss of the discoid shape and possibly secretion of granule content. Hence, for ultrastructure

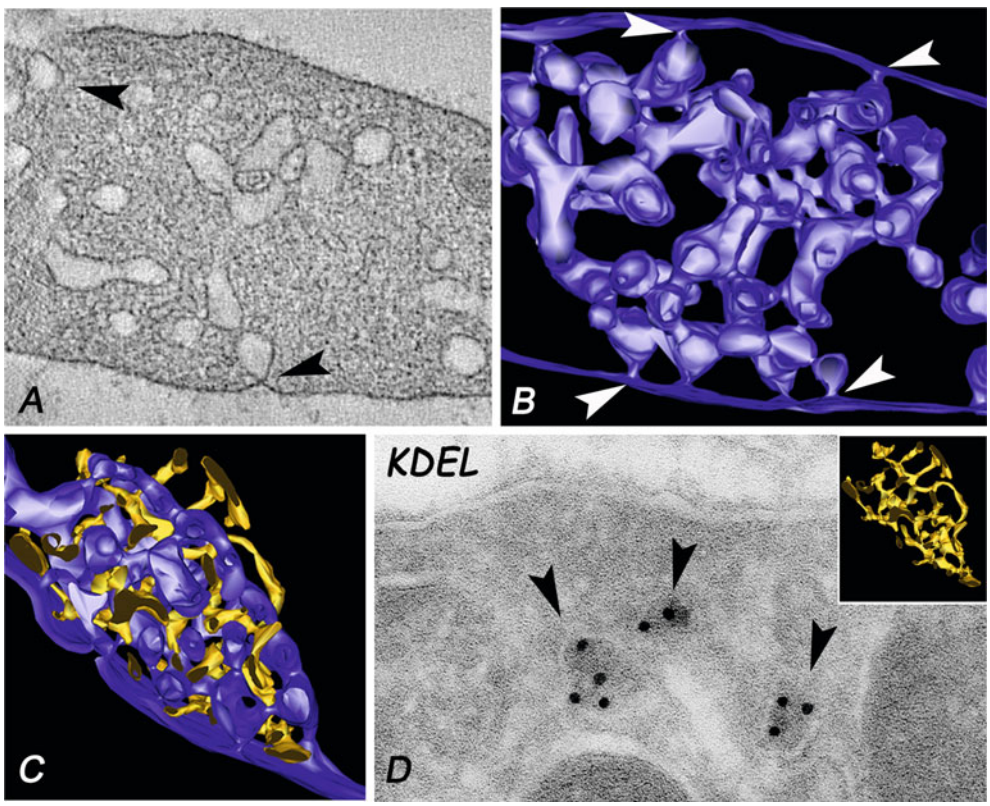

Fig. 5 Open canalicular system (OCS) and dense tubular system (DTS). Tomographic slice (**a**) and 3D reconstruction (**b**) of OCS showing multiple cell surface connections (*arrowheads*). (**c**) Closely intertwined OCS (*blue*) and DTS (*yellow*) membranes. (**d**) Identification of the DTS using immunogold labeling with an antibody directed to the ER retention motif KDEL. The electron-dense structures represent cross-sectioned membranes of the reticular DTS shown in the *inset*

analysis of the steady-state resting platelet, blood handling should be kept at a minimum. Immediate chemical fixation by collecting whole blood directly from the vein into excess aldehyde fixative is a well-recommended method to preserve the platelet resting state. Alternatively, whole blood can be drawn into citrate, followed immediately by aldehyde fixation. The platelet isolation steps can then be performed after fixation.

The Open Canalicular System

Platelets harbor an elaborate internal membrane system, termed the open canalicular system, based on the fact that it is connected at several points to the cell surface via small ~20 nm openings (Fig. 5a, b) (Behnke 1970; White and Clawson 1980). The OCS probably derives from the demarcation membrane system, a highly intertwined membrane network which develops in the MK and ultimately forms the future platelets (Behnke 1968b; Eckly et al. 2014). Although it is not considered a separate intracellular compartment, the OCS still represents an important internal membrane store with specific functions. It facilitates membrane remodeling and shape changes that occur during platelet adhesion, including filopodia formation, membrane tethering, and irreversible spreading. The increase in membrane needed for these morphological changes is believed to be provided by the OCS (Escolar et al. 1989), as well as by membranes of the secretory alpha granules (Peters et al. 2012). Whether internal OCS membranes are able to fuse with the PM, which represents the same membrane, is currently not known. It is generally thought that OCS membranes evaginate when platelets spread on physiological relevant surfaces such as VWF or fibrinogen (Escolar et al. 1989). Platelets make use of membrane-based tethers to transiently adhere to VWF under high shear conditions (Dopheide et al. 2002; Maxwell et al. 2006; Reininger et al. 2006). These membrane tethers, which can reach a length up to 50 μm, are formed when biomechanical forces generated by the blood flow act on GPIb–VWF bonds, thereby pulling membrane from internal platelet stores. Since these transient interactions do not require platelet activation, the membrane must exclusively derive from the OCS. Long membrane extensions are also formed as a combined result of platelet activation and shear forces (Cranmer et al. 2011; Tersteeg et al. 2014). Recent studies have confirmed that a link exists between the structure of the OCS and shear-dependent platelet adhesive function (Mountford et al. 2015). The dynamic nature of the OCS may explain the rapid redistribution of cell surface GPIb/IX from the cell surface toward the OCS, as proposed by some investigators (Hourdille et al. 1990; Han et al. 2003), although this has been challenged by others (White et al. 1996). Receptor redistribution may serve to regulate platelet adhesive properties (van Zanten et al. 1998).

Since the OCS has multiple openings to the plasma membrane (Fig. 5a, b), it provides a two-way route for both plasma components to "enter" the cell (Klement et al. 2009), as well as serving as a conduit for cargo secretion from alpha and dense granules (White 1987; Escolar et al. 1989). OCS membranes typically have the same cell surface distribution as the PM and are highly intertwined with the DTS (Fig. 5c) (van Nispen tot Pannerden et al. 2010). Proper identification of the OCS and its distinction from other membrane systems are essential. Early studies have made use of ruthenium red to specifically stain the OCS (Behnke 1968a). In thin frozen sections, identification of the OCS, especially its distinction from the DTS, requires specific cell surface marker antibodies (i.e., GPIb) or DTS marker antibodies (KDEL, PDI; Fig. 5d).

The Dense Tubular System

Except for the small population of young reticulated platelets, circulating platelets have no ribosomal ER. Instead, platelets contain a dense tubular system (DTS), which is a smooth endomembrane system that originates from the endoplasmic reticulum (ER) of the megakaryocyte (White 1972). The DTS stores and releases calcium in a fashion similar as the sarcoplasmic reticulum of the skeletal muscle. The DTS also harbors a series of ER enzymes that are important for the proper folding of proteins, like PDI and calreticulin. Early ultrastructural studies have demonstrated that the DTS also contains peroxidase activity, which allows specific staining in plastic sections (Breton-Gorius and Guichard 1972). When visualized in thin frozen sections, DTS membranes appear as small tubulevesicular membrane structures, with frequently an electron-dense appearance (Fig. 5d, arrowheads). This has prompted investigators to term these structures T-granules, given their tubular morphology (Thon et al. 2012). T-granules contain TLR9, PDI, and VAMP-8, and it has been suggested that these granules are recruited to the cell surface, thereby contributing to protein secretion, e.g., the secretion of PDI. Extracellular PDI released from activated platelets (Chen et al. 1995) has been shown to contribute to platelet thrombus formation (Cho et al. 2008, 2012; Furie and Flaumenhaft 2014; Schulman et al. 2016). A direct fusion step, however, of DTS membranes with the OCS or plasma membrane has so far not been established. Early work (White 1972) and recent electron tomography analysis have shown that the DTS represents a reticular membrane network (Fig. 5d, inset), frequently found in close vicinity of the OCS, suggesting functional communication between both compartments (van Nispen tot Pannerden et al. 2010).

Platelet secretion and contraction-dependent shape changes require a rapid increase in cytosolic calcium derived from internal stores (i.e., DTS). The close positioning of both membrane systems to one another foresees in local calcium delivery required for SNARE assembly as well as actin-dependent retraction.

Peroxisomes

Peroxisomes are single-membrane organelles that morphologically range from rather small vesicles in some cells to elaborate tubular networks in others (De Duve and Baudhuin 1966). Peroxisomes are thought to derive from the ER (Tabak et al. 2003). In platelets they are very small organelles and are probably closely connected to the DTS. Peroxisomes contribute to lipid metabolism, in particular the synthesis of platelet-activating factor (PAF). Deficiencies of this enzymatic activity in platelets have been identified in the cerebro-renal Zellweger syndrome (Wanders et al. 1984). A consistent feature of peroxisomes is the presence of H_2O_2-producing oxidases and catalase degrading H_2O_2. Platelet peroxisomes were identified through the presence of catalase activity using a diaminobenzidine reaction at pH 9.7 and visualization by EM (Breton-Gorius and Guichard 1972).

Mitochondria

Platelets contain on average seven mitochondria (Morgenstern 1997), which are involved in oxidative energy metabolism (Akkerman and Holmsen 1981). Platelet mitochondria have a diameter of approximately 200 nm and are easily identified by their classical double membrane structure with inward membrane projections forming the cristae (Fig. 4a, b) (Alberts et al. 2002). As in other cells, platelet mitochondria contain the typical activity of oxidative phosphorylation and respiratory control to provide ATP for regulation of platelet function. Together with glucose entry, mitochondria contribute to maintain a sufficient platelet energy content, both at steady state and during platelet activities such as adhesion, aggregation, secretion, and contraction (Garcia-Souza and Oliveira 2014). Mitochondria are particularly important in metabolically active tissues such as the skeletal muscle, heart, and liver. It is becoming more and more evident that mitochondria not only regulate activation of the metabolically active platelets by providing ATP. They also regulate intracellular signaling through the production of reactive oxygen species (ROS) as a second messenger (Zharikov and Shiva 2013). Furthermore, mitochondria initiate apoptosis through the release of cytochrome *c* (Lopez et al. 2007), which is important for the survival of platelets. An interesting aspect recently documented is that activated platelets can release their mitochondria in the form of microparticles (Zharikov and Shiva 2013).

α-Granules

α-Granules are the most abundant secretory organelles in platelets (50–80 per platelet). They constitute about 10 % of the total platelet volume, and their total membrane surface area equals that of the OCS (Morgenstern 1997). α-Granules contain a large variety of adhesive proteins that are important for primary hemostasis, including the adhesive proteins VWF, fibrinogen, fibronectin, vitronectin, and thrombospondin (Fig. 6) (Sander et al. 1983; Wencel-Drake et al. 1985, 1986). These proteins are important for platelet adhesive properties and the building of a stable thrombus. Platelet α-granules also contain a large number of mediators that function in coagulation, wound repair, inflammation, and angiogenesis. These include among others platelet factor 4 (PF4), β-thromboglobulin (CXCL7), Rantes (CCL5), interleukin-8 (IL-8), platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β), and vascular endothelial growth factor (VEGF) (Maynard et al. 2007). PF4, β-thromboglobulin, and Rantes are the most abundant chemokines in platelet α-granules (Deuel et al. 1981; Labelle et al. 2014). α-Granules acquire cargo from biosynthesis (e.g., VWF, β-thromboglobulin, PF4) as well as from endocytosis (e.g., fibrinogen, albumin, IgG) (Harrison et al. 1990). α-Granules thus have properties of both secretory organelles and late endosomes. Indeed, α-granules frequently harbor clathrin coats and luminal vesicles (Fig. 6a, a′), a tribute that is shared with sorting compartments such as the trans-Golgi network and endosomes. The classical view that platelet α-granules represent a homogeneous population of organelles has been challenged by several groups. Italiano et al. reported that anti-angiogenic factors, such as endostatin, reside in a different granule population than proangiogenic VEGF (Italiano et al. 2008). Such subpopulations of α-granules were suggested to respond to specific agonists and hence release granule contents in a thematic fashion (Chatterjee et al. 2011). Early ultrastructural studies (Cramer et al. 1985; Harrison et al. 1990) and recent electron tomography analysis (van Nispen tot Pannerden et al. 2010) have shown that cargo is heterogeneously distributed within α-granules and that morphologically different classes of α-granules exist (Fig. 6). While a majority of the α-granules have a spherical shape, tubular and multivesicular subtypes are also frequently identified (van Nispen tot Pannerden et al. 2010). These studies and recent quantitative super-resolution immunofluorescence microscopy have further established that cargo proteins within individual α-granules are spatially segregated,

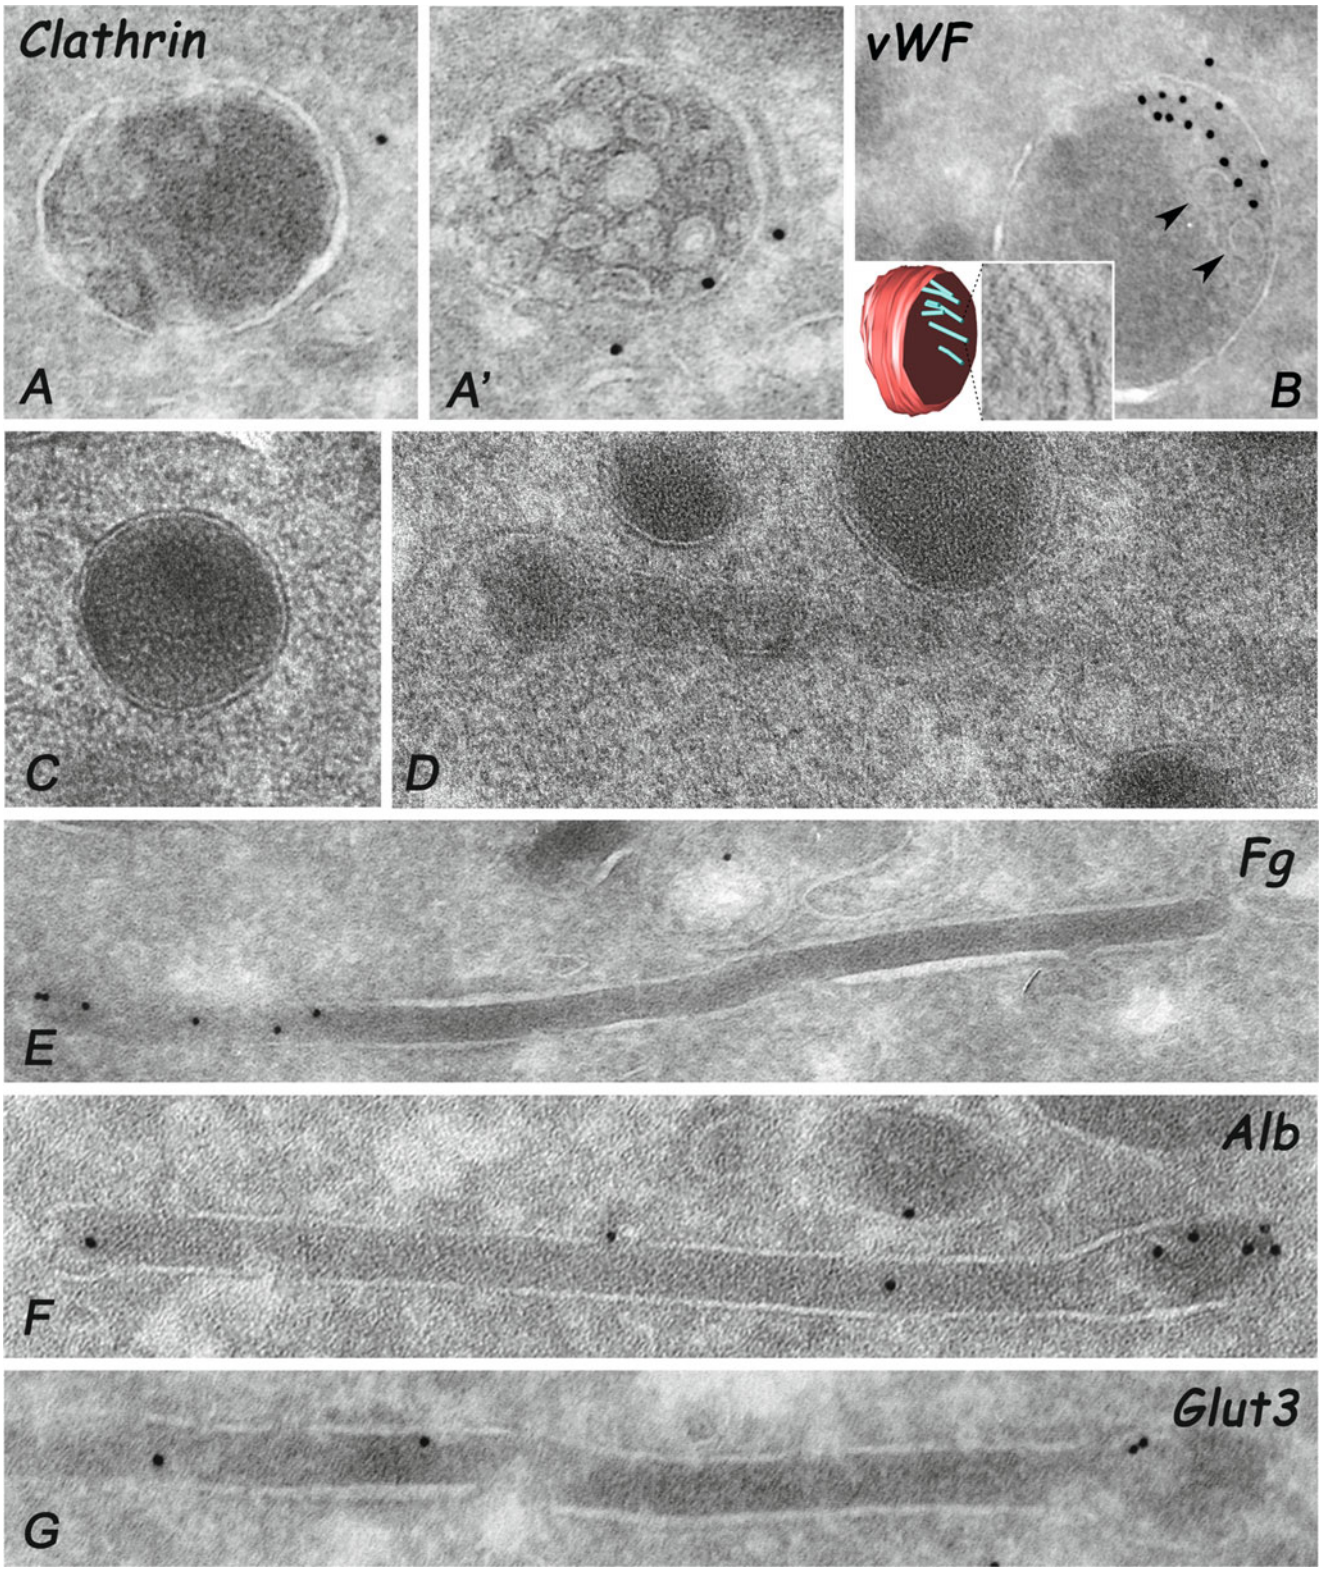

Fig. 6 Alpha granule substructure. (**a**, **a**′) Two subsequent sections through the same alpha granule containing electron-dense cargo and luminal vesicles (immunogold labeling with anti-clathrin antibody). (**b**) vWF multimeric protein assembled at the granule periphery (immunogold labeling with anti-vWF). *Arrowheads* indicate luminal vesicles. The *inset* shows a 3D reconstruction (*left*) and high magnification (*right*) of the tubular vWF inclusions. (**c**, **d**) Spherical- and tubular-shaped granules in high-pressure frozen resting platelets. (**e**–**g**) Tubular alpha granules with spatially distributed cargos including fibrinogen and albumin and the presence of the transmembrane transporter protein Glut3

apparently without much thematic selectivity (Kamykowski et al. 2011). Large cargo proteins (i.e., VWF) are thought to be sorted into secretory granules through aggregation. Recent studies in endothelial cells have provided a model by which clusters of VWF multimers aggregate and tubulate to form the Weibel-Palade bodies (WPBs) (Mourik et al. 2015). As in WPBs, multimeric VWF in α-granules is also assembled in distinct tubular structures and segregated from other molecules (Fig. 6b, inset) (Cramer et al. 1988). An important question is to what extent diverse cargo is released with different kinetics and how this is regulated, considering that these molecules originate from the same granule. Release of thematically different cargos could stem from the dilution of the protein gradient within the compartment once the granule membrane has fused with the PM or OCS or rely on specific signaling pathways and/or sorting of SNARE components (Flaumenhaft 2003; Peters et al. 2012). Early studies using cryo-fixation methods have shown transient fusion pores of α- and dense granules with the PM (Hols et al. 1985; Morgenstern et al. 1987). Such fusion pores may deliver small molecules, while the larger proteins are retained.

Patients with defects in platelet α-granule biogenesis have mild to moderate bleeding problems. The defects are mostly caused by mutations in the genes encoding neurobeachin-like 2 (NBEAL2) and the Sec1/Munc18 protein VPS33B and its binding partner VPS16B, which are required for biogenesis of α-granules. Mutations in *NBEAL2* cause gray platelet syndrome (GPS), a hereditary, usually autosomal recessive bleeding disorder, characterized by macrothrombocytopenia and specific deficiency of α-granules and/or their content (Albers et al. 2011; Gunay-Aygun et al. 2011; Kahr et al. 2011). The severity of GPS depends on the extent of α-granule deficiency (Bottega et al. 2013). GPS platelets appear pale gray when visualized by LM in whole blood smears, due to the absence of the cytoplasmic puncta representing the α-granules. EM of thin sections of platelets from GPS patients shows only vestigial α-granules and abundant channels of the OCS (Fig. 7). Recently, a nonsense mutation in the gene encoding the transcription factor growth factor independent 1B (GFI1B) was shown to cause an autosomal dominant form of GPS (Monteferrario et al. 2014).

Both VPS33B and its binding partner VPS16B are essential for the biogenesis of platelet α-granules. Mutations in both proteins result in arthrogryposis-renal dysfunction-cholestasis (ARC) syndrome that, similar to GPS, is characterized by pale-appearing platelets in whole blood smears with loss of α-granules (Urban et al. 2012).

Dense Granules

Platelet dense granules (3–8 per platelet) are the second major secretory compartment. They are mostly spherical in nature (~200 nm) but can also adopt extended forms (Fig. 8). Based on their high nucleotide content, dense granules possess a high affinity for typical nuclear stains (DAPI) and uranium ions (Richards and Da Prada 1977). Dense granules belong to the same class of organelles as acidocalcisomes (Docampo et al. 2005), which due to their acidic nature accumulate acidophilic dyes such as acridine orange and mepacrine. Dense granules contain small molecules such as ADP, ATP, serotonin, calcium, pyrophosphate, and polyphosphate (Ruiz et al. 2004). The low molecular mass content makes dense granules difficult to visualize by EM. In frozen thin sections, the dense core is often partly or completely lost, leaving only the limiting membrane, and their identification requires labeling with specific membrane

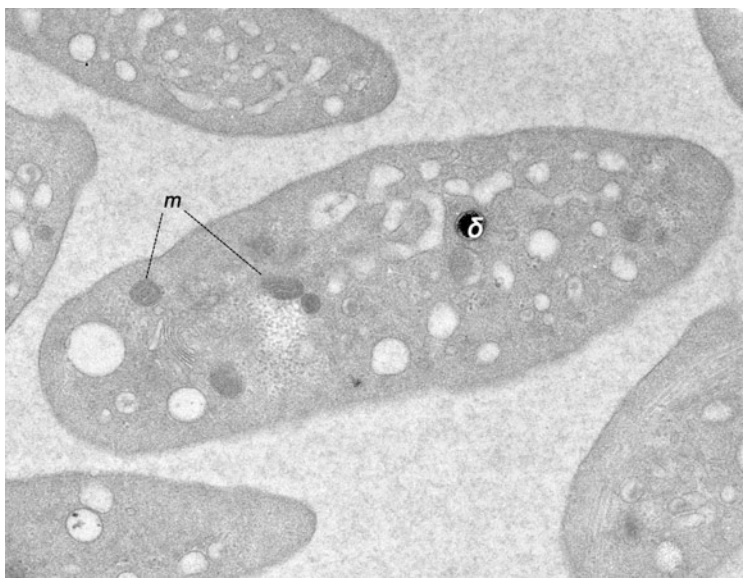

Fig. 7 Gray platelet syndrome. TEM image of platelet from a patient with gray platelet syndrome, showing lack of alpha granules. *m* Mitochondria, *δ* dense granule

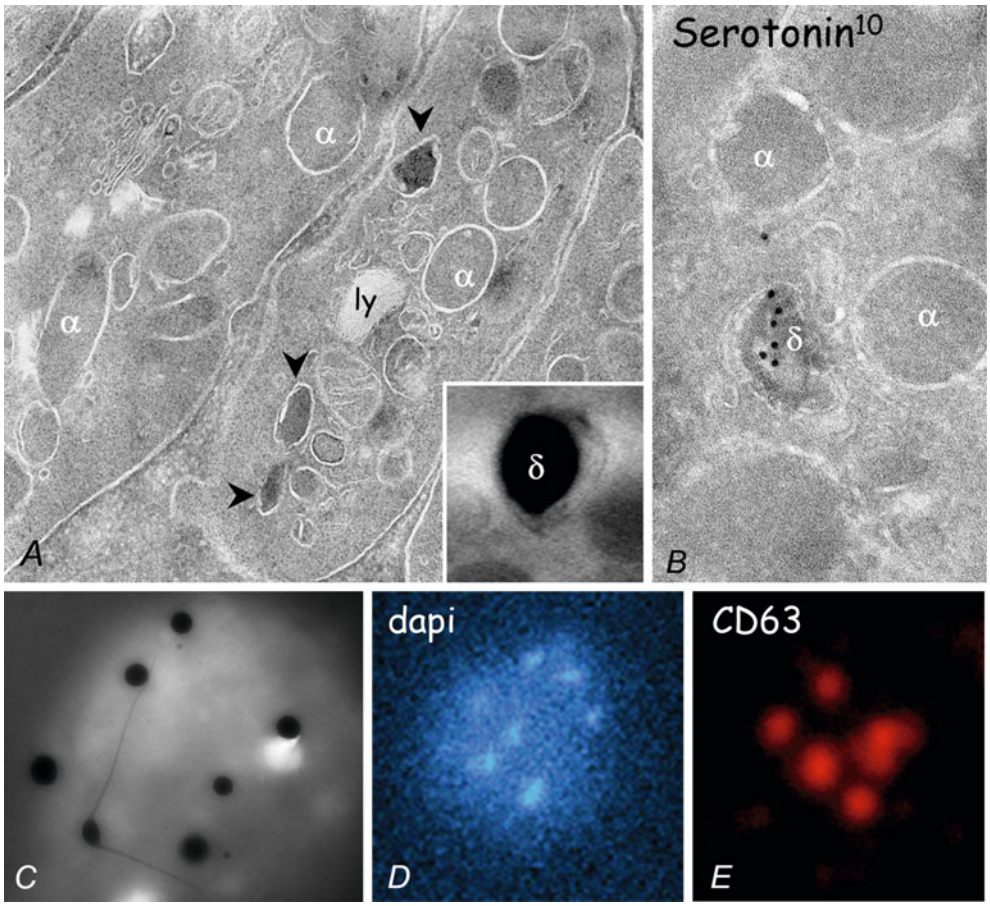

Fig. 8 Visualization of dense granules. (**a**) Uranaffin reaction on thin frozen sections showing dense granules (*arrowheads*). *Inset*, slice from a cryo-tomogram. (**b**) Immunogold labeling of serotonin in thin frozen section. (**c**) Whole-mount TEM visualization, showing the electron-opaque dense granules. or content markers (Fig. 8b). Dense granules contain the lysosomal membrane proteins CD63 and LAMP1/LAMP2 (Israels et al. 1992), which become expressed on the cell surface after activation. Translocation of these lysosomal markers to the cell surface can be monitored by FACS analysis or IF and may represent a functional readout for the identification of delta-storage pool deficiencies. Dense granules originate from endosomal precursors rather than from the trans-Golgi network (Meng et al. 2012) and play a crucial role in primary hemostasis by stimulating the platelet P2Y12 receptor after release of ADP, thereby initiating a feedback platelet activation cycle. The predominant presence of calcium and (poly)phosphates is the reason for their electron-opaque appearance in whole-mount EM and cryo-EM preparations (Fig. 8a, c, inset). This feature is lacking in the Hermansky-Pudlak (HPS) and Chediak-Higashi syndromes (CHS), two delta-storage pool disorders characterized by the absence or deficiency of dense granules. Whole-mount EM analysis represents a classic diagnostic tool for such disorders (Al Hawas et al. 2012). HPS is a rare autosomal recessive disorder caused by defects in any of nine genes, resulting in different subtypes of the syndrome, characterized by a defect in the secondary platelet response, oculocutaneous albinism, and life-threatening pulmonary fibrosis (Huizing et al. 2008). CHS is an autosomal recessive immunodeficiency disorder caused by mutations in the *LYST* or *CHS1* gene that affect the synthesis and/or maintenance of storage/secretory granules in various types of cells.

Lysosomes

Platelet lysosomes and residual bodies have been described in early immunocytochemistry studies (Bentfeld-Barker and Bainton 1982; Sixma et al. 1985; Behnke 1992). Platelet lysosomes contain acid hydrolases (e.g., cathepsins, hexosaminidase, β-galactosidase, arylsulfatase, β-glucuronidase, and acid phosphatase) as most important cargo, and similar as dense granules, they express CD63 and LAMP1/LAMP2 (Metzelaar et al. 1991). Lysosomes serve a role in the digestion of phagocytic and cytosolic components, similar to their roles in nucleated cells (Behnke 1992), and participate in the platelet secretory response (Holmsen and Day 1968). Secretion of lysosomal content may have several important extracellular functions such as supporting receptor cleavage, assisting fibrinolysis, and degradation of extracellular matrix components. Platelets have a core autophagy machinery, which is constitutively active and becomes upregulated

under starvation conditions and after activation (Feng et al. 2014; Ouseph et al. 2015). The cytosolic substrates that are target for autophagic sequestration in platelets are unknown. Platelet lysosomes may contribute to a process termed unconventional secretion, whereby selective cytosolic material is secreted (Nickel and Rabouille 2009). Recent studies have shown that platelets synthesize proteins (e.g., tissue factor, IL-1β, Bcl-3), which are released upon activation (Schwertz et al. 2006; Zimmerman and Weyrich 2008). The cytosolic nature of these newly synthesized proteins requires a special kind of secretory mechanism. Microvesicles, exosomes, and/or selective autophagic targeting and (auto)-lysosomal secretion may provide a way for these cytosolic proteins to exit the cell.

Platelet Cytoskeleton

Platelets contain three types of cytoskeletal elements: microtubules, the membrane skeleton, and the actin cytoskeleton. Microtubules in platelets are arranged in a marginal bundle at the cell periphery. Insights into the cytoskeleton and marginal band structure have come from early microscopic studies (Behnke 1967b; Behnke and Zelander 1967; Zucker-Franklin 1969; White 1982; White and Rao 1998). In contrast to the usual rigidity of microtubules in other cells, the platelet marginal band is remarkable flexible. β1-Tubulin, the major isoform, and unique for MKs and platelets, is the most important component of the microtubular coil and is thought to give the coil its flexibility and typical structural array, thereby maintaining the elliptical shape of the circulating platelets (Fig. 9). Mice lacking β1-tubulin have spherical platelets and a defective marginal band containing only 2–3 microtubule coils (Schwer et al. 2001; Italiano et al. 2003). Platelet microtubules are sensitive to environmental conditions. Platelet exposure to 4 °C induces a loss of the discoid shape (spherocytosis) due to disassembly of the microtubules (White 1982; White and Rao 1998). The marginal band in platelets has long been thought to be composed of a single microtubule, coiled at the platelet periphery. However, a recent study showed that it consists of a stable microtubular coil, with multiple associated, short dynamic microtubules and with both plus and minus ends arranged along the coil (Patel-Hett et al. 2008). Dynein-dependent sliding of microtubules, elongation, and MT band coiling induces the spherical shape during early platelet activation,

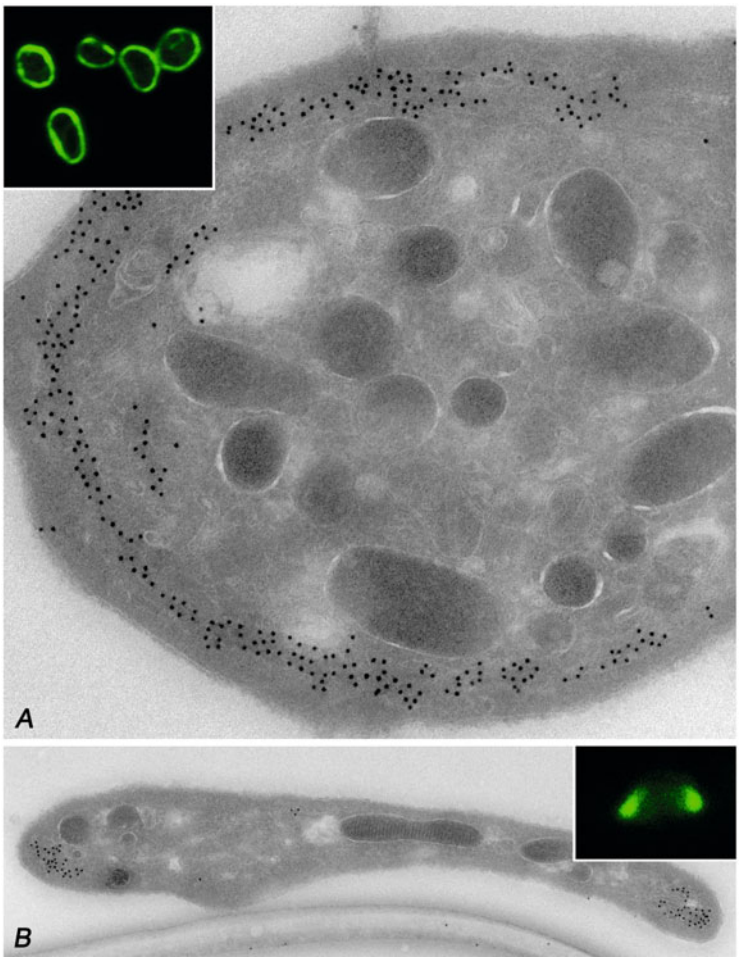

Fig. 9 Peripheral microtubular coil. Microtubules in platelets are arranged in a marginal bundle at the cell periphery. Immunofluorescence (*inset*) and immunogold staining of resting platelets using alpha-tubulin antibody. Staining patterns are shown in the equatorial (**a**) and cross-sectional plane (**b**)

whereby newly polymerizing microtubules in concert with actin-myosin tension (see below) will form a smaller microtubular ring (Diagouraga et al. 2014; Sadoul 2014).

The platelet cytoskeleton consists of a spectrin-rich membrane skeleton lining the inner plasma membrane and a network of long actin filaments that radiate from the cell center to the surface membrane (Fox et al. 1988). The percentage of filamentous actin rapidly increases upon platelet activation (Hartwig 1992, 1999), which, through actin-binding proteins, introduces a link of the cytoskeleton with surface membrane glycoproteins (Fox 1985). The membrane skeleton is essential for maintaining the structure and integrity of the surface membrane, whereas the cytoskeleton generates contractile forces within the cell, thereby regulating platelet shape change and granule dynamics during secretion (Painter and Ginsberg 1984; Flaumenhaft 2003). Early in vitro observations have shown that platelet secretion is accompanied by granule centralization, implicating actin-myosin dependent contractile forces facilitating the release of granule contents (Painter and Ginsberg 1984; White et al. 1984a; Flaumenhaft 2003). The exact mechanism, however, by which reorganization of the actin cytoskeleton affects granule fusion events remains poorly understood. Cortical actin has been reported to provide both a natural barrier as well as playing a facilitative role in regulated exocytosis in other nucleated cells (Orci et al. 1972; Muallem et al. 1995; Trifaró et al. 2008). Cytochalasins and latrunculin-A have been shown to increase cargo release from dense granules, indicating that actin depolymerization promotes dense granule exocytosis (Flaumenhaft et al. 2005; Ge et al. 2012). Actin and myosin are also required for the overall process of clot retraction (Zucker-Franklin and Grusky 1972; White and Burris 1984; Morgenstern et al. 1984, 1990), a process that is essential for stabilization of the thrombus. Specific whole-mount methods using detergent extraction and stabilization of the actin cytoskeleton by shadow-casting, freeze fracture methods, or IF staining of phalloidin have been developed to study the organization of the platelet cytoskeleton during adhesion and spreading (Hartwig and DeSisto 1991; Hartwig 1992; Poulter et al. 2015). Using a combination of EM and high-resolution IF microscopy approaches, two novel actin structures, podosomes and actin nodules, were recently characterized in megakaryocytes and platelets (Schachtner et al. 2013; Poulter et al. 2015). Actin nodules are linked by multiple actin bundles and play a key role in the spatial localization of adhesion-related proteins, e.g., integrins. Podosomes are actin-rich cytoskeletal elements required to degrade basement membranes in megakaryocytes, possibly enabling proplatelets to reach the sinusoids and form proper platelets. Loss of podosome formation has been suggested to contribute to the reduced platelet number, a smaller size of platelets, and lower granule number, observed in patients with Wiskott-Aldrich syndrome (WAS), an X-linked recessive disease (Schachtner et al. 2013; Poulter et al. 2015). Actin nodules can be monitored on adherent platelets using specific antibodies directed to actin, WASP, or ARP2/ARP3.

Platelet Microparticles (PMPs) and Exosomes

Platelet adhesion and activation is accompanied by the release of membrane-bound vesicles. The small-sized population (40–100 nm) of these membranes is secreted from the multivesicular granule population and is termed exosomes (Heijnen et al. 1999). Platelet-derived exosomes are enriched in CD63, a tetraspanin protein also found on exosomes from other cell types (Fig. 10a) (Escola et al. 1998; Raposo and Stoorvogel 2013). The larger microvesicles (100 nm–1 μm) derive directly from the PM by mechanisms that require platelet activation and calcium-dependent uncoupling of the lipid bilayer from components of the membrane skeleton (Wiedmer et al. 1990; Pasquet et al. 1996). Platelet microvesicles or PMPs are also generated as a result of the shearing forces generated by the flowing blood (Reininger et al. 2006; Cranmer et al. 2011; Tersteeg et al. 2014). Microvesicles and exosomes have been implicated in cell-to-cell communication and represent an important vehicle for interaction with leukocytes (Denzer et al. 2000; Tersteeg et al. 2014). Platelet-derived microvesicles generally have the same surface glycoprotein composition as the activated platelet plasma membrane (i.e., GPIb, the integrins $\alpha_{IIb}\beta_3$ and β1, P-selectin, and CD63). Platelet microvesicles have a high affinity for annexin-V and bind coagulation factors prothrombin and factor X in the presence of calcium. In contrast, platelet exosomes are enriched in cholesterol (Heijnen et al. 2003) and interact poorly with annexin-V, prothrombin, and factor X (Heijnen et al. 1999). Microvesicles and exosomes can function in the direct environment of adhering platelets, at sites of vascular injury, but can also generate long distance heterotypic signaling. Indeed, exosomes are found at contact sites between platelets and neutrophils (Fig. 10b), and PMPs have been observed in several diseases with an inflammatory component, e.g., in the synovial fluid of arthritic joints (Boilard et al. 2010). Platelets interact with leukocytes and monocytes ex vivo (Tersteeg et al. 2014), as well as in vivo in many inflammatory conditions (Weyrich and Zimmerman 2004; Franks et al. 2010). Recent studies have shown that platelet activation induces the synthesis and release of IL-1β (Lindemann et al. 2001), which is synthesized on polyribosomes in the cytoplasm, and can exit the cell via release of vesicles or exosomes. Indeed, IL-1β associated with PMPs supports leukocyte recruitment and the progression of arthritis (Boilard et al. 2010).

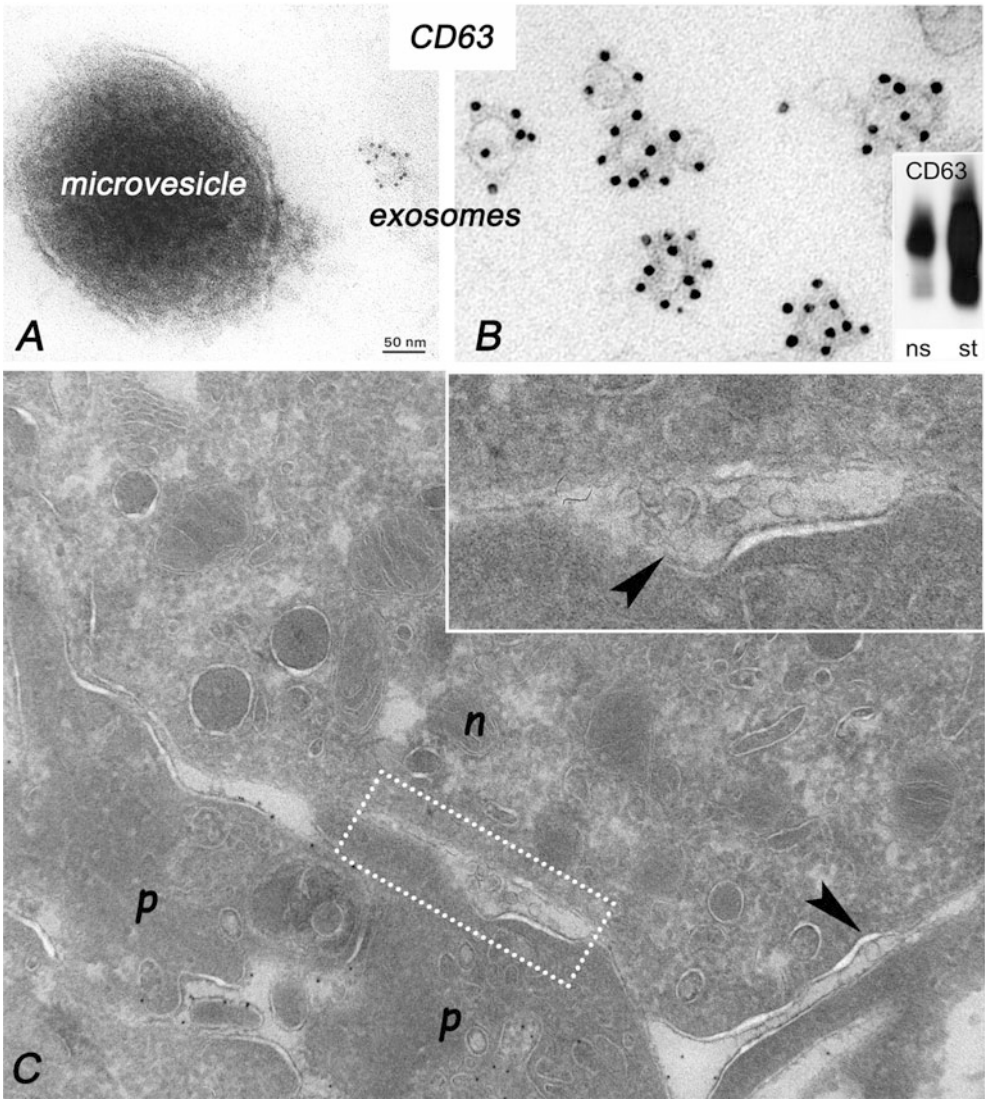

Fig. 10 Microparticles and exosomes. (**a**) Microparticles and exosomes isolated from the secretome of activated platelets. The microparticles contain predominantly cell surface glycoproteins (e.g., GPIb), whereas exosomes are enriched in CD63. *Inset* shows increase of exosome-bound CD63 in the releasate of *st* stimulated platelets. *ns* non-stimulated. (**b**) Neutrophil (N) interacting with adherent platelets (P; GPIb positive). Synaptic area between neutrophil and platelets contains released exosomes (*arrowheads* and highlighted *inset*)

Future Perspectives

The rapid developments in the field of live imaging, the use of sensitive high-speed CCD cameras, increasing subsets of specific fluorophores, and improved image analysis software will increase the applications of "real-time" imaging of platelet adhesion and thrombus formation under flow. It is expected that such methods become also available for high-throughput diagnostic studies of functional adhesion defects and platelet disorders. Rapid developments are also emerging in the field of high-resolution 3D EM, particularly cryo-electron tomography. These techniques open up the way to study (macro)-molecular complexes in their close-to-native cellular context. Such technologies will be increasingly introduced in the platelet field as well and will shed new light on fundamental aspects of platelet structure and function. Ultimately, these advances will lead to their application as high-throughput method, raising the possibility of using it as diagnostic tools in the clinical setting (Wang et al. 2015).

Take-Home Messages

New imaging technologies continuously improve our view on platelet structure and function:

- Live cell imaging is an essential tool to study platelet adhesion and aggregation defects under physiological flow.
- (Immuno)-electron microscopy remains an important tool to study macromolecular features at the ultrastructural level.
- New 3D imaging technologies provide increased insight into the platelet ultrastructure.

Megakaryocyte Development and Platelet Production

Joseph E. Italiano Jr.

Abstract

Blood platelets are 2–3 μm anucleate fragments that are formed from the megakaryocyte cytoplasm and have a distinctive discoid shape. To generate and release platelets, megakaryocytes undergo endomitosis to become polyploid and follow a maturation program that results in the transformation of the bulk of their cytoplasm into multiple long processes called *proplatelets*. To generate 1000–2000 platelets, a megakaryocyte may extend multiple proplatelets, each of which begins as a thick pseudopodium that over time elongates and branches repetitively. Platelets form predominantly at the tips of proplatelets. As platelets mature, their content of organelles and granules is delivered to them in a flow of individual cargo moving from the cell body of the megakaryocyte to the assembling platelets at the proplatelet ends. Platelet generation can be indiscriminately divided into two stages. The first stage takes days to complete and requires megakaryocyte-specific cytokines, such as thrombopoietin. Substantial nuclear proliferation to 16–32 × N and expansion of the megakaryocyte cytoplasm occur as the platelet is packed with platelet-specific granules, cytoskeletal proteins, and abundant membrane to complete the platelet assembly phase. The second stage is relatively fast and can be completed in hours. During this phase, megakaryocytes generate platelets by reorganizing their cytoplasm first into proplatelets, then preplatelets, which undergo fission to generate platelets. Each day, 100 billion platelets must be generated from megakaryocytes to sustain the normal platelet count of 2–3 × 10^8/mL.

Megakaryocyte Development

Megakaryocytes are large, specialized precursor cells that function to release platelets into the blood circulation. Uncovering mechanisms by which megakaryocytes develop and produce platelets has intrigued scientists for well over a century. Megakaryocytes are derived from pluripotent stem cells and undergo endomitosis, a process in which the cell undergoes multiple DNA replications without cell divisions. During endomitosis, polyploid megakaryocytes initiate a rapid cytoplasmic expansion stage typified by the formation of a highly invaginated demarcation membrane system (DMS) and the amassing of cytoplasmic proteins and granules fundamental for platelet function. During the final stages of development, the megakaryocyte cytoplasm undergoes a spectacular and massive reorganization into long, beaded cytoplasmic extensions called proplatelets. The proplatelets function as the assembly lines of platelet production and ultimately yield individual platelets.

Commitment to the Megakaryocyte Lineage

Megakaryocytes, like every terminally differentiated hematopoietic cell, originate from hematopoietic stem cells, which are responsible for continuous generation of all circulating blood cells. Hematopoietic cells are categorized by their surface markers, ability to reconstitute host animals, and colony assays that reflect their developmental potential. Hematopoietic stem cells are rare, making up less than 0.1 % of cells in the bone marrow. The development of megakaryocytes from hematopoietic stem cells involves an order of differentiation steps in which the developmental capacities of the progenitor cells become slowly more limited. Hematopoietic stem cells in mice are characteristically identified by the surface markers Lin-Sca-1+c-kit ^{high} (Li and Johnson 1995; Weissman et al. 2001). A comprehensive model of hematopoiesis has been developed from experiments analyzing the effects of hematopoietic growth factors on marrow cells contained in a semisolid media. Hematopoietic stem cells give rise to two major lineages, a common lymphoid progenitor that can develop into lymphocytes and a myeloid progenitor that can develop into eosinophil, macrophage, myeloid, erythroid, and megakaryocyte lineages. A common erythroid-megakaryocytic progenitor arises from the myeloid lineage (Akashi et al. 2000). However, new experiments also suggest that hematopoietic stem cells may directly develop into erythroid-megakaryocyte progenitors (Adolfsson et al. 2005). All hematopoietic progenitors express surface CD34 and CD41, and the commitment to the megakaryocyte lineage is indicated by expression of the integrin CD61 and elevated CD41 levels. From the committed myeloid progenitor cell (CFU-GEMM), there is convincing evidence for a bipotential progenitor intermediate between the pluripotential stem cell and the committed precursor that can develop into biclonal colonies composed of megakaryocytic and erythroid cells. The regulatory pathways and transcriptional factors that allow the erythroid and megakaryocyte lineages to separate from the bipotential progenitor are currently unknown. Diploid precursors that are committed to the megakaryocyte lineage have characteristically been divided into two colonies based on their functional capacities. The megakaryocyte burst-forming cell is a primitive progenitor that has a high proliferation capacity that gives rise to large megakaryocyte colonies. Under specific culture conditions, the megakaryocyte burst-forming cell can develop into 40–500 megakaryocytes within 1 week. The colony-forming cell is a more mature megakaryocyte progenitor that gives rise to a colony containing from 3 to 50 mature megakaryocytes that vary in their proliferation potential. Megakaryocyte progenitors can be readily identified in the bone marrow by immunoperoxidase and acetylcholinesterase labeling. Although both human megakaryocyte colony-forming and burst-forming cells express the CD34 antigen, only colony-forming cells express the HLA-DR antigen.

Several classification systems based on morphological features, biochemical markers, and histochemical staining have been used to categorize different stages of megakaryocyte development. In general, three types of morphologies can be identified in the bone marrow. The promegakaryoblast is the first recognizable megakaryocyte precursor. The megakaryoblast, or stage I megakaryocyte, is a more mature cell that has a well-defined morphology (Long et al. 1982). The megakaryoblast has a kidney-shaped nucleus with two sets of chromosomes (4N). It is 10–50 μm in diameter and looks intensely basophilic in Romanovsky-stained marrow preparations given the large numbers of ribosomes, although the cytoplasm at this stage lacks alpha and dense granules. The megakaryoblast displays a high nuclear-to-cytoplasmic ratio and, in rodents, is acetylcholinesterase positive. The promegakaryocyte, or stage II megakaryocyte, is 20–80 μm in diameter with a polychromatic cytoplasm. The cytoplasm of the promegakaryocyte is less basophilic than the megakaryoblast and now contains developing granules.

Polyploidization

Megakaryocytes, unlike most other cells, become polyploid by undergoing endomitosis, a process which involves repeated cycles of DNA replication without cell division (Ebbe 1976; Ebbe and Stohlman 1965; Odell et al. 1968, 1970; Therman et al. 1983). At the end of the proliferation phase, mononuclear megakaryocyte precursors exit the diploid state to differentiate and undergo endomitosis, resulting in a cell that contains multiples of a normal diploid chromosome content (i.e., 4N, 16N, 32N). Although the number of endomitotic cycles can range from 2 to 6, the majority of megakaryocytes undergo three endomitotic cycles to achieve a DNA content of 16N. Nonetheless, some megakaryocytes can acquire a DNA content as high as 256N. Megakaryocyte polyploidization results in a functional gene amplification whose probable role is an increase in protein synthesis parallel with cell expansion (Raslova et al. 2003). The mechanisms that power endomitosis are not completely understood. It was initially postulated that polyploidization may result from an absence of mitosis after each round of DNA replication. However, recent studies of primary megakaryocytes in culture indicate endomitosis does not result from a complete absence of mitosis, but rather a prematurely terminated mitosis (Raslova et al. 2003; Nagata et al. 1997; Vitrat et al. 1998). Megakaryocyte progenitors initiate the cycle and undergo a short G1

phase, a typical 6–7 h S phase for DNA synthesis, and a short G2 phase followed by endomitosis. Megakaryocytes begin the mitotic cycle and proceed from prophase to anaphase A, but do not enter anaphase B or telophase or undergo cytokinesis. During megakaryocyte polyploidization, the nuclear envelope breaks down and an abnormal spherical mitotic spindle forms. Each spindle attaches chromosomes that align to a position equidistant from the spindle poles (metaphase). Sister chromatids separate and begin to move toward their respective poles (anaphase A). However, the spindle poles fail to move apart and do not undergo the segregation typically observed during anaphase B. Individual chromatids are not moved to the poles and then a nuclear envelope reforms around the complete set of sister chromatids, assembling a single enlarged but lobed nucleus with multiple chromosome copies. The cell then skips telophase and cytokinesis to enter G1. This failure to completely segregate sets of daughter chromosomes may prevent the formation of a nuclear envelope around each individual set of chromosomes. In most cell types, feedback controls and checkpoints ensure that DNA replication and cell division are synchronized. Megakaryocytes appear to be the exception to this rule as they have managed to deregulate this process. Recent work has focused on defining the signals that regulate polyploidization in megakaryocytes (Ravid et al. 2002). It has been suggested that endomitosis may be the consequence of a reduction in mitosis-promoting factor (MPF) activity, a multiprotein complex consisting of Cdc2 and cyclin B (Gu et al. 1999; Wang et al. 1995). MPF contains a kinase activity that is necessary for entry of cells into mitosis. In most cell types, newly generated cyclin B binds to Cdc2 and produces active MPF, while cyclin degradation at the end of mitosis inactivates MPF. Conditional mutations in strains of budding and fission yeast that inhibit either cyclin B or cdc2 cause them to go through an additional round of DNA replication without mitosis (Broek et al. 1991; Hayles et al. 1994). In addition, studies using a human erythroleukemia cell line have established that these cells contain inactive cdc2 during polyploidization, and investigations with phorbol ester-induced Meg T cells have demonstrated that cyclin B is absent in this cell line during endomitosis (Brieher et al. 2006; Datta et al. 1996; Zhang et al. 1996). However, it has been hard to establish the role of MPF activity in promoting endomitosis because these cell lines have a limited ability to undergo endomitosis. Additionally, experiments using normal megakaryocytes in culture have demonstrated normal levels of cyclin B and cdc2 with functional mitotic kinase activity in megakaryocytes undergoing mitosis, suggesting that endomitosis can be regulated by signaling pathways other than MPF. Cyclins appear to play a critical role in directing endomitosis, though a triple knockout of cyclins D1, D2, and D3 does not appear to affect megakaryocyte development (Kozar 2004). Yet, cyclin E-deficient mice do exhibit a profound defect in megakaryocyte development (Geng 2003). It has recently been demonstrated that the molecular programming involved in endomitosis is characterized by the mislocalization or absence of at least two critical regulators of mitosis, the chromosomal passenger proteins Aurora-B/AIM-1 and surviving (Zhang et al. 2004). Whereas deletion of the APC/C cofactor Cdc20 causes mitotic arrest and severe thrombocytopenia, lack of the kinases Aurora-B, Cdk1, or Cdk2 does not affect endomitosis of megakaryocytes or platelet levels. Deletion of Cdk1 forces a change to endocycles without mitosis, whereas polyploidization in the absence of cdk1 and cdk2 occurs in the presence of aberrant replication events. Markedly, ablation of these kinases rescues defects in Cdc20 null megakaryocytes. The observations suggest that endomitosis can be functionally replaced by alternative polyploidization mechanisms in vivo (Trakala et al. 2015).

Cytoplasmic Maturation

During endomitosis, the megakaryocyte begins a maturation stage in which the cytoplasm rapidly fills with organelles, platelet-specific proteins, and membrane systems that will ultimately be organized and packaged into platelets. During maturation, the megakaryocyte enlarges dramatically and the cytoplasm acquires its unique ultrastructural features, including the formation of a demarcation membrane system (DMS), the development of a dense tubular system, and the assembly of granules (Fig. 1). During this phase of megakaryocyte development, the cytoplasm contains loads of ribosomes and rough endoplasmic reticulum, where protein synthesis occurs. One of the most striking features of a mature megakaryocyte is its elaborate DMS, an elaborate network of membrane channels composed of flattened cisternae and tubules. The organization of the cytoplasm into membrane-defined platelet territories was first proposed by Kautz and DeMarsh (1955), and a high-resolution description of this membrane system by Yamada soon followed (Yamada 1957). The DMS is noticeable in early promegakaryocytes, but becomes most prominent in mature megakaryocytes where it permeates the cytoplasm of the megakaryocyte, except for a thin rim of cytoplasm at the cortex from which it is excluded. It has been proposed that the DMS derives from the megakaryocyte plasma membrane in the form of tubular invaginations (Behnke 1968). The DMS is in contact with the external environment and can be labeled with extracellular tracers, such as lanthanum salts, ruthenium red, as well as tannic acid (Behnke 1968; Nakao and Angrist 1968; Zucker-Franklin et al. 1985). The DMS is enriched in polyphosphatidyl 4,5 bisphosphate and the vWf receptor. The exact function of this smooth membrane

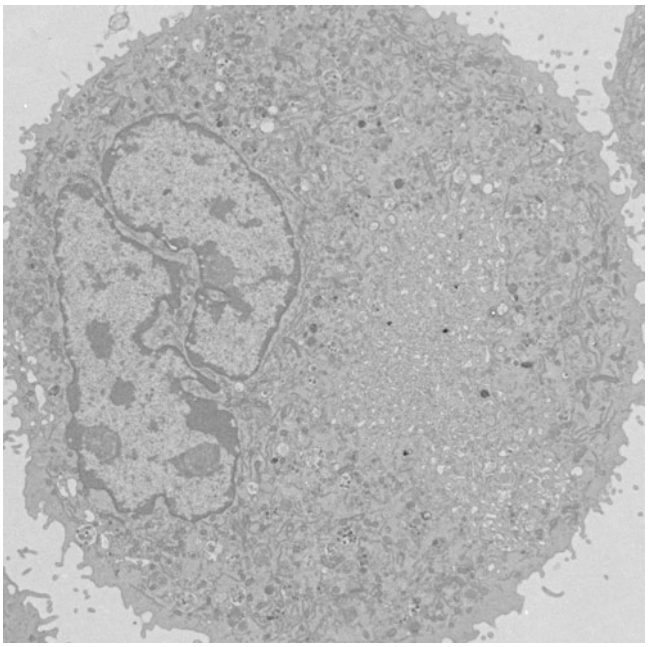

Fig. 1 Transmission electron micrograph of a mature murine megakaryocyte. Overview of one megakaryocyte showing multi-lobulated nucleus, mature cytoplasm, and invaginated membrane system. Megakaryocyte cultures generated from murine fetal liver cells were fixed with 1.25 % paraformaldehyde, 0.03 % picric acid, and 2.5 % glutaraldehyde in 0.1 M cacodylate buffer, pH 7.4, for 1 h, postfixed with 1 % osmium tetroxide, dehydrated through a series of alcohols, infiltrated with propylene oxide, and embedded in epoxy resin. Ultrathin sections were stained and examined with an electron microscope (G2 Spirit BioTwin; Tecnai) at an accelerating voltage of 80 kV. Images were recorded with a CCD camera (2K; Advanced Microscopy Techniques) using digital acquisition and analysis software

system has been debated for many years. Initially, it was proposed to play a key role in platelet production by establishing preformed "platelet territories" within the megakaryocyte cytoplasm (see below). However, more recent experiments suggest that the DMS functions mainly to dramatically increase the apparent membrane to surface ratio, functioning as a membrane reserve for proplatelet formation and extension. Experiments by Eckly et al. have begun to provide understandings into how the DMS forms and matures (Eckly et al. 2014). To develop the DMS, the megakaryocyte plasma membrane enfolds at specific sites and a perinuclear pre-DMS is generated. Next, the pre-DMS is expanded into its mature form by material added from golgi-derived vesicles and endoplasmic reticulum-mediated lipid transfer. This structural description is in line with studies on platelet glycosyltransferases, which arrive early in the developing DMS and eventually make their way to the megakaryocyte and platelet surfaces (Wandall et al. 2012). Only a few proteins have been identified this far to function in DMS formation based on alteration in its structure in certain knockout mouse models. Membrane-deforming proteins that use F-BAR domains to curve membranes, or GTP as an energy source to bud vesicles from membranes, appear to be necessary for normal megakaryocyte maturation and platelet release. Gross disruptions in DMS structure are found in megakaryocytes isolated from either filamin A knockout, dynamin 2 knockout, or Cdc42-interacting protein 4 (CIP4) knockout mice. CIP4 is an F-BAR protein that induces membrane tubulation and localizes to membrane lipids via its BAR domain and interacts with the Wiskott-Aldrich syndrome protein (Chen et al. 2013). CIP4-/- mice have a mild thrombocytopenia with a 25 % decrease in platelet counts. While megakaryocyte numbers and ploidy are normal in CIP4-/- knockout mice, megakaryocytes isolated from these mice are less effective in generating proplatelets in vitro. Dynamins are highly conserved mechanochemical GTPases that function in endocytosis and vesicle transport, and mutations in dynamin 2 have been associated with low platelet count in humans. Dynamin 2-dependent endocytosis is required for development of megakaryocytes in mice (Bender et al. 2015a). The DMS has also been proposed to mature into the open canalicular system (OCS) of the platelet, which functions as a channel for granule secretion. However, bovine megakaryocytes, which have a well-defined DMS, generate platelets that do not form an OCS, suggesting the OCS is not necessarily a remnant of the DMS (Zucker-Franklin et al. 1985).

Platelet Formation

The mechanisms by which blood platelets are produced have been studied for over a century. In 1906, James Homer Wright began a thorough analysis of how giant precursor megakaryocytes give birth to platelets (Wright 1906). Many theories have been proposed to explain how megakaryocytes yield platelets. The DMS, described in detail by Yamada in 1957, was first proposed to demarcate preformed "platelet territories" within the cytoplasm of the megakaryocyte (Yamada 1957). Microscopists recognized that developing megakaryocytes became packed with membranes and platelet-specific organelles and postulated that these membranes formed a system that defined fields for developing platelets (Shaklai et al. 1978). Release of individual platelets was proposed to occur by an immense fragmentation of the megakaryocyte cytoplasm along DMS fracture lines located between these fields. The DMS model proposes that platelets form through an elaborate internal membrane reorganization process (Kosaki 2005). Tubular membranes, which may originate from invagination of the megakaryocyte plasma membrane, are predicted to interconnect and branch, forming a continuous network throughout. The fusion of adjacent tubules has been suggested as a mechanism to generate a flat membrane that ultimately surrounds

the cytoplasm of an assembling platelet. Models attempting to use the DMS to explain how the cell cytoplasm becomes subdivided into platelet volumes and surrounded by its own membrane have lost support because of several inconsistent observations. For example, if platelets are demarcated within the cytoplasm of the megakaryocyte by the DMS, then platelet fields should exhibit the hallmark structural characteristics of resting platelets, which is not the case (Radley and Hatshorm 1987). Platelet territories within the megakaryocyte cytoplasm do not contain microtubule coils, one of the most characteristic features of resting platelet structure. In addition, there are no in vivo studies on living megakaryocytes directly demonstrating that platelet fields explosively fragment or shatter into mature, functional platelets. In contrast, studies that focused on the DMS of megakaryocytes before and after proplatelet retraction induced by microtubule-depolymerizing agents suggest this specialized membrane system may function primarily as a membrane reservoir that evaginates to deliver plasma membrane for the extensive growth of proplatelets (Radley and Haller 1982). Radley and Haller have proposed that the name DMS may be a misnomer and have suggested "invagination membrane system" as a more appropriate name to describe this membrane network.

The Proplatelet Theory

The majority of evidence that has been collected supports the proplatelet model of platelet generation. The term "proplatelet" is generally used to describe long (up to millimeters in length), thin cytoplasmic extensions radiating from megakaryocytes (Fig. 2) (Becker and De Bruyn 1976). These extensions are characterized by multiple platelet-sized beads connected together by thin cytoplasmic bridges and are thought to represent intermediate structures in the megakaryocyte to platelet transition (Fig. 3). The actual concept of platelets arising from these pseudopodia-like structures occurred when Wright recognized that platelets originate from megakaryocytes and described "the detachment of plate-like fragments or segments from pseudopods" emanating from megakaryocytes (Wright 1906). Thiery and Bessis (1956) and Behnke (1969) later described the morphology of these cytoplasmic processes extending from megakaryocytes during platelet formation in more detail. The classic "proplatelet theory" was introduced by Becker and De Bruyn, who proposed that megakaryocytes form long pseudopod-like processes that later fragment to give rise to individual platelets (Becker and De Bruyn 1976). In this early model, the DMS was still proposed to subdivide the megakaryocyte cytoplasm into platelet areas. Radley and Haller later developed the "flow model" which proposed that platelets originate exclusively from the interconnected platelet-sized beads connected along the shaft of proplatelets and suggested that the DMS did not function to define platelet fields but as a reservoir of surface membrane to be evaginated during proplatelet production (Radley and Haller 1982). Developing platelets was assumed to become encased by plasma membrane only as proplatelets were formed.

The bulk of experimental evidence now supports a modified proplatelet model of platelet formation. Proplatelets have been observed:

1. In a wide range of mammalian species, including mice, rat, guinea pigs, dogs, cows, and humans (Choi et al. 1995; Handagama et al. 1987; Leven 1987; Tablin et al. 1990).
2. Both in vivo and in vitro, and maturation of proplatelets yields platelets that are structurally and functionally similar to blood platelets (Choi et al. 1995; Cramer et al. 1997).

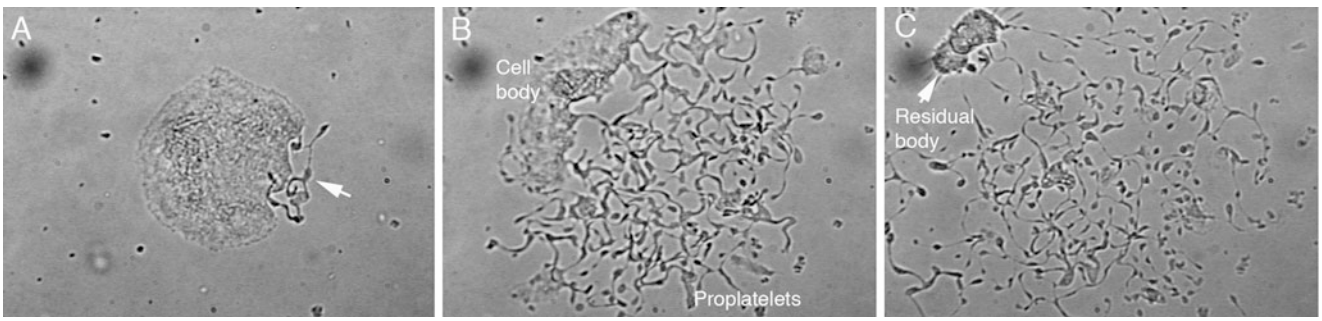

Fig. 2 Formation of proplatelets by a mouse megakaryocyte. Time-lapse sequence of a maturing megakaryocyte, showing the events that lead to elaboration of proplatelets in vitro. (**a**) Platelet production commences when the megakaryocyte cytoplasm starts to erode at one pole. (**b**) The bulk of the megakaryocyte cytoplasm has been converted into multiple proplatelet processes that continue to lengthen and form swellings along their length. These processes are highly dynamic and undergo bending and branching. (**c**) Once the bulk of the megakaryocyte cytoplasm has been converted into proplatelets, the entire process ends in a rapid retraction that separates the released proplatelets from the residual cell body

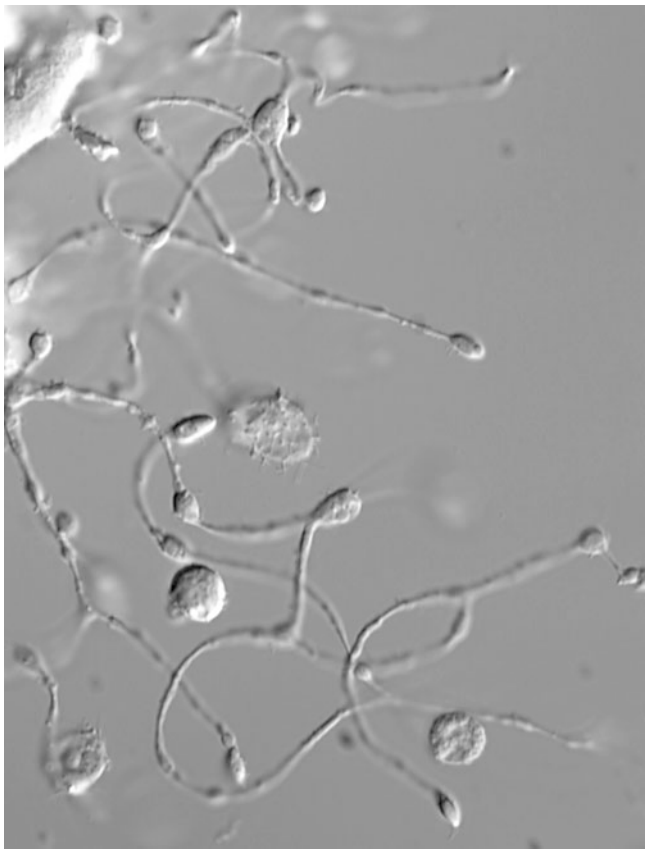

Fig. 3 Structure of proplatelets. Differential interference contrast (DIC) image of proplatelets elaborated by mouse megakaryocytes in culture. Proplatelets contain platelet-sized swellings that decorate their length giving them a beads-on-a-string appearance

3. Extending from megakaryocytes in the bone marrow through junctions in the endothelial lining where they have been hypothesized to be released into circulation and undergo further development into individual platelets (Lichtman et al. 1978; Scurfield and Radley 1981; Tavassoli and Aoki 1989).
4. To be absent in mice lacking two distinct hematopoietic transcription factors. These mice fail to generate proplatelets in vitro and display severe thrombocytopenia (Lecine et al. 1998; Shivdasani et al. 1995, 1997).

Taken together, these findings support an important role for proplatelet formation in thrombopoiesis.

Morphogenesis of Proplatelets

The discovery of thrombopoietin, the major physiological regulator of platelet production, and the development of megakaryocyte cultures that reconstitute platelet formation in vitro has provided systems to study megakaryocytes in the act of forming proplatelets. Time-lapse video microscopy of living megakaryocytes reveals both temporal and spatial changes that lead to the formation of proplatelets (Fig. 2) (Italiano et al. 1999). Conversion of the megakaryocyte cytoplasm concentrates almost all of the intracellular contents into proplatelet processes, and their platelet-sized particles, which in the final stages, appear as beads linked by thin cytoplasmic strings. The transformation unfolds over 5–10 h and commences with the erosion of one pole (Fig. 2) of the megakaryocyte cytoplasm. Thick pseudopodia initially form and then elongate into thin tubes of uniform diameter of 2–4 μm. These slender tubules, in turn, undergo a dynamic bending and branching process and form periodic densities along their length. Ultimately, the megakaryocyte is transformed into a "naked" nucleus surrounded by an extensive network of proplatelet processes. Megakaryocyte maturation ends when a rapid retraction separates the proplatelets from the cell body releasing them into culture (Fig. 2). The subsequent rupture of the cytoplasmic bridges between platelet-sized segments is believed to release individual platelets.

The Cytoskeleton Powers Platelet Production

The cytoskeleton of the mature platelet plays a crucial role in maintaining the discoid shape of the resting platelet and is responsible for the shape change that occurs during platelet activation. This same set of cytoskeletal proteins provides the force to bring about the shape changes associated with megakaryocyte maturation (Patel et al. 2005). Three cytoskeletal polymer systems exist in megakaryocytes: actin, tubulin, and spectrin. These proteins reversibly assemble into cytoskeletal filaments. Evidence supports a model of platelet production in which microtubules, actin filaments, and the spectrin-based membrane skeleton play key roles.

Microtubules Drive Proplatelet Extension Microtubules were first extensively studied in resting platelets. One of the most distinguishing features of the resting platelet is its marginal microtubule coil (White and Krivit 1967). αβ-Tubulin dimers assemble into microtubules under physiologic conditions, and in resting platelets, tubulin is equally divided between dimer and polymer fractions. In many cell types, the αβ-tubulin subunits are in a dynamic equilibrium with microtubules such that reversible cycles of assembly-disassembly of microtubules are observed. Microtubules are long, hollow polymers, 24 nm in diameter, and responsible for many types of cellular movements, such as the transport of organelles across the cell and the segregation of chromosomes during mitosis. The microtubule coil of the resting platelet, initially characterized in the late 1960s by Jim White, has been described as a single microtubule

approximately 100 μm long and is coiled 8–12 times inside the periphery of the platelet (White and Krivit 1967). The primary function of the microtubule coil is to maintain the disk shape of the resting platelet. Depolymerization of platelet microtubules with drugs such as vincristine, colchicine, or nocodazole causes platelets to become spherical and lose their discoid shape (White and Krivit 1967). Chilling platelets to 4 °C also causes disassembly of the microtubule coil and loss of the discoid shape. Furthermore, elegant studies show that mice lacking the major hematopoietic β-tubulin isoform (β1 tubulin) contain platelets that lack the characteristic disk shape and have defective marginal bands. Genetic elimination of β1 tubulin in mice results in low platelet count with mice containing circulating platelet counts below 50 % of normal. β1 tubulin-deficient platelets are spherical in shape and this appears to be due to defective marginal bands with fewer microtubule coilings. Whereas normal platelets possess a marginal band that consists of 8–12 coils, β1 tubulin knockout platelets contain only 2–3 coils (Schwer et al. 2001). Human β1 tubulin functional substitution (AG > CC) inducing both structural and functional platelet alterations has been described (Freson et al. 2005). The Q43P β1-tubulin variant was found in 10.6 % of the general population and in 24.2 % of 33 unrelated patients with undefined congenital macrothrombocytopenia. Electron microscopy revealed enlarged spherocytic platelets with a disrupted marginal band and structural alterations. Platelets with the Q43P β1-tubulin variant showed a mild platelet dysfunction, with reduced adenosine triphosphate (ATP) secretion, thrombin-receptor-activating peptide (Browne et al. 2000)-induced aggregation, and impaired adhesion to collagen under flow conditions. A more than doubled prevalence of the β1-tubulin variant was observed in healthy subjects not undergoing ischemic events, suggesting it could confer an evolutionary advantage and protective cardiovascular role. The microtubules that make up the coil are coated with proteins that regulate polymer stability (Kenney and Linck 1985). The microtubule motor proteins kinesin and dynein have been localized to platelets, but their roles in resting and activated platelets have not yet been defined.

Proplatelet formation is contingent on microtubule function as exposure of megakaryocytes to drugs that depolymerize microtubules, such as vincristine or nocodazole, blocks proplatelet production. Microtubules, hollow polymers assembled from αβ-tubulin dimers, are the major structural components of the engine that powers proplatelet elongation. Examination of the microtubule cytoskeletons of proplatelet-producing megakaryocytes provides insights as to how microtubules power platelet production (Fig. 4) (Patel, 2005 #4018). The microtubule cytoskeleton in megakaryocytes undergoes a spectacular reorganization during proplatelet production. In immature megakaryocytes without proplatelets, microtubules radiate out from the cell center (centrosome) to the cortex. As thick pseudopods form during the initiation of proplatelet formation, membrane-associated microtubules organize into thick bundles positioned just beneath the plasma membrane of these structures. And once pseudopodia begin to extend (at an average rate of 1 μm/min), microtubules form linear arrays that line the whole length of the proplatelet processes (Fig. 4). The microtubule bundles are thickest in the proplatelet near the body of the megakaryocyte but thin to bundles of approximately seven microtubules near proplatelet tips (Fig. 5). The distal end of each proplatelet always has a platelet-sized enlargement that contains a microtubule bundle that loops

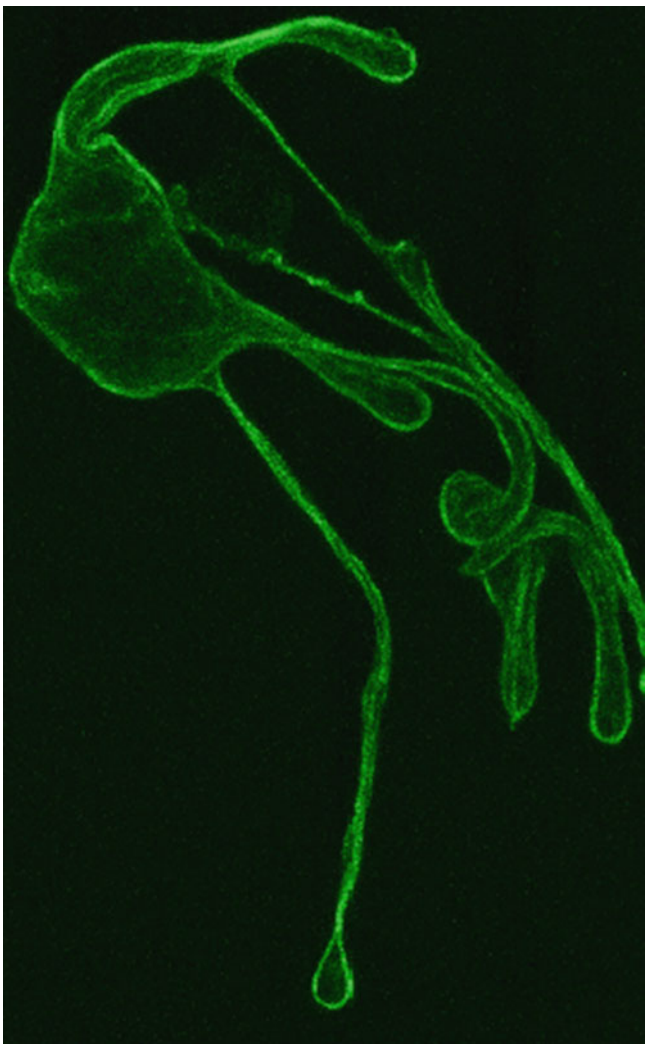

Fig. 4 Localization of microtubules within proplatelets. Immunofluorescence studies on murine megakaryocytes grown in culture and labeled with β1-tubulin antibodies indicate that microtubules line the entire length of proplatelets. The hallmark features of proplatelets, including the tip, swellings, shafts, and branch points, are visible

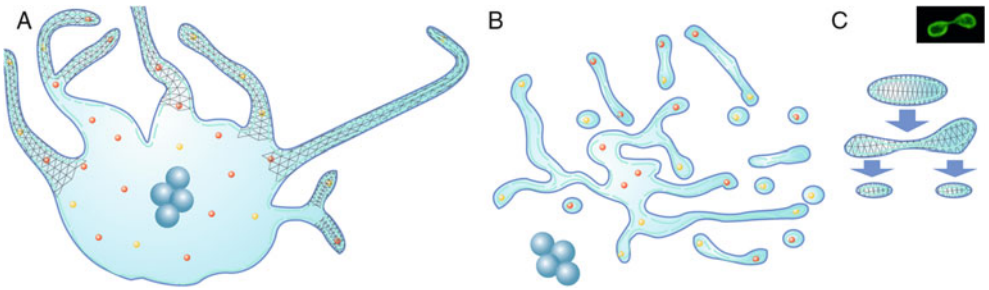

Fig. 5 Model of platelet production. (**a**) The formation of proplatelets begins with the extension of thick pseudopodia that use cortical bundles of microtubules to extend and form thin proplatelets with bulbous ends. Proplatelet membranes are laminated with an undercoat of spectrin. The ends of proplatelets contain a bundle of microtubules that loop on themselves. Proplatelet elongation involves the sliding of microtubules past one another, driven by the molecular motor cytoplasmic dynein. As proplatelets extend, development of the membrane surface area necessitates the outflow of the invaginated membrane reservoir, a process that requires reorganization of the membrane skeleton. Mitochondria and granules traffic (as indicated by the *orange* and *yellow spheres*) to the tips of proplatelets along microtubules, which function as the highways of the cell. Actin promotes the branching and amplification of proplatelet tips, representing a mechanism to augment the numbers of proplatelet tips and ultimately, platelets. (**b**) The entire megakaryocyte cytoplasm is converted into a mass of proplatelets. (**c**) Proplatelets continue to morph into preplatelets (anucleate discoid particles 2–10 μm across), which are released from the cell. Preplatelets reversibly convert into barbell proplatelets (*inset*, *top right*), a process that is driven by microtubule-based forces. The membrane skeleton stabilizes this barbell form. Platelets release from proplatelet ends after the final fission event. The nucleus is eventually extruded from the proplatelets, ending the role of the megakaryocyte in this process

just beneath the plasma membrane and reenters the shaft to form a teardrop-shaped or tennis racket-shaped structure. Because microtubule coils similar to those observed in blood platelets are detected only at the ends of proplatelets and not within the platelet-sized beads found along the length of proplatelets, mature platelets are formed predominantly at the ends of proplatelets.

Direct visualization of microtubule dynamics in living megakaryocytes using green fluorescent protein (GFP) technology has provided a window into how microtubules power proplatelet elongation (Patel et al. 2005). End-binding protein three (EB3), a microtubule plus end-binding protein associated only with growing microtubules, fused to GFP was retrovirally expressed in murine megakaryocytes and used as a marker to follow microtubule plus end dynamics. Immature megakaryocytes without proplatelets employ a centrosomal-coupled microtubule nucleation/assembly reaction, which appears as a prominent starburst pattern when visualized with EB3-GFP. Microtubules assemble only from the centrosomes and grow outward into the cell cortex where they turn and run in parallel with the cell edges. However, just before proplatelet production begins, centrosomal assembly stops and microtubules begin to consolidate into the cortex. Fluorescence time-lapse microscopy of living, proplatelet-producing megakaryocytes expressing EB3-GFP reveals that as proplatelets elongate, microtubule assembly occurs continuously throughout the entire proplatelet, including the swellings, shaft, and tip. The rates of microtubule polymerization (average of 10.2 μm/min) are approximately tenfold faster than the proplatelet elongation rate, suggesting polymerization and proplatelet elongation are not tightly coupled. The EB3-GFP studies also revealed that microtubules polymerize in both directions in proplatelets, e.g., both toward the tips and cell body, demonstrating that the microtubules composing the bundles have a mixed polarity.

Even though microtubules are continuously polymerizing in proplatelets, polymerization does not provide the force for proplatelet extension. Proplatelets continue to elongate even when microtubule polymerization is blocked by drugs that inhibit net microtubule assembly, suggesting an alternative mechanism for proplatelet extension (Patel et al. 2005). Consistent with this idea, proplatelets possess an inherent microtubule sliding mechanism. Cytoplasmic dynein, a minus-end microtubule molecular motor protein, localizes along the microtubules of the proplatelet and appears to directly contribute to microtubule sliding, since inhibition of dynein, through disassembly of the dynactin complex, prevents proplatelet formation. Microtubule sliding can also be reactivated in detergent-permeabilized proplatelets. ATP, known to support the enzymatic activity of microtubule-based molecular motors, activates proplatelet elongation in permeabilized proplatelets that contain both cytoplasmic dynein and its regulatory complex, dynactin. More recent analysis has indicated six types of behaviors characterize the elaboration of proplatelets: elongation, branching, pausing, fusions, fragmentations, and retractions. While the average elongation rate for proplatelets over time is 1 μm/min, extension normally occurs in bursts and pauses. Burst rates greatly exceed the average rates and under flow, and rates of >30 μm/min have been observed. These rates correlate well with the sliding rates of microtubules within

the bundles. Fluorescence recovery after photobleaching studies have demonstrated that microtubule sliding drives proplatelet elongation and is dependent on cytoplasmic dynein (Bender et al. 2015b). Thus, dynein-facilitated microtubule sliding appears to be the key event in driving proplatelet elongation.

Transport of Organelles and Granules into Assembling Platelets In addition to playing an essential role in proplatelet elongation, the microtubules lining the proplatelets serve a second function—the transport of membrane, organelles, and granules into proplatelets and assembling platelets at proplatelet ends. Individual organelles are sent from the cell body into the proplatelets where they move back and forth until they are captured at proplatelet tips (Richardson et al. 2005). Electron microscopy and immunofluorescence studies indicate that organelles are intimately associated with microtubules, whereas actin poisons do not block organelle motion. Thus, movement appears to involve microtubule-based forces. Bidirectional organelle movement is conveyed in part by the bipolar organization of microtubules within the proplatelet, as kinesin-coated latex beads move in both directions over the microtubule arrays of permeabilized proplatelets. Of the two major microtubule motors, kinesin and dynein, only the plus-end directed kinesin is localized in a punctate pattern similar to organelles and granules and is likely responsible for transporting these cargo along microtubules (Richardson et al. 2005). It appears that a twofold mechanism of organelle and granule movement occurs in platelet assembly. First, organelles and granules travel along microtubules, and second, the microtubules themselves can slide bidirectionally in relation to other motile filaments to indirectly move organelles along proplatelets in a piggyback manner.

Actin-Driven Branching and Elaboration of Proplatelets Actin, at a concentration of 0.5 mM, is the most plentiful of all the platelet proteins with two million molecules expressed per platelet (Nachmias and Yoshida 1988). Like tubulin, actin is in a very dynamic monomer-polymer equilibrium. Forty percent of the actin subunits polymerize to form the 2000–5000 linear actin filaments present in the resting cell (Hartwig and DeSisto 1991). The rest of the actin in the platelet cytoplasm is maintained in storage as a 1–1 complex with β4-thymosin (Safer and Nachmias 1994) and is converted to filaments during platelet activation to drive cell spreading. All evidence indicates that the filaments of the resting platelet are interconnected at various points into a rigid cytoplasmic network, as platelets express high concentrations of actin-crosslinking proteins including filamin and α-actinin (Rosenberg and Stracher 1982; Rosenberg et al. 1981). Both filamin and α-actinin are homodimers in solution. Filamin subunits are elongated strands composed primarily of 24 repeats, each ~100 amino acids in length that are folded into IgG-like beta barrels (Fucini et al. 1997; Gorlin et al. 1990). There are three filamin genes on chromosomes 3, 7, and X. Filamin A (X) (Gorlin et al. 1993) and filamin B are expressed in platelets with filamin A being present at greater than tenfold excess to filamin B. Filamin is now recognized to be a prototypical scaffolding protein that attracts binding partners and positions them adjacent to the plasma membrane (Stossel et al. 2001). Partners bound by filamin members include the small GTPase, RalA, Rac, Rho, and Cdc42 with RalA binding in a GTP-dependent manner (Ohta et al. 1999), the exchange factors Trio and Toll, kinases such as PAK1, phosphatases, and transmembrane proteins. Essential to the structural organization of the resting platelet is an interaction that occurs between filamin and the cytoplasmic tail of the GPIbα subunit of the GPIb-IX-V complex. The second rod domain (repeats 17–20) of filamin has a binding site for the cytoplasmic tail of GPIbα, and biochemical experiments have shown that the bulk of platelet filamin ($\geq$90 %) is in complex with GPIbα (Kovacsovics et al. 1995). This interaction has three consequences. First, it positions filamin's self-association domain and associated partner proteins at the plasma membrane while presenting filamin's actin-binding sites into the cytoplasm. Second, because a large fraction of filamin is bound to actin, it aligns the GPIb-IX-V complexes into rows on the surface of the platelet over the underlying filaments. Third, because the filamin linkages between actin filaments and the GPIb-IX-V complex pass through the pores of the spectrin lattice, it restrains the molecular movement of the spectrin strands in this lattice and holds the lattice in compression. The FLN-GPIbα connection is essential for the formation and release of discoid platelets by megakaryocytes as platelets lacking this connection are large and fragile and produced in low numbers. However, the role of the filamin-GPIbα connection in platelet construction per se is not fully clear. Because a low number of Bernard-Soulier platelets form and release from megakaryocytes, it can be argued that this connection is a late event in the maturation process and is not per se required for platelet shedding.

Each megakaryocyte has been estimated to release thousands of platelets (Harker 1978; Harker and Finch 1969; Kaufman et al. 1965; Trowbridge et al. 1984). Analysis of time-lapsed video microscopy of proplatelet development from megakaryocytes grown in vitro has revealed that ends of proplatelets are amplified in a dynamic process that repeatedly bends and bifurcates the proplatelet shaft (Italiano et al. 1999). Amplification of proplatelet tips initiates when a proplatelet shaft is bent into a sharp kink, which then folds back on itself, forming a loop in the microtubule bundle. The new loop eventually elongates, forming a new proplatelet shaft branching from the side of the original

proplatelet. Loops lead the proplatelet tip and define the site where nascent platelets will assemble and where platelet-specific contents are trafficked. In marked difference to the microtubule-based motor that elongates proplatelets, actin-based force is used to bend the proplatelet in end amplification. Megakaryocytes treated with the actin toxins, cytochalasin, or latrunculin can only extend long, unbranched proplatelets that are decorated with few swellings along their length. Despite extensive characterization of actin filament dynamics during platelet activation, how actin participates in this reaction and the cytoplasmic signals that regulate bending have yet to be determined. Electron microscopy and phalloidin staining of megakaryocytes undergoing proplatelet formation indicate that actin filaments are distributed throughout the proplatelet and are particularly abundant within swellings and at proplatelet branch points. One possibility is that proplatelet bending and branching is driven by the actin-based molecular motor myosin. A genetic mutation in the nonmuscle myosin heavy chain-A gene MYH9 in humans results in a group of diseases comprising May-Hegglin anomaly and (the) Sebastian, Fechtner, and Epstein syndromes, characterized by thrombocytopenia with giant platelets. Studies also indicate that protein kinase Cα (PKCα) associates with aggregated actin filaments in megakaryocytes undergoing proplatelet formation and inhibition of PKCα or integrin signaling pathways prevent actin filament aggregation and proplatelet formation in megakaryocytes (Rojnuckarin and Kaushansky 2001). Because proplatelets elongate, but do not branch in the presence of the actin-disrupting drug cytochalasin B, it is unexpected that the deletion of certain actin-associated proteins from the megakaryocyte lineage leads to macrothrombocytopenia. It seems likely that the removal of actin-modulating proteins alters and/or increases filamentous actin and the cytoskeletal structure appears to have a dominant inhibitory effect on proplatelet production and release. The absence of the cytoplasmic actin-crosslinking protein filamin A in conditional mice whose megakaryocyte lineage lacks filamin A results in macrothrombocytopenia in which platelet counts are reduced by 80–90 % (Begonja et al. 2011). Conditional mice lacking the actin turnover protein cofilin-1 in the megakaryocyte lineage also contain giant platelets with a platelet count reduced 60–80 % of normal. In contrast, mice lacking the actin turnover protein ADF have normal platelet counts and morphology (Bender et al. 2010). On the other hand, when ADF-/- mice are crossed with cofilin-1 knockout mice, platelet production is severely reduced and morphologies of platelets are highly variable. Mice that contain megakaryocytes that specifically lack profilin 1, a small protein that promotes actin filament assembly, have macrothrombocytopenia with reduced platelet counts (Bender et al. 2014). Profilin-null platelets have a thickened microtubule coil with hyper-acetylated microtubules, and in some ways, the profiling 1 knockout phenotype is similar to the behavior of platelets in Wiskott-Aldrich syndrome, or in WASp knockout mice. Defective proplatelet production has also been observed in mice in which the small regulatory GTPases Rho, Cdc42, and Rac have been deleted in the megakaryocyte lineage (Pleines et al. 2012, 2013).

The Spectrin Membrane Skeleton Whereas the functions of microtubules and actin filaments in proplatelet production have been extensively studied, our understanding of the role of the membrane skeleton has only recently been recognized. The OCS and plasma membrane of the resting platelet are supported by an elaborate cytoskeletal system. The platelet is the only other cell besides the red blood cell whose membrane skeleton has been visualized at high resolution. Like the erythrocyte, the platelet membrane skeleton is also a self-assembly of elongated spectrin strands that interconnect through their binding to actin filaments generating triangular pores. Platelets contain approximately 2000 spectrin molecules (Hartwig and DeSisto 1991; Fox et al. 1987, 1988). This spectrin network coats the cytoplasmic surface of both the OCS and plasma membrane systems. Although considerably less is known about how the spectrin-actin network forms and is connected to the plasma membrane in the platelet relative to the red blood cell, certain differences between the two membrane skeletons have been defined. First, the spectrin strands composing the platelet membrane skeleton interconnect using the ends of long actin filaments instead of short actin oligomers (Hartwig and DeSisto 1991). These ends arrive at the plasma membrane originating from filaments in the cytoplasm. Hence, the spectrin lattice is organized into a continuous network by its association with actin filaments. Second, tropomodulins are not expressed at sufficiently high levels, if at all, to have a major role in the capping of the pointed ends of the platelet actin filaments; instead, biochemical experiments have revealed that a substantial number (~2000) of these ends are free in the resting platelet. Third, although little tropomodulin protein is expressed, α-adducin is abundantly expressed and appears to cap many of the barbed ends of the filaments composing the resting actin cytoskeleton (Barkalow et al. 2003). Adducin is a key component of the membrane skeleton forming a triad complex with spectrin and actin. Capping of barbed filament ends by adducin also serves the function of targeting them to the spectrin-based membrane skeleton, as the affinity of spectrin for adducin-actin complexes is greater than for either actin or adducin alone (Kaiser et al. 1989; Kuhlman et al. 1996; Matsuoka et al. 1998, 2000). High-resolution electron microscopy reveals that proplatelets contain a spectrin-based membrane

skeleton similar in structure to that of blood platelets (Patel-Hett et al. 2011). Spectrin tetramer assembly is essential for the production of the DMS and proplatelet elaboration, as expression of a spectrin tetramer-disrupting peptide in megakaryocytes inhibits the progression of both processes. In addition, incorporation of this spectrin-disrupting construct into a detergent-permeabilized model system quickly destabilizes proplatelet morphology, causing massive swelling and blebbing. Spectrin tetramers also stabilize the barbell-shaped structures that give rise to individual platelets. Overall, these observations suggest a key role for spectrin in distinct steps of megakaryocyte development through its participation in the generation of the DMS and in the preservation of proplatelet structure.

Release of Individual Platelets

In vivo, proplatelets protrude into bone marrow sinusoids, where they are released and enter the bloodstream. Junt and colleagues as well as Massberg and colleagues have used intravital multiphoton microscopy to visualize proplatelet production in the opened cranial marrow cavity of living mice (Junt et al. 2007; Zhang et al. 2012). Fluorescently-labeled megakaryocytes could be observed to protrude proplatelets and release megakaryocyte fragments into the marrow sinusoids of living mice. Remarkably, these anucleate megakaryocyte fragments typically exceed platelet dimensions, suggesting that platelet morphogenesis continues in the circulation. Consistent with these observations, we have recently identified a previously unrecognized intermediate stage in platelet production and release, which we called the preplate (Thon et al. 2010). Preplatelets, which appear as "giant platelets," are classified as discoid cells (3–10 μm) that retain the capacity to convert into barbell-shaped proplatelets and undergo fission into platelets. Inhibitors of microtubule assembly block the conversion of preplatelets to barbells. Thus, the conversion of preplatelets to barbell proplatelets is powered by microtubule-based forces. It is tempting to speculate that the preplatelet fission reaction is a major regulator of platelet size and that some giant platelet disorders may represent a failure to convert preplatelets into barbell proplatelets. Force constraints resulting from cortical microtubule band diameter and thickness appear to regulate barbell-proplatelet formation, and platelet size is likely limited by microtubule bundling, elastic bending, and actin-myosin-spectrin cortex forces (Thon et al. 2012). Recently, it was demonstrated that individual human platelets have the innate capacity to duplicate and form new cell bodies that undergo fission into platelets (Schwertz et al. 2010). The morphological similarities between platelets that form new cell bodies and preplatelets are striking. Whether newly released platelets exhibit a preplatelet phenotype, which may allow them to form barbell shapes and divide again, is unclear.

Regulation of Platelet Formation In Vivo

While megakaryocyte maturation and platelet production have been extensively studied in vitro, studies analyzing the development of megakaryocytes in their in vivo environment have clearly lagged behind. Even though megakaryocytes arise in the bone marrow, they can migrate into the bloodstream and as a consequence platelet formation may also occur at non-marrow sites. Platelet biogenesis has been proposed to take place in many different tissues, including the bone marrow, lungs, and blood. Specific stages of platelet development have been observed in all three locations. Megakaryocytes cultured in vitro outside the borders of the bone marrow can form well-developed proplatelets in suspension, suggesting direct interaction with the marrow environment is not essential for platelet production. Nonetheless, the effectiveness of platelet production in culture appears to be reduced relative to that observed in vivo, and the bone marrow environment composed of a complex adherent cell population could play a role in platelet production by direct cell contact or secretion of cytokines. Scanning electron micrographs of bone marrow megakaryocytes with proplatelets protruding through junctions in the endothelial lining into the sinusoidal lumen have been published, suggesting platelet production occurs in the bone marrow (Behnke 1969; Lichtman et al. 1978; Scurfield and Radley 1981; Radley 1986; Radley and Scurfield 1980). Bone marrow megakaryocytes are strategically positioned in the extravascular space on the abluminal side of sinus endothelial cells and appear to extend proplatelet projections into the lumen of sinusoids. Electron micrographs show that these cells are anchored to the endothelium by organelle-free projections extended by the megakaryocytes. Several observations suggest that thrombopoiesis is dependent on the direct cellular interaction of megakaryocytes with BMECs specific adhesion molecules (Kopp et al. 2005). It has been demonstrated that the translocation of megakaryocyte progenitors to the vicinity of bone marrow vascular sinusoids was sufficient to induce maturation of megakaryocytes (Avecilla et al. 2004). Implicated in this process are the chemokines FGF-4 and SDF-1, which are known to stimulate expression of adhesion molecules, including very late antigen (VLA)-4 on megakaryocytes and VCAM-1 on BMECs (Avraham et al. 1993, 1994). Disruption of BMEC VE-cadherin-mediated homotypic intercellular adhesion interactions results in a profound inability of the vascular niche to support

megakaryocyte differentiation and to act as a conduit to the bloodstream.

Whether individual platelets are released from proplatelets into the sinus lumen or whether megakaryocytes preferentially release large proplatelet processes into the sinus lumen which later fragment into individual platelets within the circulation is not fully clear. Behnke and Forer have suggested that the final stages of platelet development occur solely in the blood circulation (Behnke and Forer 1998). In this model of thrombopoiesis, megakaryocyte fragments released into the blood become transformed into platelets while in circulation. This theory is supported by several observations:

First, the presence of megakaryocytes and megakaryocyte processes that are sometimes beaded in blood has been amply documented. Megakaryocyte fragments can represent up to 5–20 % of the platelet mass in plasma.

Second, these megakaryocyte fragments, when isolated from platelet-rich plasma, have been reported to elongate, undergo curving and bending motions, and eventually fragment to form disk-shaped structures resembling chains of platelets.

Third, since both cultured human and mouse megakaryocytes can form functional platelets in vitro, neither the bone marrow environment nor the pulmonary circulation is essential for platelet formation and release.

Lastly, many of the platelet-sized particles generated in these in vitro systems still remain attached by small cytoplasmic bridges.

It is possible that the shear forces encountered in circulation or an unidentified fragmentation factor in blood may play a crucial role in separating proplatelets into individual platelets. In response to acute platelet needs during periods of stress, thick protrusion release and megakaryocyte fragmentation have been recently described (Kowata et al. 2014; Nishimura et al. 2015).

Megakaryocytes have been visualized in intravascular sites within the lung, leading to the hypothesis that platelets are formed from their parent cell in the pulmonary circulation (Aschoff 1893). Aschoff first described pulmonary megakaryocytes and proposed that they originated in the marrow, migrated into the bloodstream, and, because of their massive size, were lodged in the capillary bed of the lung where they produced platelets. This mechanism requires the movement of megakaryocytes from the bone marrow into the circulation. Although the size of megakaryocytes would seem limiting, the transmigration of entire megakaryocytes through endothelial apertures of approximately 3–6 μm in diameter into the circulation has been observed in electron micrographs and by early living microscopy of rabbit bone marrow (Tavassoli and Aoki 1989). Megakaryocytes express the chemokine receptor CXCR4 and can respond to the CXCR4 ligand stromal cell-derived factor 1 (SDF-1) in chemotaxis assays. However, both mature megakaryocytes and platelets are non-responsive to SDF-1 suggesting the CXCR4 signaling pathway may be turned off during late stages of megakaryocyte development. This may provide a simple mechanism for retaining immature megakaryocytes in the marrow and permitting mature megakaryocytes to enter the circulation where they can liberate platelets. In humans, megakaryocytes are ten times more concentrated in pulmonary arterial blood than in blood obtained from the aorta (Levine and Willard 1983). In spite of these observations, the estimated contribution of pulmonary megakaryocytes to total platelet production remains unclear, as values have been estimated from 7 to 100 %. Experimental results using accelerated models of thrombopoiesis in mice clearly demonstrate that the fraction of platelet production occurring in the murine lung is insignificant. Davis and colleagues reported that megakaryocytes and their naked nuclei were rarely observed in lung tissue even after strong stimulation of thrombopoiesis.

Conclusion

Megakaryocytes are highly specialized precursor cells that function exclusively to generate and release platelets. After completing endomitosis, polyploid megakaryocytes undergo a rapid cytoplasmic expansion phase characterized by the formation of an extensive demarcation membrane system and the accumulation of cytoplasmic proteins and granules critical for platelet function. During the final stages of development, the megakaryocyte cytoplasm undergoes a massive remodeling in cytoplasmic extensions termed proplatelets. Proplatelets function as the assembly lines of platelet production. Microtubules, actin filaments, and the spectrin membrane skeleton all contribute to the formation of proplatelets and production of individual platelets.

Take-Home Messages

- Hundred billion new platelets are produced daily from bone marrow megakaryocytes in order to maintain platelet counts of 150–400 $\times$ 10^9 platelets/L of whole blood.
- Megakaryocytes are derived from hematopoietic stem cells in the bone marrow and migrate from the osteoblastic niche to the vascular niche during maturation.

(continued)

- Megakaryocytes undergo endomitosis and cytoplasmic maturation as they undergo cytoplasmic maturation.
- Mature megakaryocytes remodel their cytoplasm into long cytoplasmic processes called proplatelets; they extend into sinusoidal blood vessels.
- Proplatelets function as the assembly lines of platelet production.
- The cytoskeleton provides the force to power the elaboration of proplatelets.
- Growth hormones and extracellular matrix proteins in the bone marrow direct hematopoietic stem cell differentiation, megakaryocyte maturation, and proplatelet production.
- Platelet release occurs in the vasculature through barbell proplatelet and circular preplatelet intermediates.

Platelet Heterogeneity

Shawn Jobe

Abstract

The heterogeneity of platelets is present at rest, upon stimulation by agonists, and within the hemostatic plug. Circulating platelets are heterogeneous in size, age, and responsiveness. Differences in platelet size, platelet age, and platelet genetics can result in variable reactivity and altered interactions of platelets both within and between individuals. Following stimulation by strong agonists, distinct activated platelet subpopulations of spread and aggregating platelets and procoagulant platelets can be identified. Procoagulant platelets differ in morphology and function from spread and aggregating platelets. Finally, morphologically and functionally distinct platelet subpopulations participate in the spatiotemporal regulation of hemostatic plug and thrombus formation.

Platelet Size Heterogeneity

Circulating platelets vary in size from less than 2 to >15 μm^3 during steady-state hematopoiesis (Paulus 1975). This wide variation differs from the more homogeneously sized circulating white and red blood cell populations. Increased platelet size has been correlated with increased platelet reactivity and function. Larger platelet size has been correlated with increased aggregability to physiological agonists, increased dense granule number and release of dense granule contents, and increased surface density of the fibrinogen receptor, $\alpha_{IIb}\beta_3$ (Karpatkin 1978; Thompson et al. 1982; Giles et al. 1994). A prevalence of young, reticulated platelets among larger platelets may contribute to this increased reactivity. In patients treated with multiple antiplatelet agents, residual platelet reactivity of platelets to agonist stimulation is associated with higher numbers of circulating immature platelets and a higher mean platelet volume (MPV) (Cesari et al. 2008; Guthikonda et al. 2008).

The inclusion of mean platelet volume as a measured variable in automated cell counters allows its ready evaluation as a potential risk-assessment tool. This has led to numerous studies investigating potential association with inflammatory and thrombotic diseases. Although readily measured, a number of preanalytic conditions can affect the MPV. The use of EDTA-anticoagulated blood and a standard time between collection and measurement is currently recommended to minimize these differences (Lancé et al. 2012, 1993). A significant increase in MPV has been associated with greater likelihood of a plethora of conditions and events, among these being complications of obstructive sleep apnea (Sökücü et al. 2014), erectile dysfunction (Otunctemur et al. 2015), morbidity in patients with infective endocarditis (Gunebakmaz et al. 2010), progression to hepatocellular carcinoma in chronic liver disease (Kurt et al. 2012), and even likelihood of mortality in patients admitted to the intensive care unit (Zampieri et al. 2014). Best studied are thrombotic events, both arterial and venous, and their association with MPV.

Numerous studies have demonstrated an association of MPV with both the initial incidence and recurrence of acute

myocardial infarction and its complications (Martin et al. 2012). At initial presentation, the MPV of patients with non-ST-segment elevation acute myocardial infarction (AMI) is higher than controls (López-Cuenca et al. 2012). A meta-analysis published in 2010 of more than 2500 patients from 16 studies similarly demonstrated that MPV measured at the time of diagnosis was higher in patients presenting with AMI than in those without AMI (Chu et al. 2010). In this study, MPV was significantly higher regardless of whether the comparison group included studies utilizing either patients with unstable angina, with stable coronary artery disease, or those without coronary disease. Additionally, MPV was demonstrated to be associated with significantly higher risk of death or restenosis. A cross-sectional study of approximately 40,000 men and women from the Copenhagen General Population Study demonstrated an association between increasing MPV and occurrence of myocardial infarction (Klovaite et al. 2011). This association persisted even when adjusted for other cardiovascular risk factors.

Although not as strongly supported as atherothrombotic disease, platelets are increasingly recognized as a participant in venous thromboembolic disease (Schulz et al. 2013). In a population-based study of more than 25,000 subjects, MPV was found to be strongly associated with venous thromboembolism. Baseline MPV was ascertained in subjects aged 25–96 years, and these subjects were followed for 13 years (Braekkan et al. 2010). Four hundred and forty-five episodes of VTE occurred in the follow-up period with 186 of these incidents considered unprovoked. Subjects with an MPV of >9.5 fL at baseline had a 1.5-fold greater likelihood of unprovoked VTE than subjects with an MPV < 8.5 fL. This association of MPV with the incidence of VTE persisted even when adjusted for multiple additional risk factors, including age, sex, smoking, body mass index, and platelet count.

As outlined above, evidence clearly exists indicating an association between MPV and vaso-occlusive events. However, difficulties in both reproducible sampling and questions regarding its utility limit the current use of MPV as a risk stratification tool in clinical settings. It remains contested whether this association indicates a causal effect of increased MPV, meaning related to increased intrinsic platelet reactivity, or is a correlate related to other inflammatory or vascular events. Furthermore, as the etiology of these changes is uncertain, MPV at this time remains a static risk factor. Strategies to alter MPV, even if found to be useful, have yet to be determined.

Many of the first studies to investigate the etiology of variations in MPV in the general population focused on the hypothesis that platelet size heterogeneity was the result of an age-dependent decrease in size. In studies following radiolabeled platelets, both platelet size and young age were found to be positively associated with increased platelet reactivity, but these effects were independent of each either. No association between platelet size and age were identified during steady-state hematopoiesis (Thompson et al. 1983, 1984; Thompson and Jakubowski 1988). This contrasts with the non-steady-state situation observed in thrombocytopenic patients with a low platelet mass and correspondingly increased platelet production. An association between MPV, megakaryocyte size and increased megakaryocyte ploidy, and myocardial infarction has been noted (Trowbridge et al. 1984). This might suggest that intrinsic alterations in the megakaryocyte-platelet axis are causally related to both the increased MPV and its association with thrombotic events. Interestingly, recent studies indicate that alterations in the activity of the megakaryocyte scavenger receptors ABCG4 and ABCB6, regulators of cholesterol efflux and porphyrin metabolism, respectively, affect both the reactivity of circulating platelets and their thrombotic potential (Murphy et al. 2013, 2014). An intriguing hypothesis is that the megakaryocyte-platelet axis senses alterations of the vasculature through these or similar receptors and alters the platelet phenotype in response.

Age- and Maturation-Related Platelet Heterogeneity

Platelet characteristics vary throughout their lifetime in circulation. Various stages of platelet maturation have been demonstrated. To generate a platelet, mature megakaryocytes extend long, branching processes into the sinusoidal blood vessels of the bone marrow. This process of intravascular proplatelet extension by the extravascular megakaryocytes has been directly observed in murine bone marrow (Junt et al. 2007). By continued shearing of these intravascular proplatelet extensions, multiple proplatelets are thus derived from a single extravascular megakaryocyte. As these proplatelets are larger than the discoid platelet, additional stages of platelet maturation have been proposed. Fragmentation of these larger proplatelets due to shear, primarily within the lung, results in the generation of platelets (Zucker-Franklin and Philipp 2000). Another maturation stage of platelet development, the preplatelet, has recently been described (Thon et al. 2010). These circular large platelets have increased RNA content suggesting that they may be related to the young, or reticulated, platelet (Dale et al. 1995). Preplatelets convert reversibly to and from barbell-shaped platelets. Midline fission of the "barbell" results in the formation of two discoid platelets. These preplatelets may correspond to the duplicating platelet. Duplicating platelets, observed in vitro and in suspension culture, are the result of new protein translation and organelle formation from a single discoid platelet (Schwertz et al. 2010).

Proplatelet extension accounts for the large majority of newly formed platelets in non-stressed conditions. However, in response to acute platelet depletion or inflammatory stimuli, another method of platelet production accounts for a larger fraction of platelet production (Nishimura et al. 2015). Using two-photon in vivo microscopy acute megakaryocyte rupture with platelet fragmentation has recently been described in a subpopulation of megakaryocytes. This process, distinct from the slower process of proplatelet extension, results in the rapid formation of large numbers of platelets. Megakaryocyte rupture is enhanced in inflammatory conditions and acute platelet depletion and is regulated in a thrombopoietin-independent manner by the cytokine IL-1α. Interestingly, the reticulated platelet formed by this process tended to be larger in size suggesting the possibility that differential utilization of these methods of platelet production could account for some of the variations in platelet heterogeneity that have been described in human populations.

In addition to discoid platelets, platelet microparticles circulate in plasma. These cellular fragments are characterized by their size and the presence of platelet receptors on their surface. Microparticles are generated from both activated platelets and directly from megakaryocytes. When derived from activated platelets, microparticles have a short-circulating lifespan and are characterized by the presence of negatively charged phospholipids on their surface (Rand et al. 2006). These microparticles range in size from 0.1 to 1 μM in diameter with the smaller diameter particles consisting of membrane-enclosed and membrane-extruded platelet organelles. Both α-granules and isolated functional mitochondria have been demonstrated within these particles (Heijnen et al. 1999; Boudreau et al. 2014). Various functions have been attributed to these microparticle fractions. Transfer of mRNA, miRNA, and even transcription factor proteins from platelet microparticles to endothelial cells and macrophages has been demonstrated to regulate gene expression (Laffont et al. 2013, 2015; Risitano et al. 2012; Ray et al. 2008). A second class of circulating microparticles is derived directly from megakaryocytes. Distinct from activated platelet-derived microparticles, the megakaryocytic-derived microparticles express neither α-granule-derived CD62P nor the lysosomal protein LAMP-1 on their surface (Flaumenhaft et al. 2009).

Heterogeneity of Platelet Genetics

Anucleate platelets are unable to transcribe RNA from DNA. However, the machinery and templates to process and translate RNA are both present and utilized by platelets (Denis et al. 2005; Weyrich et al. 1998). Heterotypic transfer of RNA both to and from platelets has also been demonstrated. Selective transfer of specific RNAs from the megakaryocyte to the proplatelet determines the RNAs present in platelets, or the platelet transcriptome. Cecchetti et al. investigated the expression of matrix metalloproteinase (MMP)-encoding mRNAs and proteins in megakaryocytes and platelets together with their inhibitors (TIMP). Five of ten *MMP*s and one of three *TIMP*s were present in megakaryocytes but not in platelets. For example, *TIMP*-1 mRNA was abundantly expressed in both megakaryocytes and platelets, while *TIMP*-3 mRNA was highly expressed solely in megakaryocytes (Cecchetti et al. 2011). Variations of the platelet transcriptome have been demonstrated in multiple acute and chronic disease states. Compared with patients with stable coronary disease, patients with acute ST-segment elevation myocardial infarction (STEMI) had differential expression of at least 54 RNAs. Both the mRNAs for the transmembrane receptor CD69 and myeloid-related protein (MRP)-14 were increased two- to fourfold in STEMI platelets (Healy et al. 2006; Wang et al. 2014). Similarly, differential gene expression has been demonstrated in non-ST elevation acute coronary syndrome relative to those with stable cardiac disease (Colombo et al. 2011). Platelet transcriptomic differences have been associated with an increased presence of vascular disease in patients with systemic lupus erythematosus (Lood et al. 2010). Significant increases in RNAs and proteins within the type I interferon-regulated signaling pathway were found. Finally, utilization of platelets as a kind of systemic RNA surveillance mechanism has been suggested based on their ability to scavenge tumor-derived RNA-containing microvesicles. In patients with both prostate cancer and glioma, tumor-derived RNA has been detected in platelets (Nilsson et al. 2011).

Heterogeneity of Activated Platelets (Procoagulant Platelets)

Heterogeneity is also noted among platelets following platelet activation. Platelet activation is characterized by changes in both the morphologic and functional characteristics of the discoid platelet. Among these are:

A change in shape of the platelet from a rigid disc to a spread, space-filling confirmation when on a surface or an amorphous globule with filipodial extensions when observed in suspension (Hartwig 2006; Sakurai et al. 2015)

An incorporation of intracellular granules into the platelet membrane that is accompanied by the extracellular expulsion of their contents and the incorporation of the granule's membrane proteins into the plasma membrane (Ren et al. 2008)

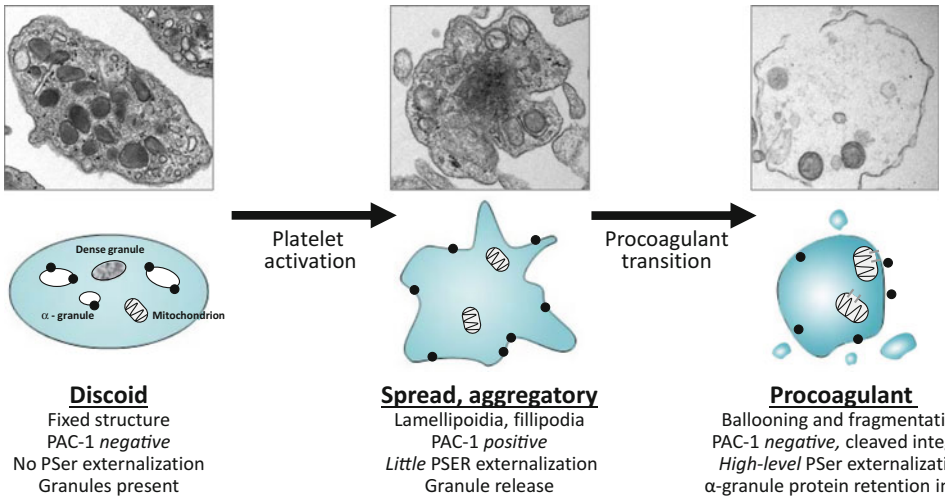

Fig. 1 Subpopulations of activated platelets. Activation of discoid platelets by platelet agonists results in extension of lamellipodia and filipodia (spreading), a change in the integrin conformation from inactive to active (PAC-1 positive), and release of alpha and dense granule. When stimulated by strong agonist(s), a subpopulation of spread platelets transition to become procoagulant platelets. These procoagulant platelets balloon and fragment; phosphatidylserine is externalized; the integrin conformation is again altered (see text), and alpha-granule proteins are retained in a cap on the platelet surface. Transmission electron micrographs (*top*) are murine platelets representative of each subpopulation prior to and following stimulation with thrombin and the GPVI agonist convulxin (Jobe SM)

A functional change in the platelet glycoprotein integrin $\alpha_{IIb}\beta_3$ that allows its interaction with soluble fibrinogen and, consequently, platelet aggregation as multiple activated platelets interact (Plow et al. 2014)

A rapid equilibration of the normally maintained plasma membrane asymmetry that results in the movement of negatively charged and procoagulant phospholipids from the internal plasmalemmal surface to the external platelet surface (Heemskerk et al. 2002)

Procoagulant Platelets and Platelet Phosphatidylserine (PSer) Externalization Not all activated platelets demonstrate all of these characteristics, and two subpopulations of activated platelets with distinctive subsets of these features can be discerned (Fig. 1). The initial experiments that described the activated platelet tended to be performed in bulk suspension. With the development of flow cytometry and epifluorescent microscopic techniques, it became clear that not all of the characteristics described above were equally distributed among activated platelets. This was true especially when these platelets had been activated by combinations of agonists or flowed over a collagen surface. Using flow cytometry in combination with labeled factor V or factor VIII, a population of platelet particles with high levels of coagulation factor binding was identified (Sims et al. 1988, 1989; Gilbert et al. 1991). Studies using annexin V, a protein with high affinity for PSer, demonstrated that the increased coagulation factor binding was due to high levels of PSer (Thiagarajan and Tait 1990, 1991; Dachary-Prigent et al. 1993).

Based on various functional and morphologic characteristics of this procoagulant subpopulation of activated platelets, a variety of names has been assigned to platelets with similar features. These include balloon-like (Heemskerk et al. 1997) or ballooned and procoagulant-spread (BAPS) (Agbani et al. 2015) platelets, convulxin and thrombin-induced-factor V (COAT-FV) platelets (Alberio et al. 2000), coated platelets (Dale 2005), sustained calcium-induced platelet morphology (SCIP) (Kulkarni and Jackson 2004), highly activated platelets (Jobe et al. 2008), and procoagulant platelets (Mattheij et al. 2013). The distinguishing characteristic of the procoagulant platelet subpopulation is the presence of high levels of PSer on the external platelet surface. PSer consists of a phospholipid tail with a negatively charged serine head. Normally, it is sequestered within the inner leaflet of the bilayer plasma membrane. In procoagulant platelets, activation of a scramblase causes this asymmetry to be rapidly lost, and PSer is externalized (Bevers et al. 1983). PSer potently facilitates the assembly of the tenase and prothrombinase coagulation complexes on the platelet surface. In the presence of small amounts of activated coagulation factors, procoagulant platelet formation results in the generation of large amounts of thrombin and the conversion of fibrinogen to fibrin (Rosing et al. 1985a, b). Externalized PSer is also recognized by macrophages and may be an important marker for the clearance of procoagulant platelets (Fadok et al. 1992).

Procoagulant Platelets and Platelet Morphology Unique morphologic characteristics distinguish the procoagulant platelet subpopulation from other activated platelets.

Among collagen-adherent platelets, procoagulant platelets are distinguished by their balloon-like appearance (Heemskerk et al. 1997; Agbani et al. 2015). This ballooning is the consequence of a rapid expansion of a small membrane extension from a non-collagen-adherent portion of the platelet surface (Agbani et al. 2015). These balloon-like platelets are also observed in hemostatic plugs, primarily in regions adjacent to collagen and on the non-luminal (vascular lumen) surface of the hemostatic plug (Wester et al. 1978; Hovig et al. 1967). Procoagulant platelets that had previously spread on fibrinogen or another extracellular surface due to integrin activation have a variant of this morphology. A central rounded platelet fragment, or balloon, is surrounded by numerous small particles distributed in the region where the platelet had previously spread (Kulkarni and Jackson 2004; Jobe et al. 2008).

Intracellularly, procoagulant platelets are marked by the absence of distinguishing organelles, including platelet granules, with the exception of occasional mitochondria seen in apposition to the cell membrane, and an electron-lucent amorphous cytoplasm (Agbani et al. 2015). In suspension, the spherical procoagulant platelet has a small portion of the plasma membrane or "cap" consisting of fibrin and other α-granule proteins (Abaeva et al. 2013). In the presence of flowing leukocytes, adherent procoagulant platelets extrude long tethers called flow-induced protrusions or FLIPRs that extend as long as 250 μm in the direction of flow (Tersteeg et al. 2014). These FLIPRs break to generate small fragments or microparticles. Similarly, ballooned and procoagulant-spread (BAPS) platelets in situations of low or minimal flow will disintegrate into a multitude of small procoagulant microvesicles that can support prothrombinase activity and fibrin formation (Agbani et al. 2015).

Procoagulant Platelet Formation and Platelet Adherence The adherence properties of the procoagulant platelet markedly differ from the spread or aggregating activated platelet. When platelets are flowed over a monolayer of spread platelets, such as fibrinogen-adherent platelets activated by a low dose of thrombin, the flowing platelets first adhere loosely to the platelet monolayer and then become stably adherent. However, on a procoagulant platelet monolayer, flowing platelets transiently interact with the monolayer, but stable interactions are decreased. The end consequence of this decrease in stable interactions is only minimal recruitment and accumulation of platelets on the procoagulant platelet surface (Kulkarni et al. 2007; Liu et al. 2013). This decreased platelet adhesiveness is also evident when a monolayer of procoagulant platelets is subjected to increasing shear stresses. Relative to spread and adherent platelets, the procoagulant platelet is less able to maintain contact with the surface as the shear stress is increased to arterial levels (Artemenko et al. 2015).

Corresponding with these functional alterations in adhesiveness, both the structure and interactions of the major adhesive receptor integrin $\alpha_{IIb}\beta_3$ are altered in procoagulant platelets. In resting platelets, $\alpha_{IIb}\beta_3$ is in an inactive state limiting its ability to engage with soluble fibrinogen and preventing platelet aggregation. Agonist stimulation results in an integrin $\alpha_{IIb}\beta_3$ extracellular conformational change and activation through the engagement of talin and kindlin with the cytoplasmic tail of the integrin β_3-subunit (Tadokoro et al. 2003; Moser et al. 2008). Integrin activation allows platelet spreading and aggregate formation. Activated integrin can be detected on the platelet surface by antibodies with specific affinity for the activated integrin $\alpha_{IIb}\beta_3$ conformation, such as PAC-1 (human) or JON/A (mouse) (Bergmeier et al. 2002). On spread and aggregating platelets, integrin $\alpha_{IIb}\beta_3$ is activated, the platelets are recognized by PAC-1, and P-selectin, a marker of platelet granule release, is expressed on the platelet surface; on procoagulant platelets, P-selectin is expressed on the platelet surface, but these platelets are not recognized by PAC-1 or JON/A (Jobe et al. 2005; Munnix et al. 2007; Dale et al. 2002). Since normal or increased levels of integrin $\alpha_{IIb}\beta_3$ are present on the procoagulant platelet surface, either the integrin is no longer in an active state or access to the integrin by the antibodies is limited. Together with this altered configuration, the cytoplasmic tail of integrin β_3 is cleaved in procoagulant platelets at a site close to the plasma membrane (Liu et al. 2013; Mattheij et al. 2013). Cleavage of this large portion of the cytoplasmic domain of integrin is predicted to limit integrin interaction with the integrin-activating proteins talin and kindlin (Du et al. 1995; Calderwood et al. 2003). Elimination of this key interaction may contribute to the observed alteration in integrin configuration and decreased platelet adherence seen in the procoagulant platelet subpopulation. Another consequence of this protein cleavage event is to limit the interaction of integrin with the platelet cytoskeleton (Schoenwaelder et al. 1997). This decreased interaction of integrin and other platelet membrane proteins, including GPIb-IX and P-selectin, with the platelet cytoskeleton may also limit the procoagulant platelet's ability to adhere in the presence of increased shear stress (Artemenko et al. 2015).

Procoagulant Platelets and α-Granule Protein Retention A distinct feature of the procoagulant platelet is the accumulation of high levels of α-granule proteins on the platelet surface (Dale 2005). Relative to spread and aggregated platelets, procoagulant platelets demonstrate increased accumulation of numerous α-granule proteins when measured

using flow cytometry, including fibrinogen, von Willebrand factor, fibronectin, and thrombospondin (Dale et al. 2002; Jobe et al. 2005). The surface association of another platelet-derived protein, tissue-factor pathway inhibitor (TFPI)-α, although not present in platelet α-granules, is similarly localized to the procoagulant platelet surface (Maroney et al. 2007). α-Granule protein retention is not evenly distributed, or coated, on the procoagulant platelet surface; instead it is localized to a single patch, or cap, on the procoagulant platelet surface (Abaeva et al. 2013).

The mechanism of increased α-granule protein retention on the procoagulant platelet surface remains uncertain. Covalent linkage of proteins released from α-granules to serotonin, which is released from dense granules, occurs on the surface of procoagulant platelets (Dale et al. 2002). Thrombospondin and fibrinogen can both interact with these serotonin-derivatized α-granule proteins. This suggests a model in which serotonin-derivatized α-granule proteins interact with both their various receptors on the platelet surface, for example, fibrin(ogen) with integrin $\alpha_{IIb}\beta_3$, and with serotonin binding sites on thrombospondin and fibrinogen to form a stable, multivalent cap on the platelet surface (Szasz and Dale 2002). However, FXIII deficiency or transglutaminase inhibition neither prevents increased α-granule protein retention nor formation of the platelet cap (Jobe et al. 2005; Abaeva et al. 2013). An alternative mechanism has also been proposed that suggests a primary role for fibrin polymerization in this process (Abaeva et al. 2013). In this proposed model, initial binding of α-granule proteins to their cognate surface receptors is followed by cell-mediated clustering of these receptors to a distinct region. Fibrin(ogen) polymerization then allows increased protein retention and stabilizes cap formation. Supporting this mechanism, cap formation was inhibited both in a patient with altered formation of fibrin polymers and by pharmacologic inhibition of fibrin. Formation of the protein cap may be essential in the retention of procoagulant platelets within the aggregate as inhibition of cap formation blocked the incorporation of procoagulant platelets into aggregates.

A recent study using a fluorescent transglutaminase substrate suggests the presence of heterogeneity of platelet surface protein modifications even within the procoagulant platelet subpopulation (Mattheij et al. 2015). Using this probe, transglutaminase activity, identified as factor XIII, was found to be isolated to a subpopulation of procoagulant platelets. Increased surface transglutaminase activity was a delayed event on this subpopulation of procoagulant platelets and followed both platelet PSer externalization and changes in integrin conformation. In the absence of FXIII activity, platelet localization of fibrin formation to procoagulant platelet surfaces did not occur in flow conditions. The authors thus suggest a role for procoagulant-mediated transglutaminase activity in fibrin localization within forming thrombi.

Procoagulant Platelets and Leukocyte Recruitment and Activation Following the establishment of hemostasis, a key component of the response to a break in vascular integrity is the recruitment of leukocytes to the site of injury. Soon after hemostatic plug formation in vivo, platelets and neutrophils can be observed in close apposition at the edge of the thrombus (Hovig et al. 1968; Jorgensen et al. 1967; Wester et al. 1979). This neutrophil recruitment prevents bacterial colonization of the wound. Dysregulated neutrophil recruitment by platelets, however, may contribute to the pathogenesis of multiple inflammatory processes, including lung injury (Zarbock et al. 2006), asthma (Pitchford et al. 2003), atherosclerosis (May et al. 2008), ischemia-reperfusion injury (Lefer et al. 1998), and sepsis (Singer et al. 2006). Activated platelets, both aggregating and procoagulant, facilitate neutrophil recruitment through granule release and elaboration of P-selectin on the platelet surface. Engagement of P-selectin by PSGL-1 on the leukocyte surface can tether leukocytes at the site of injury (Diacovo et al. 1996; Moore et al. 1995). Generation of a cytokine gradient through release of the α-granule protein NAP-2 (neutrophil-activating peptide-2) can direct leukocyte transmigration through the thrombus (Ghasemzadeh et al. 2013). Consolidation of neutrophil recruitment is then dependent on activation of neutrophil β_2-containing integrins, such as Mac-1 and LFA1 (Diacovo et al. 1996), in a process facilitated by platelet-activating factor (PAF) and certain cytokines generated by activated platelets (Ostrovsky et al. 1998).

Procoagulant platelets may play a unique role in mediating neutrophil activation and firm adhesion of platelets to neutrophils both within the hemostatic plug and in circulating monocyte/neutrophil microparticle complexes. Neutrophil interactions have been reported with “lysed” or balloon-like platelets in both in vitro and in vivo studies of clot morphology (Jorgensen et al. 1967; Hagberg et al. 1998). Studies evaluating the interaction of neutrophils with an adherent platelet monolayer have demonstrated that stable neutrophil adhesion and spreading, unlike platelet tethering, is closely correlated with the number of procoagulant platelets in the adherent platelet monolayer (Kulkarni et al. 2007). Synthesis of PAF was closely correlated with an increase in procoagulant platelet formation, and inhibition of the neutrophil PAF receptor blunted neutrophil activation and spreading on immobilized, spread platelets. A role for procoagulant-derived PAF is further suggested by studies examining neutrophil recruitment and migration in newly generated platelet thrombi (Ghasemzadeh et al. 2013). PAF receptor antagonists substantially reduced neutrophil Mac-1 activation and directed leukocyte migration to the core of the

hemostatic plug. Monocyte and neutrophil interactions with procoagulant-generated flow-induced protrusions (FLIPRs) can similarly result in leukocyte activation (Tersteeg et al. 2014). Mac-1 activation, L-selectin shedding (another marker of activation), and the formation of leukocyte/platelet microparticle aggregates were all dependent on FLIPR formation when monocytes or neutrophils were flowed over adherent platelets.

Molecular Mechanisms of Procoagulant Platelet Formation The molecular mechanisms driving procoagulant platelet formation are distinct. Strong agonist stimulation drives procoagulant platelet formation. High doses of thrombin, adhesion to collagen, or stimulation with multiple agonists have all been demonstrated to initiate procoagulant platelet formation (Rosing et al. 1985a; Alberio et al. 2000; Heemskerk et al. 1997). Other weaker stimuli that can potentiate formation by stronger agonists include von Willebrand factor, shear stress, and ADP (Kulkarni and Jackson 2004; Leytin et al. 2004; Delaney et al. 2014). Among soluble agonists, the combination of a collagen mimetic, which stimulates intracellular signaling via the GPVI receptor, and thrombin, which stimulates intracellular signaling through the G-protein-coupled protease-activated receptors (PARs), is the most potent stimulus (Jobe et al. 2005; Alberio et al. 2000). In flowing whole blood, collagen alone can stimulate procoagulant platelet formation (Heemskerk et al. 1997). However, even with the most potent of physiologic agonists, not all platelets become procoagulant (Dale 2005; Schoenwaelder et al. 1997).

Sustained elevation of cytoplasmic calcium levels is an essential trigger for procoagulant platelet formation in collagen and dual-stimulated platelets (Smeets et al. 1993; Dachary-Prigent et al. 1995; Choo et al. 2012). Store-operated calcium entry of extracellular calcium through the STIM1/Orai1 complex contributes to the sustained elevations of calcium seen in dual-stimulated platelets (Gilio et al. 2010). Coincident signaling through the GPVI and thrombin-activated signaling pathways also activates cation entry via the transient receptor potential channels TRPC3 and TRPC6 that drive further elevation of cytoplasmic calcium levels (Harper et al. 2013).

Another unique feature of procoagulant platelets is the role of mitochondria. The mitochondrial permeability transition pore (mPTP) is a multiprotein complex within the inner mitochondrial membrane, the opening of which results in a large non-gated pore (Halestrap and Richardson 2015). Cyclophilin D is a mitochondrial peptidylprolyl isomerase that is an important positive regulator of mPTP opening (Baines et al. 2005). In the absence of cyclophilin D activity, either through genetic deletion in mice or via pharmacologic inhibition in humans, platelet mPTP formation and, subsequently, procoagulant platelet formation are markedly impaired (Jobe et al. 2008; Remenyi et al. 2005). Platelet granule release and integrin activation are unaffected in cyclophilin D's absence, but the morphologic and functional changes associated with procoagulant platelets, including PSer externalization and integrin activation, are attenuated. An increase in mitochondrial calcium levels can cause mPTP opening, and it has been proposed that entry of cytosolic calcium through the mitochondrial calcium uniporter (MCU) may trigger this event (Choo et al. 2012).

Intracellular events downstream of mPTP formation and cytosolic calcium elevation mediate the morphologic and functional changes associated with procoagulant platelet formation (Brooks et al. 2007; van Kruchten et al. 2013). Two separate pathways mediate the changes in adherence and platelet PSer exposure (Briedé et al. 1999; Liu et al. 2013). Elevated cytosolic calcium levels and other, yet to be identified, mitochondrial-mediated changes trigger massive activation of intracellular calpain (Liu et al. 2013; Choo et al. 2012). This results in the cleavage of cytoskeletal proteins and major platelet adhesive receptors, including integrin $\alpha_{IIb}\beta_3$ (Schoenwaelder et al. 1997). Inhibition of calpain activity prevents both cellular rounding and the alterations in platelet adherence (Schoenwaelder et al. 1997; Kulkarni and Jackson 2004; Mattheij et al. 2013; Artemenko et al. 2015). PSer exposure is unaffected by inhibition of calpain activity (Ivanciu et al. 2014). TMEM16F, also known as anoctamin-6, regulates PSer exposure in procoagulant platelets (Suzuki et al. 2010; Yang et al. 2012; Fujii et al. 2015). TMEM16F's absence results in an absence of PSer exposure in procoagulant platelets but only partially inhibits the morphologic and adhesive changes observed in procoagulant platelets (Mattheij et al. 2013).

Necrotic Versus Apoptotic Procoagulant Platelets Procoagulant platelet formation, regulated by cyclophilin D and calcium, is reminiscent of cellular necrosis (Zong and Thompson 2006). Platelet rounding and phosphatidylserine exposure are also observed in platelets exposed to Bcl-2 antagonists (Mason et al. 2007; Zhang et al. 2007; Vogler et al. 2011). Unlike in procoagulant platelets formed as a result of platelet activation, formation of these PSer-exposing platelets requires neither sustained calcium elevation nor cyclophilin D (Schoenwaelder et al. 2009). Instead, PSer exposure by Bcl-2 antagonists requires the proapoptotic Bcl-2 family proteins Bax and Bak in a process more reminiscent of cellular apoptosis than cellular necrosis. While cyclophilin D-regulated necrotic platelet formation regulates activated platelet phenotype, this process of Bax-Bak-dependent platelet apoptosis is a key determinant of platelet lifespan (Mason et al. 2007). In the absence of the pro-survival Bcl-2

protein Bcl-xL, a key cellular inhibitor of Bax and Bak, platelet lifespan is severely shortened resulting in thrombocytopenia. This thrombocytopenia is also seen in vivo following treatment with a Bcl-xL inhibitor (Zhang et al. 2007).

Platelet Heterogeneity Within the Hemostatic Plug and Thrombus

Within a forming thrombus or hemostatic plug discoid platelets, aggregated and spread platelets and procoagulant platelets are all observed. Electron microscopy studies and in vivo fluorescent microscopy demonstrate distinct distributions of each of these types of activated platelet (Fig. 2). Electron microscopy studies of the newly formed hemostatic plug demonstrate a distinct architecture of the hemostatic plug (Wester et al. 1978; Hovig et al. 1967). In the center of the plug partially to fully degranulated platelets form a consolidated aggregate. Platelets are in close contact; granules, mitochondria, and other structures can be visualized; varying degrees of pseudopod formation are evident; and little fibrin is interspersed between the platelets. In contrast to the appearance of platelets in the center of the plug, platelets adjacent to collagen and platelets at the periphery of the hemostatic plug were electron lucent and had lost their internal structure, including both granules and mitochondria, appeared to have gaps in their membranes, and were typically located adjacent to fibrin strands. Based on this empty, electron-lucent appearance, some investigators have compared their appearance to balloons. Over time, progressively more platelets within the center of the thrombus also transitioned to a balloon morphology and become surrounded by fibrin (Hovig et al. 1968; Wester et al. 1979). Arterial thrombus formation following disruption of the endothelial layer demonstrates patches of both interdigitated and degranulated platelets intermixed with discoid platelets with intact platelet granules (Hechler et al. 2010; Jorgensen et al. 1967).

Dynamic in vivo imaging of hemostatic plug and thrombus formation has provided further insight into the evolution of this distinct platelet architecture. Typically, in these in vivo imaging studies, a focus of endothelial injury is induced using a laser, and the extent and depth of injury are controlled by altering the laser intensity. A characteristic pattern of platelet activation is observed when a penetrating laser injury with a small amount of bleeding is caused or when a small external puncture is formed (Ivanciu and Stalker 2015). Platelet accumulation begins almost immediately after injury. Given the instability of this original platelet accumulation, presumably these are discoid platelets. Discoid platelets have been observed as the first accumulating platelets at sites of endothelial injury, especially in the presence of shear gradients (Jackson shear gradient and Heemskerk geometries) (Nesbitt et al. 2009; Westein et al. 2013). Within the first minute after injury, a core of activated platelets is gradually formed at the site of injury (Stalker et al. 2013). Using fluorescent antibodies and sensors, the molecular nature of this core can be determined. Fibrin slowly accumulates both within and immediately inferior to the platelet core accompanied by increased thrombin activity (Welsh et al. 2012; Ivanciu et al. 2014); platelets within the core are P-selectin positive indicating

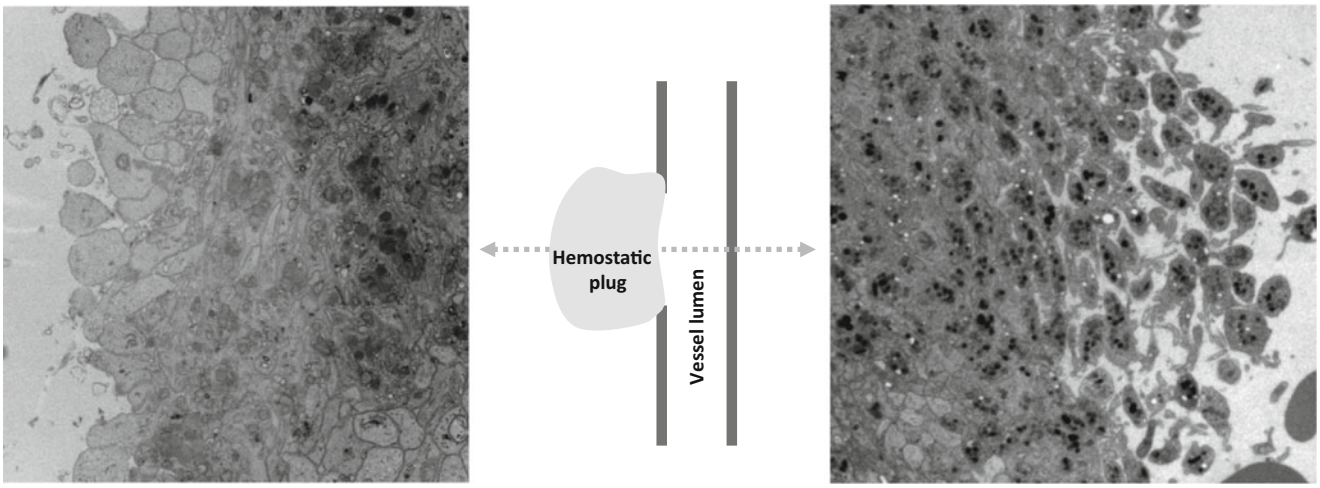

Fig. 2 Heterogeneity within the hemostatic plug. Representative transmission electron micrographs of section of a murine, mesenteric hemostatic plug 5 min after injury. *Left*. Section from the non-luminal periphery of the hemostatic plug. Electron-lucent platelets (balloon platelets) rim the hemostatic plug with consolidation of the hemostatic plug toward the core. On the luminal periphery, loosely-associated and granule-containing discoid platelets aggregate next to a consolidated, plug of platelets (Jobe SM)

that granule release has occurred (Stalker et al. 2013); and the platelets are densely packed limiting solute transport (Welsh et al. 2014). Superior to the core, a shell of platelets is observed, consisting of less densely packed platelets without evidence of platelet granule release. Platelets within this shell are transients within the thrombus with constant dissolution and reaccumulation of single platelets and loosely connected aggregates (Stalker et al. 2013).

How and whether procoagulant platelets accumulate in the thrombus or hemostatic plug appears to vary depending on the nature of the injury. In electron microscopy studies, balloon platelets are distributed as described above. Markers of phosphatidylserine exposure, however, cannot be used in fixed platelets, and their utility in in vivo studies is not clear. Using annexin V to label procoagulant platelets and labeled fibrinogen, distinct patches of procoagulant platelets were noted spread among fibrinogen-binding aggregated platelets in ferric chloride-damaged and ferric chloride-ligated carotid arteries (Munnix et al. 2007; Berny et al. 2010). Similarly, small patches of procoagulant platelets distributed throughout the thrombus were seen in a model of venous thrombosis. Procoagulant platelets within the thrombus can also be identified using 4-[N-(S-glutathionylacetyl)amino] phenylarsonous acid (GSAO), a marker of cell death. Accumulation of GSAO-labeled platelets varied depending on the mechanism of injury (Hua et al. 2015). In a model of injury with minimal endothelial damage and collagen exposure, only very little, if any, accumulation of procoagulant platelets was noted. In an occlusive model of carotid injury induced by ferric chloride, procoagulant platelets in association with fibrin were noted throughout the occlusive thrombus.

Take-Home Messages

- Interindividual differences in mean platelet volume (MPV) have been correlated with multiple pathologies, including an association of increased MPV with increased risk of both arterial and venous thrombosis.
- Within an individual, platelet characteristics vary throughout their lifetime in vivo. In addition to discoid platelets, preplatelets, proplatelets, and microparticles circulate in plasma.
- The anucleate platelet contains genetic information in the form of both RNA and miRNA. Differential transfer of genetic material from the megakaryocyte to the platelet, and from heterologous cells in circulation, can alter gene expression in platelets.
- Distinct aggregatory and procoagulant subpopulations occur within collagen-adherent platelets and strongly stimulated platelets in suspension.
- Procoagulant platelets have distinct morphologic and functional characteristics including:
  - Externalization of high levels of phosphatidylserine and increased procoagulant activity
  - A rounded, balloon-like morphology
  - Impaired adhesive characteristics associated with changes in integrin $\alpha_{IIb}\beta_3$ structure and function
  - Proinflammatory recruitment of neutrophils
- Distinct intracellular signaling mechanisms regulate procoagulant platelet formation.
- In vivo, platelet heterogeneity is a prominent characteristic of hemostatic plugs. Discoid, aggregatory, and balloon-like platelets can be distinguished by electron microscopy.

Regulation of Platelet Adhesion Receptors

Ana Kasirer-Friede and Sanford J. Shattil

Abstract

Platelet adhesion to subendothelial matrices and cohesion to other platelets is essential for hemostasis, but recent studies have revealed that platelet adhesive interactions may also generate cross-talk with other cell types, including leukocytes, tumor cells, and microbial pathogens. In so doing, these adhesive interactions may impact a variety of protective or disease-promoting processes, and they are mediated by platelet adhesion receptors from several gene families, most notably integrins, as exemplified by the platelet-restricted integrin, $\alpha_{IIb}\beta_3$. During hemostasis, multiple brakes and controls on platelet adhesion receptors prevent pathological thrombosis. Thus, threshold levels of excitatory stimuli must be surpassed and sufficient to drive intracellular signaling for full activation of integrin receptors. Stimuli for primary hemostasis derive from released or generated soluble agonists, vascular matrices exposed by vessel injury, or by hydrodynamic shear stress. While the non-integrin adhesion receptor, GPIb-V-IX, is critical for platelet adhesion to matrix von Willebrand factor (VWF) during hemostasis and is a mediator of platelet aggregation through interactions with VWF at pathologically high shear stresses in atherosclerotic arteries, finely regulated interactions of $\alpha_{IIb}\beta_3$ with fibrinogen and other Arg-Gly-Asp (RGD)-containing ligands are required for platelet aggregation in hemostatic thrombi. In this chapter we present an overview of classical and nonclassical regulation of platelet adhesion receptors and associated signaling pathways, with a principle focus on platelet signaling pathways that converge on and regulate $\alpha_{IIb}\beta_3$.

Introduction

Platelets are adhesion machines. Indeed, every known biological function or pathological role of platelets, from hemostasis-thrombosis (Varga-Szabo et al. 2008), to regulation of aspects of embryonic development (Echtler et al. 2010; Watson et al. 2014), to participation in innate and adaptive immunity (Herter et al. 2014; Kapur et al. 2015), and to tumor promotion (Labelle et al. 2011) involves platelet adhesion receptors in one way or another. As epitomized by integrin $\alpha_{IIb}\beta_3$, the adhesion and signaling functions of these plasma membrane receptors are tightly regulated to enable rapid platelet hemostatic responses to vascular injury and to avoid excessive platelet responses leading to pathological thrombosis, including myocardial infarction and stroke (Bennett 2015; Coller 2015; Plow et al. 2014; Shattil et al. 2010). Here we review what is known about how platelet adhesion receptor function is regulated, a subject relevant to other chapters that discuss broader aspects of platelet function in health and disease.

Regulation of Platelet Integrins

Platelets express several members of the integrin superfamily (Hynes 2002): $\alpha_{IIb}\beta_3$, $\alpha_V\beta_3$, $\alpha_2\beta_1$, $\alpha_5\beta_1$, and $\alpha_6\beta_1$. All are type I transmembrane α- and β-heterodimers, each subunit consisting of a relatively large extracellular domain, a single-span transmembrane domain, and a short cytoplasmic domain of ~20–47 amino acids. $\alpha_{IIb}\beta_3$ is highly expressed, with ~80,000 copies on the surface of resting platelets, a number so high that individual $\alpha_{IIb}\beta_3$ heterodimers are estimated to be spaced a mere ~125 Å apart (Wagner et al. 1996). There is a smaller internal pool of $\alpha_{IIb}\beta_3$ expressed on granule membranes that can become surface expressed during granule secretion (Woods et al. 1986).

The principal extracellular ligands for $\alpha_{IIb}\beta_3$ are fibrinogen and VWF, although under appropriate experimental conditions, the receptor can engage other RGD-containing ligands such as vitronectin and fibronectin (Plow et al. 1985). Binding of $\alpha_{IIb}\beta_3$ to soluble plasma fibrinogen (Bennett and Vilaire 1979) or VWF (Jackson 2007; Ruggeri 2002) supports platelet aggregation because these multivalent ligands can engage in trans-interactions, thereby functioning as bridges between $\alpha_{IIb}\beta_3$ receptors on adjacent platelets. Initial platelet adhesion to damaged vessels involves the interaction of immobilized VWF with the non-integrin platelet adhesion receptor, GP Ib-V-IX (discussed below), and immobilized RGD ligands can support platelet adhesion and spreading via $\alpha_{IIb}\beta_3$ (Jirouskova et al. 2007).

The principal ligands for platelet $\alpha_V\beta_3$, $\alpha_2\beta_1$, $\alpha_5\beta_1$, and $\alpha_6\beta1$ are vitronectin (Felding-Habermann and Cheresh 1993), collagen (Nieswandt and Watson 2003a), fibronectin (McCarty et al. 2004), and laminin (Schaff et al. 2013), respectively. Compared to $\alpha_{IIb}\beta_3$, expression of these integrins in platelets is Lilliputian, e.g., being less than 1–2 % that of $\alpha_{IIb}\beta_3$. This does not mean they have no functional role, but their roles are likely relatively minor under physiologic conditions. For example, studies of mouse or human platelets indicate that $\alpha_2\beta_1$ plays a secondary role as a collagen receptor, with GP VI playing the dominant signaling role (Nieswandt and Watson 2003a).

Platelets contain RNA and the machinery for translation of RNA into proteins, but they do not contain their own DNA (Schubert et al. 2014). Consequently, the function of platelet integrins is regulated primarily at the posttranslational level, a process studied most intensively for $\alpha_{IIb}\beta_3$ (Bennett 2015; Plow et al. 2014; Shattil et al. 2010). Regulation of $\alpha_{IIb}\beta_3$ is often divided arbitrarily into two phases: **inside-out signaling**, which controls integrin activation state and ligand binding, and **outside-in signaling**, which is triggered by ligand binding leading to the generation of inward signals that promote further platelet responses, including activation of additional integrins, cytoskeletal rearrangements, platelet secretion, and the development of platelet procoagulant activity (Coller and Shattil 2008).

Positive Regulators of Integrin Activation

"Classical" Fluid-Phase Excitatory Platelet Agonists

Platelets are equipped with multiple routes of activation that together unleash an avalanche of complex signaling events to effect platelet shape change and exocytosis from platelet alpha and dense granules (Golebiewska and Poole 2015) as well as activation of pathways that convert $\alpha_{IIb}\beta_3$ and other integrins to a high-affinity state. A wide array of molecular species is involved in this inside-out signaling process, including kinases, phosphatases, isomerases, adaptor proteins, and those controlling lipid trafficking (Brass et al. 2013; Furie and Flaumenhaft 2014; O'Donnell et al. 2014). The concerted action of multiple agonist receptors ensures that initial responses to individual agonists are amplified to support stable, irreversible platelet aggregation and thrombus formation to effect hemostasis.

The classical excitatory platelet agonists engage G protein-coupled receptors (GPCR) in the plasma membrane that signal through heterotrimeric G proteins, the latter consisting of α-, β-, and γ-subunits. Ligand binding to GPCRs induces exchange of GTP for GDP on Gα and its separation from the Gβγ subunits, each then promoting downstream activation or repression of distinct pathways (Gurbel et al. 2015; Offermanns 2006). Classical GPCR agonists include (1) ADP released from hemolyzed red blood cells or from dense granules during platelet secretion; (2) thromboxane A2 generated de novo following release of arachidonic acid from membrane phospholipids and its conversion to prostaglandin endoperoxides by cyclooxygenase-1 (Samuelsson et al. 1978); (3) thrombin, a product of the coagulation cascade; and (4) epinephrine, a circulating hormone (Brass et al. 2013). Under normal circumstances, none of these agonists is available to circulating platelets at sufficient concentrations to surmount normal restraints to platelet activation, arguing that a minimal threshold trigger must exist to initiate the release or generation of these soluble agonists at effective microenvironmental concentrations.

ADP is an example of a so-called "weak" agonist that by itself promotes little secretion and submaximal $\alpha_{IIb}\beta_3$ activation, yet is central to full platelet activation initiated by other agonists. ADP binds three purinergic receptors on platelets, P2Y1 and P2Y12 (Cattaneo 2015) and P2X1 (Jones et al. 2014). P2Y1 and P2Y12 are needed for a full aggregation response to ADP, whereas Ca^{2+} influx through P2X1 amplifies ADP-induced calcium signaling triggered by

P2Y1. P2Y1 associates with Gαq to regulate platelet shape change and granule secretion, and platelets from P2Y1 knockout mice fail to aggregate in response to low concentrations of ADP and respond only partially to other agonists (Leon et al. 1999). P2Y12 associates with Gαi2 to repress ADP-mediated generation of cAMP, a negative regulator of platelet activation (Smolenski 2012). P2Y12 also promotes signaling through phosphatidyl inositide 3-OH kinase (PI3-K) independently of protein kinase C (PKC) (Kauffenstein et al. 2001), and supports the slow, irreversible phase of platelet aggregation (Jarvis et al. 2000). Src family kinases (SFKs) also appear to play a role in Gi-mediated signaling, as ADP- and epinephrine-induced platelet aggregation is decreased in the presence of SFK inhibitors (Nash et al. 2010). Mice lacking P2Y12 show decreased $\alpha_{IIb}\beta_3$ activation, reduced adhesion to VWF under flow, and small, unstable thrombi on damaged mesenteric arteries (Andre et al. 2003). In a recent in vivo thrombosis model, Stalker et al. found that thrombi were hierarchically organized, with a core of highly activated platelets and a shell of less-activated platelets, whose size and stability were strongly dependent on P2Y12 and Gi signaling (Stalker et al. 2013). Defects in ADP receptors in patients mimic those seen in P2Y1 and P2Y12 knockout mice and produce a mild hemorrhagic phenotype (Cattaneo and Gachet 1999; Nurden et al. 1995; Cattaneo 2011). Moreover, P2Y12 antagonists have proven to be extremely useful in the prophylaxis and treatment of acute coronary syndromes (Rollini et al. 2015).

Thromboxane A2 is a clinically important platelet agonist, as suggested by the widespread use of aspirin in the primary prevention of cardiovascular events. Aspirin inhibits COX1 and thromboxane production in platelets. Thromboxane A2 binds the TP receptor and signals through Gq and G12/13 leading to shape change and intracellular calcium mobilization (Offermanns 2006). Full platelet aggregation in response to thromboxane A2 is dependent on released ADP (Paul et al. 1999). TP knockout mice have prolonged bleeding times (Thomas et al. 1998). **Thrombin** is a "strong" agonist that binds with high affinity to the non-GPCR, GPIb-V-IX, as well as to the protease-activated GPCR receptors, PAR1 and PAR4 in humans and PAR3 and PAR4 in mice. Thrombin cleaves the extracellular N-terminus of PAR1 and PAR4 to expose the novel tethered ligands, SFLLRN and AYPGKF, respectively (Coughlin 2005). Platelet activation through PAR receptors is mediated by Gαq and Gα13 (Brass et al. 2013). **Epinephrine** binds the α2A adrenergic receptor (Kaywin et al. 1978). It is a weak agonist that functions primarily to potentiate platelet aggregation induced by other agonists, and it can overcome P2Y12 blockade through Gαz signaling (Lova et al. 2011).

"Nonclassical" Excitatory Agonists

Matrix-Associated Platelet Agonists Functioning Through Hemostatic Pathways

Platelet adhesion receptors are hardwired to promote and amplify mechanisms that enhance the activation of integrins, particularly $\alpha_{IIb}\beta_3$, for stable platelet adhesion to immobilized ligands or for binding of soluble integrin ligands. Resting platelets under static, non-flow conditions can adhere via integrins to immobilized ligands, e.g., to immobilized fibrinogen via $\alpha_{IIb}\beta_3$ (Savage et al. 1992), to collagen via $\alpha_2\beta_1$ (Nieswandt and Watson 2003a), to laminin via $\alpha_6\beta_1$ (Geberhiwot et al. 1999), and to fibronectin via $\alpha_5\beta_1$ (McCarty et al. 2004). These interactions can trigger outside-in signaling pathways that serve as feedback activation loops for upregulation of integrin affinity and/or clustering (Ruggeri and Mendolicchio 2007). Additionally, fibrinogen and vitronectin may become immobilized on extracellular matrices upon vessel injury, bind to platelets through β_3 integrins, and contribute to outside-in integrin signaling and thrombus formation. Under shear flow conditions, where hydrodynamic forces can easily sweep away loosely attached platelets, a priori activation of integrins for attachment to fibronectin and VWF is needed (Beumer et al. 1994; Savage et al. 1996).

The non-integrin platelet adhesion receptors, GPVI and GPIb-V-IX, recognize exposed matrix collagen and VWF, respectively, and in so doing signal to activate integrins through either of two associated co-receptors, FcRγ and FcγRIIA, that contain immunoreceptor tyrosine-based activation motifs (ITAM) with tandem YXXL sequences (Canobbio et al. 2001; Falati et al. 1999). In addition, GPIb-V-IX can signal independently to $\alpha_{IIb}\beta_3$ (Kasirer-Friede et al. 2004). Under flow conditions, GPVI and GPIb-V-IX serve to bridge the temporary anchoring of platelets onto matrices with stable adhesion through activation of $\alpha_{IIb}\beta_3$. At arterial shear rates, platelet attachment to collagen is mediated through the VWF/GPIb-V-IX axis (discussed below), and at lower shear, collagen-induced signaling to $\alpha_{IIb}\beta_3$ is primarily through GPVI (Lecut et al. 2004). Studies utilizing various inhibitors and genetically modified mice have helped to identify proteins downstream of GPIb-V-IX and GPVI and their Fc co-receptors that relay signals involved in integrin activation. These include protein tyrosine kinases (e.g., SFKs, Syk, Tec family kinases), serine-threonine kinases (e.g., phospholipase C (PLC), PKC, PI3-K), and adaptor proteins (e.g., SLP-76, ADAP) (Bergmeier and Stefanini 2013; Bryckaert et al. 2015).

$\alpha_V\beta_3$ is expressed in platelets in small numbers relative to $\alpha_{IIb}\beta_3$ and can engage vitronectin, adenovirus penton base (Wickham et al. 1993) and other ligands, such as osteopontin

(Bennett et al. 1997), which may be present in atherosclerotic plaques. In experimental cell assays, $\alpha_V\beta_3$ can undergo activation similar to that of $\alpha_{IIb}\beta_3$ in response to ADP (Kasirer-Friede et al. 2006). In vitro experiments have suggested that long VWF strings secreted from Weibel-Palade bodies of activated endothelial cells can be sequestered by endothelial surface-expressed $\alpha_V\beta_3$ for subsequent recognition by platelet GPIb-V-IX (Huang et al. 2009). Under in vivo conditions, however, VWF strings are observed only in the venous vasculature and appear to be independent of P-selectin and β_3 integrin (De Ceunynck et al. 2013).

Platelet Agonists Functioning Through Non-hemostatic Pathways

It is becoming increasingly evident that platelets do not function exclusively in the realm of hemostasis but are actively involved in communication with and co-regulation of multiple cell types in the processes of host defense, innate immunity, atherosclerosis, airway and liver disease, and cancer progression (Franco et al. 2015; McFadyen and Kaplan 2015). These interactions may result in mutual cellular activation and often utilize platelet adhesion receptors that normally operate in hemostasis.

Platelet-immune cell interactions are manifold. GPIbα on matrix-attached platelets may facilitate recruitment of neutrophils to vessel walls through binding to leukocyte integrin $\alpha_M\beta_2$ (Mac-1) (Ehlers et al. 2003; Simon et al. 2000). In addition, microparticles bearing active Mac-1 and released from stimulated neutrophils can bind to platelets via GPIbα and promote platelet P-selectin surface expression and $\alpha_{IIb}\beta_3$ activation (Pluskota et al. 2008). Dying neutrophils may also release extracellular traps (NETS) that are part of their antibacterial defense mechanisms (Martinod and Wagner 2014) and contain DNA, histones, and alkaline proteins. NETS can enmesh platelets and provide a NET scaffold for thrombus growth (Fuchs et al. 2010). While VWF has been found closely associated with DNA (Grassle et al. 2014), platelets may directly interact with histones H3 and H4 in part through platelet Toll-like receptors (TLR)'s 2 and 4 (Semeraro et al. 2011). Furthermore, several histones have the ability to act as substrates for platelet adhesion and spreading and to stimulate fibrinogen binding to $\alpha_{IIb}\beta_3$. Platelet activation triggered by histones is mediated by ERK, Akt, and p38 (Carestia et al. 2013).

Galectins (Gal-) are a family of highly conserved lectins, which recognize cell surface and matrix β-galactosidases. They may be found in soluble or immobilized form in a wide variety of tissues and are implicated in immune and tumor responses (Schattner and Rabinovich 2013). Galectins recognize the carbohydrate moieties of $\alpha_{IIb}\beta_3$ and GPIb-V-IX, resulting in mild increases in platelet adhesion, aggregation, and spreading (Schattner 2014).

A chemically distinct nonclassical integrin activator is the CXCR6 receptor, recently identified in platelets. The CXC motif ligand 16 (CXL16), found in atherosclerotic plaques, or purified in vitro, can serve as an adhesive ligand for platelets under shear flow (Meyer Dos Santos et al. 2015) and promote $\alpha_{IIb}\beta_3$ activation and platelet secretion through PI3-K dependent pathways (Borst et al. 2012).

Microbial pathogens constitute a large class of potential platelet modulators, as both bacteria and viruses have been implicated under various experimental conditions in direct binding to GPIb-V-IX, $\alpha_{IIb}\beta_3$, and other receptors on platelets, leading to $\alpha_{IIb}\beta_3$ activation, fibrinogen binding, and alpha-granule secretion (Hamzeh-Cognasse et al. 2015). A novel mechanism for dengue virus invasion of platelets was recently demonstrated that utilizes platelet surface-expressed DC-SIGN and heparin sulfate for entry and replication, thereby sheltering the virus from patrolling immune cells (Simon et al. 2015). The FcγRIIA receptor may also be hijacked by pathogens to breach and activate platelets (Boilard et al. 2014; Arman et al. 2014). Platelets express TLRs 2, 7, and 9, which harbor pathogen recognition sequences. Certain pathogens can activate platelets (Cox et al. 2011), perhaps helping to explain in part the thrombotic consequence of sepsis (de Stoppelaar et al. 2014).

Principal Signaling Pathways Downstream of Agonist Receptors Involved in Activation of $\alpha_{IIb}\beta_3$

G proteins connect to an array of signaling molecules, and agonist pathway specificity results, in part, by distinct isoform expression of signaling intermediates (Min and Abrams 2013; O'Donnell et al. 2014).

Platelets contain at least five isoforms of PLC, including PLCβ and PLCγ2. PLCβ promotes signaling through G protein βγ subunits, Gq and G12/13, while PLCγ2 is implicated downstream of protein tyrosine kinases. Both isoforms hydrolyze the polar head group of membrane phosphatidyl inositol 4,5 biphosphate (PtdIns (4,5) P2) to yield diacylglycerol (DAG) and inositol (1,4,5) triphosphate (IP3), which releases calcium from dense tubules (Brass and Joseph 1985). Influx of extracellular calcium through the Orai-1 channel (Braun et al. 2009, 2011) further drives cyclical intracellular calcium elevations. Multiple cytoplasmic and cytoskeletal proteins affecting integrin activation harbor calcium binding sites and become activated in response to calcium transients, including regulatory proteins such as calpain and calmodulin (Elsaraj and Bhullar 2008), the classical and nonclassical members of the PKC family, and CALDAG-GEFI which, as discussed below, functions as a guanine nucleotide exchange factor for Rap1b (Crittenden et al. 2004; Cifuni et al. 2008).

Protein kinase C family members are serine/threonine kinases that may positively or negatively regulate $\alpha_{IIb}\beta_3$

and platelet activation, depending on the agonist and PKC isoform involved (Harper and Poole 2010). Tyrosine phosphorylation of PKC may be induced by thrombin and collagen (Hall et al. 2007; Murugappan et al. 2005) and can affect its activity, localization (Crosby and Poole 2003; Pula et al. 2005), or association with receptors for activated C-kinase (RACK) proteins (Schechtman and Mochly-Rosen 2001). PKCα is best known for phosphorylating substrates that regulate alpha- and dense-granule secretion, including SNAPs, SNAREs, and VAMPs, and for regulating integrin activation by promoting Rap1-mediated activation of talin (Cifuni et al. 2008; Gilio et al. 2010; Han et al. 2006; Strehl et al. 2007). PKCβ and PKCθ appear to significantly modulate outside-in $\alpha_{IIb}\beta_3$ signaling (Buensuceso et al. 2005; Soriani et al. 2006). Although the specific PKC subtypes have not been identified, pan-PKC inhibitors were used to identify novel roles for PKC in promoting 12-lipoxygenase-induced $\alpha_{IIb}\beta_3$ activation (Yeung et al. 2012) and in maintaining proteasomal activity (Nayak et al. 2011) that sustains platelet aggregation by low-dose thrombin or GPIb-V-IX (Gupta et al. 2014).

PI-3Ks phosphorylate the 3-OH group of the inositol ring of phosphatidyl inositols (PI), which can then bind specific PH and Src homology-2 (SH2) domains in proteins (Min and Abrams 2013; O'Donnell et al. 2014). At least four PI-3K isoforms are expressed in platelets, (Guidetti et al. 2015). The two best characterized are the Class Ia member, p85/p110 PI-3Kβ, and the Class Ib member, p110 PI-3Kγ (Rittenhouse 1996; Zhang et al. 1996), with PI3-Kβ thought to play the predominant role in platelet inside-out signaling to $\alpha_{IIb}\beta_3$ downstream of GPCRs and ITAM-bearing receptors (Guidetti et al. 2015). However, platelet signaling may involve other PI3-K isoforms, such as PI3-Kα acting downstream of the insulin-like growth factor receptor (Hers 2007), or PI3-Kγ acting downstream of ADP stimulation (Hirsch et al. 2001). One of the principal effectors of PI3-K in platelets is Akt (Protein kinase B, PKB), with three platelet isoforms expressed, each supporting platelet aggregation in an agonist-selective manner (Laurent et al. 2014; Moroi and Watson 2015). PI3-K helps recruit PDK1 to phosphorylate Akt at the platelet membrane (Dangelmaier et al. 2014). Mice deficient in Akt1 and Akt2 have impaired thrombin-induced fibrinogen binding and thrombus formation in vivo (Woulfe et al. 2004), and Akt3 mice exhibit defects in thrombus growth that may be due to ineffective deactivation of the Akt platelet inhibitory target, glycogen synthase kinase-3b (GSK3β) (O'Brien et al. 2011). The potential importance of Akt activation and GSK3β inhibition is supported by recent studies showing that deacetylation of Akt lysine residues by sirtuin 2 (SIRT2) can modulate its capacity to phosphorylate and thereby deactivate GSK3β to allow full platelet aggregation (Moscardo et al. 2015).

While signaling pathways downstream of platelet excitatory receptors are multiple and often interacting, major attention has focused on Rap1b, a membrane-anchored Ras family GTPase, because it has been implicated in integrin activation in many cell types, including platelets (Fig. 1, Table 1) (Gloerich and Bos 2011). Knockout of Rap1b in mice is associated with reduced, but not absent, platelet fibrinogen binding and aggregation in response to both GPRC- or non-GPRC-coupled agonists (Chrzanowska-Wodnicka et al. 2005).

Rap1 is inactive as a pro-aggregatory signaling intermediate when bound to GDP in unstimulated platelets. The Rap1-GDP state is promoted by a Rap1 GAP, RASA3. Upon platelet stimulation through the $P2Y_{12}$ ADP receptor and activation of PI3K, the inhibitory effect of RASA3 on Rap1b is blocked (Stefanini et al. 2015). In addition, platelet activation mediated by ADP and other agonists leads to the generation of ionized free calcium and diacylglycerol, and the former activates a Rap1 GEF, CalDAG-GEFI (RASGRP2), that converts Rap1-GDP to active Rap1-GTP (Crittenden et al. 2004; Eto et al. 2002; Larson et al. 2003). CalDAG-GEFI overexpression enhances agonist-induced fibrinogen binding to $\alpha_{IIb}\beta_3$ in murine megakaryocytes (Eto et al. 2002), and CalDAG-GEFI knockout mouse platelets show reduced aggregation in response to agonists (Crittenden et al. 2004). Moreover, a mutation in CalDAG-GEFI (cG742T) in man is associated with impaired activation of Rap1 and $\alpha_{IIb}\beta_3$ in platelets, although leukocyte adhesion is normal (Canault et al. 2014). Bergmeier and co-workers suggest that fast but reversible Rap1 activation in platelets is dependent on calcium and CalDAG-GEFI, while sustained Rap1 activation requires signaling through P2Y12, PKC, and PI3K (Cifuni et al. 2008; Stefanini et al. 2015).

One Rap1 effector that is expressed in platelets is RIAM, and its role in integrin activation was studied initially in leukocytes and in model cell systems (Han et al. 2006; Lafuente et al. 2004). In a CHO cell system frequently utilized to study ectopically-expressed human $\alpha_{IIb}\beta_3$, sh-RNA mediated knockdown of Rap1 or RIAM impaired PAR1 thrombin receptor-mediated activation of $\alpha_{IIb}\beta_3$, and similar results were obtained in embryonic stem cell-derived murine megakaryocytes (Kahner et al. 2012; Watanabe et al. 2008). One current model is that platelet agonists trigger activation of Rap1, which then recruits RIAM to the membrane. Since RIAM can bind to talin directly (Chang et al. 2014; Lee et al. 2009), this provides talin direct access to the integrin β_3 cytoplasmic tail, thus triggering activation of $\alpha_{IIb}\beta_3$ (Shattil et al. 2010).

Recent work indicates that this model of inside-out $\alpha_{IIb}\beta_3$ signaling is incomplete. First, there must be Rap1-independent routes to $\alpha_{IIb}\beta_3$ activation, since as mentioned, agonist-induced fibrinogen binding to and aggregation of

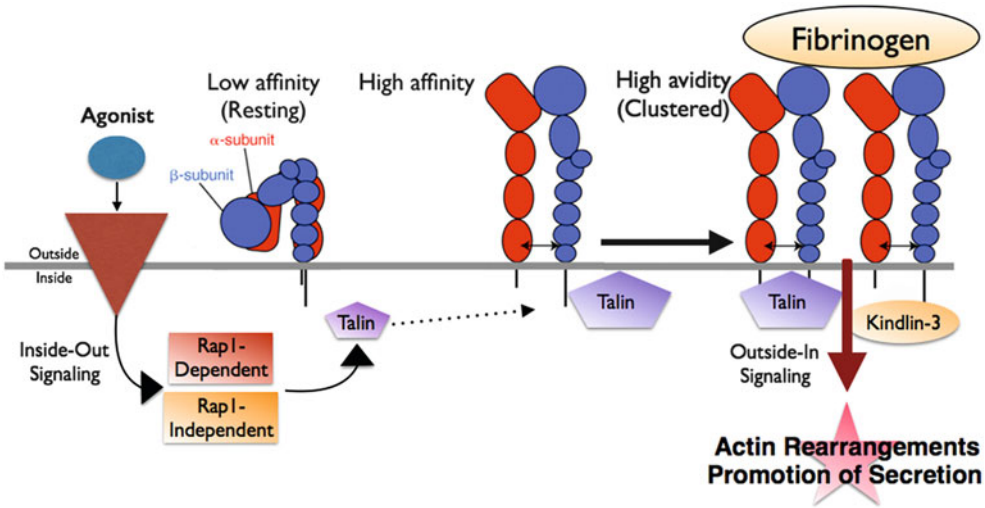

Fig. 1 Schematic overview of signaling impacting the most abundant platelet adhesion receptor, $\alpha_{IIb}\beta_3$. In resting platelets, $\alpha_{IIb}\beta_3$ is in a low-affinity state. Upon platelet activation by a range of excitatory agonists (Table 1), inside-out signaling is triggered, and $\alpha_{IIb}\beta_3$ is converted through propagated conformational changes starting at the α_{IIb} and β_3 cytoplasmic tails and transmembrane domains to a high-affinity state capable of productive interactions with soluble fibrinogen and other cognate agonists, including von Willebrand factor and fibronectin. Inside-out signals converge on poorly defined Rap1-dependent or Rap1-independent effectors that act on talin, resulting in its recruitment to the plasma membrane and its interaction with the integrin β_3 cytoplasmic tail to induce the high-affinity state of $\alpha_{IIb}\beta_3$. The *double arrows* indicate that the transmembrane domains separate during activation. In addition, kindlin interacts with the β_3 cytoplasmic tail to promote $\alpha_{IIb}\beta_3$ clustering within the plane of the plasma membrane, thereby enhancing $\alpha_{IIb}\beta_3$ avidity for its matrix ligands. Fibrinogen binding to high-affinity-clustered $\alpha_{IIb}\beta_3$ triggers outside-in signaling mediated by talin, kindlin-3, and a host of other proteins, including Src, Syk, and FAK protein tyrosine kinases to help promote additional responses during platelet activation, including actin rearrangements, and platelet spreading, granule secretion, and development of platelet procoagulant activity

Table 1 Summary of excitatory agonists regulating activation of integrin $\alpha_{IIb}\beta_3$

Excitatory agonists of $\alpha_{IIb}\beta_3$ activation					
Classical		Nonclassical		Nonclassical	
Soluble agonists	Platelet receptors	Principal matrix ligands	Platelet receptor	Cellular stimulation	Platelet receptors
ADP	P2X1, P2Y1, P2Y12	VWF, fibrinogen, fibronectin	$\alpha_{IIb}\beta_3$	Tumor cells	GPIb-V-IX
Thrombin	GPIbα, PAR1, PAR4	Vitronectin, osteopontin	$\alpha_V\beta_3$	Leukocytes	GPIb-V-IX, P-selectin
Epinephrine	α2A	Collagen	$\alpha_2\beta_1$	Endothelial cells	GPIb-V-IX, P-selectin
TXA2	TP	Fibronectin	$\alpha_5\beta_1$	Pathogens	GPIb-V-IX, FcR's,
		VWF	GPIb-V-IX		$\alpha_{IIb}\beta_3$, TLR's, DC-SIGN
		Collagen, Laminin	GPVI		

Classical soluble agonists in the extracellular space bind their cognate platelet receptors to initiate inside-out signaling. Nonclassical signaling pathways to $\alpha_{IIb}\beta_3$ may be initiated in response to platelet adhesion receptor binding to subendothelial matrix ligands (VWF, laminin, fibronectin, collagen) or to immobilized fibrinogen or vitronectin deposited from plasma. Alternatively, platelet interactions with multiple cell types may engage platelet receptors to promote and amplify signaling to $\alpha_{IIb}\beta_3$. These stimulatory pathways may utilize different isoform-specific signaling intermediates of the same families, such as PI-3K and PLC, but ultimately unite to converge on integrin proximal regulatory molecules, such as talin and kindlin-3

Rap1b-null murine platelets is decreased, but not abolished (Fig. 1) (Chrzanowska-Wodnicka et al. 2005). Rap1-independent routes to $\alpha_{IIb}\beta_3$ activation remain to be clarified, but likely include yet-to-be-identified substrates of PKC. Second, RIAM is dispensible for $\alpha_{IIb}\beta_3$ activation in mouse platelets (Stritt et al. 2015), indicating that another, as yet unidentified, Rap1b effector must participate in integrin activation in these cells. Regardless, both Rap1-dependent and Rap1-independent pathways eventually must merge in proximity to the $\alpha_{IIb}\beta_3$ cytoplasmic tails to stimulate $\alpha_{IIb}\beta_3$ activation by the integrin cytoplasmic tail-binding proteins, talin and kindlin-3.

Integrin-Proximal Regulatory Events

Talin-1 is a 215 kDa adaptor protein whose functions in platelets include promotion of integrin activation, linkage of integrins to the actin cytoskeleton, and promotion of clot retraction (Plow et al. 2014; Shattil et al. 2010). A related gene product, talin-2, is not expressed in platelets. Talin is composed of an N-terminal head domain containing a

FERM domain with four sub-domains (F0–F3) and a long C-terminal rod domain. It can interact directly with integrin cytoplasmic tails and with actin and other proteins (Roberts and Critchley 2009). In unstimulated platelets, a large pool of talin is in the cytoplasm, presumably in the form of auto-inhibited, antiparallel homodimers, and in response to platelet stimulation with thrombin, talin becomes phosphorylated on Ser and/or Thr residues and translocates to the plasma membrane in a process that does not require $\alpha_{IIb}\beta_3$ (Bertagnolli et al. 1993). As discussed above, Rap1 and its effector(s) are involved in this recruitment process (Fig. 1). It is still not known precisely how talin is converted from its auto-inhibited conformation to a conformation that enables it to interact with binding partners, such as integrins, vinculin, and actin, although talin interaction with PIP_2 may be important in this regard (Wang 2012). In addition, the role of talin phosphorylation (Ratnikov et al. 2005) as well as the precise mechanism of Rap1-independent talin recruitment to the plasma membrane remain to be determined.

Talin interactions of known importance to $\alpha_{IIb}\beta_3$ activation include that of the talin head domain with negatively charged plasma membrane phospholipids, such as PIP_2, and with the β_3 cytoplasmic tail (Fig. 1) (Garcia-Alvarez et al. 2003; Ginsberg 2014; Wegener et al. 2007). Two regions of the β_3 tail are involved in this interaction. One is centered at the first of two NPXY sequences that are present in the tail, and it provides most of the free energy for the interaction with the F3 sub-domain of the talin head. The other involves a juxtamembrane region of the β_3 tail, and this interaction is directly required for inducing conformational changes that lead to full-blown $\alpha_{IIb}\beta_3$ activation and fibrinogen binding (Ginsberg 2014; Petrich et al. 2007; Ye et al. 2014). Talin also plays a necessary role in outside-in $\alpha_{IIb}\beta_3$ signaling leading to the spreading of fibrinogen-adherent platelets and fibrin clot retraction (Haling et al. 2011) and in promoting the adhesive functions of platelet β_1 integrins (Petrich et al. 2007).

Over the past decade, crystallographic and electron microscopic studies of the extracellular domain of $\alpha_{IIb}\beta_3$ and $\alpha_V\beta_3$, coupled with NMR studies of the α_{IIb} and β_3 transmembrane and cytoplasmic domains, have provided a working model of talin-dependent $\alpha_{IIb}\beta_3$ activation (Coller 2015; Ginsberg 2014; Lau et al. 2009; Luo et al. 2007; Park et al. 2015; Xiao et al. 2004; Zhu et al. 2010). Key elements include a transmembrane allosteric rearrangement of the α_{IIb} and β_3 subunits whereby agonist-triggered inside-out signals and the binding of talin to the β_3 tail disrupt α_{IIb} and β_3 transmembrane interactions to induce a change in tilt angle of the β3 transmembrane domain with respect to α_{IIb}. In the inactive integrin, the transmembrane domains of α_{IIb} and β_3 feature a so-called outer membrane clasp promoted by glycine packing interactions and an inner membrane clasp promoted by hydrophobic stacking of amino acid side chains and by formation of a salt bridge involving α_{IIb} (R995) and β_3 (D723). In this conformation, the side chain of a positively charged β_3 residue (K716) orients to snorkel back toward the membrane boundary, where it associates with a negatively charged phospholipid group. This results in a 25° tilt of the β_3 alpha helix that embeds the β_3 transmembrane helix at an angle through the membrane (Kim et al. 2011). Conformational activation occurs when talin binds to the β_3 tail NPXY sequence and to acidic membrane lipid groups, leading to disruption of the (D723)/β_3 and (R995)/α_{IIb} salt bridge, and formation of a new salt bridge between β_3 and talin. The resulting increase in crossing angle of the β_3 transmembrane domain disturbs the outer membrane clasp leading to propagation of conformational changes to the extracellular domains of $\alpha_{IIb}\beta_3$ that foster ligand binding (Ginsberg 2014; Iwamoto and Calderwood 2015). The changes include conversion of $\alpha_{IIb}\beta_3$ from a bent to an upright conformation, a piston-like downward axial displacement of the β_3 I-like domain C-terminal helix resulting in a swing-out of the β_3 hybrid and PSI domains from the I-like domain, and a conversion of the N-terminal ligand-binding headpiece from closed to open. The β_3 I-like domain contains three metal ion sites termed MIDAS, ADMIDAS, and SyMBS that play important roles in the activation and ligand-binding processes (Coller 2015). Current models of $\alpha_{IIb}\beta_3$ activation may be of general relevance to other integrins.

Studies of purified talin added to phospholipid nanodiscs containing $\alpha_{IIb}\beta_3$ indicate that talin binding is sufficient to initiate $\alpha_{IIb}\beta_3$ activation, at least in vitro (Ye et al. 2010). However, talin is not sufficient for normal agonist-induced fibrinogen binding to murine or human platelets, and at least one other molecular adaptor protein, kindlin-3, is involved (Kuijpers et al. 2009; Malinin et al. 2009; Moser et al. 2008; Svensson et al. 2009).

Kindlin-3 is a ~76 kDa protein expressed almost exclusively in hematopoietic cells, including platelets (Malinin et al. 2010; Moser et al. 2009a). It is a member of the kindlin family of adaptor molecules that includes kindlin-1 and kindlin-2. Its modular structure includes a FERM domain near the C-terminus which can engage several integrin β tails, including β_3, and in which the F2 sub-domain is uniquely split by a PH domain. Some kindlin family members have been shown to contain binding sites for other proteins, including integrin-linked kinase, migfilin, c-Src, and RACK1 (Feng et al. 2012; Malinin et al. 2010; Moser et al. 2009b; Qu et al. 2014). The extent to which kindlin-3 can engage any of these proteins in platelets remains to be determined.

Given the necessary and sufficient role for talin in $\alpha_{IIb}\beta_3$ activation in membrane nanodiscs in vitro, the inability of stimulated mouse or human platelets deficient in kindlin-3 to

bind fibrinogen and aggregate normally provides an additional layer of complexity to the $\alpha_{IIb}\beta_3$ activation story. Kindlin-3 deficiency also impairs leukocyte integrin function, and in humans this combined platelet and leukocyte defect is associated with serious recurrent infections and bleeding and is referred to as Leukocyte Adhesion Deficiency III (or LAD I variant) (Etzioni 2014; Kuijpers et al. 2009; Malinin et al. 2009; Svensson et al. 2009). Talin and kindlin-3 binding to the β_3 cytoplasmic tail is not mutually exclusive, and kindlin depletion or excess does not affect agonist-induced talin recruitment to $\alpha_{IIb}\beta_3$ (Kahner et al. 2012). One idea based on recent experimental work is that talin functions primarily to induce conformational change and affinity modulation of $\alpha_{IIb}\beta_3$, while kindlin functions primarily to promote $\alpha_{IIb}\beta_3$ clustering within the plane of the plasma membrane (avidity modulation) (Fig. 1) (Ye et al. 2013, 2014). It is also possible that kindlin-3 interacts with other proteins to promote platelet activation and further studies are needed to address this issue.

ADAP, also known as FYB for Fyn binding protein, is another hematopoietic-specific adaptor involved in integrin-mediated leukocyte and platelet adhesion, although the mechanism of ADAP's effects on integrins in these two cell types differs (Wang and Rudd 2008; Kasirer-Friede et al. 2014). Based on studies with human platelets and gene-targeted murine platelets, ADAP functions downstream of $\alpha_2\beta_1$ (Jarvis et al. 2012) and both upstream and downstream of $\alpha_{IIb}\beta_3$ (Kasirer-Friede et al. 2006, 2010,). Its upstream function is suggested by the finding that fibrinogen binding to $\alpha_{IIb}\beta_3$ and platelet aggregation in response to agonists is reduced in ADAP-null murine platelets (Kasirer-Friede et al. 2007). However, in contrast to the severe $\alpha_{IIb}\beta_3$ activation defect in talin- or kindlin-3-deficient mouse platelets, the defect in ADAP-null platelets is dependent on the agonist used and is generally partial. Biochemical studies indicate that ADAP can interact with talin and kindlin-3 in vitro, although it is not known if these interactions are direct (Kasirer-Friede et al. 2014). These proteins also co-localize with each other in platelets, and in ADAP-deficient platelets, there is reduced co-localization of talin with $\alpha_{IIb}\beta_3$, coupled with reduced irreversible fibrinogen binding to $\alpha_{IIb}\beta_3$. ADAP can also associate with an $\alpha_{IIb}\beta_3$-talin complex in a CHO cell expression system and enable kindlin-3 to promote agonist-dependent ligand binding to $\alpha_{IIb}\beta_3$ in these cells (Kasirer-Friede et al. 2014).

A homozygous nonsense mutation in ADAP in five members of an Arab-Christian family has been associated with thrombocytopenia with small platelets, with the remaining platelets exhibiting increased basal binding of an activation-dependent antibody to $\alpha_{IIb}\beta_3$, but reduced antibody binding in response to ADP (Levin et al. 2015). An Iraqi family with recessive thrombocytopenia with small platelets exhibiting a different homozygous deletion in Fyb has been reported, but platelet function was not studied (Hamamy et al. 2014). Taken together, these studies point to a role for ADAP in platelet biogenesis and in inside-out $\alpha_{IIb}\beta_3$ signaling mediated by talin and kindlin-3.

$G\alpha_{13}$ and $\alpha_{IIb}\beta_3$ function. As illustrated above by talin, kindlin-3, and ADAP, intracellular proteins that interact directly with $\alpha_{IIb}\beta_3$ may function in both inside-out and outside-in signaling. An interesting twist to this phenomenon is suggested by recent studies of the $G\alpha_{13}$ G protein subunit. On the one hand, the switch region 2 of $G\alpha_{13}$ can interact directly with the talin head domain in a calcium-dependent manner, leading the authors to suggest a role for this interaction in $\alpha_{IIb}\beta_3$ inside-out signaling (Srinivasan et al. 2015). On the other hand, $G\alpha_{13}$ functions downstream of PAR1 in platelets to activate a Rho GEF, leading to the activation of RhoA and platelet shape change (Brass et al. 2013). The potential involvement of fibrinogen-bound $\alpha_{IIb}\beta_3$ in mediating cytoskeletal events downstream of Gα13 is illustrated by the demonstration that Gα13 can interact directly with the β_3 cytoplasmic tail, and interference with this interaction in mouse platelets blocks outside-in $\alpha_{IIb}\beta_3$ signaling and platelet spreading on fibrinogen (Gong et al. 2010).

Negative Regulators of Integrin Activation

Proteins that Prevent Basal Activation of Integrins

Platelet activation may normally be downregulated by several mechanisms in order to prevent pathological thrombosis. These include (1) production of PGI_2 by endothelial cells leading to PGI_2 receptor-mediated production of cyclic AMP in platelets (Moncada and Vane 1981; Raslan and Naseem 2014; Weksler 1982); (2) production of nitric oxide within endothelial cells, leukocytes, and platelets leading to increased platelet cyclic GMP (Naseem and Riba 2008); and (3) enzymatic reduction in levels of extracellular ADP by endothelial cell surface-expressed CD39 (Marcus et al. 2005). cAMP and cGMP activate protein kinase A (PKA) and protein kinase G (PKG), respectively, which through their serine kinase activity serve to attenuate platelet responses. Two important substrates of PKA are the IP3 receptor, leading to prohibition of intracellular calcium elevations, and CALDAG-GEFI, the principal GTP exchange factor for Rap1b in platelets. PKA and PKG also directly phosphorylate Rap1b and VASP at distinct sites, to maintain platelets in a resting state. Platelet phosphodiesterases further regulate the impact of NO and PGI2 by degrading the phosphodiester bond in cAMP and cGMP and thus countering their effects (Smolenski 2012; Jones et al. 2012). A deficiency in one or more of these negative regulatory mechanisms could in theory increase the basal state of $\alpha_{IIb}\beta_3$ activation in platelets, although there is little direct evidence for this in humans. A number of cyclic AMP and

cyclic GMP substrates in platelets have been identified, and their effects on platelet signaling mechanisms demonstrated (e.g. inhibition of calcium fluxes). The precise roles of many of these substrates in dampening the process of $\alpha_{IIb}\beta_3$ activation are unclear.

Proteins that Promote Integrin Deactivation by Their Presence

Given that the interaction of talin and kindlin-3 with the β_3 tail promotes $\alpha_{IIb}\beta_3$ activation, it is reasonable to assume that there may be tail-interacting proteins in platelets that inhibit integrin activation. The α_{IIb} cytoplasmic tail is not a completely passive player in inside-out signaling (Liu et al. 2015b), and several proteins can bind to the highly conserved membrane-proximal GFFKR region of α integrin cytoplasmic tails to dampen integrin activation, at least in nucleated cells. Examples include MDGI and Sharpin, the latter hypothesized to indirectly block talin interaction with the integrin β_1 tail (Bouvard et al. 2013). Proteins such as filamin that bind to β cytoplasmic tails may also dampen integrin activation by blocking tail interactions with talin or kindlins (Bouvard et al. 2013; Liu et al. 2015a; Truong et al. 2015). Additional studies are required to determine the extent to which these proteins are expressed and function in platelets as negative regulators of $\alpha_{IIb}\beta_3$.

Regulation of Non-integrin Platelet Adhesion Receptors

Non-integrin platelet adhesion receptors include the highly glycosylated single-pass transmembrane proteins, GPVI, GPIb-V-IX, and CLEC-2 (Ozaki et al. 2013). Under physiological conditions, the adhesive activities of GPVI and GPIb-V-IX are controlled, in part, by de novo expression of their cognate ligands (collagen and VWF, respectively) on injured vessels or ruptured plaque, and during embryonic development by platelet CLEC-2 encounters with podoplanin expressed on the surface of lymphatic endothelial cells. Localization to lipid rafts or receptor oligomerization may further regulate the function of these particular adhesion receptors (Ozaki et al. 2013). As an example, greater than one third of GPVI exists as dimers on resting platelets, and this increases to up to 50 % following ligation or platelet thrombin activation (Jung et al. 2012), supporting the idea that the dimerized state may be the functional GPVI unit for binding to collagen (Horii et al. 2006) and possibly to laminin (Inoue et al. 2006) and fibrin (Mammadova-Bach et al. 2015). In order to selectively study GPVI signaling independently of integrin $\alpha_2\beta_1$, which also binds collagen, collagen-related peptide (CRP) (Asselin et al. 1997) and the snake-venom convulxin (CVX) (Francischetti et al. 1997) are often used in vitro to engage GPVI. GPVI is solely expressed in platelets and megakaryocytes and therefore is considered to be a potential therapeutic hemostatic target.

CLEC-2 is a member of the Dectin family of hemITAM receptors that contain only a single YXXL motif (Ozaki et al. 2013), but compensates by signaling to Syk from the dimerized state (Hughes et al. 2010). Although signaling by CLEC-2 to activate integrins is transduced through coupled tyrosine kinase cascades, as for GPVI, the architecture and hierarchy of signaling pathways may vary (Manne et al. 2015). Interaction of CLEC-2 in platelets and podoplanin in lymphatic endothelial cells is necessary for the separation of lymphatic and blood vessels (Ozaki et al. 2013). Recently, platelet CLEC-2 has been shown to associate with S100A13 in vascular smooth muscle cells and contribute to thrombus formation (Inoue et al. 2015).

Although studies in vitro and in mice implicate GPVI/Fc receptors and CLEC-2 in hemostasis and thrombosis, patients with mutations in GPVI suffer from only a mild bleeding phenotype (Arthur et al. 2007; Dumont et al. 2009), and mutations of CLEC-2 in patients are awaiting discovery. The case for GPIb-V-IX is very different. Patients lacking or with mutated GPIb-V-IX suffer from Bernard-Soulier syndrome and can exhibit a severe bleeding phenotype. The consequences of disruption of GPIB-V-IX in mice in fact overshadow those of its principal hemostatic ligand, VWF (Bergmeier et al. 2006), as noted by an absolute GPIb-V-IX requirement for platelet incorporation into arterial thrombi, but residual thrombus growth in the absence of VWF (Ni et al. 2000). This may reflect interactions of GPIb-V-IX with a range of additional binding partners and their respective contributions to thrombosis (Gardiner and Andrews 2014).

The subunits of the GPIb-V-IX complex are present in a molecular ratio of 2 GPIb α: 4 GPIb β: 2 GPIX: 1 GPV (Li and Emsley 2013; Ruggeri and Mendolicchio 2007). In contrast to GPIb-V-IX's ability to directly bind immobilized VWF at low to high shear rates, regulation of receptor and/or ligand must occur to permit platelet interactions with soluble VWF and to drive downstream signaling to activate $\alpha_{IIb}\beta_3$. While hydrodynamic stretching of multimeric VWF can cause unraveling of constituent subunits (Siedlecki et al. 1996), GPIb-V-IX binding epitopes may not be exposed and additional modifications may be needed (Miyata et al. 1996). It is likely that conformational changes in GPIb-V-IX also occur that regulate binding to VWF, as activating mutations in GPIbα, mostly in the partially ordered β-switch region in the C-terminal cap, result in the spontaneous platelet binding to VWF seen in patients with platelet-type VWD (Huizinga et al. 2002; Weiss et al. 1982). A shift in the macroglycosidic stalk region of GPIb-V-IX also appears to occur following ligation by a VWF A1 domain fragment, producing a novel epitope recognized by a recently developed antibody against this region (Zhang

et al. 2015). These and other studies have led to the model of a force-induced super affinity state that integrates several transitions in GPIb-V-IX/VWF bond behavior, from slip, flex to catch bonds as a function of applied stress, and provide a structural basis for their interactions under flow (Blenner et al. 2014). GPIb-V-IX function may be further regulated by the cytoskeletal protein, filamin A, which binds to residues 540–590 in GPIbα, and by the signaling protein, 14-3-3-ζ, which binds to residues 605–610. The 14-3-3-ζ interaction is hypothesized to repress GPIb-V-IX stimulation of $\alpha_{IIb}\beta_3$-mediated platelet spreading through Rac1 and Cdc42 (Bialkowska et al. 2003). At high shear stresses exceeding 90 dyn/cm^2, 14-3-3-ζ may dissociate from GPIb-V-IX to allow recruitment of filamin and enhance anchoring to the cytoskeleton (Cranmer et al. 2011). Several of these observations were made in heterologous cells and need to be confirmed in platelets.

Several mechanisms exist to downregulate the function of the non-integrin adhesion receptors. Immune receptor-based inhibitory motif (ITIM) domain-containing proteins such as PECAM-1 or G6b-B that recruit phosphatases (Jones et al. 2009), or inhibit Src and Syk signaling (Mori et al. 2008), may dampen responses propagated by ITAM containing receptors. Functional adhesion receptors may be reduced on the platelet surface by internalization after ligand binding (Lorenz et al. 2015; Michelson et al. 1991; Rabie et al. 2007) or by proteolysis, although thrombin cleavage of GPV may actually enhance its interaction with GPIbα (Dong et al. 1997; Phillips and Agin 1977). Metalloproteinases of the ADAM family have recently been identified as key regulators of surface expression of the non-integrin platelet adhesion receptors: ADAM 17 can cleave GPIbα and GPVI, and ADAM 10 can cleave GPVI and CLEC-2 (Gardiner et al. 2007; Al-Tamimi et al. 2012). The shed receptor domains are released into the circulation (Gawaz et al. 2014), and plasma levels appear to correlate with cardiovascular events (Qiao et al. 2010). Our understanding of how the relevant metalloproteinases are regulated in vivo is incomplete.

Perspective

Many, if not most, adhesion receptors in platelets are regulated at the posttranslational level, integrin $\alpha_{IIb}\beta_3$ being the poster child because it is the most abundant and has been studied most. Lessons learned about the regulation of $\alpha_{IIb}\beta_3$ in platelets resulted in the development of the first anti-integrin therapeutics in the 1990s with important indications in cardiovascular medicine. Candidate therapeutics targeted to non-integrin platelet adhesion receptors, particularly GP Ib-V-IX, are the subject of current studies, and they might eventually prove useful in some clinical settings. Continued investigation into how platelet adhesion receptors are regulated promises to provide additional opportunities for therapeutic intervention in thrombosis and to clarify the molecular basis of defects in platelet function in individuals with poorly understood bleeding diatheses.

Take-Home Messages

- Platelets are equipped with integrin (section "Regulation of Platelet Integrins") and non-integrin platelet adhesion receptors (section "Regulation of Non-integrin Platelet Adhesion Receptors") that together function to secure platelets to damaged endothelium under a wide range of hemodynamic stress conditions, corresponding to the arterial and venous circulation. Non-integrin platelet adhesion receptors often establish the first contacts with vascular matrices, but require integrins for stable adhesion.
- Platelets respond to classical soluble excitatory agonists, as well as to stimulation through platelet adhesion receptors bound to vascular matrices (Table 1). Agonist-associated signaling through G-protein-coupled or tyrosine-coupled receptors promotes integrin activation through *inside-out* signaling pathways to mediate stable platelet adhesion, and aggregation through cross-bridging of ligands bound to αIIbβ3 integrin.
- Intermediate signaling networks are vast and complex and include hundreds of proteins including adapter proteins, kinases, phosphatases, phospholipid mediators, and calcium (section "Principal Signaling Pathways Downstream of Agonist Receptors Involved in Activation of αIIbβ3").
- Signaling pathways converge on integrin-proximal proteins such as talin and kindlin-3 that activate the integrin by strategically binding to integrin cytoplasmic tails, provoking conformational changes in integrin extracellular domains and receptor clustering (section "Integrin-Proximal Regulatory Events").
- Ligand binding to αIIbβ3 induces inward signals (*outside-in*) to promote cytoskeletal remodeling leading to ligand stabilization, platelet spreading, and subsequent clot retraction.

The Platelet Glycoprotein Ib-IX-V Complex

José A. López

Abstract

The glycoprotein (GP) Ib-IX-V complex is an abundant plasma membrane receptor that is expressed almost exclusively on platelets and megakaryocytes. It is highly specialized to carry out its most import important function: the initial adhesion of platelets to sites of vessel wall injury in regions of the vasculature where the wall shear stresses are very high. It does this by binding the plasma and vessel wall protein von Willebrand factor. Failure of these hemostatic mechanisms because of deficiency or dysfunction of either ligand or receptor greatly increases the risk for pathological bleeding. The complex also has other important functions, including facilitating the response of platelets to the important agonist thrombin, and involvement in inflammatory processes by interacting with neutrophil and monocyte integrin $\alpha_M\beta_2$. In this chapter, the structure, synthesis, and functions of the GPIb-IX-V complex are discussed.

Introduction

The GPIb-IX-V complex is a unique membrane adhesion complex whose existence was first inferred with the description and early characterization of a rare bleeding disorder characterized by moderate thrombocytopenia, a prolonged bleeding time, and very large platelets (Bernard and Soulier 1948). This disorder, now known as the Bernard–Soulier syndrome in honor of the two French physicians who first described it, illustrates several characteristics of the complex: its vital role in platelet adhesion, its association with the cytoskeleton, and its role in platelet formation. In this chapter, I will attempt to summarize a portion of the vast literature related to this receptor.

GPIb-IX-V Complex Structure and Biosynthesis

The term GPIb-IX-V complex generally refers to a complex of four primary polypeptides: GPIbα, GPIbβ, GPIX, and GPV, present on the platelet membrane in a stoichiometry of 2:4:2:1, respectively (Fig. 1). Other membrane proteins of platelets are known to associate with this complex, but for the purposes of this chapter, they are not considered part of the complex because they have been shown to function independently and not require the complex for their expression.

Each of the GPIb-IX-V complex polypeptides is produced by its own gene, and each is a type I membrane protein with a single hydrophobic transmembrane domain (López 1994). Although the genes are not clustered in the genome, they are similar in being compact, each gene having only one intron, except the *GPIX* gene, which has two (López et al. 1998). Each of the genes also contains the entire protein-coding sequence within a single exon, with the exception of *GPIBB*, which has a small intron interrupting the coding sequence only ten base pairs after the first base of the initiator methionine. The proteins these genes encode are also related, each belonging to the large,

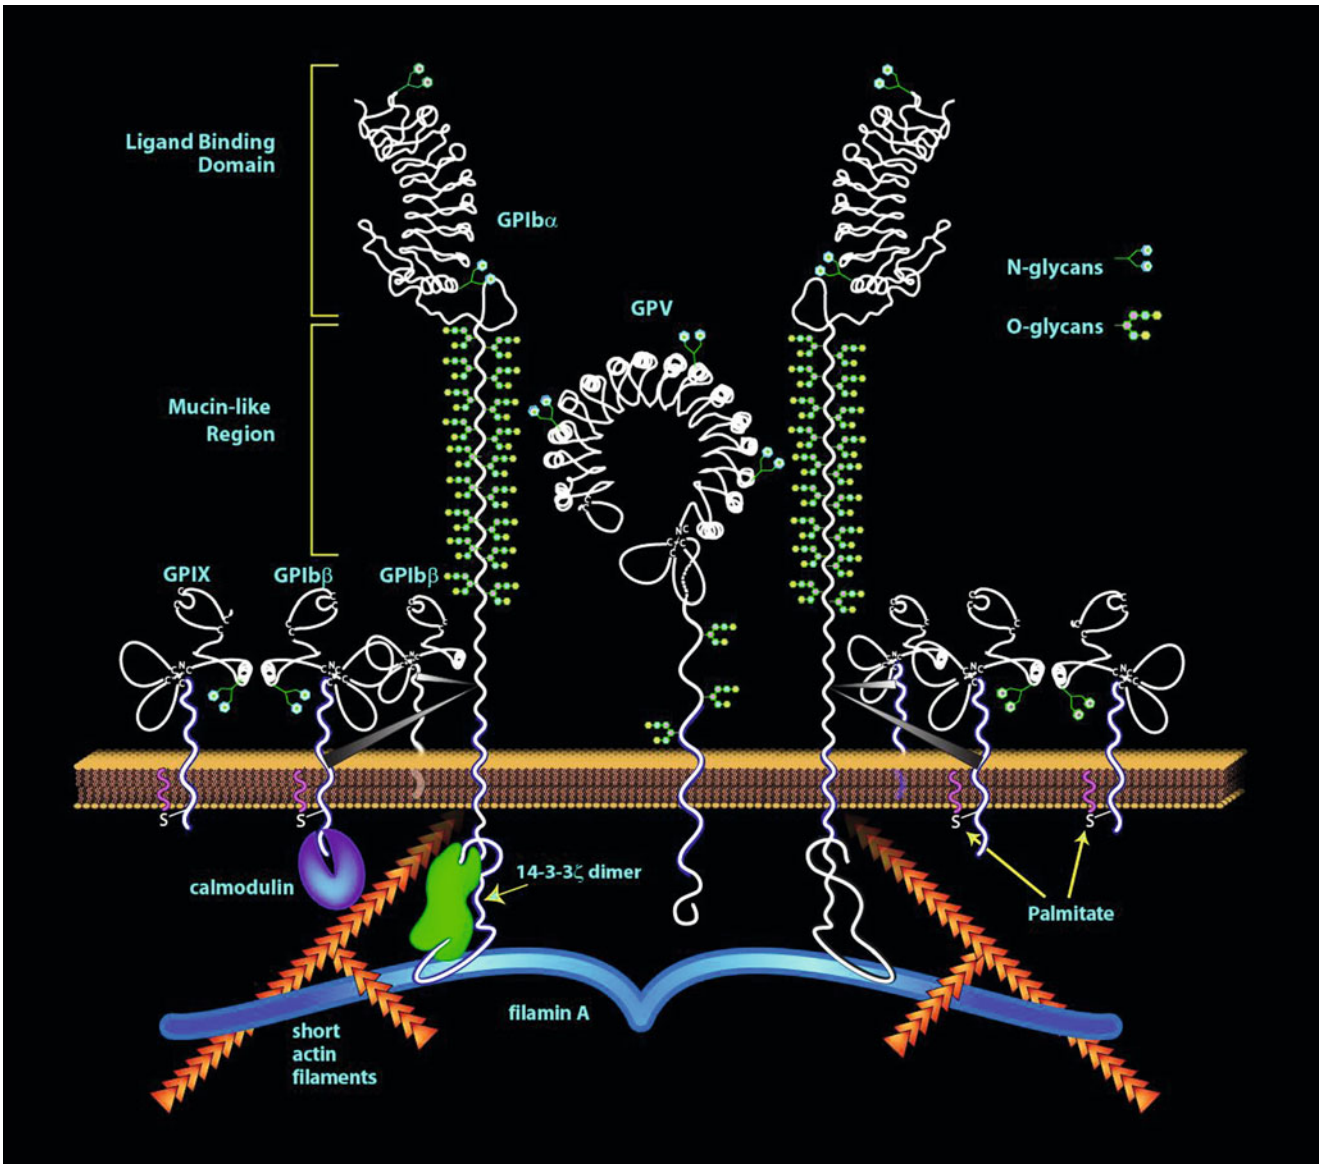

Fig. 1 Schematic representation of the glycoprotein Ib-IX-complex and associated cytoplasmic proteins

phylogenetically widespread leucine-rich repeat protein superfamily (Bella et al. 2008; López 1994). This protein superfamily is characterized by the presence of a single or tandem copies of a 20–30 amino acid motif containing leucine residues at conserved positions and generally adapting a structure known as an α-/β-horseshoe fold, based on the structure of ribonuclease 1, which was the first leucine-rich repeat structure determined (Bella et al. 2008). In this structure, α-helices alternate with β-strands, the β-strands of consecutive repeats residing on the inside of a curved toroid structure to form parallel β-sheets (Bella et al. 2008). It is this β-sheet that makes the leucine-rich repeat proteins so versatile in being able to bind a variety of ligands. Of interest, the GPIb-IX-V leucine-rich repeat structures that have been determined demonstrate very little α-helical structure, but in GPIbα, with tandem repeats, the β-sheet motif is maintained (Uff et al. 2002).

Within the complex, one GPIbα is disulfide linked to two GPIbβ polypeptides (Luo et al. 2007a), and GPIX is noncovalently, and rather tightly, associated with GPIb ($\alpha\beta_2$) (Du et al. 1987; Luo et al. 2007b). GPV is associated more loosely, as it remains associated in the presence of the mild nonionic detergent digitonin, but dissociates in the presence of another nonionic detergent, Nonidet P-40 (Modderman et al. 1992). This hierarchy of association is reflected in the fact that no complex is expressed on the plasma membrane in the absence of GPIbα, GPIbβ, or GPIX, but a GPIb-IX complex can be expressed in the absence of GPV (López et al. 1992a). Whether GPV is fully complexed with GPIb-IX at all times on the platelet

membrane is unknown. Assembly of the complex occurs cotranslationally; in other words, as soon as the polypeptides are synthesized and inserted into the membrane of the endoplasmic reticulum, the four polypeptides assemble into an immature complex (Dong et al. 1998). Recent studies indicate that the primary regions mediating the associations of the GPIb-IX-V polypeptides are the transmembrane domains of the polypeptides (Luo et al. 2007b; Mo et al. 2006, 2012). The GPIbα transmembrane domain associates with two GPIbβ polypeptides, and also with GPV, whereas the GPIX transmembrane domain binds GPIbβ. Full maturation of the complex, as determined by studies in transfected heterologous cells, requires approximately 3 h (Dong et al. 1998). The fully mature complex has a number of posttranslational modifications, including extensive N- and O-glycosylation (López 1994), tyrosine sulfation (Dong et al. 1994), and palmitoylation of Cys residues on the cytoplasmic tails of GPIbβ and GPIX (Muszbek and Laposata 1989).

Polypeptide Structures

Glycoprotein Ibα GPIbα is not only the largest of the GPIb-IX-V polypeptides, it is also the one that binds most of the extracellular ligands and cytoplasmic molecules that interact with the complex. GPIbα is polymorphic in length in the human population, being present in any of four different lengths based on variable numbers of a 13-amino acid sequence present once or repeated up to three additional times within the mucin-like macroglycopeptide region (Ishida et al. 1995; López et al. 1992b). These variants are designated A, B, C, and D, from largest two smallest, the D isoform containing 610 amino acids in its mature form (López et al. 1987). When specific regions or amino acid residues are discussed in the literature, the numbering of the residue positions is usually based on the sequence of the D isoform. This polypeptide has an N-terminal extracellular region of approximately 485 amino acids, a transmembrane domain of 31 amino acids, and a cytoplasmic domain of 94 amino acids (López et al. 1987) (see Fig. 1). The extracellular region can be subdivided into three individual domains. The 300 amino acids at the N-terminus constitute the ligand-binding domain, containing binding sites for all of the known GPIb-IX-V ligands. This domain is characterized by the presence of seven leucine-rich repeats flanked by conserved disulfide loop structures at both the N- and C-termini (López 1994). Following the C-terminal flank is a highly acidic sequence rich in aspartic acid and glutamic acid residues that also contains three tyrosine residues that undergo posttranslational sulfation (Dong et al. 1994; Ward et al. 1996). This anionic sulfated region contains 13 negative charges within a stretch of 19 amino acids, a feature important in determining its ability to bind thrombin exosites I and II (Zarpellon et al. 2011). The ligand-binding domain also contains two N-linked glycan chains, three disulfide bonds, and an exposed, unpaired Cys residue. The crystal structure of this region has been solved, both as an isolated domain (Uff et al. 2002), and in complex with ligands VWF (Dumas et al. 2004; Huizinga et al. 2002) and thrombin (Celikel et al. 2003; Dumas et al. 2003). The GPIbα N-terminus forms a cupped-hand-like structure, with the palm of the hand representing the concave β-sheet surface of the leucine-rich repeats, the fingertips representing the N-terminal disulfide loop known as the β-finger, and the thumb representing the β-switch C-terminal to the leucine-rich repeats (López and Munday 2009).

C-terminal to the anionic sulfated region is a domain known as the macroglycopeptide that is rich in Thr, Ser, and Pro residues. This sequence has 59 potential sites for O-glycosylation and two sites with a consensus for N-glycosylation. Addition of one copy of the repeated sequence adds five additional sites for potential O-glycosylation, the largest (A) form therefore containing up to 15 additional O-glycan chains. The macroglycopeptide is indeed heavily O-glycosylated, carbohydrate in this region accounting for approximately half of the molecular mass of GPIbα as it migrates on SDS-polyacrylamide gels (Okumura et al. 1976). The heavy glycosylation and high Pro content of the macroglycopeptide prevents the region from developing extended secondary structure, the consequence being that the region functions as a test-tube-brush–like spacer to separate the ligand-binding domain from the platelet plasma membrane (see Fig. 1). This feature is important for the normal function of GPIbα as demonstrated by the fact that expression of a complex containing a GPIbα mutant with deletion of the sequence 318–452 (which includes most of the macroglycopeptide) produced a receptor that was expressed normally on the cell surface and could bind VWF under static conditions but which was incapable of mediating the capture of cells to a VWF surface under flow (Li et al. 2002).

It is not clear where the region of glycosylation ends, but the region of high Pro content ends after residue 420. The region 421–483 contains not only fewer Pro residues, it also has fewer Ser and Thr residues that can be O-glycosylated. This region contains what has been termed a "mechanosensitive domain" based on the fact that it has been shown to unfold when tensile force is applied to the extracellular domain after the formation of VWF–GPIbα bonds (Zhang et al. 2015). This unfolding was proposed to be necessary for the transmission of extracellular mechanical signals generated after ligand binding to the N-terminus. Following the mechanosensitive domain are vicinal Cys residues involved in asymmetric disulfide bonds with two GPIbβ peptides (Luo et al. 2007a). The GPIbα transmembrane domain is typical for a type I transmembrane protein,

but its specific sequence is required for interaction with GPIbβ and GPV (Li and Emsley 2013). The ~94 amino acid GPIbα cytoplasmic domain is unique among proteins (no known paralogs) and is notable for what it does and does not contain. It does not contain a domain recognizable as a tyrosine kinase, nor does it contain ITAM sequences. It also only contains one Tyr residue but not within a sequence motif that favors its phosphorylation. This region does, however, contain five sequences that loosely fit consensus sites for glycosylation by Ser/Thr kinases, particularly protein kinase A (PKA). Several sites have been identified as binding sites for the adaptor protein 14-3-3ζ (Andrews et al. 1998; Du et al. 1996; Mangin et al. 2004; Yuan et al. 2009), and these sites have several functions, including regulating the ability of GPIb-IX-V to bind VWF (Yuan et al. 2009), attachment of the complex to the membrane skeletal protein filamin A (Yuan et al. 2009), and downstream signal transduction (Zhang et al. 2012). Interaction of the GPIbα cytoplasmic domain with 14-3-3ζ appears to require phosphorylation of serine residues, particularly at sites Ser609, Ser559, and Ser587/Ser590, but little evidence exists that the state of the phosphorylated residues is dynamic, as it has not been possible to metabolically label GPIbα with radioactive phosphate (Fox et al. 1979; Wardell et al. 1989). Nevertheless, Bodnar et al. and Yuan et al. used sequence-specific anti-phosphopeptide antibodies to identify phosphorylation at Ser609 and 559, respectively (Bodnar et al. 1999; Yuan et al. 2009). Using a phosphoSer609-specific antibody, Bodnar et al. (1999) found that in unstimulated platelets, virtually all GPIbα molecules were phosphorylated at Ser609. These investigators later found that both the unphosphorylated and phosphorylated C-terminal peptides had the capacity to bind 14-3-3ζ, with a phosphorylated peptide being capable of competing with GP Ibα for 14-3-3ζ association while the corresponding non-phosphorylated peptide was not (Bodnar et al. 1999). Binding sites for 14-3-3ζ have also been reported within the sequences Arg557–Gly575 (Mu et al. 2008) and Leu580–Ser 590 (Mangin et al. 2004). The filamin A binding site was first identified to be located between residues 536–568 (Andrews and Fox 1992), later refined to 557–575 (Feng et al. 2003), with residues Phe568 and Trp570 being vital for the interaction (Cranmer et al. 2005). A crystal structure of a complex between the GPIbα peptide 556–577 and filamin A domain 17 reveals that this region of GPIbα contributes a β-strand to a bimolecular β-sheet (Nakamura et al. 2006). In addition to binding 14-3-3ζ and filamin A, the GPIbα contains a binding site for phosphoinositide (PI)-3 kinase (Mu et al. 2008; Munday et al. 2000).

Glycoprotein Ibβ and Glycoprotein IX GPIbβ and GPIX are both much smaller polypeptides than GPIbα, their mature forms being of lengths 181 and 161 residues, respectively. These two polypeptides have closely related extracellular structures, with approximately 60 % sequence similarity, but their cytoplasmic sequences are completely divergent (López 1994). The extracellular domains each essentially comprise one leucine-rich repeat domain containing one copy each of the leucine-rich sequence that characterizes these domains and conserved N- and C-terminal flanking sequences. The flanking sequences form two disulfide bonds N-terminal to the leucine-rich repeat and two disulfide bonds C-terminal to the domain. All Cys residues present in GPIbβ are conserved in GPIX except one, which lies immediately before the transmembrane domain in GPIbβ and is replaced by Ser in GPIX. This GPIbβ Cys forms a disulfide bond with either Cys484 or Cys485 of GPIbα, the mature complex containing two GPIbβ subunits asymmetrically disulfide bonded to one GPIbα (Luo et al. 2007a). GPIbβ and GPIX can form a complex independently of the other polypeptides (López et al. 1994), the binding sites between the two involving the transmembrane and extracellular domains (Li and Emsley 2013). The GPIbβ transmembrane domain also binds directly to the GPIbα transmembrane domain (Luo and Li 2008). The cytoplasmic domains of GPIbβ and GPIX are both relatively short, that of GPIX containing only seven residues and that of GPIbβ containing approximately 34. Both contain Cys residues in the immediate juxtamembrane position of the cytoplasmic domain which have been shown to become posttranslationally palmitoylated (Muszbek and Laposata 1989), a modification that may help to localize the complex to membrane microdomains, although evidence exists that this modification is not required for raft association (Xu et al. 2015). No other functions have been described for the short GPIX cytoplasmic domain, but the GPIbβ sequence has at least two important features of functional importance. Immediately following the palmitoylated Cys residue is an 18-residue sequence that contains eight Arg residues and ends with a Ser (Ser166) known to be phosphorylated by PKA (Wardell et al. 1989). The membrane-proximal Arg-rich sequence can bind both calmodulin and tumor necrosis factor receptor-associated factor 4 (TRAF4) (Andrews et al. 2001; Arthur et al. 2011). Calmodulin binding in this region has been proposed to regulate access to a cleavage site on GPIbα for membrane metalloproteinases of the ADAM family (Aktas et al. 2005; Gardiner et al. 2007), because treatment with the calmodulin inhibitor W7 induces GPIbα cleavage. Nevertheless, the relationship between GPIbβ calmodulin binding and GPIbα proteolysis is not direct, as mutation of two GPIbβ residues prevented calmodulin binding but had no effect on GPIbα shedding (Mo et al. 2010). TRAF4 association with GPIbβ and with GPVI is proposed to link ligand binding to GPIbα to downstream redox pathways involving platelet NADPH oxidase (Arthur et al. 2011). At the C-terminus of this Arg-rich basic sequence, Ser166 becomes phosphorylated when the

cytosolic cAMP concentration rises, thereby mediating one of the platelet inhibitory effects of substances such as prostaglandins I_2 and E_1 (Wardell et al. 1989). Phosphorylation of Ser166 provides another binding site within the complex for 14-3-3ζ (Andrews et al. 1998; Calverley et al. 1998), which likely mediates the platelet inhibitory actions.

Glycoprotein V GPV is the second largest polypeptide of the complex but so far the most mysterious and least studied. GPV was the first identified target for thrombin proteolysis on the platelet plasma membrane, cleavage producing a soluble fragment, GPVf1, that circulates in the plasma (Mosher et al. 1979; Phillips and Agin 1977). The concentration of GPVf1 in normal plasma is approximately 17 ng/mL based on measurements from 100 normal individuals (Azorsa et al. 1999). This concentration increases during thrombotic episodes (Morel et al. 2004; Ravanat et al. 2000).

GPV contains 544 amino acids, of which 504 are extracellular, 22 comprise a transmembrane domain, and only 18 reside within the cytoplasm (Lanza et al. 1993). The extracellular region is heavily glycosylated (Berndt and Phillips 1981) and contains a structure similar to that of the other GPIb-IX-V complex polypeptides, with 15 leucine-rich repeats flanked by conserved N- and C-terminal disulfide loops. A thrombin cleavage site, after Arg460, is situated only a few residues from the end of the C-terminal flank. It is of interest to note that the thrombin cleavage site is conserved in humans, mice, and rats (Ravanat et al. 1997). The GPV cytoplasmic domain contains only 18 amino acids, but this sequence has been shown to bind calmodulin (Andrews et al. 2001). As with other platelet receptors, inhibition of calmodulin binding to the GPV cytoplasmic domain also induces GPV shedding, a process that has been shown to be mediated by ADAM17 (Gardiner et al. 2007).

The most important physiological function of GPV is still very likely undetermined. From studies of deficient mice, the function of this protein is not obvious. GPV is not necessary for expression of the GPIb-IX-V complex, although its own expression is enhanced in the presence of the other subunits (Kahn et al. 1999; Li et al. 1995). GPV-deficient platelets are morphologically normal. In addition, GPV-deficient mice have been shown to lack a hemostatic defect (Kahn et al. 1999) and to have normal thrombin signaling. In contrast, however, other studies showed GPV-deficient platelets to be more responsive to thrombin (Ramakrishnan et al. 2001), and studies in thrombosis models demonstrated increased platelet adhesion and aggregation that was dependent on both thrombin and VWF (Ni et al. 2001). More recent studies of deficient mice backcrossed into the C57B/6 background indicate that the effect on thrombus size and survival after agonist injection depends on the nature of the injury and the agonist injected (Nonne et al. 2008).

Functions of the Complex

The GPIb-IX-V complex has many physiological ligands, which include adhesion molecules such as VWF, thrombospondin-1, and fibrin, membrane counter-receptors on leukocytes ($\alpha_M\beta_2$) and endothelial cells (P-selectin), and a variety of plasma proteins, including thrombin, factors XI and XII, and high molecular weight kininogen (López et al. 1998). In addition, the complex has been shown to recognize misfolded proteins with amyloid properties, triggering platelet activation (Herczenik et al. 2007). Here, we will limit the discussion to the interactions of the complex with VWF, thrombin, and $\alpha_M\beta_2$.

von Willebrand Factor Interaction VWF is an enormous plasma protein produced in endothelial cells (the major plasma source) and megakaryocytes and stored in endothelial Weibel–Palade bodies and platelet α-granules. In healthy individuals, the normal VWF concentration in the plasma is approximately 10 μg/mL but can be much higher in disease states, particularly those characterized by systemic endothelial activation (Schwameis et al. 2015). Given that platelets and VWF both circulate, a mechanism must exist to prevent VWF from binding GPIb-IX-V before there is a hemostatic need. Indeed, under static conditions with no flow, the interaction between the two molecules requires the presence of a modulator, usually the antibiotic ristocetin from the soil bacterium *Nocardia lurida* (Howard and Firkin 1971), or botrocetin, a C-type lectin from the venom of the pit viper *Bothrops jararaca* (Andrews et al. 1989; Read et al. 1989). Ristocetin binds VWF in a region next to the GPIbα-binding A1 domain (Azuma et al. 1993; Berndt et al. 1992; Girma et al. 1990) and changes VWF's conformation to one that favors GPIbα binding, whereas botrocetin promotes the formation of a trimolecular complex (Fukuda et al. 2005). In vivo, the binding of VWF to collagen at the site of vascular injury immobilizes VWF in a conformation that can bind platelets. In addition, elevated shear stress can alter the conformation of VWF to enable it to bind GPIb-IX-V even in the fluid phase (Chen and López 2005b). The two molecules also interact on the surface of intact endothelium in the setting of deficiency of the VWF-cleaving metalloproteinase ADAMTS13 (Dong et al. 2002), a situation that leads to the devastating microvascular thrombotic disorder, thrombotic thrombocytopenic purpura.

Shear stress, in addition to exposing GPIbα-binding sites on VWF, also influences the GPIbα–VWF bond by exerting force on the bond. The bond is regarded as a catch bond: a bond that increases in lifetime when force is applied to it (Liu et al. 2015; Thomas 2009). A consequence of this bond characteristic is that the attachment of platelets to a VWF surface becomes tighter as shear stress increases, explaining the importance of the VWF-GPIbα bond in regions of the

vasculature with the highest shear, where platelets accumulate very efficiently (Weiss et al. 1978), both because of increased bond lifetime and enhanced delivery of platelets. Recently, evidence has emerged that increased bond lifetimes can also result from tension exerted on the bond from the inside of the platelet through cytoskeletal forces after the platelets have adhered (Feghhi et al. 2016). In this way, this adhesive complex behaves like the platelet integrin $\alpha_{IIb}\beta_3$: it is capable of both inside–out and outside–in signaling. But, in contrast to the integrin, the sequence of these signaling processes is reversed. In the interaction of GPIb-IX-V with VWF, the complex first signals *into* the platelet after engaging VWF, and these signals then activate cytoskeletal machinery to pull on the GPIbα cytoplasmic tail to reinforce the bond with VWF on the *outside* of the platelet.

Crystal structures of GPIbα–VWF A1 reveal that GPIbα interacts with the VWF A1 domain through the concave side of the leucine-rich repeat motif, but the interacting surface is discontinuous, primarily involving sequences from the N- and C-terminal flanking disulfide loops. At both the N- and C-termini, the GPIbα interaction sites involve β-hairpin structures, known as the β-finger and β-switch, respectively. The β-switch C-terminal loop goes from a disordered structure to a β-hairpin upon A1 domain binding, contributing two β-strands to an eight-stranded intermolecular β-sheet that stabilizes the interaction (Dumas et al. 2004; Huizinga et al. 2002) (see Fig. 2). Within the leucine-rich repeat region, leucine-rich repeats 5–8 contribute to the interaction, the remainder of the leucine-rich repeats making only long-range electrostatic contacts with the A1 domain. Recently, evidence has been presented that when force is applied to the GPIbα–A1 bond, the GPIbα N-terminus unfolds to some extent, which could account for or contribute to the catch bond nature of the interaction (Ju et al. 2016).

Role of Lipid Rafts Although all of the sequences necessary for GPIbα to bind VWF appear to be present within the N-terminal 300 amino acids of GPIbα and attachment of a polypeptide bearing this sequence is sufficient to allow coated beads to bind VWF, the binding of platelets to VWF requires that the GPIb-IX-V complex be positioned appropriately within the platelet plasma membrane. Early studies in transfected heterologous cells revealed that truncation of as few as six amino acid residues from the GPIbα C-terminus increased diffusion of the complex within the plane of the plasma membrane and diminished the ability of the cells to bind VWF in the presence of ristocetin (Dong et al. 1997). Subsequent studies by several groups suggested that this effect is the result of disrupting the binding of 14-3-3ζ and filamin A to the GPIbα cytoplasmic domain (Feng et al. 2000, 2003; Williamson et al. 2002).

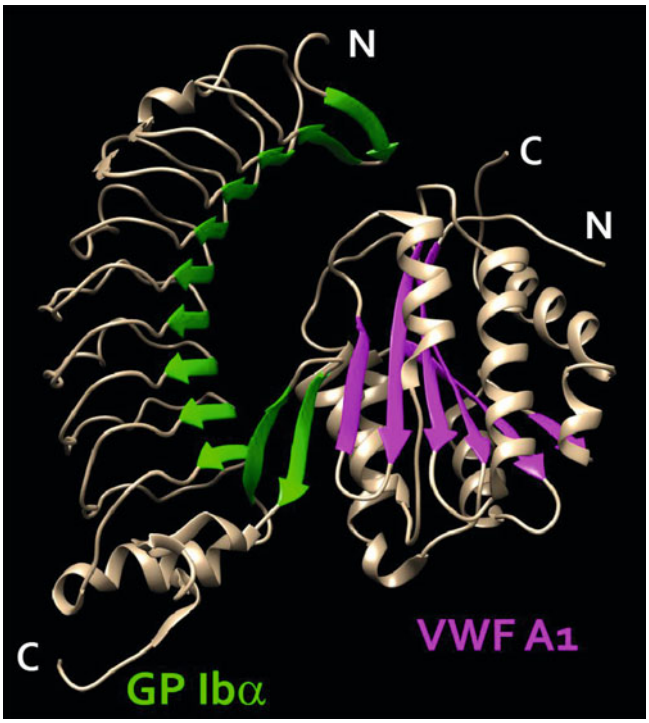

Fig. 2 Crystal structure of the GPIbα N-terminus bound to the VWF A1 domain. *Green* shows GPIbα β-strands from the N-terminal β-finger, through the leucine-rich repeats, to the C-terminal β-switch. Note that the β-switch contributes to β-strands to an 8-strand β-sheet between GPIbα and VWF. The VWF β-sheet is shown in *magenta*. Structures based on structures from reference (Huizinga et al. 2002)

Another important requirement for the VWF-binding function of the complex is localization of the complex to lipid raft domains, regions of the plasma membrane that represent dynamic assemblies of sphingolipids and cholesterol with greater order than the surrounding phospholipid-rich regions of the membrane (López et al. 2005). In unactivated platelets, only a small percentage of all GPIb-IX-V complexes are present in the lipid raft fraction. The quantity of the complex associated with rafts increases three- to sixfold when platelets are activated by VWF but not when activated by ADP (Shrimpton et al. 2002). Raft localization of the complex is required for platelets to be able to adhere to VWF surfaces, although the mechanism for this is not understood. One possibility is that raft localization requires, or is required for, the complex to associate with the platelet membrane skeleton (Munday et al. 2010), an association that when disrupted also disrupts the ability of platelets to bind VWF (Feng et al. 2000; Williamson et al. 2002). Another very likely consequence of complex raft localization is the need to effectively transmit downstream signals after the complex engages VWF. Raft regions are known to attract, on their cytoplasmic sides, signaling molecules such

as kinases and adaptor proteins, particularly if they are modified by cysteine acylation (López et al. 2005). This feature enables signal transduction. For example, it was shown that after VWF binds to GPIb-IX-V, only the populations of phospholipase Cγ2 and the tyrosine kinase Syk that reside in lipid rafts become phosphorylated (Jin et al. 2007). Raft localization of the complex also allows the complex to contact other molecules, with functional consequences. For example, GPIb-IX-V and the platelet Fc receptor, FcγRIIa, physically associate (Sullam et al. 1998), but only within lipid rafts (Shrimpton et al. 2002). Raft association is important for FcγRIIa to be able to transmit intracellular signals, a requirement that explains why some GPIbα antibodies are able to inhibit activation of platelets by immune complexes or aggregated IgG (Sullam et al. 1998).

Congenital Hemorrhagic Disorders Affecting the GPIb-IX-V Complex The interaction between the GPIb-IX-V complex and VWF can be disrupted by naturally occurring mutations. When those mutations affect GPIbα, they produce Bernard–Soulier syndrome (BSS) or platelet-type (pseudo) von Willebrand disease (VWD), and when they affect VWF, they produce VWD. Mutations in GPIbα, GPIX, or GPIbβ can cause BSS, usually producing unstable proteins that cannot be incorporated into a complex before they are removed by the cell's quality control system (Andrews and Berndt 2013; López et al. 1998). A small number of mutations of GPIbα have been described that yield mutant complexes defective in VWF binding (Savoia et al. 2014).

The prevalence of BSS is very low, probably less than one per 1,000,000 in the population. Patients with the full-blown disorder usually present in early childhood, and typically have findings of mucocutaneous bleeding: epistaxis, gingival and cutaneous bleeding, and menorrhagia in females (López et al. 1998). Laboratory findings include thrombocytopenia, extremely large platelets on the blood smear, and defective ristocetin-induced platelet agglutination with normal ristocetin cofactor activity. Almost all BSS mutations that have been described are autosomal recessive, requiring the presence of two mutant alleles. One exception has been described in a family in which BSS is caused by a single allele mutation that converts Asn41 of GPIbα to His (Vettore et al. 2008). Patients with this mutation appear to have a mild form of the syndrome, and normal levels of GPIbα on their platelets, suggesting a dominant-negative mode of inheritance. Recently, an Indian family was described in which only one GPIbα allele was found to be mutated, a missense mutation that substituted GPIbα Val31 with Leu (Ali et al. 2016). Whether this represents a dominant-negative mutation cannot be determined from the characterization of the patient's proteins. Although dominant transmission is unusual, heterozygosity for recessive mutations is not necessarily without phenotype, as heterozygosity for a common BSS allele (Ala156Val) has been shown to be responsible for most of the cases of macrothrombocytopenia seen in Italy (Noris et al. 2012). With this mutation, thrombocytopenia is usually mild; in one study only 18 of 103 patients examined had platelet counts below 50,000/μL (Noris et al. 2012).

Selected naturally occurring mutations of GPIbα also produce a polypeptide that can bind VWF in the absence of shear stress or modulators, a condition known as platelet-type VWD (Othman et al. 2011). Four naturally occurring mutations have been described in the GPIbα β-switch region: M239V, G233V, G233S, and D235Y. These mutations produce structural changes that favor the conversion of the β-switch region from a disordered loop to a β-hairpin as is found in the GPIbα–VWF complex (Othman et al. 2011). Another very interesting mutation that produces platelet-type VWD involves an in-frame deletion of 27 nucleotides encoding a stretch of nine amino acids (del420–428) (Chen and López 2005a; Othman et al. 2005). This mutation involves a sequence within the recently identified "mechanosensitive domain" (Zhang et al. 2015), but how deletion of this sequence induces spontaneous VWF binding is still a mystery. Platelet-type VWD mutations, although gain of function, produce a bleeding phenotype because they induce clearance of the largest and hemostatically most active VWF multimers from the circulation. An analogous condition is produced by mutation of VWF: type 2B VWD. The fact that gain-of-function mutations of both GPIbα and VWF can induce the two molecules to interact spontaneously indicates that the mechanism by which shear stress regulates the bond is not merely by revealing a previously cryptic A1 domain in VWF. If this were true, there would be no way in which mutations in GPIbα would be able to induce exposure of the A1 domain. Thus, binding accessibility appears to be regulated at the level of both the receptor and the ligand.

Role of the GPIb-IX-V Complex in the Actions of Thrombin The role of the GPIb-IX-V complex as a major thrombin-binding site on platelets has been appreciated for over four decades (López 1994). Studies of equilibrium thrombin binding to the platelet membrane identified both high-affinity and moderate-affinity sites, present at 500–4000 and 20,000–50,000 per platelet, respectively (Harmon and Jamieson 1986; Shuman and Majerus 1975; Workman et al. 1977). From studies of BSS platelets, it was clear that both the high- and moderate-affinity sites reside with the GPIb-IX-V complex (Jamieson and Okumura 1978), and Okumura et al. (1978) determined that the 45-kDa N-terminal fragment of GPIbα contained both sites. Binding of thrombin to the GPIb-IX-V complex is necessary for platelet activation at low concentrations of

the agonist (Jamieson and Okumura 1978), an activation that also involves proteolysis of the G-protein-coupled receptor PAR-1 (Vu et al. 1991). The cleavage of PAR-1 is accelerated by binding of thrombin to GPIb-IX-V (De Candia et al. 2001), and removal or absence of GPV yields a signaling function to the complex upon thrombin binding that no longer requires thrombin's protease activity (Ramakrishnan et al. 2001). Signals generated after thrombin binds GPIb-IX-V activate the 14-3-3/Rac-1/LIMK-1 pathway that is also involved in transmitting signals after GPIb-IX-V engages VWF (Estevez et al. 2016).

Thrombin binds exclusively within the N-terminal 300 amino acids of GPIbα. Two structures of this region in complex with thrombin have been determined (Celikel et al. 2003; Dumas et al. 2003). Both structures show two thrombin molecules bound to one GPIbα N-terminus, and both of the thrombin interacting sites reside in the GPIbα ligand-binding domain, involving sequences in the C-terminal flanking region and the anionic sulfated region. Nevertheless, the two structures are in fact different, the difference involving flexibility of the anionic sulfated tail (Sadler 2003). The two molecules of thrombin bind to GPIbα through distinct regions raising the possibility that each thrombin can also bind two GPIbα molecules. Figure 3 depicts a bimolecular complex based on a crystal structure of the complex from Celikel et al. (Celikel et al. 2003) in which thrombin interacts with GPIbα at two sites: in the C-terminal flank of GPIbα and in the anion sulfated region. This binding is compatible with data from monoclonal antibody blocking studies. Antibodies that map to the C-terminal flank (TM60 (Yamamoto et al. 1985) and VM16d (Mazurov et al. 1991)) or to the anionic sulfated region (SZ2 (Ward et al. 1996) and LJIb10 (Mazzucato et al. 1998)) are all capable of blocking thrombin binding to GPIbα (Shen et al. 2000). AP1 is another antibody that blocks low-dose thrombin aggregation (Pidard et al. 1982), and its epitope has been mapped in detail within the sequence Glu212–Tyr228 (Peng et al. 2004). Thus, at low thrombin concentrations, thrombin may form a multimolecular complex with GPIb-IX-V in which each molecule of GPIbα binds two thrombin molecules, and each thrombin in turn is bound to two GPIbα molecules. The minimal size of a complex that would allow each bound thrombin to bind two GPIbα polypeptides would contain four GPIbα and four thrombin molecules and would resemble a ring structure.

The capacity of one GPIbα to bind two molecules of thrombin also raises the possibility that once the first thrombin is bound, the second binds more readily, yielding a cooperative interaction. Alternatively, the binding of the second thrombin could exhibit negative cooperativity. In fact, early studies from Tollefsen and Majerus (1976) of thrombin binding to platelets demonstrated that both high- and low-affinity sites resided within the same molecule and thrombin binding exhibited negative cooperativity.

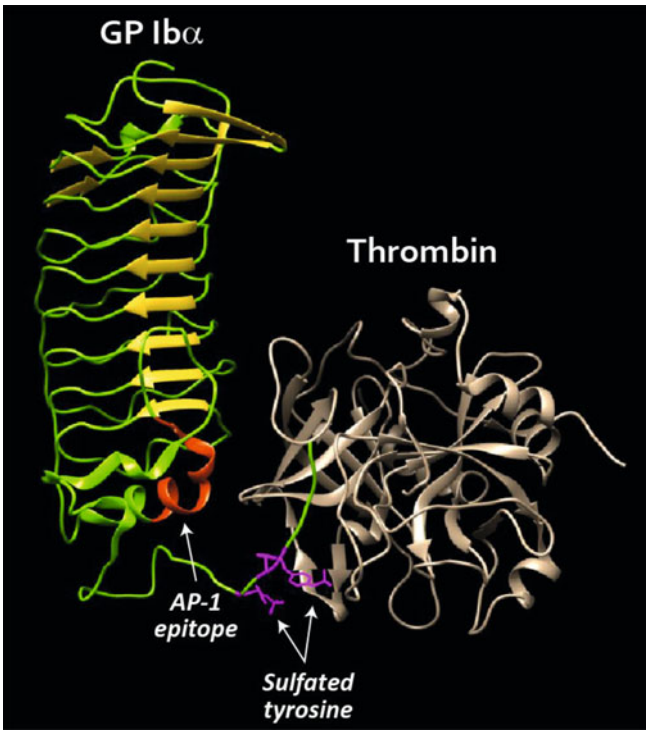

Fig. 3 Crystal structure of a complex between one GPIbα N-terminus and one thrombin molecule. Note that thrombin makes two major contacts with GPIbα, with the α-helical region at the C-terminal flank of the GPIbα ligand-binding domain that contains the epitope for the monoclonal antibody AP1 (shown in *orange*) and with the anionic sulfated region. The sulfated tyrosines are shown in *magenta*. Based on one of the complexes from reference (Celikel et al. 2003)

The Interaction of the GPIb-IX-V Complex with Leukocyte $\alpha_M\beta_2$ (MAC-1) Another important counter-receptor for the platelet GPIb-IX-V complex is the leukocyte integrin $\alpha_M\beta_2$ (Simon et al. 2000). Search for a counter-receptor on platelets for leukocyte $\alpha_M\beta_2$ was inspired by the observation that experimental arterial restenosis in mice after vessel injury could largely be prevented by depletion of either neutrophils or platelets or by the absence of $\alpha_M\beta_2$ (Simon et al. 2000). One characteristic of $\alpha_M\beta_2$ that provided a clue to the identity of the counter-receptor was the presence in the α_M chain of an inserted domain (I-domain). I-domains are found in many integrins and are usually involved in adhesion. They also bear a striking structural similarity to the A domains of VWF, including the GPIbα-binding A1 domain. Examination of the potential for GPIbα to serve as a platelet counter-receptor for $\alpha_M\beta_2$ showed that the two membrane proteins could indeed interact, the interaction involving the N-terminal 45-kDa ligand-binding domain of GPIbα and

the α_M I-domain (Simon et al. 2000). Within the α_M I-domain, the region was localized to a short sequence, Pro201 to Lys217 (Ehlers et al. 2003). The I-domain from the related integrin $\alpha_L\beta_2$ does not interact with GPIbα, but when the α_L I-domain was mutated so as to replace only two amino acids with the corresponding $\alpha_M\beta_2$ residues from the GPIbα-binding site, α_L gained the capacity to bind GPIbα (Ehlers et al. 2003). Within GPIbα, binding to $\alpha_M\beta_2$ involves sequences C-terminal to the leucine-rich repeat regions, as the binding is blocked by two antibodies that bind within this region AP-1 and VM16d (Simon et al. 2000). Of these two antibodies, only AP-1 interferes with VWF binding, indicating that the binding sites within GPIbα are distinct. A crystal structure of the complex has yet to be reported.

In addition to its role in restenosis after vessel injury, the GPIbα–$\alpha_M\beta_2$ interaction is important in other inflammatory conditions. In a model of experimental thrombotic glomerulonephritis induced by lipopolysaccharide and anti-glomerular basement membrane antibodies, the severity of glomerular thrombosis was attenuated by neutrophil depletion or by treatment with an antibody that targets the GPIbα-binding region of the α_M I-domain, an antibody known as anti-M2 (Hirahashi et al. 2009). Likewise, the GPIbα–$\alpha_M\beta_2$ interaction is very likely to play a role in multiple sclerosis (MS). Platelets have been shown to localize to the demyelination plaques of the brain and spinal cord in both humans with MS and mice with experimental autoimmune encephalomyelitis (EAE), the mouse disease that models human MS (Langer et al. 2012). Platelet depletion significantly improved the clinical disease scores and diminished the CNS inflammatory response in EAE (Langer et al. 2012). A similar amelioration of CNS inflammation was observed in mice treated with a rat monoclonal antibody against mouse GPIbα or with anti-M2. These two examples illustrate the importance of the GPIbα–$\alpha_M\beta_2$ interaction in inflammatory conditions. This interaction therefore represents a therapeutic target for anti-inflammatory drug development. Further, the fact that the binding of $\alpha_M\beta_2$ to GPIbα can be selectively targeted by GPIbα inhibitors indicates that platelets can be targeted in inflammatory disorders without compromising their hemostatic function.

GPIb-IX-V Complex Signaling

Signals are transmitted across the platelet plasma membrane by the engagement of the GPIb-IX-V complex by either VWF or thrombin and probably by other interactions. These signals activate integrins $\alpha_{IIb}\beta_3$ (Kasirer-Friede et al. 2004) and $\alpha_2\beta_1$ (Cruz et al. 2005) and thereby enable stable platelet adhesion and subsequent aggregation. As mentioned above, localization of the complex to lipid raft domains is a requirement for this signal transduction (Jin et al. 2007; Shrimpton et al. 2002), bringing the complex in proximity to a variety of signaling molecules. Attached to the cytoplasmic domains of the GPIb-IX-V polypeptides are a variety of molecules involved in signal transduction, including 14-3-3ζ, PI3-kinase, filamin, calmodulin, and Src family kinases (Canobbio et al. 2004). In addition, the GPIb-IX-V complex associates with two other membrane proteins capable of signal transduction: GPVI/Fcγ chain complex (Wu et al. 2001) and the platelet low-affinity Fc receptor, FcγRIIa (Sullam et al. 1998). Both of these receptors contain cytoplasmic motifs known as immunoreceptor tyrosine-based activation motifs (ITAMs) which, when phosphorylated by Src family tyrosine kinases, attract the tyrosine kinase Syk, which phosphorylates downstream effectors. GPIb-IX-V associates with these receptors primarily in lipid raft domains (Ozaki et al. 2013; Shrimpton et al. 2002).

Association of GPIbα with both filamin (Feng et al. 2003) and 14-3-3ζ (Dai et al. 2005) is required for binding VWF, as is localization to lipid rafts (Shrimpton et al. 2002). Upon engagement of the complex by VWF, PI-3 kinase activates the downstream Ser/Thr kinase Akt, and FcγRIIa (Canobbio et al. 2001) and the GPVI/FcγR chain complex (Falati et al. 1999; Gardiner et al. 2010) become rapidly tyrosine phosphorylated by Src family tyrosine kinases. This phosphorylation induces recruitment of Syk to the ITAMs and its subsequent activation with downstream phosphorylation of phospholipase (PL) Cγ2 and LAT (Wu et al. 2001). Wu et al. (2001) observed that despite the fact that VWF/botrocetin stimulated phosphorylation of PLCγ2, the stimulus did not lead to the production of inositol 1,4,5 trisphosphate (IP_3) or an elevation in cytosolic Ca2+ concentration. Other investigators, however, have reported calcium fluxes after GPIbα engagement by immobilized VWF (Kasirer-Friede et al. 2004; Mazzucato et al. 2002) or during shear-induced platelet aggregation (Chow et al. 1992).

The binding of VWF to the GPIb-IX-V complex is inhibited in at least two ways: by GPIbβ phosphorylation (Bodnar et al. 2002) and PECAM-1 engagement (Jones et al. 2014). GPIbβ is phosphorylated by PKA when cAMP concentrations rise and requires localization of the complex to rafts, along with the A-kinase anchoring protein moesin (Raslan et al. 2015). PECAM-1 induces the internalization of the GPIb-IX-V complex through a pathway that involves AKT and glycogen synthase kinase and requires the involvement of the cytoskeleton and the $\alpha_{IIb}\beta_3$ integrin.

Summary

The GPIb-IX-V complex is a remarkable platelet membrane receptor that carries out many functions important for normal physiology. Despite the fact that it has been studied

extensively for over half a century, much remains to be learned about its structure, functions, membrane topology, signaling functions, and involvement in diseases. These aspects will remain fertile fields of investigation.

Take-Home Messages

- The GPIb-IX-V complex has many functions in hemostasis, thrombosis, and inflammation.
- Normal expression of the complex requires GPIbα, GPIbβ, and GPIX but not GPV.
- The complex is unique in that no other complexes with a similar organization are found in nature.

$\alpha_{IIb}\beta_3$ (GPIIb/IIIa) Structure and Function

Joel S. Bennett

Abstract

The platelet membrane protein $\alpha_{IIb}\beta_3$, otherwise known as glycoprotein IIb/IIIa (GPIIb/IIIa), is a member of the ubiquitous integrin family of transmembrane (TM) heterodimers and is absolutely required for platelet aggregation. $\alpha_{IIb}\beta_3$ mediates platelet aggregation when fibrinogen or von Willebrand factor (vWF) bound to active $\alpha_{IIb}\beta_3$ cross-links adjacent stimulated platelets into stable aggregates. $\alpha_{IIb}\beta_3$ heterodimers are assembled from α_{IIb} and β_3 monomers in the endoplasmic reticulum. Mutations impairing the synthesis of either subunit decrease $\alpha_{IIb}\beta_3$ expression, thereby causing the autosomal bleeding disorder Glanzmann thrombasthenia. Conversely, $\alpha_{IIb}\beta_3$-mediated platelet aggregation is responsible for the arterial thrombi that cause heart attack and stroke. $\alpha_{IIb}\beta_3$ is present on platelets in an equilibrium between an inactive bent conformation and an active extended conformation. To prevent spontaneous platelet aggregation, however, $\alpha_{IIb}\beta_3$ on circulating platelets is constrained to its inactive conformation via intramolecular interactions involving its transmembrane and cytoplasmic domains. When platelets encounter a damaged blood vessel, stimulation by agonists such as thrombin and ADP causes nearly instantaneous $\alpha_{IIb}\beta_3$ activation by inducing talin-1 and kindlin-3 binding to the β3 cytoplasmic domain, thereby relieving the transmembrane and cytoplasmic domain restraints. $\alpha_{IIb}\beta_3$ binds to fibrin as well as fibrinogen. Thus, following $\alpha_{IIb}\beta_3$ activation, $\alpha_{IIb}\beta_3$ bound to fibrin transmits the retraction forces that consolidate fibrin clots, enabling them to resist the potentially disruptive shear forces present in circulating blood.

Introduction

Blood platelets aggregate to form shear-resistant thrombi at sites of vascular injury, thereby providing primary hemostasis when the injury occurs in the microcirculation but also producing vascular obstruction when the injury occurs in coronary and cerebral arteries. Platelet thrombus formation is a highly orchestrated process in which a layer of platelets adherent to the site of injury becomes a nidus for the subsequent aggregation of stimulated circulating platelets. Both platelet adherence and aggregation require the participation of members of the integrin family of adhesion receptors. Integrins are ubiquitous transmembrane (TM) α/β heterodimers that mediate diverse processes requiring cell-matrix and cell-cell interactions such as cellular migration during embryogenesis, cellular adhesion, cancer metastases, and T lymphocyte function (Hynes 2002). In mammals, 18 integrin α subunits and 8 integrin β subunits have been identified. These combine to form 24 different integrin heterodimers. The heterodimers can be grouped into subfamilies according to the identity of the β subunit (Hynes 2002). Platelets express three members of the β_1 subfamily ($\alpha_2\beta_1$, $\alpha_5\beta_1$, and $\alpha_6\beta_1$) mediating platelet adhesion to the extracellular matrix proteins, collagen, fibronectin, and laminins, respectively (Piotrowicz et al. 1988; Ill et al. 1984;

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_8

Sonnenberg et al. 1988; Staatz et al. 1989), and both members of the β_3 subfamily ($\alpha_v\beta_3$ and $\alpha_{IIb}\beta_3$). In vitro, $\alpha_v\beta_3$ mediates platelet adhesion to vitronectin and osteopontin (Bennett et al. 1997; Paul et al. 2003), but whether this is important for platelet function in vivo is unclear. By contrast, $\alpha_{IIb}\beta_3$, also known as glycoprotein IIb/IIIa (GPIIb/IIIa), is a receptor for fibrinogen, von Willebrand factor (VWF), fibronectin, and vitronectin on activated platelets and is absolutely required for platelet aggregation in vitro and in vivo (Fig. 1). Moreover, inherited decreases in the level of $\alpha_{IIb}\beta_3$ expression or in $\alpha_{IIb}\beta_3$ function produce the bleeding disorder Glanzmann thrombasthenia (George et al. 1990). Further, $\alpha_{IIb}\beta_3$-mediated platelet aggregation is responsible for the thrombi that form on damaged arteries (Lefkovits et al. 1995). Thus, $\alpha_{IIb}\beta_3$ is indispensable for normal hemostasis and plays a critical role in arterial thrombosis. Consequently, it has been intensively studied and it serves as the paradigm for regulated integrin function. This chapter will review the current knowledge of $\alpha_{IIb}\beta_3$ structure and function.

$\alpha_{IIb}\beta_3$ Biosynthesis

$\alpha_{IIb}\beta_3$ expression is restricted primarily to cells of the megakaryocyte lineage, although α_{IIb} has been detected on embryonic (Dumon et al. 2012) and myeloid-biased adult hematopoietic stem cells (Gekas and Graf 2013) and functional $\alpha_{IIb}\beta_3$ is expressed on mast cells where it participates in chronic inflammation and innate immunity (Oki et al. 2009). $\alpha_{IIb}\beta_3$ is a calcium-dependent heterodimer that dissociates into α_{IIb} and β_3 monomers in the presence of calcium chelators such as EDTA (Jennings and Phillips 1982). α_{IIb} has an unreduced molecular weight of 136,000 and dissociates into a 125,000 molecular weight heavy chain ($\alpha_{IIb}\alpha$) and 23,000 molecular weight light chain ($\alpha_{IIb}\beta$) following disulfide bond reduction. β_3 is a single chain protein containing 56 cysteine residues and 28 disulfide bonds (Fitzgerald et al. 1987); its apparent molecular weight of 90,000 on unreduced SDS gels increases to 110,000 following disulfide bond reduction (Jennings and Phillips 1982). In megakaryocytes, $\alpha_{IIb}\beta_3$ is assembled from α_{IIb} and β_3 precursors in the rough endoplasmic reticulum (ER) (Duperray et al. 1987) after which the assembled heterodimers are transported to the Golgi complex where pro-α_{IIb} undergoes cleavage into heavy and light chains, presumably by furin or a furin-like protease (Kolodziej et al. 1991a). Functional consequences of α_{IIb} cleavage, if any, have not been detected. In the absence of heterodimer formation, monomeric α_{IIb} and β_3 are retained in the ER and are eventually degraded (Kolodziej et al. 1991b). Moreover, as shown by the deleterious effect on $\alpha_{IIb}\beta_3$ expression of point mutations causing Glanzmann thrombasthenia, assembly of $\alpha_{IIb}\beta_3$ heterodimers alone is insufficient to guarantee $\alpha_{IIb}\beta_3$ egress from the ER and misfolded heterodimers are retained as well (Kolodziej et al. 1991b; Poncz et al. 1994). There are approximately 80,000 copies of $\alpha_{IIb}\beta_3$ on the surface of unstimulated platelets (Wagner et al. 1996) and additional copies located in platelet granule membranes are translocated to the platelet surface during platelet secretion (Niiya et al. 1987). The platelets of obligate Glanzmann thrombasthenia heterozygotes aggregate normally, indicating that 50 % of the normal amount of $\alpha_{IIb}\beta_3$ is at least sufficient to support platelet aggregation (McEver JCI 1980). However, the observation that as little as 5 % of the normal amount of kindlin 3, a β_3 binding protein that is required to convert inactive $\alpha_{IIb}\beta_3$ to its active state, is sufficient to prevent spontaneous bleeding in mice suggests that only small amounts of active $\alpha_{IIb}\beta_3$ are required to support basal hemostasis (Klapproth et al. 2015).

The α_{IIb} and β_3 genes, *ITGA2B* and *ITGB3*, are located on the long arm of chromosome 17 at q21 → 23 (Sosnoski et al. 1988) with *ITGA2B* at least 365 kb centromeric from *ITGB3* (Thornton et al. 1999). *ITGA2B* spans ≈18 kb and consists of 30 exons ranging in size from 46 to 220 bp (Heidenreich et al. 1990). Like other megakaryocyte-specific genes, its 5′ flanking region lacks TATA or CAAT boxes but contains a linear array of regulatory elements including two motifs recognized by the GATA-1 transcription factor and its cofactor FOG (Martin et al. 1993; Gaines et al. 2000),

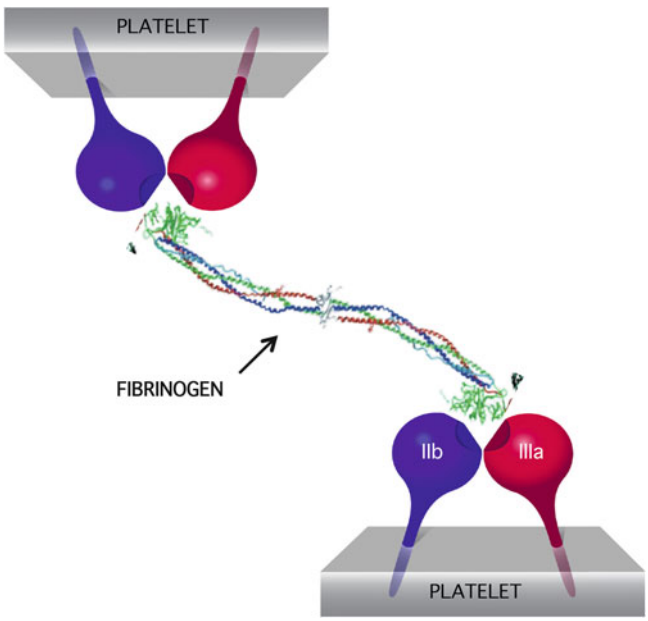

Fig. 1 Mechanism of $\alpha_{IIb}\beta_3$-mediated platelet aggregation. Platelet agonists initiate intracellular signals that convert inactive $\alpha_{IIb}\beta_3$ on resting platelets to its active conformation. This opens the binding site for macromolecular ligands such as fibrinogen in the $\alpha_{IIb}\beta_3$ headpiece. Fibrinogen then binds to the active $\alpha_{IIb}\beta_3$ on adjacent platelets, cross-linking platelets into aggregates. In the figure, α_{IIb} is designated IIb and β_3 is designated IIIa. The figure is modified from Yin et al. (2007)

sequences flanking the GATA-1 binding sites that are recognized by Fli-1 and perhaps other members of the Ets family of transcription factors (Wang et al. 2002; Jackers et al. 2004), and an Sp1-binding silencer element located between the GATA-1 sites (Shou et al. 1998). *IGTB3* spans 63 kb and contains 15 exons (Zimrin et al. 1990). Like *ITGA2B*, its 5′ flanking region lacks TATA or CAAT boxes (Villa Garcia et al. 1994). Although the transcription factors HOXA10 and Foxc2 have been reported to regulate *IGTB3* expression in myeloid (Bei et al. 2007) and endothelial (Hayashi et al. 2008) cells, respectively, there is no information about their role in megakaryocytes.

Structure of the $\alpha_{IIb}\beta_3$ Extracellular Domains

Platelets circulate in a milieu containing fibrinogen, the principle $\alpha_{IIb}\beta_3$ ligand, whose concentration in plasma is 100-fold greater than its dissociation constant for activated $\alpha_{IIb}\beta_3$ (Bennett and Vilaire 1979). Thus, the $\alpha_{IIb}\beta_3$ on circulating platelets is maintained in an inactive conformation to prevent the spontaneous formation of platelet aggregates. However, when platelets encounter a damaged blood vessel, the $\alpha_{IIb}\beta_3$ on their surfaces is almost instantaneously converted to its active conformation. This essential feature of $\alpha_{IIb}\beta_3$ function is only partially understood.

Insight into the changes in $\alpha_{IIb}\beta_3$ structure that enable it to bind soluble ligands has been provided by the solution of high-resolution crystal structures for the extracellular domains of $\alpha_{IIb}\beta_3$ and the related integrin $\alpha_v\beta_3$ (Xiao et al. 2004; Xiong et al. 2001; Zhu et al. 2008) (Fig. 2). Surprisingly, these crystal structures, thought to represent the structures of inactive $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$, reveal that the amino-terminal headpieces of both extracellular domains are severely bent over two nearly parallel extracellular stalks (Xiong et al. 2001). The amino-termini of α_{IIb} and α_v consist of seven contiguous repeats that fold into β-propeller configurations (Springer 1997; Xiong et al. 2001). Each blade of the propeller is formed from four antiparallel β strands; loops connecting the strands are located on either the upper or the lower surface of the propeller. The β-propellers are then followed by a "thigh" and two "calf" domains, constituting the α subunit stalk. A knee or "genu" located between the thigh and first calf domain is the point at which α subunit bending occurs. The β_3 headpiece consists of a series of tandem nested domains: a βA domain whose fold resembles that of integrin α subunit I-domains inserted into a "hybrid" domain whose fold is similar to an I-set Ig domain inserted into a PSI (plexin, semaphorin, integrin) domain containing the β_3 amino-terminus (Xiong et al. 2004; Xiao et al. 2004). The carboxyl-terminus of the PSI domain is continuous with four tandem EGF-like repeats constituting the β_3 stalk, followed by a carboxyl-terminal βTD domain (Zhu et al. 2008). The α_{IIb} and α_v β-propellers interact with the β_3 βA domain at an interface resembling the interface between the Gα and Gβ subunits of G proteins to form the complete $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$ headpieces (Xiao et al. 2004). The bent conformation of the extracellular domains is maintained by insertion of the third and fourth EGF-like β_3 domains into a crevice formed by the upper α leg on one side and the upper and lower α subunit leg on the other and with the β-propeller and βA domains forming the back of the crevice (Zhu et al. 2008).

Subsequent crystal structures of putative active $\alpha_v\beta_3$ and $\alpha_{IIb}\beta_3$ headpieces reveal that they are "open" because of a 62° angle of separation between the α and β subunits that results from a 10 Å downward movement of the α7 helix of the βA domain relative to the hybrid and PSI domain. This

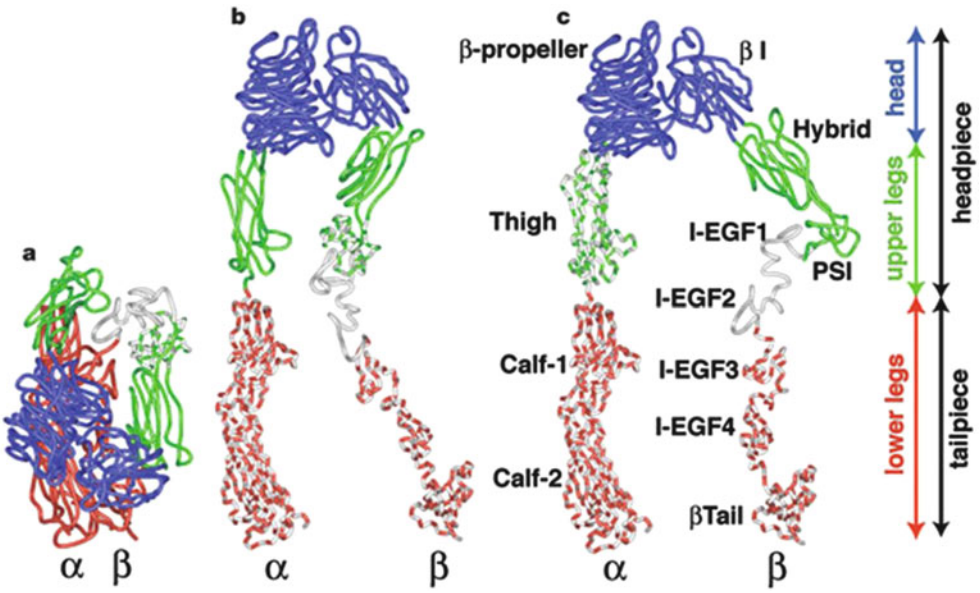

Fig. 2 The domain structure of the $\alpha_{IIb}\beta_3$ extracellular domain as derived from solved crystal structures and visualized by electron microscopy. (**a**) The bent structure of inactive $\alpha_{IIb}\beta_3$. (**b**) Extended $\alpha_{IIb}\beta_3$ with a closed headpiece. (**c**) Extended $\alpha_{IIb}\beta_3$ with an extended and open headpiece. Adapted from Xiao et al. (2004) with permission

causes reorganization of hydrogen bonds in the interface between the α7 helix and the βC strand of the hybrid domain, allowing the hybrid domain and the rigidly connected PSI domain to "swing out" (Takagi et al. 2002a; Xiao et al. 2004). In turn, this causes a 70 Å separation of the α_{IIb} and β_3 stalks at their "knees," a feature of active $\alpha_{IIb}\beta_3$ observed in rotary-shadowed EM images (Litvinov et al. 2004).

Despite the concordance of the various $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$ extracellular domain crystal structures, their relevance to the structures of full-length $\alpha_v\beta_3$ and $\alpha_{IIb}\beta_3$ has been controversial. Negatively stained electron microscope (EM) images of active and inactive full-length $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$, either free in solution or embedded in phospholipid nanodiscs, suggest that the bent conformation present in the crystals corresponds to low-affinity $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$ and the shift to an open high-affinity conformation results from a "switchblade"-like movement to an extended (unbent) structure accompanied by a "scissor"-like separation of the α- and β-subunit stalks (Takagi et al. 2002b; Ye et al. 2010; Eng et al. 2011; Dai et al. 2015). Small angle X-ray scattering and size exclusion chromatography of Mn^{2+}-activated $\alpha_{IIb}\beta_3$ (Eng et al. 2011) support this suggestion, as does the ability to engineer an inactivating disulfide bond between a cysteine introduced into the β-propeller domains of α_v and α_{IIb} and a cysteine introduced into the first EGF-like domain of β_3, indicating that these regions are in proximity in inactive integrin heterodimers (Takagi et al. 2002b). On the other hand, it has been suggested that the bent conformation present in the crystals resulted from flexibility at the α_v and β_3 genus and/or from crystal contacts not likely to occur in nature (Xiong et al. 2001). This was supported by cryo-EM reconstructions of full-length presumably inactive $\alpha_{IIb}\beta_3$ that revealed an unbent structure consisting of a large globular head and an L-shaped stalk whose axis was rotated ≈60° with respect to the head and connected at an angle of ≈90° to a rod containing the α_{IIb} and β_3 TM domains (Adair and Yeager 2002). It has also been suggested that extension is a post-ligand binding event and the transition from an inactive to an active conformation results from the removal of "deadbolt" represented by the CD loop of the β_3 βTD domain locked into the βA domain (Xiong et al. 2003). However, more recent cryo-EM reconstructions of $\alpha_{IIb}\beta_3$ inserted in nanodiscs suggest that inactive $\alpha_{IIb}\beta_3$ is indeed bent, although the reconstructions differ with regard to the orientation of the $\alpha_{IIb}\beta_3$ headpiece away (Ye et al. 2010) or toward (Choi et al. 2013) the membrane surface.

$\alpha_{IIb}\beta_3$ Activation

The conversion of $\alpha_{IIb}\beta_3$ to its extended conformation is an essential event for $\alpha_{IIb}\beta_3$ activation. However, extended $\alpha_{IIb}\beta_3$ is not necessarily capable of binding ligands (Takagi et al. 2002b) since "opening" of its ligand binding site is also required. $\alpha_{IIb}\beta_3$ activation results from signals originating in the platelet cytosol that are transmitted across the plasma membrane. Moreover, truncated integrins lacking TM and cytoplasmic domains are constitutively active (Dana et al. 1991; Peterson et al. 1998; Mehta et al. 1998). Thus, specific intramolecular interactions involving their cytoplasmic (Hughes et al. 1996; Vinogradova et al. 2002) and/or TM domains constrain basal integrin activity.

Intramolecular Interactions Involving the α_{IIb} and β_3 Cytoplasmic Domains

$\alpha_{IIb}\beta_3$ can be converted from its inactive to its active form by truncating the α_{IIb} or β_3 cytoplasmic domains immediately distal to the conserved membrane-proximal α_{IIb} sequence GFFKR or the conserved membrane-proximal β_3 sequence LLITIHD (O'Toole et al. 1994) (Table 1). Substituting Ala for Arg in GFFKR or for Asp in LLITIHD has the same effect, whereas interchanging these residues does not (Hughes et al. 1996). This suggests that the membrane-proximal cytoplasmic domain sequences interact to form an activation-constraining "clasp," a feature of which is an electrostatic interaction (Metcalf et al. 2010) or salt bridge (Hughes et al. 1996) between α_{IIb} R995 and β_3 D723. Surprisingly, biophysical experiments designed to detect the clasp have generated substantially different structures, and none have directly detected an α_{IIb} R995-β_3 D723 salt bridge (Haas and Plow 1996; Vallar et al. 1999; Weljie et al. 2002; Vinogradova et al. 2004). Further, neither Li et al. (2001b) nor Ulmer et al. (2001) detected the spontaneous

[a]The amino acids in the α_{IIb} and β_3 cytoplasmic and transmembrane domains are designated in the single letter code; the *subscripted numbers* correspond to the position of the preceding amino acid in the sequence for mature α_{IIb} and β_3 (Poncz et al. 1987; Zimrin et al. 1988). The αIIb GxxxG motif, β_3 G708, the membrane-proximal regions of both cytoplasmic domains, and both β_3 NxxY motifs are *underlined*

heteromeric association of peptides corresponding to the TM and cytoplasmic domains of α_{IIb} and β_3. On the other hand, the NMR structure for a disulfide-linked $\alpha_{IIb}\beta_3$ cytoplasmic domain construct (Metcalf et al. 2010) indicated that β_3 residues Lys716 and Ile719 interact directly with α_{IIb}, but a salt bridge between R995 and D723 was not identified (Fig. 3). Nonetheless, this result, coupled with the consequences of mutating the membrane-proximal α_{IIb} or β_3 cytoplasmic domains, is strong evidence that heteromeric cytoplasmic domain interactions play a role in regulating $\alpha_{IIb}\beta_3$ activity.

Ensembles of NMR structures for the β_3 cytoplasmic domain either alone or complexed with the α_{IIb} cytoplasmic domain revealed that the β_3 cytoplasmic domain is structured and composed by three helices, a membrane-proximal helix contiguous with the β_3 TM domain and two distal helices that pack together in a helix-turn-helix motif (Li et al. 2002; Metcalf et al. 2010). By contrast, while the membrane-proximal α_{IIb} cytoplasmic domain is helical, the portion distal to Asn996 is intrinsically unstructured (Metcalf et al. 2010). The two distal β_3 helices are both amphiphilic and dynamic and are stabilized by interacting with membrane bilayers. Thus, in resting platelets, hydrophobic interactions likely drive the association of the helices with the inner leaflet of the platelet plasma membrane. However, because of their dynamic nature, they likely make excursions into non-helical conformations in the aqueous cytoplasmic environment where they can interact with cytoplasmic proteins.

Heteromeric Interaction of the α_{IIb} and β_3 TM Domains

Although TM helices function as hydrophobic anchors for membrane proteins, they also commonly mediate protein oligomerization via specific sequence motifs (Moore et al. 2008). A sequence motif consisting of two glycine residues separated by one helical turn, designated GxxxG where x is any amino acid, for example, is the most overrepresented sequence motif in TM domain databases (Senes et al. 2000). GxxxG mediates the stable association of glycophorin A homodimers in red cell membranes by forming a tightly packed surface of complementary ridges and grooves (Lemmon et al. 1992; MacKenzie et al. 1997; Russ and Engelman 2000). It is noteworthy that the α_{IIb} TM helix contains the canonical GxxxG motif and the β_3 helix contains a similar motif consisting of two amino acids with small side chains separated by one helical turn (SxxxA) (Table 1). Thus, the presence of two well-characterized oligomerization motifs in the α_{IIb} and β_3 TM helices has suggested that the helices function to constrain basal $\alpha_{IIb}\beta_3$ activity.

$\alpha_{IIb}\beta_3$ becomes constitutively active when G708 in the β_3 TM domain (Li et al. 2003) or G972 or G976 in the α_{IIb} TM domain (Li et al. 2004, 2005) are replaced with polar Asn residues, consistent with the presence of an $\alpha_{IIb}\beta_3$ TM domain heterodimer when $\alpha_{IIb}\beta_3$ is inactive and its absence when $\alpha_{IIb}\beta_3$ is active (Li et al. 2003). Of two plausible explanations for the effect of the Asn replacements, it is more likely that introducing a bulky Asn residue into a closely packed $\alpha_{IIb}\beta_3$ TM domain heterodimer physically "pushes" apart the heterodimer, while on the other hand the TM domains are "pulled" into homo-oligomers when the Asn replacements form a hydrogen bonding network that neutralizes their polarity in the hydrophobic membrane core (Li et al. 2005). Regardless, these experiments provide compelling evidence that a heterodimeric TM domain interaction constrains $\alpha_{IIb}\beta_3$ in a low-affinity state and that disrupting the association of the TM domains is sufficient to cause $\alpha_{IIb}\beta_3$ activation. A number of functional and structural observations support this conclusion. First, although

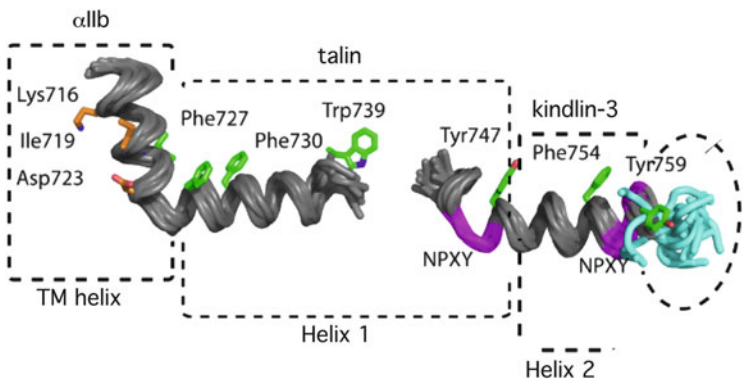

Fig. 3 Structure of the β_3 cytoplasmic domain as determined by NMR. Twenty structures in the NMR ensemble, consisting of two regions encompassing residues Leu713-Trp739 and Asp740-Thr762, were aligned separately over well-ordered regions. Domains interacting with α_{IIb}, talin, kindlin-3, and Src kinase are enclosed by *dashed lines* and *side chains* that make up interfaces are depicted as sticks. α_{IIb} or β_3 TM domain peptides with or without contiguous cytoplasmic domains readily associate homomerically (Li et al. 2001a, 2004), their homomeric association is disrupted when the complementary α_{IIb} or β_3 TM domain peptide is co-expressed (Berger et al. 2010). Second, scanning the TM helices of full-length recombinant $\alpha_{IIb}\beta_3$ with cysteine residues resulted in the formation of disulfide bonds with a helical periodicity, consistent with the presence of a unique α_{IIb}/β_3 TM heterodimer (Luo et al. 2004). Third, an ensemble of NMR structures for α_{IIb} and β_3 TM domain peptides reconstituted in phospholipid bicelles indicated that the peptides can associate to form heterodimers (Lau et al. 2009). A feature of the heterodimer is an "outer membrane clasp," a region of helix-helix interaction containing the α_{IIb} GxxxG motif and β_3 residue G708, which enforces a right-handed 25° crossing angle of the α_{IIb} and β_3 helices. The structures also identify an "inner membrane clasp" featuring hydrophobic interactions involving α_{IIb} residues F992 and F993 and an electrostatic interaction between α_{IIb} R995 and β_3 D723. However, it is possible that the inner membrane clasp is located in the cytoplasm because it is distal to the WK sequences that signify the C-terminal extent of the α_{IIb} and β_3 TM helices (Li et al. 2001a). Because mutations designed to alter the 25° crossing angle between the α_{IIb} and β_3 TM domains cause $\alpha_{IIb}\beta_3$ activation, maintaining this crossing angle is important to preserve the integrity of the outer and inner membrane clasps (Kim et al. 2012a, b).

The NMR structure of the $\alpha_{IIb}\beta_3$ TM heterodimer indicates that the GxxxG motif in α_{IIb} is located in the interface of the heterodimer. Indeed, scanning mutagenesis of the α_{IIb} and other integrin α subunit TM domains with Leu and Ala residues has confirmed that a small residue-XXX-small residue-XXX-large residue motif (Gly_{972}-xxx-Gly_{976}-xxx-Leu_{980} in α_{IIb}) represents the α subunit component of the helical interface (Berger et al. 2010). Unexpectedly, the β subunit component consisted of the converse of the α motif: a large residue-xxx-large residue-xxx-small residue motif (Val_{700}-XXX-Ile_{704}-XXX-Gly_{708} in β_3) (Berger et al. 2010). This TM helix packing arrangement juxtaposes the β_3 VxxxIxxxG motif and the α_{IIb} GxxxGxxxL motif, resulting in a closely packed and energetically favorable zipper-like interface that is conserved across the entire integrin family (Fig. 4). The interface is demonstrably weaker than the canonical glycophorin A GxxxG homodimerization motif (MacKenzie et al. 1997) and likely has evolved to support helix-helix interactions whose strength is appropriate for a system like $\alpha_{IIb}\beta_3$ that must undergo rapid conformational switching.

Protein Binding to the β_3 Cytoplasmic Domain Causes $\alpha_{IIb}\beta_3$ Activation

Remarkably, considering their short lengths, the α_{IIb} and β_3 cytoplasmic domains have been reported to interact with a large number of cytosolic proteins (Buensuceso et al. 2004). Although the significance of most of these interactions is uncertain, binding of the FERM (four-point-one, ezrin, radixin, moesin) domains of the cytoskeletal protein talin-1 and the focal adhesion protein kindlin-3 to the β_3 cytoplasmic domain is necessary for physiologic $\alpha_{IIb}\beta_3$ activation.

Talin, an abundant 250-kDa cytoskeletal protein, binds to the cytoplasmic domain of integrin β subunits as well as to cytoskeletal proteins such as actin and vinculin (Calderwood 2004). Of the two talin isoforms, talin-1 is the predominant platelet isoform and is present in the platelet cytoplasm as an antiparallel homodimer (Critchley 2009; Goult et al. 2013). The talin-1 monomer is composed of a 50-kDa head domain (THD) containing its principal integrin binding site and a 220-kDa rod domain that binds to integrins with lower affinity (Kloeker et al. 2004). The THD is an ≈300-residue

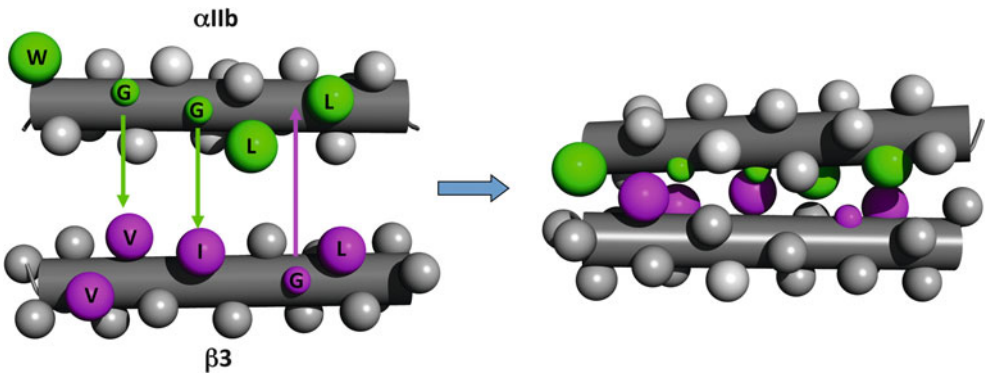

Fig. 4 Model of the reciprocal "large-small" integrin TM heterodimer interface. The integrin heterodimer is represented as an idealized pair of helices with *large spheres* denoting large hydrophobic residues and *small spheres* representing small polar residues. *G* glycine, *L* leucine, *V* valine, *I* isoleucine, and *W* tryptophan. Adapted from Bennett, J.S., and Moore, D.T. *Haematologica*. 2010; 95:1049–1051. Regulation of platelet β_3 integrins. Obtained from the Haematologica Journal website http://www.haematologica.org

FERM domain that folds into F0, F1, F2, and F3 subdomains (Kloeker et al. 2004); both F2 and F3 bind to the β_3 cytoplasmic domain (Moore et al. 2012), although the affinity of F3 binding is substantially greater (Calderwood et al. 2002). In resting platelets, the β_3 binding site in the F3 subdomain is masked by sequences located in the rod domain (Goult et al. 2013). A structural model of the talin-1 dimer that accounts for this auto-inhibition revealed that the dimer is folded into a donut shape with the two rods forming the donut and the two heads packed into the central donut hole (Goult et al. 2013). How talin auto-inhibition is relieved after platelet stimulation remains a fundamental problem in understanding physiologic $\alpha_{IIb}\beta_3$ activation. The enzyme calpain cleaves talin, releasing its head domain (Yan et al. 2001), but calpain activation in platelets occurs relatively late after platelet stimulation (Fox et al. 1993) and would be unlikely to contribute to initial $\alpha_{IIb}\beta_3$ activation. More likely possibilities include talin activation after binding to membrane-associated phosphoinositol 4,5-bisphosphate, an interaction previously found to enable talin binding to the β_1 cytoplasmic domain (Martel et al. 2001); the formation of a complex containing talin, the low molecular weight GTP binding protein Rap-1, and RIAM (Rap1-GTP interacting adapter molecule) that can deliver talin to the platelet plasma membrane to bind to β_3 (Lee et al. 2009) [surprisingly, $\alpha_{IIb}\beta_3$ function was found to be normal in a RIAM knockout mouse (Stritt et al. 2015)]; and the agonist-stimulated transfer of talin $\pm$ kindlin to β_3 via the scaffolding protein ADAP (adhesion and degranulation promoter protein) (Kasirer-Friede et al. 2014).

In vitro, THD binding to the proximal β_3 cytoplasmic domain helix is sufficient to cause $\alpha_{IIb}\beta_3$ extension and activation (Ye et al. 2010). Importantly, in vivo, the platelet-specific deletion of talin-1 in mice also either profoundly impairs (Petrich et al. 2007) or abrogates (Nieswandt et al. 2007) ligand binding to $\alpha_{IIb}\beta_3$ and platelet aggregation. THD binding to the β_3 cytoplasmic domain helix occurs in two steps (Calderwood et al. 2002; Wegener et al. 2007; Anthis et al. 2009) (Fig. 5). In the first step, the F3 subdomain binds to the β_3 NPLY motif and to β_3 W739 in a hydrophobic interaction that resembles canonical PTB domain binding to ligands (Garcia-Alvarez et al. 2003). This interaction is necessary but not sufficient to cause $\alpha_{IIb}\beta_3$ activation (Wegener et al. 2007). A second step is required in which β_3 residues F727 and F730 are buried in the F3 subdomain, thereby enabling $\alpha_{IIb}\beta_3$ activation when a salt bridge between talin-1 residue K324 and β_3 D723 competes with the electrostatic interaction between β_3 D723 and α_{IIb} R995 (Anthis et al. 2009) to initiate the separation of the β_3 and α_{IIb} cytoplasmic and TM domains.

Given the evidence that talin alone is sufficient to activate $\alpha_{IIb}\beta_3$ in vitro, it was perplexing that patients with leukocyte adhesion deficiency (LAD) type III—whose blood cells specifically lack the focal adhesion protein kindlin-3 but contain normal amounts of talin—manifest a bleeding disorder resembling Glanzmann thrombasthenia, as well as perturbed β_2 integrin-mediated leukocyte function (Moser et al. 2008, 2009a, b). Kindlin-3 is the third member of a three-member family identified initially because mutations in the first family member, kindlin-1, cause the Kindler syndrome, an

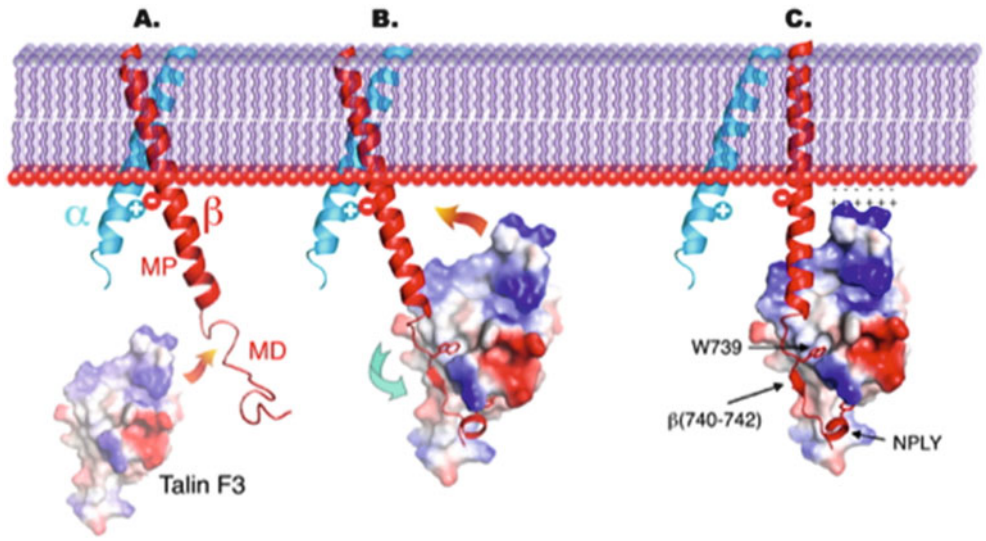

Fig. 5 Model of talin-induced integrin activation. (**a**) The talin F3 subdomain, no longer auto-inhibited, is available to bind to the β_3 cytoplasmic domain. (**b**) F3 engages its membrane-distal β_3 cytoplasmic domain binding site that includes an NPLY motif as well as W739, but does not cause $\alpha_{IIb}\beta_3$ activation. (**c**) F3 now engages the membrane-proximal of the β_3 cytoplasmic domain, disrupting the electrostatic interactions between the membrane-proximal portions of the α_{IIb} and β_3 cytoplasmic domains and causing separation of the α_{IIb} and β_3 transmembrane domains. In turn, this results in $\alpha_{IIb}\beta_3$ extension and activation (not shown). Adapted from Wegener et al. (2007) with permission from Elsevier Inc.

autosomal recessive blistering skin disease affecting actin attachment in basal keratinocytes (Karakose et al. 2010). Kindlin-3 is a 76-kDa protein whose FERM domain, like the talin FERM domain, contains F0, F1, F2, and F3 subdomains. But unlike talin, its F2 domain contains an inserted PH domain that facilitates the interaction of kindlin-3 with membranes (Karakose et al. 2010; Liu et al. 2011). Kindlin-3 binds to the β_3 cytoplasmic domain via its FERM domain, but at a site distinct from the site bound by talin (Bledzka et al. 2012; Yates et al. 2012). Although kindlin-3 binding to β_3 alone is not sufficient to cause $\alpha_{IIb}\beta_3$ activation, agonist-stimulated $\alpha_{IIb}\beta_3$ activation in platelets does not occur when kindlin-3 is absent (Moser et al. 2008). Kindlin-3 and talin-1 are present in essentially stoichiometric amounts in mouse platelets (Klapproth et al. 2015). However, in mice hypomorphic for kindlin-3 gene expression, $\alpha_{IIb}\beta_3$ activity can be titrated by varying the amount of kindlin-3, with 5–10 % of the wild-type amount sufficient to support basal platelet function (Klapproth et al. 2015). These observations are consistent with the idea that kindlin-3 plays a permissive role in enabling talin to activate $\alpha_{IIb}\beta_3$ (Fig. 6). How this occurs is not known. It has been suggested that kindlin-3 does not enhance $\alpha_{IIb}\beta_3$ activation but rather increases the avidity of active $\alpha_{IIb}\beta_3$ for multivalent, but not univalent ligands, by promoting $\alpha_{IIb}\beta_3$ clustering (Ye et al. 2013). However, kindlins are monomeric (Calderwood et al. 2013) so their ability to promote $\alpha_{IIb}\beta_3$ clustering would have to be indirect and additional kindlin binding partners such as migfilin (Brahme et al. 2013) and ILK (Bottcher et al. 2009; Jones et al. 2014) would be required. A second possibility is that kindlin-3 binds transiently to the distal β_3 cytoplasmic domain to expose and stabilize the more proximal talin binding site (Metcalf et al. 2010). Thus, kindlin might bind simultaneously with talin in a positively cooperative manner, although it has not yet been possible to trap a putative ternary complex.

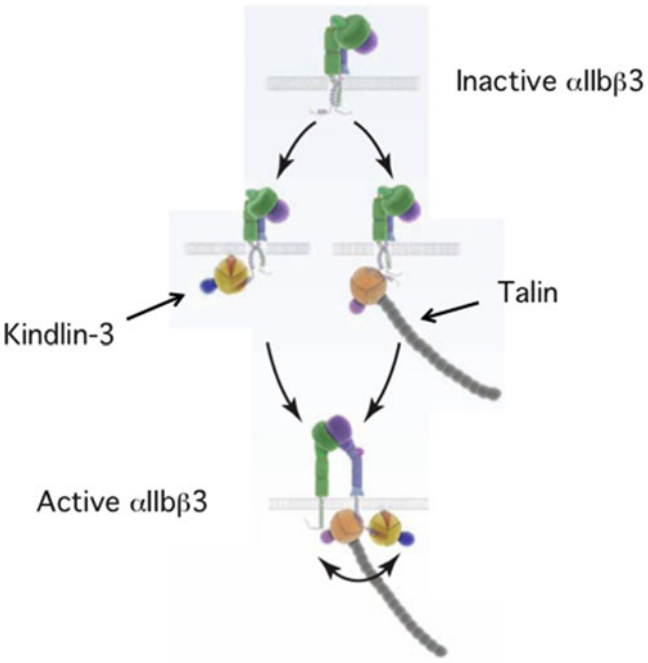

Fig. 6 Binding of both talin-1 and kindlin-3 are required to cause physiologic $\alpha_{IIb}\beta_3$ activation. Talin-1 and kindlin-3 bind to separate sites on the β_3 cytoplasmic tail. It is not known whether binding is simultaneous or sequential, and if it is the latter, what is the order of binding. Adapted from Moser et al. (2009b). Reprinted with permission from AAAS

$\alpha_{IIb}\beta_3$-Mediated Outside-In Signaling in Platelets

$\alpha_{IIb}\beta_3$-mediated "outside-in" signaling is initiated by the trans-autophosphorylation of the tyrosine kinase c-Src bound via its SH3 domain to the β_3 cytoplasmic domain of active $\alpha_{IIb}\beta_3$ (Arias-Salgado et al. 2003; Senis et al. 2014). In turn, activated c-Src initiates a signaling cascade resulting in platelet spreading on fibrinogen-coated surfaces and the retraction of fibrin clots (Shattil et al. 1998; Haling et al. 2011). The c-Src SH3 domain binds to the carboxyl-terminal β_3 sequence Arg-Gly-Thr (RGT), an interaction inhibited by proline-rich peptides selective for SH3 domains (Arias-Salgado et al. 2003). However, the carboxyl-terminus of β_3 is quite different from the polyproline sequences recognized by SH3 domains (Metcalf et al. 2010; Li 2005). Moreover, inactive c-Src adopts a compact structure that is stabilized by intramolecular interactions including binding of the linker connecting its SH2 and kinase domains to the polyproline binding site in the SH3 domain. Thus, in resting platelets, there is little or no specific interaction between β_3 and c-Src. However, following agonist-stimulated platelet activation, c-Src is "unlatched" by dephosphorylation of pTyr530 (Arias-Salgado et al. 2005), and the β_3 cytoplasmic domain is now able to bind to SH3 domain residues 98–103 vacated by the linker between the c-Src SH2 and kinase domains. Subsequent $\alpha_{IIb}\beta_3$ clustering increases the concentration of β_3-bond c-Src, enabling the completion of c-Src autotransphosphorylation and the initiation of outside-in platelet signaling.

The G-protein subunit $G\alpha_{13}$ has also been reported to bind to an ExE motif ($E_{731}E_{732}E_{733}$ in β_3) in the proximal β_3 cytoplasmic domain and to facilitate in some way the phosphorylation of β_3-bound c-Src (Gong et al. 2010; Shen et al. 2013). $G\alpha_{13}$ and the THD appeared to compete for binding to β_3 such that there were reciprocal waves of talin and $G\alpha_{13}$ binding with talin bound during inside-out signaling and $G\alpha_{13}$ bound during outside-in signaling. This suggested that talin and $G\alpha_{13}$ binding might act as a molecular switch to modulate the direction of $\alpha_{IIb}\beta_3$-mediated signaling.

Ligand Binding to $\alpha_{IIb}\beta_3$

Fibrinogen, the major $\alpha_{IIb}\beta_3$ ligand, is composed of pairs of Aα, Bβ, and γ chains folded into three nodular domains. Although fibrinogen, like many other integrin ligands, contains canonical RGD motifs, binding of soluble fibrinogen to active $\alpha_{IIb}\beta_3$ is mediated by the sequence located at the carboxyl-terminus of the fibrinogen γ chain (Farrell et al. 1992). Nevertheless, both carboxyl-terminal γ chain peptides (Kloczewiak et al. 1983) and peptides containing an RGD motif inhibit fibrinogen binding to $\alpha_{IIb}\beta_3$ (Gartner and Bennett 1985). However, competitive binding measurements have revealed that γ chain and RGD peptides cannot bind simultaneously to $\alpha_{IIb}\beta_3$, suggesting that they either bind to the same or overlapping sites or that binding of one peptide induces a conformational change in the $\alpha_{IIb}\beta_3$ headpiece that prevents binding of the other (Bennett et al. 1988).

Crystal structures of the $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$ headpieces containing γ chain and RGD peptides have provided a structural explanation for these puzzling observations. The binding site for fibrinogen on the $\alpha_{IIb}\beta_3$ headpiece is located at the interface of the β_3 βA and α_{IIb} β-propeller domains and consists of a "specificity-determining" loop in the β_3 βA domain and a "cap" composed of four loops linking blades 2 and 3 and blades 3 and 4 on the upper surface of the β-propeller domain (Xiao et al. 2004). The structures confirm suggestions based on the consequences of β-propeller mutations that fibrinogen binds to the upper surface of the β-propeller in a region centered around the third amino-terminal repeat (Tozer et al. 1999; Basani et al. 2000; Kamata et al. 2001). It is noteworthy, however, that the intact fibrinogen molecule binds to $\alpha_{IIb}\beta_3$ with an affinity several orders of magnitude greater than the affinity of peptides. Thus, crystal structures solved in the presence of peptides may not completely account for fibrinogen binding.

Fibrinogen binding to $\alpha_{IIb}\beta_3$ requires divalent cations (Bennett and Vilaire 1979). Although there are eight divalent cation-binding sites in the $\alpha_{IIb}\beta_3$ crystal structure (Xiong et al. 2001), only the three located in a linear array in the βA domain participate in ligand binding (Chen et al. 2003). The middle site, the βA MIDAS (metal ion-dependent adhesion site), coordinates Mg^{2+}, whereas the flanking sites, ADMIDAS (adjacent to MIDAS) and SyMBS (synergistic metal binding site), normally contain Ca^{2+}. When fibrinogen γ chain peptides were soaked into $\alpha_{IIb}\beta_3$ headpiece crystals, they bound in a groove in the interface between the β3 βA and α_{IIb} β-propeller domains (Springer et al. 2008). Like the Asp of RGD, the side chain of the penultimate γ chain peptide residue, Asp_{410}, coordinated with the MIDAS Mg^{2+} and the free carboxyl of carboxyl-terminal Val_{411} coordinated with the ADMIDAS Ca^{2+} through a water molecule as well. The γ chain peptide also made hydrophobic contacts with α_{IIb} residues located in the loops connecting β-propeller blades 2 and 3 and blades 3 and 4. Lastly, like the Arg of RGD, γ chain residue Lys_{406} made a charged hydrogen bond with α_{IIb} residue Asp_{224}. Thus, the binding sites for γ and RGD peptides overlap, but the γ chain binding site is substantially larger.

Although RGD-containing peptides are $\alpha_{IIb}\beta_3$ antagonists, preincubating $\alpha_{IIb}\beta_3$ with these peptides can surprisingly cause $\alpha_{IIb}\beta_3$ activation (Du et al. 1991). Soaking increasing concentrations of the peptide GRGDSP into $\alpha_{IIb}\beta_3$ headpiece crystals in the presence of various combinations of Mg^{2+}/Ca^{2+} or Mn^{2+}/Ca^{2+} has made it possible to characterize sequential changes in the headpiece that convert it from a closed low-affinity to an open high-affinity conformation (Zhu et al. 2013). The changes occur exclusively in the βA domain and eventually result in a piston-like movement of its α7 helix toward the hybrid domain, accompanied by "swing out" of the hybrid domain and headpiece opening. Repeating these experiments in the presence of the γ chain sequence AGDV rather than GRGDSP produced the same sequence of headpiece changes (Lin et al. 2016). Unlike GRGDSP, however, AGDV has little contact with αIIb, confirming the predominant role of the βA domain in modulating the conformation of the $\alpha_{IIb}\beta_3$ headpiece.

Besides interacting with fibrinogen, individual activated $\alpha_{IIb}\beta_3$ molecules attach to fibrin fibers (Dai et al. 2015) such that aggregated platelets are major components of hemostatic blood clots and thrombi (Collet et al. 2002). Further, the interaction of $\alpha_{IIb}\beta_3$ with fibrin is involved in platelet-driven clot contraction (Carr 2003; Lam et al. 2011). $\alpha_{IIb}\beta_3$ activation and fibrinogen conversion to fibrin in vivo occur almost simultaneously. Thus, while the formation of hemostatic platelet plugs and platelet thrombi is initially due to fibrinogen binding to $\alpha_{IIb}\beta_3$, it evolves into an interaction between $\alpha_{IIb}\beta_3$ and monomeric and oligomeric fibrin as fibrinogen is converted to fibrin by thrombin generated on or near the surface of activated platelets (Fig. 7). Measurements of $\alpha_{IIb}\beta_3$ binding to fibrinogen and fibrin monomer using optical trap-based force spectroscopy revealed that the binding of surface-attached fibrin and fibrinogen to $\alpha_{IIb}\beta_3$ are both quantitatively and qualitatively different (Litvinov et al. 2016). First, $\alpha_{IIb}\beta_3$ has a greater propensity to interact with monomeric fibrin than fibrinogen at the same surface density. Second, the strength of $\alpha_{IIb}\beta_3$ binding to monomeric fibrin is greater. Taken together, these observations imply that the affinity of $\alpha_{IIb}\beta_3$ for monomeric fibrin is greater than its affinity for fibrinogen. Further, fibrin lacking wild-type γ/γ chains retains $\alpha_{IIb}\beta_3$-binding activity, suggesting that the γC-terminal AGDV motif may not be the major $\alpha_{IIb}\beta_3$ binding site in fibrin, whereas it is indispensable for soluble fibrinogen binding to $\alpha_{IIb}\beta_3$ (Farrell et al. 1992). This suggestion is supported by the reduced $\alpha_{IIb}\beta_3$ binding activity of fibrin mutants lacking α chain RGD motifs. In fact, binding to these motifs in fibrin may even be preferred since the affinity of RGD for $\alpha_{IIb}\beta_3$ is greater than of AGDV

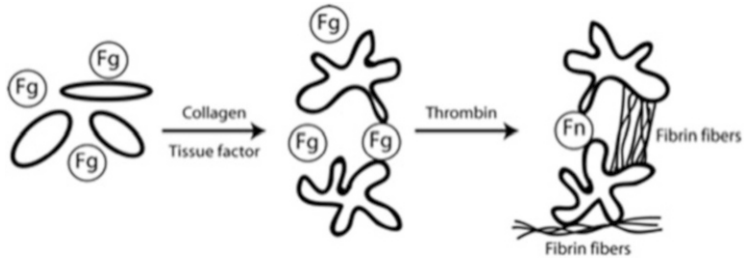

Fig. 7 Platelet aggregation initially begins with fibrinogen binding to $\alpha_{IIb}\beta_3$, but quickly evolves into $\alpha_{IIb}\beta_3$ interaction with monomeric, oligomeric, or polymeric fibrin as fibrinogen is converted to fibrin by thrombin generated at or near the surface of the activated platelets. This figure was originally published in *The Journal of Biological Chemistry*: Litvinov, R.I., Farrell, D.H., Weisel, J.W., and Bennett, J.S. The platelet integrin $\alpha_{IIb}\beta_3$ differentially interacts with fibrin versus fibrinogen. 2106; 291:7858–7867. ©The American Society for Biochemistry and Molecular Biology

(Sun et al. 2012; Kloczewiak et al. 1983). Nonetheless, the absence of RGD in the presence of free γC-dodecapeptide does not completely abrogate the interactions of fibrin with $\alpha_{IIb}\beta_3$, suggesting that additional sites in fibrin other than γAGDV, αRGDF, and αRGDS can interact with $\alpha_{IIb}\beta_3$.

Take-Home Messages

- Binding of macromolecular ligands such as fibrinogen or von Willebrand factor to the major platelet integrin $\alpha_{IIb}\beta_3$ is required for platelet aggregation.
- $\alpha_{IIb}\beta_3$ on circulating platelets is inactive, unable to bind macromolecular ligands. Platelet stimulation by agonists such as ADP and thrombin causes $\alpha_{IIb}\beta_3$ to assume its active ligand binding conformation.
- $\alpha_{IIb}\beta_3$ is a heterodimer, assembled from independently synthesized α_{IIb} and β_3 monomers in the endoplasmic reticulum. Failure to synthesize sufficient numbers of correctly folded heterodimers prevents $\alpha_{IIb}\beta_3$ expression and produces the bleeding disorder Glanzmann thrombasthenia.
- $\alpha_{IIb}\beta_3$ on circulating platelets is constrained in its inactive conformation by a clasp composed by specific intramolecular interactions involving the α_{IIb} and β_3 transmembrane domains and membrane-proximal portions of the α_{IIb} and β_3 cytoplasmic domains.
- Crystal structures of inactive $\alpha_{IIb}\beta_3$ reveal that the amino-terminal headpiece of its extracellular domain is severely bent over two nearly parallel extracellular stalks. Conversion of $\alpha_{IIb}\beta_3$ to an extended conformation is an essential event for $\alpha_{IIb}\beta_3$ activation.
- Binding of the cytoskeletal protein talin-1 and the focal adhesion protein kindlin-3 to the β_3 cytoplasmic domain causes disruption of the clasp that maintains inactive $\alpha_{IIb}\beta_3$ to initiate $\alpha_{IIb}\beta_3$ extension and activation.
- $\alpha_{IIb}\beta_3$ binds to both fibrinogen and fibrin. Fibrinogen binding to $\alpha_{IIb}\beta_3$ mediates platelet aggregation, whereas fibrin binding to $\alpha_{IIb}\beta_3$ mediates the retraction of fibrin clots.

GPVI

Yacine Boulaftali, Benoit Ho Tin Noé, Martine Jandrot-Perrus, and Pierre H. Mangin

Abstract

Platelet membrane glycoprotein VI has been identified relatively recently as compared to other major platelet glycoproteins such as the GPIb-V-IX complex and integrin $\alpha_{IIb}\beta_3$. This is probably due to the poor clinical manifestations associated to a GPVI deficiency although strong evidence have been accumulated during the past 15 years that this receptor is critically involved in pathology. The role of GPVI is first to promote thrombus formation, but a rapidly increasing number of studies reveal that GPVI contributes to many processes beyond thrombosis including inflammation, host defence and cancer dissemination.

Key Discoveries

Glycoprotein VI (GPVI), initially described in 1982 as a 58–60 kDa glycosylated platelet membrane protein, was identified 5 years later as a collagen receptor on the observation that platelets from a patient with a GPVI deficiency did not respond to collagen (Clemetson et al. 1982; Sugiyama et al. 1987). Key progresses were made with the discovery that GPVI signals via the γ chain common to Fc receptors (FcRγ) and with the identification of GPVI-specific agonists, the snake venom protein convulxin and collagen-related peptides (CRP) (Tsuji et al. 1997; Ezumi et al. 1998; Jandrot-Perrus et al. 1997; Polgar et al. 1997; Morton et al. 1995; Kehrel et al. 1998). Last but not least, the cloning of GPVI at the end of the 1990s permitted to determine its structure, to produce recombinant GPVI and specific anti-GPVI antibodies, to obtain genetically modified animals and in turn to dissect the role of GPVI in physiology and pathology (Clemetson et al. 1999; Jandrot-Perrus et al. 2000). At the same time, the identification of patients with genetic or acquired GPVI deficiency showed that the absence of GPVI is not associated with severe bleeding; however results obtained in animal models implicated GPVI as having a role in arterial thrombosis. These observations led to a novel important concept that targeting GPVI could be beneficial in the prevention and treatment of thrombosis without generating a bleeding risk (Dutting et al. 2012; Zahid et al. 2012). In addition there is a growing evidence that GPVI supports platelet functions beyond haemostasis and thrombosis: this includes the contribution of platelets to inflammation (Gros et al. 2014) and to tumour metastasis (Jain et al. 2009).

GPVI Structure

GPVI is type I transmembrane protein with a 58–60 kDa molecular mass, 45 % of which is carbohydrate (Clemetson et al. 1999; Jandrot-Perrus et al. 2000). GPVI belongs to the immunoglobulin superfamily. The human gene is located on chromosome 19 within the leukocyte receptor cluster (LCR) together with leukocyte Ig-like receptors (LIRs), killer-cell Ig-like receptors (KIRs), leukocyte-associated Ig-like receptors (LAIRs) and the receptor for IgA FcαRI (Jandrot-Perrus et al. 2000). The first loop of GPVI is of the Ig constant type C2-1 type found in LILRs, while the

second is of the C2-2 type also found in KIRs (Martin et al. 2002). LRC genes must have a common ancestor and have evolved by domain's recombination, duplication and shuffling. Although most ligands of LRC receptors are HLA class I molecules, some of them interact with non-HLA ligands and this is the case of GPVI. Interestingly, LAIR-1, which is structurally related to GPVI, also binds to collagen (Brondijk et al. 2010). However GPVI and LAIR-1 have opposite functions since GPVI is an activating receptor on platelets and LAIR-1 is an inhibitory receptor on immune cells.

The 339 amino acids (AA) sequence comprise a 21 AA signal peptide followed by the 247 AA of the extracellular portion of GPVI which harbours two immunoglobulin-like loops formed by disulphide bridges (D1 and D2) linked by an interdomain and that exposes the structural determinants for binding to collagen (Fig. 1). The crystal structure solved at 2.4 Å showed that the two loops are orientated at ~90° as described in other receptors of this family such as FcαRI (Horii et al. 2006). Combining data of crystallography, docking of collagen-related peptides, mutagenesis and epitope mapping converge to propose a model in which clusters of residues at the surface of the D1 loop and hinge region are implicated in GPVI binding to collagen: a putative collagen-binding domain (CBD) composed of a basic groove form of K41, K59, R60 and R166 is added a more distal site including hydrophobic residues L36, V34 and the N-glycan chain at N72 (Lecut et al. 2004a; Smethurst et al. 2004; Kunicki et al. 2005; Dumont et al. 2006; Horii et al. 2006; O'Connor et al. 2006). However, the recently determined crystal structure and collagen-binding surface of LAIR-1 suggest another collagen-binding mode involving GPVI residues R38, E40 and possibly W76 (Brondijk et al. 2010). In the GPVI crystal, the D2 loop is also involved in the formation of a back-to-back dimer that brings the two CBD nearly antiparallel and in a configuration allowing a simultaneous binding on two parallel collagen triple helices (Horii et al. 2006). Indeed, GPVI dimers have a high affinity for collagen while the monomer has a poor affinity (see below) (Miura et al. 2002). A highly O-glycosylated membrane proximal sequence forms a mucin-like stalk domain assumed to maintain D1–D2 at a distance from the platelet surface. Proximal to the membrane, GPVI presents a site of cleavage by metalloproteinases (Gardiner et al. 2004).

The 19 AA-transmembrane domain contains a charged residue, R252 that forms a salt bridge with D11 of the FcR-γ-chain allowing the expression of the complex at the platelet surface.

The cytoplasmic domain contains 51 AA without apparent homology with other receptor of this family and no tyrosine. The cytoplasmic tail of mouse GPVI lacks the 24 C-terminal residues of human GPVI (Jandrot-Perrus et al. 2000). Adjacent to the membrane are identified a basic sequence that stabilizes the interaction with FcRγ and a calmodulin-binding motif followed by a proline-rich domain (PRD) to which the Src family kinases, Lyn and Fyn are constitutively bound (Suzuki-Inoue et al. 2002; Bori-Sanz et al. 2003; Gardiner et al. 2004).

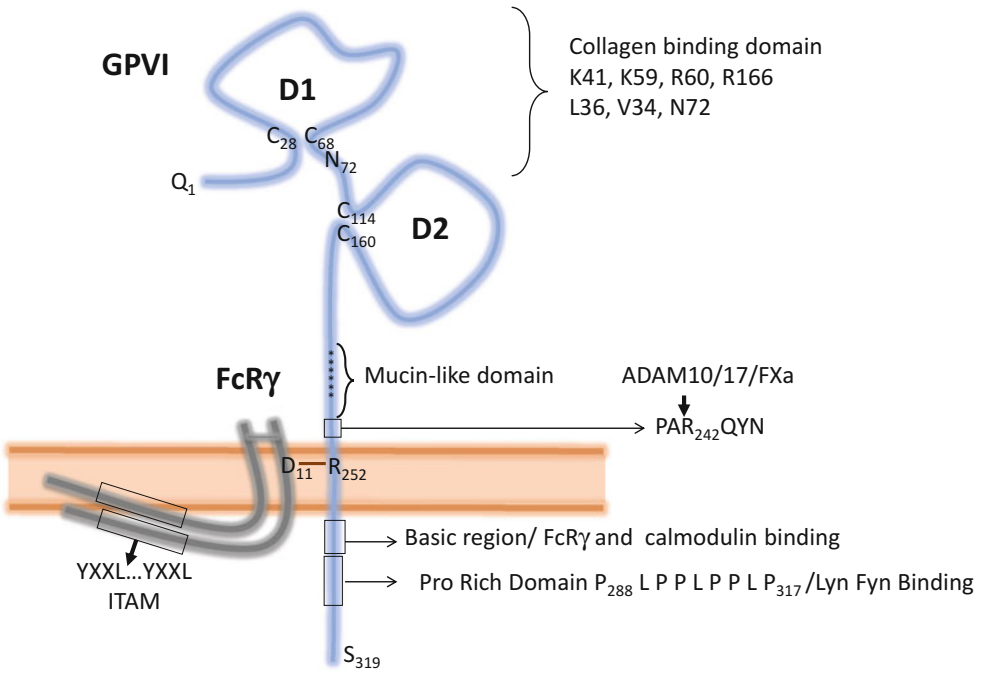

Fig. 1 Schematic representation of the GPVI-FcRγ complex. GPVI numbering starts at the first residue after the signal peptide. FcRγ chain C-terminus is represented buried in the membrane as assumed to be in resting platelets

The GPVI Receptor-Signalling Pathway

The first event in GPVI signalling is the phosphorylation of two tyrosine residues located within a conserved motif in the FcRγ chain known as immunoreceptor tyrosine-based activation motif (ITAM). Upon ligand binding, the ITAM tyrosine residues are phosphorylated by the Src family kinases (SFK). Lyn and Fyn are the major SFK mediating FcRγ phosphorylation (Ezumi et al. 1998; Quek et al. 2000; Severin et al. 2012). Binding of Lyn and Fyn via their SH3 domains to the PRD of the GPVI cytoplasmic allows them to acquire a partial activated state and bring them in contact with their substrate upon receptor ligation resulting in a fast phosphorylation (Schmaier et al. 2009). Interestingly, the protein tyrosine phosphatase CD148 has been shown to regulate Fyn and Lyn downstream of GPVI by dephosphorylating an inhibitory tyrosine residue, which holds the SFK in an inactive conformation (Senis et al. 2009) and additional yet unidentified phosphatases may contribute to regulate SFK activation. Phosphorylated ITAMs of clustered FcRγ chains provide a docking site for the tandem SH2 domains of the spleen tyrosine kinase, Syk. Binding of Syk to the phosphorylated ITAM leads to its activation through a combination of conformational change, phosphorylation by SFKs and autophosphorylation (Mocsai et al. 2010). Mouse platelets, which are deficient in Syk, are unresponsive to collagen confirming the critical role of the tyrosine kinase in platelet activation by collagen (Poole et al. 1997). Interestingly, Syk deficiency or treatments by the Syk inhibitors, fostamatinib or PRT060318, developed to treat inflammatory disease as rheumatoid arthritis or asthma as to reduce heparin-induced thrombocytopenia and immune complex-mediated thrombosis, have a minimal impact on bleeding (Law et al. 1999; Andre et al. 2011) (Table 1).

The binding and activation of Syk is a critical event in the formation of a signalosome consisting of various adapter and effector proteins. Central to the formation of the signalosome is linker for activation of T cells (LAT), a transmembrane protein localized to lipid rafts with nine conserved tyrosine residues in its cytoplasmic domain (Pasquet et al. 1999). Phosphorylated LAT recruits the adapter proteins Grb2 (growth factor receptor bound protein 2), Gads (Grb2-related adaptor protein downstream of Shc) and SLP-76 (SH2 domain containing leukocyte protein of 76 kDa) (Asazuma et al. 2000; Hughes et al. 2008). LAT also binds class I PI-3 kinases (phosphatidylinositol 3-kinase) that catalyse the formation of the phosphotinositide 3,4,5-trisphosphate (PIP3) (Gibbins et al. 1998). The PI3K regulatory subunit p85α plays a key role in GPVI signalling and the catalytic subunits p110α and β have non-redundant roles in GPVI-induced platelet activation and thrombus formation (Gilio et al. 2009). Interestingly, drugs targeting PI3Kβ do not inhibit platelet adhesion but provoke thrombus instability (Laurent et al. 2015). Altogether LAT, SLP76 and PIP3 lead to the recruitment of the phospholipase Cγ2 (PLCγ2) via its SH2 and PH domains and to its phosphorylation by kinases of the Tec family, Btk (Bruton's tyrosine kinase) and Tec, which also bind to PIP3 (Quek et al. 1998; Atkinson et al. 2003). Mice deficient in

PLCγ2 are protected from experimental thrombosis but also exhibit a marked defect in haemostasis, which may reflect the well-documented role of PLCγ2 signalling downstream of GPIbα and $\alpha_{IIb}\beta_3$ (Mangin et al. 2003; Rathore et al. 2004; Wang et al. 2000). Several other scaffolding and effector proteins assemble into the signalosome, including the GTP exchange factor Vav1 and 3 (Pearce et al. 2004), the small GTPase Rac1 (Pleines et al. 2009; Stefanini et al. 2012) and signal transducer and activator of transcription 3 (STAT3) (Zhou et al. 2013). All the proteins in the signalosome do not carry the same weight in the signalling cascade. While Syk (Poole et al. 1997), SLP76 and to a lesser degree LAT (Judd et al. 2002; Bezman et al. 2008) are critical for the activation of PLCγ2, a functional redundancy between closely related proteins such as SFK, Btk and Tec, Vav1 and 3 limits the consequence of their isolated deficiency (Table 1).

Activation of PLCγ2 leads to hydrolysis of its substrate, phosphatidylinositol-4,5-bisphosphate (PIP2), to form the two second messengers, inositol-1,4,5-trisphosphate (IP3) and 1,2-diacylglycerol (DAG), that respectively trigger the release of Ca^{2+} from intracellular stores and activation of protein kinase C (PKC). At this level, the signalling pathways downstream ITAM receptors, including GPVI, and GPCR converge and act synergistically. The guanine nucleotide exchange factor, CalDAG-GEFI, senses increased levels of cytosolic calcium and facilitates the rapid but reversible activation of the small GTPase Rap1 (Stefanini et al. 2009). Sustained activation of Rap1 results from PKC activation downstream of GPVI and feedback activation through the G_i-coupled receptor for ADP, $P2Y_{12}$ (Stefanini et al. 2012). Therefore, GPVI signalling depends on the ability of the CalDAG-GEFI/Rap1 couple to respond to threshold levels of Ca^{2+} by inducing ADP release via the activation of a Rac1, ADP that in turn triggers the second wave of PKC/Rap1 activation. Rap1 activation promotes integrin activation, thromboxane A2 generation and granule secretion, and the importance of this pathway is demonstrated by the fact that a deficiency in CalDAG-GEFI protects mice from collagen-induced thrombosis (Crittenden et al. 2004).

GPVI Ligands

Since, the initial observation that platelets lacking GPVI do not respond to collagen, numerous publications have provided clear evidence that GPVI is a central platelet receptor for collagens (Clemetson and Clemetson 2001; Nieswandt and Watson 2003). GPVI binds to the fibrillar and non-fibrillar forms of collagen, but not to soluble forms (Jung et al. 2008). Synthetic triple-helical collagen-like peptides (CRP) have been developed and are particularly convenient for the study of GPVI (Morton et al. 1995; Pasquet et al. 1999). GPVI binding increases with GPO content, but this minimal motif is not sufficient to secure GPVI binding, suggesting that nearby additional primary sequences must be involved (Smethurst et al. 2007; Jarvis et al. 2008).

Several snake venom peptides were reported to mediate their effects on activating platelets through GPVI. Some of them were extensively utilized as selective agonists, representing useful tools to study the function of GPVI (Andrews et al. 2001). This is notably the case of convulxin, a C-type lectin, which was of importance for GPVI cloning (Polgar et al. 1997; Jandrot-Perrus et al. 1997). Other snake venom toxins, which are more or less specific for GPVI, comprise alborhagin, alboaggregin A and trymucitin (Andrews et al. 2001).

In the last decade, a series of publications highlighted a multiplicity of additional GPVI natural ligands, notably adhesive proteins. First, GPVI was reported to directly bind to laminin, thereby promoting platelet activation and spreading (Inoue et al. 2006). This observation was confirmed independently in a study suggesting that the vascular α5-chain, but not α4-chain laminins promote platelet activation through GPVI (Schaff et al. 2013). In addition, Bultmann and collaborators proposed GPVI as a potential receptor for fibronectin that might participate in platelet/endothelial cell interaction, thereby promoting atheroprogression (Bultmann et al. 2010). The authors provided evidence of a direct GPVI/fibronectin interaction in a purified system and showed that soluble GPVI-Fc and a blocking anti-GPVI antibody reduced platelet adhesion to immobilized fibronectin under flow conditions. These observations were recently challenged in a study, which could not confirm a major role of GPVI as a platelet receptor for fibronectin (Maurer et al. 2015). Indeed, the absence or blockade of GPVI did not impair platelet adhesion and activation onto plasma or cellular fibronectin immobilized under their soluble or fibrillar forms. Recently, two independent groups reported a novel role for GPVI as a functional receptor for fibrin (Mammadova-Bach et al. 2015; Alshehri et al. 2015a). Both publications provided evidence that GPVI supports platelet adhesion under low and elevated blood flow conditions, resulting in activation, aggregation and procoagulant activity of platelets, suggesting a novel role for GPVI in enhancing thrombus growth. Beside adhesive proteins, GPVI was proposed to interact with a surface receptor of the IgG family, EMMPRIN, which could thereby mediate platelet/monocyte interactions and allow the recruitment of these aggregates at the vessel wall (Seizer et al. 2009; Schulz et al. 2011). GPVI has also been proposed to bind to globular adiponectin, an adipocyte-derived cytokine, which could promote platelet activation and aggregation (Riba et al. 2008). This observation will need to be confirmed and its physiological relevance identified. Finally,

it has recently been described that GPVI binds to charged hydrophobic ligands including diesel exhaust particles and large polysaccharides, thereby activating platelets (Alshehri et al. 2015b). In summary, even though GPVI is still mainly considered as a platelet receptor for collagen, the increasing number of additional natural ligands identified raises questions about the function of GPVI and the physiological relevance of these interactions. Whereas it becomes evident that the pathophysiological role of GPVI is not limited to arterial thrombosis, identification of specific binding sites for its ligands and development of selective blockers are mandatory to improve our knowledge on this receptor.

GPVI in Platelet Physiology

GPVI expression is restricted to platelets and megakaryocytes (Jandrot-Perrus et al. 2000). GPVI expression starts early and is upregulated at the late stage of megakaryocyte differentiation at which it is functional (Berlanga et al. 2000; Lagrue-Lak-Hal et al. 2001), but in contrast to α2β1 does not appear to regulate proplatelet formation (Sabri et al. 2004).

Using flow cytometry, a density of 3730 ± 453 GPVI copies was determined on human platelets with a 1.5-fold variation between individuals (Best et al. 2003). In contrast, quantitative proteomic analysis estimated the number of GPVI copies per platelet at 9600 (Burkhart et al. 2012). The reason of this important difference is not elucidated but could be linked to an internal pool of GPVI that has been detected by transmission electron microscopy (Suzuki et al. 2003). This pool was localized on the membranes of the surface-connected open canalicular system and α-granules and observed to be redistributed to the surface membrane and to microparticles following platelet activation, but requires to be quantified (Table 1).

The GP6 locus is highly polymorphic and two common haplotypes are associated with differences in protein expression resulting in distinct levels of platelet responses to specific ligand (Joutsi-Korhonen et al. 2003; Watkins et al. 2006). In fact, in cells expressing recombinant GPVI in variable amounts, collagen-triggered responses were dependent on receptor density (Chen et al. 2002). Interestingly, however, in vitro thrombus formation was not different with the blood of mice expressing 20 % or 100 % GPVI (Best et al. 2003) suggesting that moderate variations in GPVI expression should not represent a significant risk factor for thrombosis.

The function of GPVI is subject to two types of control resulting from homotypic interactions on one hand and from proteolysis on the other. Miura and co-workers, using soluble recombinant GPVI either dimeric (GPVI-Fc) or monomeric, demonstrated that only GPVI dimers bind to collagen with a good affinity consistent with structural analysis (Miura et al. 2002). Studies, using antibodies that distinguish between monomers and dimers, showed that platelet GPVI exists in the two forms but that GPVI dimerization is an active process closely regulated and which promotes binding to collagen (Jung et al. 2009; Loyau et al. 2012). GPVI dimerization is prevented by NO and prostacyclin continuously produced by endothelial cells in healthy vessels, but it is facilitated by platelet stimulation by shear-induced von Willebrand interaction with GPIb-V-IX, ADP or thrombin (Loyau et al. 2012). It is thus assumed that in pathological conditions, GPVI dimerization would increase the efficiency of platelet adhesion and activation onto collagen. An additional step is reached with the clustering of the receptor into higher ordered multimers by its ligands, a step required to initiate signalling. Convulxin, and to a lesser extent collagen, were reported to trigger the rapid formation of high molecular weight complexes composed disulphide-linked GPVI (Arthur et al. 2007b) involving Cys 338 within the cytoplasmic domain. However, this Cys is missing in mouse GPVI and whether disulphide-linked GPVI complexes are relevant in thrombosis remains to be elucidated.

Proteolysis of the extracellular domain of GPVI produces two fragments: a 55 kDa soluble fragment (sGPVI) representing almost the entire extracellular domain of GPVI and a 10 kDa membrane-associated remnant. The shedding of GPVI is induced by activation-dependent and independent pathways. Prolonged exposure to GPVI ligands (collagen, convulxin, CRP) triggers an activation-dependent shedding of GPVI resulting from its cleavage by several metalloproteinases including ADAM17 and ADAM10 (Bender et al. 2010). The dissociation of calmodulin from its binding motif in the cytoplasmic domain of GPVI leads to the activation proteases of the ADAM family (Gardiner et al. 2004). Both elevated shear and the coagulation factor Xa were reported to induce GPVI shedding by ADAM10-dependent and activation-independent mechanisms (Al-Tamimi et al. 2011, 2012b). Anti-GPVI antibodies have been shown to induce depletion of platelet surface GPVI in vivo and, for some but not all, in vitro. The mechanisms responsible for antibody-induced GPVI depletion are multiple, including internalization and shedding, and appear to be dependent on the antibody and the context (Rabie et al. 2007). As examples some antibodies, but not all, act via the engagement of platelet FcγRIIa, and some but not all also result in thrombocytopenia (Boylan et al. 2004; Arthur et al. 2007a; Nurden et al. 2009). High levels of sGPVI have been reported in the plasma of patients with (1) coronary artery stenosis (Al-Tamimi et al. 2012b), (2) disseminated intravascular coagulation (Al-Tamimi et al. 2011), and (3) autoimmune anti-GPVI antibodies (Gardiner et al. 2008). Plasma levels of sGPVI are thus increasingly considered as being a reliable

marker of in vivo platelet activation (Al-Tamimi et al. 2012a).

The first recognized function of GPVI is to be a receptor for fibrillar collagens (mainly of types I and III). The heterologous expression of GPVI is sufficient to induce cell adhesion to collagen (Jandrot-Perrus et al. 2000). However, it is accepted that initial recruitment of platelets is ensured by the GPIb-V-IX interaction with collagen-bound VWF, especially under elevated blood flow conditions. This interaction induces GPVI dimerization that promotes firm binding to collagen (Loyau et al. 2012). GPVI is required for stable platelet adhesion, through direct interaction with collagen but also indirectly through its ability to promote sustained platelet activation, thereby upregulating platelet integrins (Nieswandt et al. 2001b; Nieswandt and Watson 2003). Yet, synergy between GPVI and other platelet receptors including GPIb-V-IX, integrin $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$ enables to achieve optimal rates and extents of thrombus formation in flowing blood (Lecut et al. 2004b; Siljander et al. 2004; Pugh et al. 2010). Moreover, GPVI clustering by collagen triggers the secretion of thromboxane A2 (TXA2) and ADP, two key soluble agonists that in turn promote effective thrombus growth and stability (Nieswandt et al. 2001a).

Importantly, GPVI plays a central role in collagen-induced exposure of procoagulant phospholipids at the platelet surface, which permits the assembly of the coagulation complexes tennase and prothrombinase (Heemskerk et al. 1999; Lecut et al. 2003). The resulting efficient local thrombin generation at the site of collagen-activated platelets is assumed to be critical for the formation of the thrombus core composed of hyperactivated and stacked platelets (Ivanciu et al. 2014; Stalker et al. 2014). Furthermore, thrombin triggers the formation of fibrin and it was recently shown that GPVI is also a receptor of polymerized fibrin (Alshehri et al. 2015a; Mammadova-Bach et al. 2015). The GPVI-fibrin interaction allows the recruitment of additional platelets and further amplifies thrombin generation and thus promotes thrombus stability and growth (Mammadova-Bach et al. 2015).

The Role of GPVI in Thrombus Formation and Stability

The absence or blockade of GPVI in whole blood perfused under large range of wall shear rate conditions over immobilized collagen has been widely shown to abolish thrombus formation with only few residual platelets adhering to the surface (Nieswandt et al. 2001b). Whereas this assay is widely accepted as an "in vitro thrombosis model," concluding from these observations that GPVI is key in thrombosis is probably overrated given that this model relies primarily on collagen. Of note, Cheli et al. reported that perfusion of whole blood from GPVI-deficient mice resulted in the formation of normal thrombi on a fibroblast matrix, indicating that additional platelet receptors can promote thrombus growth (Cheli et al. 2008). This study highlights the major impact of the choice of the adhesive surface on the experimental outcome. To convincingly address the role of GPVI in thrombus formation in vitro, a seductive and relevant strategy was based on the use of atherosclerotic plaque homogenates. Such an approach has been used by the group of Wolfgang Siess, which showed a major role for GPVI in in vitro thrombus formation (Penz et al. 2005). This key role for GPVI is in agreement with the high content of type I collagen fibres contained in atheroma plaques. The role of GPVI in thrombus formation has also been extensively studied in vivo. Contrasting data arise from various thrombosis models performed on healthy mouse vessels, with studies showing a crucial importance of GPVI in platelet recruitment and thrombus growth (Massberg et al. 2003), whereas other reported a minor role (Mangin et al. 2006). These discrepancies probably relate on the model and experimental conditions utilized which might expose different amounts of GPVI ligands, notably collagen. They could also find an explanation in compensatory mechanisms including thrombin generation at site of injury, which could compensate for the lack of GPVI deficiency. The role of GPVI in arterial thrombosis became much clearer in models closer to pathological conditions based on atherosclerotic plaque rupture in $ApoE^{-/-}$ mice. Kuijpers and co-workers showed that GPVI deficiency significantly impaired thrombus formation caused by ultrasound-induced plaque rupture (Kuijpers et al. 2009). This result was confirmed by an independent group, which also showed that GPVI is critical in a model of mechanical plaque rupture with a needle (Hechler and Gachet 2011).

GPVI is believed to participate in the initiation of thrombus formation through its ability to interact with several exposed subendothelial proteins, mainly collagen. These interactions initiate a signalling cascade leading to sustained integrin $\alpha_{IIb}\beta_3$ activation, which in turn supports platelet recruitment, i.e. thrombus growth (Nieswandt and Watson 2003). The reason why GPVI promotes a signal strong enough to support platelet aggregation, while other adhesive receptors do not, probably relies in its unique ability to efficiently release the potent soluble agonists, ADP and TxA2. Whereas GPVI has been proposed to initiate thrombus formation, it has been reported that the thrombosis defect in some animal models were not in the initial phase of thrombus growth but rather in the phase of thrombus stabilization as evidenced by a marked embolization in GPVI-deficient mice (Bender et al. 2011). This observation might be the consequence of the defective activation and release of soluble agonists occurring in GPVI-deficient

platelets, which ultimately results in a decrease in $\alpha_{IIb}\beta_3$ activation and thrombus instability. Alternatively, this observation could also suggest that GPVI directly participates in thrombus growth by supporting platelet/platelet interaction. This has recently be proposed in a study showing that blockade of GPVI reduces platelet recruitment to a growing thrombus, potentially through interaction via fibrin (Mammadova-Bach et al. 2015). Moreover, GPVI also appears to regulate thrombus growth, i.e. platelet/platelet interaction independently of fibrin (Maurer et al. 2015). Further studies are required to identify the molecular mechanism involved in this process.

A role for GPVI in ischemic stroke has also been evidenced in mice immunodepleted for this receptor in a model of transient middle cerebral artery occlusion (Kleinschnitz et al. 2007). GPVI-deficient mice presented a significant decrease in infarct volume with no apparent bleeding complications. The effect of GPVI in this process has been proposed to rely on a thrombo-inflammatory role of this receptor rather than a classical haemostatic function (Nieswandt et al. 2011).

GPVI in Haemostasis

Overall, the reported clinical observations of patients suffering of a GPVI deficiency indicate that the symptoms are rather benign going from no manifestation to easy bruising epistaxis and gum bleeding (Matus et al. 2013; Dumont et al. 2009). In fact, due to the paucity of the symptoms, it is likely that GPVI deficiencies are most often undiagnosed. However, more severe symptoms have occasionally been reported (Hermans et al. 2009) suggesting that the association of a GPVI deficiency with other factors that may affect the platelet count or functions, or the haemostatic function of the endothelium could lead to more severe haemorrhagic manifestations.

Five mutations in the GP6 gene have so far been described: two are insertions in exons 4 (Dumont et al. 2009) and 6 (Matus et al. 2013), one is a deletion in exon 3 (Hermans et al. 2009), all leading to reading frame shift and a premature stop codon; two others are missense mutations (R38C and S175N) altering the structure and the expression of the protein (Dumont et al. 2009; Hermans et al. 2009). Transmission was recessive with patients being homozygous (four patients) or compound heterozygous (two patients). Acquired GPVI deficiencies are more frequently reported. Most often these are patients with autoimmune thrombocytopenia characterized by the presence of autoantibodies that cause GPVI shedding and/or internalization (Arthur et al. 2007a). Consistent with the observations in patients, the genetic or antibody-induced absence of GPVI in mice has no serious haemorrhagic consequence.

The scarcity of bleeding in patients suffering from a GPVI deficiency, even severe, shows that GPVI is not strictly required to ensure physiological haemostasis, which is permitted thanks to the redundancy of the activation pathways in platelets (Kato et al. 2003; Lockyer et al. 2006). In particular, the vasoconstriction in response to vascular injury at the site of the lesion facilitates the GPIb/vWF interaction and platelet recruitment at the site of the lesion. This also encourages the development of new antithrombotic strategies based on inhibiting GPVI function (Dutting et al. 2012; Zahid et al. 2012).

GPVI in Inflammation

In addition to being the cellular orchestrators of thrombus formation, it is now evident that platelets are also major actors of inflammatory reactions (Fig. 2). In particular, it is well established that platelets promote leukocyte infiltration in inflamed tissues and organs. Although it may seem counter-intuitive, as platelets are mostly known for securing blood vessels and maintaining their barrier function, platelets have also been shown to promote the opening of endothelial junctions and thereby oedema formation, one of the earliest steps of inflammatory reactions (Boilard et al. 2012; Hillgruber et al. 2015; Hara et al. 2010; Petri et al. 2010). Interactions of platelets with the inflamed vasculature and local release of soluble compounds from activated platelets constitute the predominant basic mechanism by which platelets enhance vascular permeability and leukocyte infiltration. The identity of the involved platelet receptors is highly dependent on the inflammatory context, which is defined by the cause and site of inflammation, but it appears that there are situations in which GPVI plays a central role (Gros et al. 2014). In particular, GPVI was shown to mediate the recruitment of platelets to the inflamed joints in a mouse model of autoimmune rheumatoid arthritis (Boilard et al. 2012; Cloutier et al. 2012). In this model, platelets were responsible for the increased permeability of the synovial microvasculature and for the local recruitment of neutrophils. These pro-inflammatory effects of platelets were proposed to be dependent on GPVI, whose engagement led to the release of serotonin and microparticles in synovial fluid that, in turn, promoted gap formation in joint vasculature and the secretion of the neutrophil chemoattractant interleukin-8 by synovial fibroblasts, thus amplifying murine inflammatory arthritis. Remarkably, synovial fluid from patients with rheumatoid arthritis also displays elevated levels of serotonin and platelet-derived microparticles. Therefore, GPVI-dependent platelet activation could contribute to these increases and might represent a promising

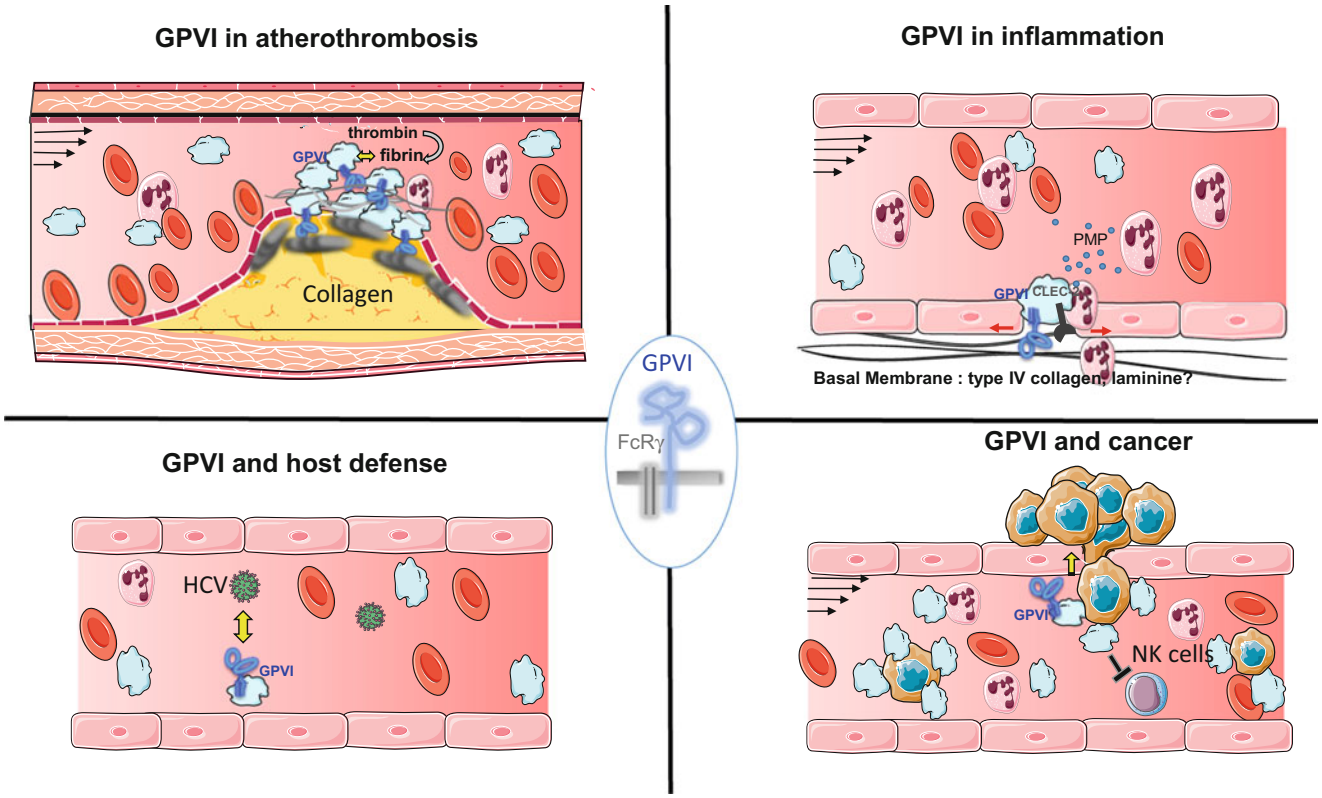

Fig. 2 Schematic representation of GPVI functions in thrombosis and beyond. These schemes illustrate the roles of GPVI in thrombus formation, inflammation, interaction with pathogens and cancer dissemination as described in the text. *PMP* platelet microparticle, *HCV* hepatitis C virus

therapeutic target to dampen inflammation in autoimmune rheumatoid arthritis.

Another inflammatory situation in which GPVI is suspected to play an important role is during glomerulonephritis. Clinical observations have suggested that platelets could mediate or amplify glomerular inflammation in various forms of glomerulonephritis (Zoja and Remuzzi 1995). Like in rheumatoid arthritis, platelets increased vascular permeability and leukocyte infiltration in the inflamed glomerulus, thus promoting glomerular injury and dysfunction. Clinical studies launched years ago to determine the possible efficacy of antiplatelet agents in progressive renal disease and using inhibitors of ADP-mediated platelet activation were mostly inconclusive. Instead, they underscored the need to identify the exact mechanisms by which platelets intervene in glomerular disease. Insights regarding these mechanisms have been brought by more recent studies using a mouse model of immune complex-mediated glomerulonephritis. In this model, GPVI was shown to support the early adhesion of platelets to the inflamed glomerular vasculature and subsequent platelet P-selectin-dependent leukocyte infiltration (Devi et al. 2010; Kuligowski et al. 2006). These findings are thus consistent with a mechanism whereby GPVI plays a critical role in the initiation of leukocyte-dependent glomerular injury, a process that is fundamental to the pathogenesis of many forms of glomerulonephritis.

Adhesion and migration within tissues is not the only leukocyte function that platelets can modulate. In fact, platelets are also able to regulate various effector functions of leukocytes including phagocytosis, generation of reactive oxygen species, granule secretion, cytokine production, as well as the release of neutrophil extracellular traps (Gros et al. 2014). How platelets regulate all these leukocyte functions remains unclear, but there is experimental evidence indicating that GPVI contributes to certain regulatory effects of platelets. For instance, a role for GPVI in the regulation of MMP-9 production by innate immune cells was suggested by the results showing that platelets stimulated MMP-9 production in monocytes in the presence of collagen (Galt et al. 2001). Concordantly, GPVI-dependent enhancement of MMP-9 secretion by neutrophils was recently reported in a mouse model of immune complex-mediated inflammation (Gros et al. 2015). Therefore, platelet GPVI might be considered as a collagen sensor used by leukocytes, so that they can release collagenases where appropriate. However, it appears that GPVI does not solely act as a bridge between collagen, platelets and leukocytes. In fact, besides collagen and other extracellular ligands like fibrin (Alshehri et al. 2015a; Mammadova-Bach

et al. 2015), it has been shown that GPVI is also capable of supporting direct platelet/leukocyte interactions and reciprocal regulations. As mentioned above, EMMPRIN, a surface receptor widely expressed in human tumours but also by platelets, monocytes, and activated lymphocytes, was recently identified as a ligand for GPVI (Seizer et al. 2009; Schulz et al. 2011). Furthermore, microspheres coated with a chimeric form of GPVI consisting of its extracellular domain fused to the Fc part of a human IgG1 molecule (Jandrot-Perrus et al. 2000) were shown to bind to neutrophils accumulating in inflamed microvessels during immune complex-mediated inflammation (Gros et al. 2015). Given the ability of EMMPRIN to stimulate the production of various MMPs, including MMP-9, one could postulate that EMMPRIN mediates the GPVI-dependent induction of MMP-9 production and secretion in monocytes and neutrophils.

While platelets promote oedema formation and leukocyte infiltration and activities, all events potentially damaging for blood vessels, recent studies have shown that in parallel, platelets continuously secure the inflamed vasculature by preventing bleeding throughout the entire course of inflammation (Goerge et al. 2008; Ho-Tin-Noe et al. 2009). This protective action of platelets was reported in various mouse models of inflammation including immune complex-mediated and irritant contact dermatitis (Goerge et al. 2008), glomerulonephritis (Hirahashi et al. 2009), endotoxin-induced acute lung injury (Goerge et al. 2008; Boulaftali et al. 2013) and solid tumours (Ho-Tin-Noe et al. 2008). Together with CLEC-2, another ITAM-associated platelet receptor, GPVI was identified as being responsible for this beneficial effect of platelets in at least two of these situations, immune complex-mediated dermatitis and endotoxin-induced acute lung injury (Boulaftali et al. 2013). In contrast, in these models, prevention of inflammatory bleeding was shown to be independent of the classical mechanisms of haemostasis (Goerge et al. 2008; Boulaftali et al. 2013). In the context of inflammation, prevention of bleeding by platelets and GPVI is thus mostly independent of thrombus formation. The results from a recent study indicate that instead, GPVI mediates the recruitment of individual platelets to seal vascular breaches due to neutrophil trafficking through inflamed post-capillary venules (Gros et al. 2015). Considering that GPVI is the main platelet receptor for collagen, it is likely that single platelets stop bleeding by covering small areas where the basement membrane gets exposed and disrupted by neutrophils. Nevertheless, whereas single adherent platelets could exert a purely mechanical action by plugging small holes in the endothelial lining, it was shown that defective ITAM signalling, either due to a genetic deficiency or to pharmacological inhibition, partially impaired the ability of platelets to prevent inflammatory bleeding (Boulaftali et al. 2013; Gros et al. 2015). Thus, in addition to GPVI-dependent platelet adhesion, GPVI and/or CLEC-2 signal-mediated platelet responses likely also contribute to sealing of the vascular breaches inflicted by neutrophils. In that regard, it was shown that even when not causing aggregation, collagen binding to GPVI can lead to the release of soluble platelet factors such as angiopoietin-1, serotonin, and ATP, all of which are regulators of endothelial cell barrier function (Ollivier et al. 2014).

Finally, the implication of GPVI in various inflammatory functions of platelets, as well as its ability to mediate the release of potent immunomodulators and regulators of vascular permeability without evoking platelet aggregation or procoagulant activity, provides a new perspective on GPVI that somehow reconciles it with its immune receptor nature.

Avenues for Future

Development of new efficient and safe anti-thrombotic drugs

If we take into account the important role that GPVI may play in atherothrombosis and little effect of its deficit on the physiological haemostasis, targeting GPVI appears as an attractive strategy to treat thrombosis without bleeding side effects. Research activities are mainly focus on two strategies: antibody-based inhibition of GPVI and competitive inhibition of GPVI binding to collagen. The later approach is based on the use of soluble dimeric recombinant protein (GPVI-Fc) that binds to collagen, purified or in atherosclerotic plaques (Jandrot-Perrus et al. 2000; Bultmann et al. 2010). Infusion of GPVI-Fc was observed to reduce thrombus formation following arterial injury without increasing bleeding in different animal models (Massberg et al. 2004; Jamasbi et al. 2015). GPVI-Fc (Revacept) was found as safe and well tolerated in a phase I study (Ungerer et al. 2011) and is under safety and feasibility evaluation in a phase II study in patients with symptomatic carotid artery disease (clinicaltrials.gov/NCT01645306). The former strategy is based on the use of antibodies. Several blocking antibodies were reported to inhibit thrombosis in animal models (Li et al. 2007; Mangin et al. 2012; Jamasbi et al. 2015) without increasing the bleeding time. Monovalent Fab fragments are preferable to avoid GPVI dimerization and cross-linking to FcγRIIA on human platelets and need to be humanized (Muzard et al. 2009). A transgenic mouse, humanized for GPVI, has been obtained allowing preclinical studies (Mangin et al. 2012). Phase I clinical trials are awaited to ensure the safety of these antibodies, but the fact that patients with a genetic and total deficiency or autoantibodies do not bleed, allows to be confident in the results.

GPVI and immune defence

In invertebrate and early vertebrates, one cell type, the haemocytes, mediates host defence and haemostasis. It is hypothesized that during evolution, the haemostatic and host defence functions diverged as specialized cell types support them. However, platelets have retained structures and functions of immune cells and still contribute to host defence. Since they are equipped with multiple receptors, platelets sense their environment and answer to danger signal: principally endothelial damages but also inflammatory signals as described above and even pathogens. Platelets interact with parasites, bacteria and viruses (Morrell 2014; Cox et al. 2011; Assinger 2014). In this area, Hepatitis C virus was found to bind to the extracellular domain of GPVI by a mechanism that could mimic collagen binding (Zahn et al. 2006). As a consequence of the receptor cross-linking, platelet P-selectin exposure may lead to subsequent removal of platelets from the circulation by the reticuloendothelial system. The recent observation that GPVI interacts with fibrin raises the possibility that fibrin(ogen)-bound pathogens may indirectly activate platelets via GPVI. Another unsolved issue is whether GPVI activation leads to the secretion of antimicrobial factors.

GPVI and cancer

Tumour cells interact with components of the haemostatic system, including platelets. The contribution of platelets and platelet activation to malignancy progression is complex and bidirectional and may underlie cancer growth and dissemination. Regarding the role of GPVI, the data so far reported showed that in GPVI-deficient mice, experimental metastasis based on inoculation of lung carcinoma and melanoma was reduced (Jain et al. 2009). Interestingly, there is growing evidence that platelets may facilitate tumour immune escape and metastasis, at least in part by modulating NK cell reactivity (Placke et al. 2011), and the place of GPVI in this process merits examination. The possible contribution of GPVI to the well-described pro-malignancy effects of tumour cell-associated EMMPRIN (Yan et al. 2005) is raised.

Take-Home Messages

GPVI is

- Involved in the initiation and growth of the thrombus
- Critically involved in atherothrombosis but dispensable for physiological haemostasis
- Contributing to the patrol role of platelets with respect to inflammation and host defence
- Contributing to the platelet-cancer cells dialogue
- A seducing target to develop new drugs associating safety to efficacy towards thrombosis and even beyond

The Role of CLEC-2 in and Beyond the Vasculature

Julie Rayes, Alexander T. Hardy, Stephanie E. Lombard, Samantha J. Montague, Steve P. Watson, and Kate L. Lowe

Abstract

C-type lectin-like receptor 2 (CLEC-2) is a glycoprotein expressed on the surface of platelets that induces platelet activation including aggregation. Binding of the endogenous ligand podoplanin or the exogenous ligand rhodocytin to CLEC-2 induces tyrosine phosphorylation of the hemITAM motif expressed in its cytoplasmic tail. This hemITAM phosphorylation induces subsequent downstream signalling leading to calcium mobilisation and platelet activation. Although CLEC-2 stimulation induces powerful platelet activation, the interaction of CLEC-2 with podoplanin is not crucial for haemostasis. During development, CLEC-2 interacts with podoplanin on lymphatic endothelial cells (LECs) and is crucial for blood/lymphatic vessels separation, as well as development of the cerebrovasculature. Moreover, CLEC-2 critically maintains the integrity of high-endothelial venules within lymph nodes post-development through its interaction with podoplanin on fibroblastic reticular cells.

Under pathologic conditions, blockade of the CLEC-2/podoplanin interaction has been shown to elicit both detrimental and beneficial effects in a disease-dependent manner. The interaction has been shown to be detrimental in the case of tumour metastasis, HIV propagation and salmonella-mediated liver thrombosis and inflammation. In contrast, upregulation of podoplanin on TH17 cells impairs T-cell expansion and survival in multiple sclerosis and results in enhanced resolution of the disease. This book chapter will discuss the structure and function of the novel platelet receptor CLEC-2 from its discovery to the latest studies carried out on the physiological and pathological role of CLEC-2. This chapter is divided into four sections that cover the identification of CLEC-2 on platelets, the key signalling pathways involved, the role of CLEC-2 in embryonic development and its function in and beyond the vasculature.

Introduction

In 2000, Colonna et al. performed a bioinformatics study and identified the CLEC-2 gene *Clec1B* on chromosome 12 in the Dectin-1 gene cluster. The CLEC-2 gene is located near the genes for six other C-type lectin receptors and was identified as a novel member of the C-type lectin-like superfamily (Colonna et al. 2000). Originally, CLEC-2 mRNA was found in the liver and on some haematopoietic cells, in particular dendritic cells (DCs) and natural killer cells in human and mice (Colonna et al. 2000). Later, in 2006, CLEC-2 mRNA and CLEC-2 protein expression was found to be abundant in the megakaryocyte/platelet lineage, liver sinusoidal endothelial cells and liver Kupffer cells, although expression in liver has yet to be independently confirmed (Chaipan et al. 2006; Suzuki-Inoue et al. 2006; Senis et al.

2007). In 2009, CLEC-2 was further shown to be expressed on subsets of murine myeloid cells and dendritic cells under basal conditions as well as on a variety of leukocyte subsets in response to inflammatory stimuli (Kerrigan et al. 2009; Acton et al. 2012). However, a recent study identified a much more restrictive expression profile, demonstrating CLEC-2- expression to be localised on platelets and on a subset of circulating inflammatory dendritic cells, which was lost upon entry into secondary lymphoid organs (Lowe et al. 2015a, b). The discrepancy in regard to expression to haematopoietic subsets is explained by off-target actions of the available antibodies. Investigation of the function of CLEC-2 in platelets was facilitated by its identification as a receptor for the snake venom rhodocytin using affinity chromatography and mass spectrometry (Suzuki-Inoue et al. 2006). CLEC-2 is a type II membrane protein with an extracellular carbohydrate-like recognition domain, a transmembrane domain and a cytoplasmic tail that is essential for downstream signalling. The CLEC-2 cytosolic tail has a hemi (or half) immunoreceptor tyrosine-based activation motif (ITAM) which consists of a single YXXL sequence which is phosphorylated by Src and Syk tyrosine kinases. CLEC-2 has two well-characterised ligands: an exogenous ligand, rhodocytin, and an endogenous ligand, podoplanin. In addition, it has been shown to be activated by the sulphated sugar, fucoidan, which also activates the platelet collagen receptor GPVI.

Podoplanin is a transmembrane glycoprotein that is widely expressed outside of the vasculature under physiological conditions including on kidney podocytes, alveolar type 1 epithelial cells, lymphatic endothelial cells (LECs), cerebral choroid plexus and many epithelial beds as well as being induced in subsets of haematopoietic cells. The expression of podoplanin on LECs is crucial for prevention of mixing of the blood and lymphatic vasculatures during development through its interaction with platelet CLEC-2- (Bertozzi et al. 2010; Herzog et al. 2013; Lowe et al. 2015a, b). On kidney podocytes, the absence of podoplanin was suggested to impair blood filtration, resulting in the presence of proteins in the urine (Koop et al. 2008). However, with the generation of transgenic mice with targeted deletion of podoplanin on kidney podocytes, the function of podoplanin in the kidney, both physiologically and under inflammatory conditions, is now questionable and requires further investigation (Rayes and Watson, unpublished). Podoplanin has been shown to be upregulated under pathologic conditions, such as inflammation, cancer and autoimmune disease on inflammatory macrophages, tumour cells and T-helper 17 (Th17) cells, respectively, and in development.

The role of podoplanin and CLEC-2 has been studied in a variety of disorders. It is important to note that the beneficial or detrimental effect of the CLEC-2-podoplanin interaction seems to be disease-dependent. Upregulation of podoplanin on macrophages and tumour cells induces platelet aggregation and thrombosis, whereas the expression of podoplanin on TH17 cells alters TH17 cell function and survival and improves recovery in a mouse model of multiple sclerosis (spontaneous experimental autoimmune encephalomyelitis) on a susceptible background.

In this chapter, CLEC-2 signalling pathways and the role of CLEC-2 in developmental pathways and in both thrombotic and non-thrombotic disorders will be discussed.

CLEC-2 Signalling

(Hem)ITAM Receptors in Platelets

As mentioned above, the C-type lectin receptor CLEC-2 is a glycoprotein receptor and a member of the (hem)ITAM family of receptors, which includes other receptors such as the B-cell antigen receptor, the low affinity immune receptor FcγRIIa and the major platelet signalling collagen receptor, GPVI/FcRγ chain (referred to as GPVI). An ITAM consists of two YXXL sequences (single amino acid code) separated by 6–12 amino acids. HemITAM receptors such as CLEC-2 differ as they contain only one YXXL sequence in their intracellular tails (Fuller et al. 2007). CLEC-2 signalling is additionally dependent on a conserved triacidic amino acid sequence immediately upstream of the hemITAM motif, which is also a feature of all but one of the other five known hemITAM-containing receptors (Hughes et al. 2013; Ruckrich and Steinle 2013). CLEC-2 is expressed as a dimer, thus providing two YXXL sequences (Fig. 1).

(Hem)ITAM Signalling

Upon receptor engagement via endogenous or exogenous ligands, the tyrosine residues contained within ITAM domains become targets of phosphorylation via Src family kinases (SFKs) such as Src and Lyn (Senis et al. 2014). A key difference between CLEC-2 and traditional ITAM signalling is that the hemITAM motif appears to be more reliant upon spleen tyrosine kinase (Syk) than SFKs for initial phosphorylation, with SFKs being important for activation of Syk and for signalling further downstream (Spalton et al. 2009; Severin et al. 2011). Upon platelet activation by agonists such as rhodocytin or podoplanin, the hemITAM sequence is phosphorylated, allowing recruitment and docking of the tandem SH2 domain-containing kinase Syk. Once recruited to the phosphorylated hemITAM via its SH2 domains, Syk undergoes a conformational change, moving from an auto-inhibited to an active conformation. In this active conformation, Syk undergoes further auto- and trans-phosphorylation. The latter is mediated by SFKs, allowing for full activation of Syk and phosphorylation of

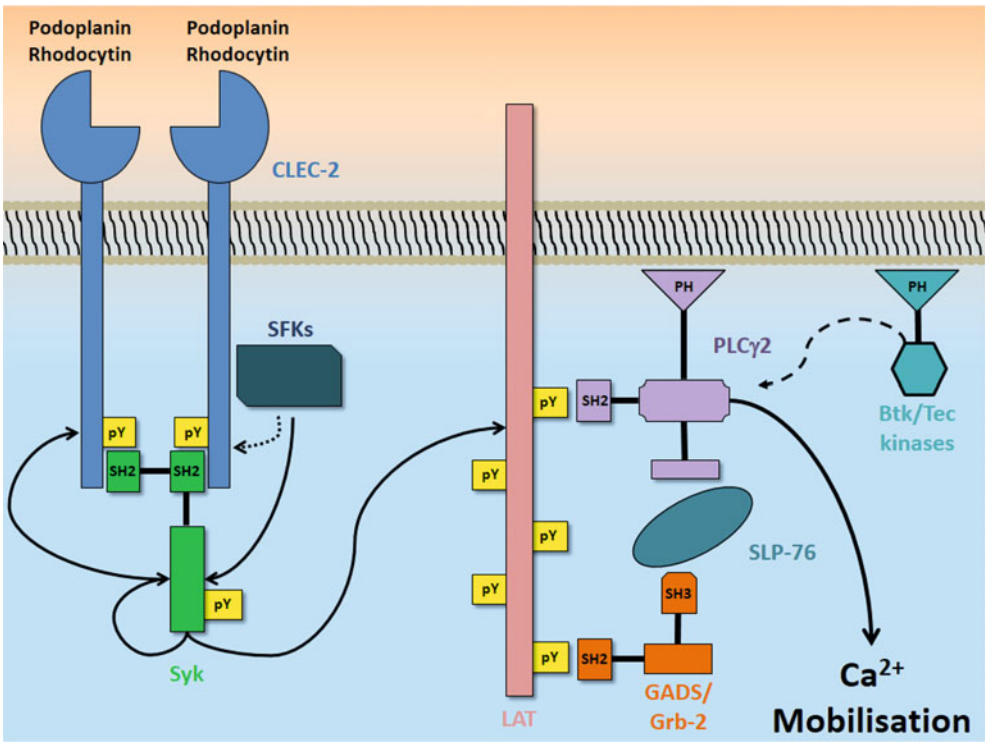

Fig. 1 Graphical representation of the proximal events in CLEC-2-mediated platelet activation. Upon receptor engagement, the hemITAM contained within the intracellular tail of CLEC-2 becomes phosphorylated by Syk and possibly also by Src family kinases. HemITAM phosphorylation allows recruitment of Syk via its SH2 domains, allowing downstream phosphorylation of LAT and the formation of the LAT signalosome. The result of this signalosome formation is the mobilisation of intracellular Ca^{2+} via recruitment and activation of PLCγ2

several downstream proteins. One of the most important of these is LAT, an adapter protein containing several tyrosine residues that undergo phosphorylation. LAT has no intrinsic activity and serves as the core of the 'LAT signalosome', allowing the docking and activation of many of the effectors of this pathway including Grb-2, Gads, SLP-76, PI3-K, Btk and PLCγ2 (Suzuki-Inoue et al. 2006; Fuller et al. 2007). PLCγ2 is generally considered to be the most important, giving rise to formation of inositol 1,4,5-trisphosphate (IP3) and 1,2-dacylglycerol (DAG) which mobilise Ca^{2+} and activate protein kinase C, respectively. These changes culminate in the exocytosis of intracellular granules, such as α- and dense granules, as well as inside-out activation of platelet integrins including $\alpha_{IIb}\beta_3$ (Hughes et al. 2015; Zheng et al. 2015). The release of ADP from dense granules and formation of thromboxane A_2, made *de novo* from membrane phospholipids, play critical positive feedback roles in activation of CLEC-2 in human platelets (Pollitt et al. 2010). CLEC-2 activation in human is also dependent on the Rho GTPase, Rac (Pollitt et al. 2010). This contrasts with activation by the collagen ITAM receptor GPVI which shows a reduced rather than complete dependency on the role of the two feedback messengers and Rac.

Functional Roles of CLEC-2 Signalling

Platelet activation and aggregation is a multistep process that involves different receptors and signalling pathways with the aim of prevention of excessive blood loss following vessel injury. CLEC-2 is expressed on platelets with an average copy number of 2000 receptor per platelet. Several studies have investigated a possible role of CLEC-2 in haemostasis and thrombus formation using various mouse models. CLEC-2-deficient platelets aggregate normally in response to classical platelet agonists but not to rhodocytin. Moreover, CLEC-2-deficient platelets have normal adhesion and spreading on extracellular matrices including collagen, laminin, von Willebrand factor and fibrinogen (Suzuki-Inoue et al. 2010). Several groups have investigated the consequence of CLEC-2 deficiency in a tail bleeding assay (haemostasis) or laser, photochemical or $FeCl_3$ thrombosis model with contrasting results. Using an anti-CLEC-2 antibody to deplete CLEC-2 from the platelet surface in vivo, May et al. (2009) showed a prolonged bleeding time and profound defect in arterial thrombus formation following $FeCl_3$ injury (May et al. 2009). Using irradiated mice reconstituted with Clec-$2^{-/-}$ foetal liver, Suzuki-Inoue

et al. (2010) showed a reduction in thrombus formation following photochemical injury but no significant change in tail bleeding times (Suzuki-Inoue et al. 2010). In contrast, Hughes et al. (2010) did not observe a significant change in tail bleeding time or aggregation on collagen at high shear using radiation chimeric mice reconstituted with CLEC-2-deficient bone marrow, and additionally were unable to demonstrate phosphorylation of CLEC-2 under flow conditions, providing indirect evidence that it is not activated (Hughes et al. 2010). The reason for the discrepancy between the various studies remains unclear. A recent study showed a profound defect in thrombus formation in mice double deficient in GPVI and CLEC-2 suggesting possible compensatory roles of the two (hem)ITAM receptors (Bender et al. 2013), although this which must involve adhesion and signalling as a similar result is not seen in mice deficient in Syk. Overall the consensus is that CLEC-2 has a minor role (at best) in haemostasis, consistent with the absence of an identified ligand in the vasculature, and that its primary role is to support many of the non-canonical roles for platelets that are beginning to emerge.

CLEC-2 in Development

Blood-Lymphatic Vascular Separation Defect in CLEC-2-Deficient Mice

Two decades ago, mice deficient in the downstream CLEC-2 signalling molecule, Syk, were shown to develop subcutaneous haemorrhages in the skin and oedema at mid-gestation (Cheng et al. 1995; Turner et al. 1995). A similar phenotype was observed in mice deficient in the adaptor protein SLP-76 (Clements et al. 1998; Pivniouk et al. 1998; Clements et al. 1999) or PLC-γ2 (Wang et al. 2000). The development of haemorrhages and oedema was later shown to result from aberrant connections between the blood and lymphatic vasculatures causing the appearance of blood-filled lymphatic vessels and impaired lymphatic drainage, respectively (Abtahian et al. 2003; Ichise et al. 2009). Support for the involvement of CLEC-2 in this phenotype came following the characterisation of mice deficient in its endogenous ligand, podoplanin, which were also shown to harbour blood-filled lymphatic vessels in the skin and gut at birth (Schacht et al. 2003), a phenotype later identified in CLEC-2-deficient embryos in mid-gestation (Bertozzi et al. 2010; Suzuki-Inoue et al. 2010; Finney et al. 2012). Both CLEC-2- and podoplanin-deficient mice experience almost 100 % perinatal mortality that is thought to be caused by defective lymphatic function and fluid retention leading to a failure to inflate the lungs (Schacht et al. 2003; Finney et al. 2012). Furthermore, the mice that survived for sufficient time to suckle developed chylous ascites, further indicative of impaired lymphatic function (Abtahian et al. 2003; Finney et al. 2012; Hess et al. 2014).

Identifying the Causative CLEC-2-Expressing Cell That Underlies the Defects in Lymphatic Development

The mechanism by which podoplanin and CLEC-2 prevent the mixing of the blood and lymphatic vasculatures during development remains controversial. A role for podoplanin specifically on the lymphatic endothelium has been confirmed by the presence of blood-filled lymphatic vessels in mice with a Tie-2-Cre-mediated deletion of podoplanin or the glycosyltransferase enzyme, T-synthase, which is important for the glycosylation of the podoplanin extracellular domain (Fu et al. 2008; Herzog et al. 2013). The interacting CLEC-2-expressing cell type has been investigated through a series of lineage tracing studies that initially pinpointed Syk/SLP-76 activity in a circulating endothelial progenitor (Abtahian et al. 2003; Sebzda et al. 2006) but which was later shown to be a circulating cell of the myeloid lineage (Bohmer et al. 2010). Using a series of transgenic mice, a role for Syk in macrophages, T- and B-lymphocytes, was eliminated, while the loss of CLEC-2, Syk or SLP-76 in the megakaryocyte/platelet lineage (generated by crossing floxed homozygotes to a PF4-Cre transgenic) was shown to be indispensable for blood-lymphatic vascular separation (Bertozzi et al. 2010; Finney et al. 2012).

A role for CLEC-2 on platelets/megakaryocytes is supported by the presence of blood-filled lymphatic vessels following the selective ablation of this lineage using diphtheria toxin (again achieved using a PF4-Cre transgenic), through treatment with aspirin *in utero* or in mice that lack functional megakaryocytes due to a deficiency in the transcription factor Meis-1 (Carramolino et al. 2010; Uhrin et al. 2010). Furthermore, the contribution of platelet-specific effects over megakaryocytes is supported by the development of blood-filled intestinal lymphatic vessels in irradiated mice reconstituted with Syk-, SLP-76-, PLCγ2- or CLEC-2-deficient bone marrow, where the number of circulating megakaryocytes is negligible (Ichise et al. 2009; Bertozzi et al. 2010; Finney et al. 2012).

Unravelling the Molecular Mechanism of the Impairment in Lymphatic Development

Initially it was proposed that a direct interaction between platelets and LECs at the cardinal vein was critical to ‘clot off’ the primary budding lymphatic structures and prevent

the formation of blood-lymphatic vascular connections (Bertozzi et al. 2010; Uhrin et al. 2010; Hess et al. 2014). However, high-resolution microscopy studies of developing embryos have failed to identify any connection between the blood and lymphatic vasculatures at this stage (Hagerling et al. 2013). Furthermore, blood-filled lymphatic vessels can be seen in irradiated adult mice reconstituted with CLEC-2- or Syk-deficient bone marrow where the lymphatic system is already established (Bertozzi et al. 2010; Finney et al. 2012). It was recently proposed that a thrombus, formed through podoplanin-induced CLEC-2 activation on platelets, forms at the joining of the thoracic duct and the subclavian vein to prevent backflow of blood into the lymphatic system during development and throughout adulthood (Hess et al. 2014). However, an important role for thrombus formation is disputed by the absence of a blood-lymphatic vascular separation defect in mice lacking the major platelet integrin $\alpha_{IIb}\beta_3$ (Uhrin et al. 2010).

It has also been proposed that one or more of the bioactive molecules or growth factors that are abundant in platelet dense, α- and lysosomal secretory granules and released upon their activation could contribute towards influencing lymphatic endothelial cell behaviour. So far, there has been little evidence to support this mechanism since patients or mice with defective dense- or α-granule secretion syndromes known as Hermansky-Pudlak syndrome or grey platelet syndrome, respectively, have not been described to exhibit lymphatic defects (e.g. Deppermann et al. 2013). Platelets additionally store large concentrations of the bioactive lipid sphingosine-1-phosphate (S1-P), which have been shown to have potent effects on endothelial cell migration, but while the loss of S1-P in mice is associated with widespread haemorrhaging and embryonic lethality, no phenotype of blood-lymphatic mixing was observed (Liu et al. 2000).

Other potential mechanisms include the direct interaction between platelet-CLEC-2 and podoplanin on LECs, which has been shown to inhibit LEC migration (Finney et al. 2012). It is proposed that these inhibitory signals are critical to arrest the growth of budding lymphatic vessels and prevent the formation of aberrant connections (anastomoses) with the blood vascular endothelium (Finney et al. 2012). The ability of CLEC-2 to cluster its receptor podoplanin on the surface of LECs was later demonstrated. This interaction supports platelet adhesion and is also proposed to inhibit signalling by podoplanin in LECs as shown in other cell types (Pollitt et al. 2014). The presence of anastomoses between veins and lymphatic veins has been described by many groups, including direct visualisation of mixing of the two vasculatures in mice with a platelet-specific loss of functional Syk (Hughes et al. 2015).

Other Developmental Functions of CLEC-2

Podoplanin was identified on fibroblastic reticular cells (FRCs) of the spleen over two decades ago and has since been shown to have several important roles in the organisation and function of lymphoid compartments (Farr et al. 1992; Yu et al. 2007). Recently, a number of these functions have been linked to CLEC-2 including trafficking of CLEC-2-expressing DCs to lymph nodes which is dependent on podoplanin expression on lymphatic endothelium and on FRCs (Acton et al. 2012). In addition, CLEC-2 has been shown to play a role in maintaining the integrity of high-endothelial venules within lymph nodes through its interaction with podoplanin on FRCs (Herzog et al. 2013). In this study, mice with a platelet/megakaryocyte-specific loss of CLEC-2 (i.e. PF4-Cre transgenic CLEC-$2^{fl/fl}$) developed blood-filled lymph nodes, and while this does not influence the primary immune response, it impairs the regulation of acquired immune responses (Herzog et al. 2013; Benezech et al. 2014). A much more severe phenotype is observed following constitutive loss of CLEC-2 or podoplanin where pups are born with a complete absence of mesenteric and inguinal lymph nodes due to a defect in lymph node maturation during late embryogenesis (Peters et al. 2011; Benezech et al. 2014). Significantly, lymph nodes are present in PF4-CLEC-2-deficient mice indicating that the developmental defect is not due to loss of platelet activation. This suggests a potential role for CLEC-2 outside of the platelet lineage during development and a second critical role for platelet-derived CLEC-2 in maintaining lymph node vascular integrity post-development.

A role for CLEC-2 in maintaining vascular integrity has been described in the developing brain. Podoplanin expression was shown to be restricted to the choroid plexus and ependymal lining of the ventricles at E16.5, but has since been seen to be widely expressed throughout the neuroepithelium between E10.5 and E12.5 (Williams et al. 1996; Schacht et al. 2003; Lowe et al. 2015a, b). Haemorrhages were first reported in the midbrain parenchyma of CLEC-2-deficient embryos at E12.0 (Tang et al. 2010). While severe cerebral haemorrhaging had been described in T-synthase-deficient embryos at E12.0, only recently were podoplanin-deficient embryos characterised and shown to exhibit extensive cerebral haemorrhaging between E11.5 and E12.5 (Lowe et al. 2015). Developing cerebral blood vessels in CLEC-2- and podoplanin-deficient mice were visibly tortuous and prone to haemorrhage at E10.5 caused by aberrant associations between the endothelium and the surrounding mural cells. CLEC-2-induced platelet aggregation is implicated in the haemorrhaging as bleeding is also seen in αIIb-deficient

embryos. Thus, activation of platelets by podoplanin-CLEC-2 leads to platelet aggregation and sealing of gaps in developing vessels. It remains unclear whether this also contributes to the altered patterning of vessels that is seen before the onset of haemorrhage.

CLEC-2- and podoplanin-deficient mice experience respiratory failure at birth due to the inability to inflate their lungs (Ramirez et al. 2003; Finney et al. 2012). This is likely secondary to impairment in lymphatic function leading to fluid retention. In addition, it has been speculated that this may also be due to loss of podoplanin on alveolar type I cells, although as yet there is no direct evidence for this (Millien et al. 2006).

Podoplanin-deficient mice have been reported to exhibit myocardial pathology, where hypoplasia in the myocardium is proposed to result from impaired development of the epicardium (Mahtab et al. 2008). However, no such phenotype has been reported in CLEC-2-deficient mice, suggesting podoplanin plays a functional role independent of CLEC-2 in cardiac development.

CLEC-2 Beyond Haemostasis: The Beneficial and Detrimental Role of the Interaction of CLEC-2 and Podoplanin

In the last few years, increasing evidence for a role of platelets in the regulation of inflammation, infection and cancer has emerged in human disease and mouse models. Platelets are now recognised as having multiple roles in inflammation and infection, including the ability to regulate leukocyte functions, such as secretion of granular contents and production of reactive oxygen species (ROS) from neutrophils (Gros et al. 2015), while the formation of a thrombus inside a blood vessel supports innate immunity through pathogen recognition and containment (Engelmann and Massberg 2013). Many

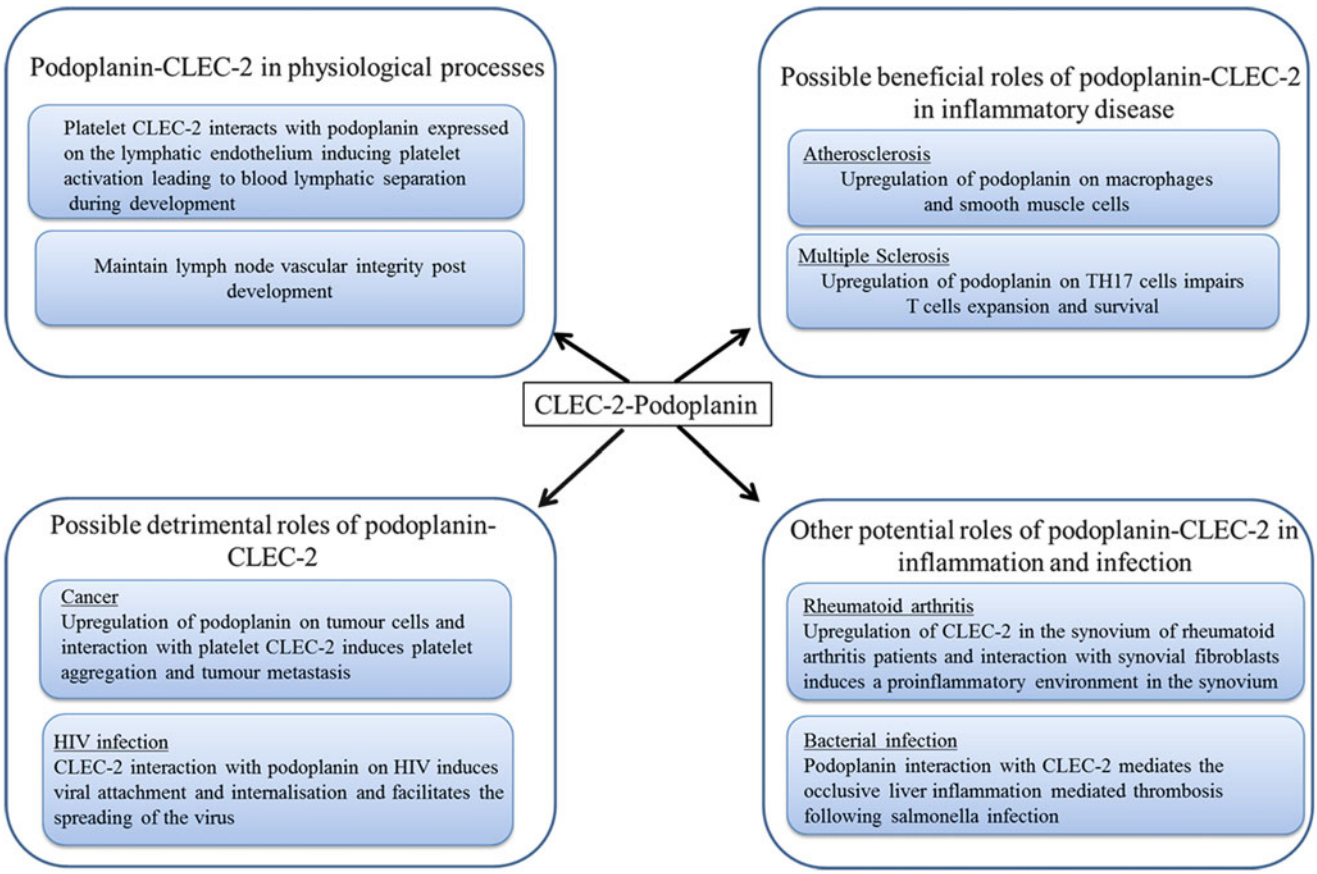

Fig. 2 Possible beneficial and detrimental roles of platelet CLEC-2/podoplanin interactions in normal physiology and in disease

of these new roles for platelets have been shown to involve CLEC-2 and podoplanin (Fig. 2).

The Role of CLEC-2-Podoplanin in Inflammatory Diseases

Multiple studies have shown the selective role of CLEC-2-podoplanin interaction in inflammatory and non-inflammatory conditions. The beneficial or detrimental effect depends largely on the inflammatory state and the nature of the platelet-leukocyte interaction. Indeed, in a mouse model of multiple sclerosis (MS), an autoimmune inflammatory disorder of the central nervous system (CNS), podoplanin expression on a subset of CD4+ cells, TH17 cells, alters TH17 expansion and survival resulting in an increased rate of resolution of the inflammation (Peters et al. 2015). This beneficial effect of podoplanin was abrogated by a global deletion of CLEC-2 showing that the interaction between CLEC-2 and podoplanin mediates the resolution of the inflammation. However, whether CLEC-2 on platelets, DCs or possibly B-cells (where expression is controversial) contributes to this effect remains unclear. Significantly, upregulation of podoplanin was also observed in human patients with active MS plaque but not in glioblastoma multiforme (GBM), an aggressive malignant primary brain tumour (Nylander et al. 2015) indicating this upregulation is disease-specific. Thus, podoplanin-CLEC-2 interaction seems to modulate the inflammatory response in MS infiltrates, and this effect depends on the presence of a specific microenvironment.

It has been suggested that platelets contribute to several stages of atherosclerosis, including initiation, lesion growth and thrombus formation upon plaque disruption. Interestingly, the level of expression of podoplanin on smooth muscle cells and macrophages in atherosclerotic lesions from human patients correlates with the severity of the lesion, although the significance of this remains to be determined (Hatakeyama et al. 2012).

CLEC-2 expression has been reported in synovium of patients with rheumatoid arthritis (RA), a chronic systemic inflammatory disease leading to progressive destruction of the articular cartilage and bone (Del Rey et al. 2014). Importantly, the interaction of synovial fibroblasts with platelet CLEC-2 has been shown to lead to an increase in the proinflammatory cytokines IL6 and IL8 (Del Rey et al. 2014). CLEC-2 expression on microvesicles is also increased in RA patients (Gitz et al. 2014). It has been speculated that the abundant levels of microvesicles in RA may induce potent pro-inflammatory effects on the synovial fluid (Boilard et al. 2010; Del Rey et al. 2014). Moreover, podoplanin expression is increased in areas of inflammation, and synovial fibroblast activation and synovial transformation (Ekwall et al. 2011; Miyamoto et al. 2013; Del Rey et al. 2014).

The Role of CLEC-2 and Podoplanin in Infection

There is increasing recognition of the importance of platelets in bacterial and viral infections (Cox et al. 2011; Chabert et al. 2015). Severe and sometimes life-threatening bleeding can occur in certain viral infections, with thrombocytopenia often arising from viral-induced platelet destruction, consumption or sequestration. Platelet-viral interactions are complex and will depend on the species of the virus and/or the platelet environment. One of the most important viral agents that CLEC-2 associates with is the human immunodeficiency virus (HIV-type 1). Zucker-Franklin et al. (1990) were the first group to visualise HIV internalisation by megakaryocytes and platelets (Zucker-Franklin et al. 1990). HIV-1-infected cells release HIV-1 virions expressing podoplanin on their capsules that allow HIV-1 to interact with CLEC-2 and DC-SIGN on platelets. This interaction mediates HIV-1 capture and facilitates the spread of infection (Chaipan et al. 2006; Chaipan et al. 2010). Encouragingly, a CLEC-2-specific antiserum reduced HIV-1 transmission by platelets by approximately 50 % (Chaipan et al. 2006). Podoplanin depletion only diminished CLEC-2-dependent HIV transmission in B-THP cells, a Raji B-cell line, suggesting that podoplanin incorporation for HIV spread is dependent on podoplanin expression in the targeted cell for HIV infection (Chaipan et al. 2010). Therefore, incorporation of a second, as yet unrecognised, CLEC-2 ligand may be responsible for CLEC-2-dependent capture of T-cell-derived and peripheral blood mononuclear cell-derived viruses, facilitating CLEC-2-driven HIV transmission (Ozaki et al. 2009; Chaipan et al. 2010; Lowe et al. 2015a, b).

In a mouse model of salmonella infection, Hitchcock et al. (2015) have recently reported that upregulation of podoplanin in the liver leads to an inflammation-driven occlusive thrombosis. Significantly, the venous thrombosis was substantially abrogated in the absence of CLEC-2 on platelets or in the absence of macrophages without affecting the time course of the bacteraemia. The upregulation of podoplanin in the liver is driven by a TLR4- and INF-γ-dependent inflammation. Given that CLEC-2 does not have a major role in haemostasis, this highlights the C-type lectin-like receptor as a novel target in some forms of thromboinflammatory disease.

The Role of CLEC-2 and Podoplanin in Cancer

A potential role of podoplanin in cancer metastasis has also emerged. Podoplanin is upregulated in a wide range of cancer types such as colorectal adenocarcinoma (Kato et al. 2003), testicular germ cell tumours (Kato et al. 2004), squamous cell carcinomas of the lung, cervix, oral cavity, larynx and mesothelioma and in tumours of the central nervous system (Kato et al. 2005; Kimura and

Kimura 2005; Schacht et al. 2005; Shibahara et al. 2006; Rodrigo et al. 2010). Tumour cells can interact with platelets to form heterogeneous aggregates which protect the invasive cells from shear stress and immunological assault (Gay and Felding-Habermann 2011). It is speculated that the coating of platelets allows the tumour cells to evade the immune system as well as supporting adherence to the vessel wall. The antihuman podoplanin antibody (MS-1 mAb) has been shown to reduce platelet aggregation in vitro and pulmonary metastasis in vivo (Takagi et al. 2013). This highlights podoplanin as a promising target for developing novel antitumour and anti-metastatic agents.

Take-Home Messages

- CLEC-2 interaction with podoplanin induces platelet activation and aggregation.
- During development, CLEC-2-podopanin interaction is crucial for blood/lymphatic vessel separation.
- Post-development, CLEC-2-podoplanin interaction maintains the integrity of high endothelial venules in lymph nodes.
- CLEC-2-podoplanin is not crucial for haemostasis.
- Detrimental role of CLEC-2-podoplanin: HIV propagation, salmonella-induced liver thrombosis and cancer metastasis.
- Beneficial role of CLEC-2-podoplanin inhibition of T-cell expansion and survival in multiple sclerosis.

Conclusion

Although CLEC-2 and podoplanin have been intensively studied in the last decade, many questions concerning their roles remain unanswered, most notably the roles outside of the vasculature. Anti-CLEC-2 or anti-podoplanin drugs may have a beneficial effect in many diseases, in particular in inflammatory disorders. Additional studies are required to fully understand the mechanism underlying the role of CLEC-2 and podoplanin in physiology and pathology.

Anatomy of the Platelet Cytoskeleton

Hervé Falet

Abstract

The platelet cytoskeleton maintains the discoid shape of the resting platelet and mediates a rapid shape change in response to external stimuli at sites of vascular injury. At rest, specific cytoskeletal structures and molecules maintain the unique architecture of the platelet actin cytoskeleton, connect it to the plasma membrane, and prevent actin monomer assembly onto actin filaments. Platelet activation stimulates the interactions of cytoplasmic signals with actin regulatory proteins to initiate and amplify actin filament growth necessary for platelet shape change. This chapter reviews the cellular mechanisms and proteins maintaining the morphology of resting and activated platelets, focusing on the actin cytoskeleton and exciting recent mRNA and protein profiling studies, clinical observations, and mouse models.

Introduction

Following blood vessel injury and disruption of the vascular endothelium, platelets interact avidly with exposed elements of the basement membrane and rapidly change from resting discs to active forms, first by rounding and then by extending finger-like filopodia and spreading thin sheet-like lamellipodia. This shape change reaction is further amplified by soluble factors released by activated platelets. Shape change is orchestrated by the platelet cytoskeleton, which has therefore two main functions: (1) to maintain the biconvex discoid shape of the resting platelet and (2) to mediate a rapid shape change in response to external stimuli at sites of vascular injury. The platelet cytoskeleton is composed of actin and tubulin polymers and associated cytoskeletal proteins, which compose a large fraction of the platelet proteome. Mutations and single nucleotide polymorphisms (SNPs) in genes encoding cytoskeletal proteins often lead to altered platelet counts and mean platelet volume. Table 1 lists the major cytoskeletal proteins regulating the resting and activated platelet cytoskeleton, based on recent mRNA and protein profiling studies, clinical observations, and mouse models, while the major actin regulatory proteins regulating the platelet actin assembly reaction are listed in Table 2.

The Cytoskeleton of the Resting Platelet

Actin

Actin is by far the most abundant protein in platelets, where it represents 15–20 % of the total cellular protein mass. Platelet actin is evenly distributed between β-actin and γ-actin, also called cytoplasmic actins 1 and 2, respectively (Rowley et al. 2011; Burkhart et al. 2012) (Table 1). In resting platelets, about 40 % of total actin is assembled into dynamic polymers or filaments (F-actin) that can be reversibly assembled from monomeric or globular actin (G-actin). The distribution of actin in filaments reaches 80 % in activated platelets.

Actin filaments are polarized structures, first recognized by electron microscopy by the way filaments can be decorated with the myosin head domain, which binds periodically along

the filament length to define barbed and pointed ends. This polarity is reflected in different rates of monomer addition to the two ends. The barbed end of the filament is the preferred end of actin filament assembly in vitro, as it has high affinity for G-actin and elongates at a rate approximately ten times faster than the pointed end. Barbed ends are the only ends contributing to actin assembly in cells, particularly in platelets. When assembled, actin filaments can be cross-linked or bundled into higher-order structures or fragmented into smaller pieces. A large number of platelet cytoskeletal-associated proteins control these dynamic processes.

The Membrane Cytoskeleton

The morphology of the resting platelet is maintained by a membrane cytoskeleton, a thick protein meshwork composed principally of spectrin, adducin, actin filaments, and

actin-associated proteins laminating the cytoplasmic side of the platelet plasma membrane (Fig. 1) (Fox and Boyles 1988; Hartwig and DeSisto 1991). Analogies have been made with the well-characterized spectrin-based erythrocyte membrane cytoskeleton (Lux 2016). Platelet spectrin is composed of both erythroid and non-erythroid α/β-spectrin heterodimers forming 200-nm long tetramers assembled head-to-head. Assembly of spectrin into tetramers is required for platelet production by megakaryocytes (Patel-Hett et al. 2011). Contrary to erythrocytes, where spectrin is connected to short actin oligomers capped by adducin at their barbed end and tropomodulin at their pointed end (Lux 2016), platelet spectrin strands interconnect at the barbed ends of the actin filament network originating from the cytoplasm (Fox and Boyles 1988; Hartwig and DeSisto 1991). Therefore, the dense platelet spectrin lattice and its associated actin filaments assemble into a continuous ultrastructure.

Capture of actin filament barbed ends by spectrin requires adducin, which forms a high-affinity ternary complex with spectrin and actin (Fig. 1) (Gilligan et al. 2002; Barkalow et al. 2003). Platelet express both erythroid α-adducin (encoded by human *ADD1*, mouse *Add1*) and non-erythroid γ-adducin (human *ADD3*, mouse *Add3*). *Add1*-null mice lack both α- and γ-adducin in platelets and have slightly elevated platelet counts with reduced mean platelet volume (Robledo et al. 2008), indicating that α-adducin regulates both the expression of γ-adducin and the morphology of the resting platelet membrane cytoskeleton. By contrast, the role of γ-adducin appears redundant, as *Add3*-null mice have normal platelet counts and morphology and express α-adducin normally in platelets (Robledo et al. 2008).

Platelets express several other cytoskeletal proteins previously characterized in the erythrocyte membrane cytoskeleton. These include the pointed-end capping protein tropomodulin and tropomyosin, which binds along the side of the short actin oligomers of the erythrocyte membrane cytoskeleton, where it is believed to control their length (Lux 2016). Megakaryocytes and platelets principally express tropomodulin 3 (human *TMOD3*, mouse *Tmod3*), deficiency of which is embryonic lethal in mice (Sui et al. 2014). *Tmod3*-null embryos develop thrombocytopenia with large platelets, due to impaired platelet production by megakaryocytes, which show increased actin assembly and actin redistribution from the cortical membrane cytoskeleton to the cytoplasm (Sui et al. 2015). In humans, SNPs in *TPM1* and *TPM4* encoding tropomyosin 1 and 4 have been associated with altered platelet counts and mean platelet volume (Soranzo et al. 2009; Gieger et al. 2011; Qayyum et al. 2012). However, further functional studies are required to determine the role of tropomyosin 1 and 4 in megakaryocytes and platelets.

Dematin is an actin-bundling protein of the erythrocyte membrane skeleton abundantly expressed in platelets (Wieschhaus et al. 2012). Dematin consists of a C-terminal headpiece and an N-terminal tail that both contain F-actin binding sites. Dematin binds to spectrin and enhances its binding to actin filaments. Platelets lacking the dematin headpiece exhibit defects in calcium mobilization in response to multiple agonists, associated with concomitant inhibition of platelet aggregation and granule secretion, unveiling dematin as a regulator of internal calcium mobilization affecting multiple platelet cytoskeletal and signaling functions.

Cross-Linking and Bundling Proteins

Actin filaments in the resting platelet are organized into a rigid cytoplasmic scaffold by filamin A (FlnA; previously known as ABP-280), which cross-links actin filaments at a distinctive 90° angle, and by α-actinins, which tend to align actin filaments in parallel bundles.

FlnA (human *FLNA*, mouse *Flna*) is a large antiparallel homodimer that cross-links actin filaments, tethers membrane glycoproteins, and serves as a scaffold for signaling intermediates (Falet 2013). FlnA contains an N-terminal tandem calponin-homology actin-binding domain followed by 24 immunoglobulin-like repeats of 90–100 amino acid residues, the C-terminal of which mediates dimerization (Nakamura et al. 2007; Seo et al. 2009). Two calpain-sensitive hinges separate FlnA repeats into an elongated and linear rod 1 (repeats 1–15) that can bind to actin filaments independently of the actin-binding domain, a compact rod 2 (repeats 16–23), and the self-association domain (repeat 24) (Nakamura et al. 2007). Rod 2 contains most of the binding sites for FlnA partners, e.g., the von Willebrand factor (VWF) receptor subunit GPIbα (repeat 17) and β-integrins (repeat 21) (Nakamura et al. 2006; Kiema et al. 2006).

FlnA traverses the pores of the spectrin-based membrane cytoskeleton to link the VWF receptor GPIb-IX, specifically the GPIbα subunit (Cranmer et al. 2005, 2011; Nakamura et al. 2006), to the underlying actin filaments (Fig. 1). The FlnA–GPIbα linkage initiates in mature megakaryocytes and is constitutively maintained during the platelet lifespan (Begonja et al. 2011). It plays a critical role in maintaining the platelet discoid shape, as has been established in studies of Bernard–Soulier syndrome (BSS) platelets lacking the VWF receptor subunits GPIbα, GPIbβ, or GPIX, or in platelets lacking functional FlnA, all of which are abnormally large in size, are fragile, and circulate poorly. FlnA also interacts with the β-subunits of integrins, thereby competing with talin 1 (Kiema et al. 2006), an essential activator of integrin $\alpha_{IIb}\beta_3$ in activated platelets (Petrich et al. 2007; Nieswandt et al. 2007). FlnA binding to β-integrin subunits is not constitutive,

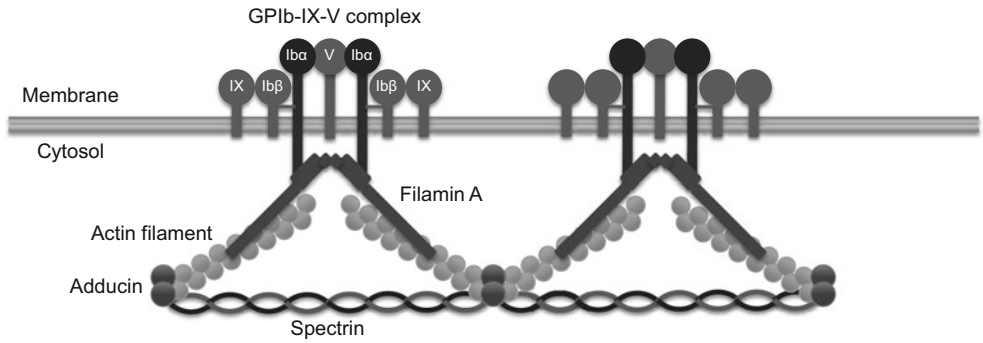

Fig. 1 Organization of the resting platelet cytoskeleton. Spectrin strands laminate the cytoplasmic surface of the plasma membrane and interconnect using barbed ends of actin filaments. Adducin binding to the actin filament barbed end targets spectrin. Actin filaments are cross-linked by FlnA, which provides the major membrane–cytoskeletal connection linking the actin cytoskeleton to the cytoplasmic tail of the GPIbα subunit of the VWF receptor complex GPIb-IX-V

but regulated by mechanotransduction (Ehrlicher et al. 2011), the significance of which for platelet production and function remains to be investigated.

The gene encoding FlnA is X-linked in both humans and mice. *FLNA* mutations causing early truncation of FlnA are typically embryonic lethal in males, due to cardiovascular defects and hemorrhage, and lead to the brain malformation disorder, periventricular heterotopia (PH) in females (Feng and Walsh 2004). Missense mutations cause otopalatodigital (OPD) syndrome spectrum disorders, primarily affecting skeletal development. Thrombocytopenia, bleeding tendency, and giant platelets have been associated with *FLNA* mutations and multiple FlnA degradation products have been observed in platelets of female carriers (Nurden et al. 2011; Berrou et al. 2013; Li et al. 2015). However, the distribution of mutant platelets is not easily detectable and analysis of their hemostatic function is cumbersome, due to the mosaicity of the platelet population and the high proportion of normal platelets in female carriers.

In mice, *Flna* deficiency is embryonic lethal in hemizygous males, due to pericardiac and visceral hemorrhage, severe cardiac structural defects, and aberrant vascular patterning (Hart et al. 2006; Feng et al. 2006). Heterozygous female mice carrier for *Flna* deficiency have mild thrombocytopenia, and more than 95 % of their platelets contain FlnA, which can be differentiated from *Flna*-null platelets by intracellular flow cytometry (Falet et al. 2010). Mice specifically lacking FlnA in the megakaryocyte/platelet lineage develop severe thrombocytopenia, giant platelets, and increased tail bleeding time, due to severely impaired platelet hemostatic functions (Falet et al. 2010). As expected, GPIbα is not linked to the actin cytoskeleton in *Flna*-null megakaryocytes and platelets, where its surface expression is reduced and altered (Falet et al. 2010; Begonja et al. 2011). *Flna*-null megakaryocytes prematurely release large and fragile platelets that undergo microvesiculation and are cleared rapidly from the circulation by macrophages (Begonja et al. 2011). These observations corroborate earlier studies showing that cleavage of FlnA by the protease calpain causes microvesiculation in aggregating platelets or during platelet storage (Robey et al. 1979; Basse et al. 1994). Thus, the FlnA–GPIbα linkage not only regulates platelet size but also maintains the mechanical stability of the platelet plasma membrane. *Flna*-null megakaryocytes have impaired demarcation membrane system (DMS) formation, which is likely due to FlnA interaction with the endocytic membrane-binding and membrane-deforming Fes/CIP4 homology Bin/amphiphysin/Rvs (F-BAR) protein PACSIN2, an internal component of the initiating DMS (Begonja et al. 2015). Expression of the FlnA paralog FlnB has been reported in megakaryocytes and platelets (Falet et al. 2010; Kanaji et al. 2012). However, FlnB does not appear to compensate for loss of FlnA.

The role of α-actinins in the actin organization of resting platelets is less well defined. α-Actinins belong to the spectrin gene superfamily, including α/β-spectrins and dystrophins. α-Actinins are antiparallel homodimers composed of an N-terminal tandem calponin-homology actin-binding domain, four spectrin repeats, and a C-terminal calmodulin-like domain. Platelets primarily express α-actinins 1 and 4. α-Actinin 1 is an abundant actin filament bundling protein often associated with adhesion sites, where it binds to the cytoplasmic tail of β_1-integrins, suggesting that α-actinin 1 links platelet actin filaments to the membrane, particularly at adhesion sites. Mutations in *ACTN1* encoding α-actinin 1 have been associated with mild thrombocytopenia, large platelets, and low risk for bleeding (Kunishima et al. 2013; Gueguen et al. 2013; Bottega et al. 2015; Yasutomi et al. 2015). These mutations in the α-actinin 1 actin-binding domain enhance association with actin filaments (Murphy et al. 2016). Mouse fetal liver cell-derived megakaryocytes transfected with α-actinin 1 variants display altered proplatelet formation and size (Kunishima et al. 2013).

Focal Adhesion and Membrane-Associated Proteins

Focal adhesions are integrin-associated actin-rich structures that enable cells to adhere to the extracellular matrix and at which protein complexes involved in signal transduction assemble. Platelet activation leads to a conformational change of integrin $\alpha_{IIb}\beta_3$ to promote fibrinogen binding and platelet aggregation. Several cytoskeletal proteins modulate integrin $\alpha_{IIb}\beta_3$ activation, including talin 1 (human *TLN1*, mouse *Tln1*) and kindlin 3 (human FERMT3, mouse *Fermt3*). Talin 1 is composed of an N-terminal head domain binding to β-integrin subunits, followed by an elongated C-terminal actin-binding rod domain. Talin 1 binding to β_3 is required for $\alpha_{IIb}\beta_3$ activation in platelets, as *Tln1*-null platelets have impaired agonist-mediated platelet aggregation (Petrich et al. 2007; Nieswandt et al. 2007). Mice specifically lacking talin 1 in platelets exhibit prolonged tail bleeding time and pathological gastrointestinal bleeding, similar to mice lacking the integrin β_3 (Hodivala-Dilke et al. 1999). *FERMT3* mutations cause leukocyte adhesion deficiency (LAD), which is characterized by impaired activation of the β_2-integrin in leukocytes and β_3 in platelets (Shattil et al. 2010; van de Vijver et al. 2012). *Fermt3*-null platelets exhibit defective integrin $\alpha_{IIb}\beta_3$ activation and impaired platelet aggregation (Moser et al. 2008). However, kindlins are unable to activate $\alpha_{IIb}\beta_3$ in the absence of talin 1 head domain (Ma et al. 2008; Harburger et al. 2009), suggesting that kindlins co-activate $\alpha_{IIb}\beta_3$ in synergy with talin 1.

Other notable platelet focal adhesion proteins include vinculin, zyxin, and paxillin. Vinculin (human *VCL*, mouse *Vcl*) links integrins to the actin cytoskeleton by virtue of binding of its N-terminal globular head domain to talin 1 and α-actinins, while its C-terminal tail region binds actin filaments, paxillin, and membrane phospholipids. Vinculin has been implicated in the transmission of mechanical forces from the extracellular matrix to the cytoskeleton of migrating cells (Bailly 2003). However, *Vcl*-null platelets display normal agonist-induced integrin $\alpha_{IIb}\beta_3$ activation, aggregation, spreading, and actin polymerization and organization and adhere normally to immobilized fibrinogen or collagen under both static and flow conditions (Mitsios et al. 2010), indicating that platelet vinculin is not required for the traditional functions of $\alpha_{IIb}\beta_3$ or the actin cytoskeleton. Both zyxin and paxillin contain lin-11/Islet-1/mec-3 (LIM) domains composed of zinc fingers that mediate protein–protein interactions and serve as targeting motif for focal adhesions. Similar to vinculin, the role of platelet zyxin and paxillin appears redundant based on the generation of mutant mice (Hoffman et al. 2003; Sakata et al. 2014).

Yeast two-hybrid system screening has identified skelemin (also called myomesin 1) as another cytoskeletal protein interacting with the integrin β_3 cytoplasmic tail (Reddy et al. 1998). Skelemin is a member of a superfamily of cytoskeletal proteins that regulate the three-dimensional organization of myosin filaments in skeletal muscle cells. Skelemin does not associate with $\alpha_{IIb}\beta_3$ in resting platelets but is recruited to $\alpha_{IIb}\beta_3$ during cell adhesion (Podolnikova et al. 2009). Biochemical and structural studies have shown that the skelemin-binding domain on β_3 is cryptic but becomes exposed as a result of $\alpha_{IIb}\beta_3$ binding to immobilized ligands (Podolnikova et al. 2009; Gorbatyuk et al. 2014). These studies illuminate a potential link between $\alpha_{IIb}\beta_3$ and actomyosin filaments, which may serve as a basis for generating the mechanical forces necessary for cell migration and remodeling.

Moesin is a member of the ezrin/radixin/moesin (ERM) family of proteins, which localize in cell extensions like filopodia and function as cross-linkers between the plasma membrane and actin filaments. Moesin associates with the tips of filopodia in spread platelets and associates with platelet/endothelial cell adhesion molecule 1 (PECAM-1) in lysates from thrombin-stimulated, but not resting platelets (Nakamura et al. 1995; Gamulescu et al. 2003), suggesting that moesin may play a role in platelet adhesion, linking PECAM-1 with the actin cytoskeleton. Mice lacking moesin develop normally and are fertile, with no obvious histological abnormalities. Particularly, targeted moesin deletion does not affect platelet aggregation in response to stimulation (Doi et al. 1999).

Contractile Proteins

Myosin-mediated contractile forces are critical for maintaining the integrity of a hemostatic plug at wound sites independently of thrombin and fibrin generation. The principal myosin isoform in platelets is non-muscle myosin heavy chain (NMMHC)-IIA (human *MYH9*, mouse *Myh9*). NMMHC-IIA is a parallel homodimer, whose two subunits are composed of an N-terminal head domain that binds actin filaments, a neck region, and a C-terminal coiled-coil rod domain holding the two chains together. A myosin regulatory light chain of 20 kDa (LC20, also called MRLC1) and an essential light chain of 17 kDa (LC17) bind each NMMHC-IIA subunit in the neck region, between the head and the tail. The functional properties of NMMHC-IIA are controlled by phosphorylation of both its heavy and light chains. Phosphorylated myosin assembles into filaments that are essential for its interaction with actin to form a contractile unit whose function is analogous to that of actomyosin filaments in smooth muscle cells. Phosphorylation of LC20 by myosin light chain kinase (MLCK), RhoA-associated kinase (ROCK), or p21-activated kinase 1 (PAK1) increases its actin-stimulated ATPase activity and is required for NMMHC-IIA to move along actin filaments, thereby

providing contractile force. LC17 is believed to contribute to the structural stability of NMMHC-IIA along with LC20. NMMHC-IIA is homogeneously distributed in resting platelets (Painter and Ginsberg 1984). Following activation, NMMHC-IIA localizes in the platelet center and contributes to the initiation of platelet shape change, platelet internal contraction, granule exocytosis, and centralization of GPIb-IX on the platelet surface (Kovacsovics and Hartwig 1996; Johnson et al. 2007).

MYH9 mutations cause MYH9-related disease (MYH9-RD), previously classified as May–Hegglin anomaly or Epstein, Fechtner, or Sebastian syndromes and characterized by macrothrombocytopenia, mild bleeding tendency, and leukocyte inclusions, with or without loss of hearing, cataract, or nephritis (Favier and Raslova 2015). The mechanisms of thrombocytopenia underlying *MYH9* mutations are linked to defects in proplatelet formation by megakaryocytes, which show decreased branching and increased tip size in cultures from patient progenitors (Pecci et al. 2010; Chen et al. 2013). In mice, NMMHC-IIA is required to form the megakaryocyte DMS and to maintain the megakaryocyte shape through internal tension and anchorage to the extracellular matrix (Eckly et al. 2009). Mice specifically lacking NMMHC-IIA in megakaryocytes develop severe macrothrombocytopenia. However, *Myh9* deletion in mouse megakaryocytes results in enhanced proplatelet formation (Chen et al. 2007; Leon et al. 2007; Eckly et al. 2009), suggesting that large *Myh9*-null platelets are prematurely released from the bone marrow and cleared rapidly from the circulation.

MYH10-encoded NMMHC-IIB is expressed in immature megakaryocytes, where it specifically localizes in the contractile ring (Lordier et al. 2012). NMMHC-IIB expression is silenced by the hematopoietic Runt-related transcription factor 1 (RUNX1), a requirement for megakaryocyte ploidization and maturation. Anomalous NMMHC-IIB expression in platelets has been proposed as a tool to identify inherited platelet disorders and myeloid neoplasms with abnormalities in RUNX1 and associated proteins (Antony-Debre et al. 2012). Mutations in RUNX1 have also been associated with reduced platelet expression of *MYL9*-encoded LC20 (Sun et al. 2007; Jalagadugula et al. 2010).

The Marginal Band

Microtubules contribute to the maintenance of the discoid shape of the resting platelet (Sadoul 2015). Microtubules are highly dynamic tubular polymers formed by the polymerization of a dimer of α- and β-tubulin. Approximately 40 % of tubulin in platelets is assembled into a specialized microtubule coil, called the marginal band, which lies at the periphery of resting platelets, below the plasma membrane. Many proteins bind microtubules, including the motor proteins kinesin and dynein, and other proteins important for regulating microtubule dynamics.

The marginal band is maintained in its resting state by both tubulin acetylation and antagonistic microtubule motors (Sadoul 2015). During platelet activation, microtubules undergo major reorganization, thereby contributing to the shape change of activated platelets. A dramatic tubulin deacetylation mediated by the cytoplasmic histone deacetylase 6 (HDAC6) occurs (Sadoul et al. 2012; Aslan et al. 2013). Dynein slides microtubules apart, resulting in marginal band extension and further coiling. New microtubule polymerization within the coiled marginal band leads to the formation of a smaller microtubule ring, in concerted action with NMMHC-IIA-mediated tension (Diagouraga et al. 2014). Microtubules are then reacetylated in spread platelets, and the capacity of HDAC6 to prevent tubulin hyperacetylation influences the speed of platelet spreading.

Microtubules play an essential role in proplatelet formation by megakaryocytes (Italiano et al. 1999; Patel et al. 2005; Bender et al. 2015b). The predominant β-tubulin isoform in platelets and megakaryocytes is the hematopoietic β_1-tubulin (human *TUBB1*, mouse *Tubb1*). Early studies have shown that *Tubb1*-null mice develop thrombocytopenia due to defective proplatelet production by megakaryocytes (Schwer et al. 2001). Circulating mouse *Tubb1*-null platelets have normal platelet size, but develop spherocytosis, lacking their characteristic discoid shape, and have defective marginal bands with reduced microtubule coilings and frequent kinks and breaks (Italiano et al. 2003). Following platelet activation, the disorganized microtubules in *Tubb1*-null platelets fail to condense into central rings and instead are dispersed in short bundles and linear arrays. More recently, an SNP in *TUBB1* has been associated with altered mean platelet volume in humans (Gieger et al. 2011), and *TUBB1* mutations have been associated with congenital macrothrombocytopenia due to impaired proplatelet formation by megakaryocytes (Kunishima et al. 2009, 2014; Stachele et al. 2015). The discrepancies between mouse and human phenotypes relative to platelet size and morphology are likely due to compensation by different β-tubulin isoforms.

The Cytoskeleton of the Activated Platelet

Actin Filament Assembly

Following receptor-mediated activation, platelet shape change proceeds through two recognizable steps. First, platelets convert from disc into an irregular or round shape. With further surface contact, platelets extend finger-like filopodia and spread thin sheet-like lamellipodia, as evidenced by electron microscopy (Fig. 2). Temporal and spatial actin filament assembly by specific cytoskeletal

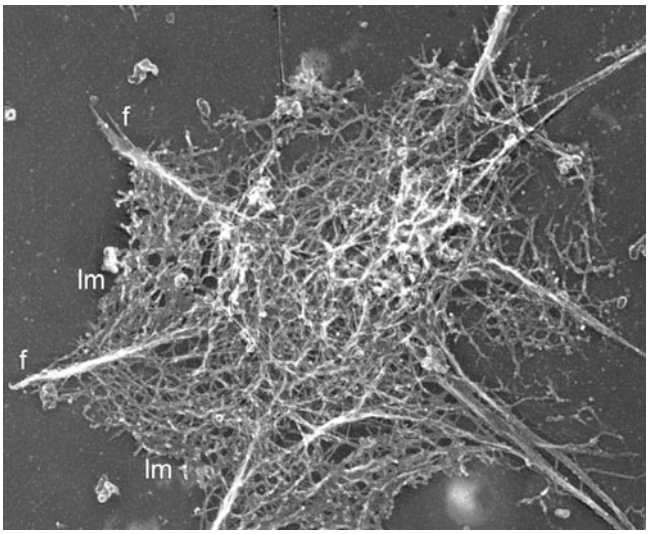

Fig. 2 Cytoskeleton of the activated platelet. Platelet activation is accompanied by a striking reorganization of the actin cytoskeleton. Platelets generate finger-like projections called filopodia (*f*) composed of long bundled actin filaments that derive from the cytoskeletal center. Platelets spread using thin sheet-like extensions called lamellipodia (*lm*) that are densely filled with a three-dimensional network of newly assembled short actin filaments

proteins orchestrates these morphological changes (Fig. 3 and Table 2) (Hartwig 1992).

In vitro, G-actin reversibly polymerizes into F-actin in three sequential phases defined as nucleation, elongation, and steady state. Nucleation is marked by a lag period in which G-actin slowly aggregates into short, unstable oligomers. Once a stable nucleus of three or four actin subunits is formed, it rapidly elongates into a filament by the addition of G-actin to its ends. In cells, actin monomers incorporated into filaments are bound to ATP. As filaments elongate, the bound ATP is slowly hydrolyzed to ADP. As a result of this hydrolysis, only actin filament barbed ends are composed of ATP-bound actin, and most of the filament consists of ADP-bound actin.

Actin Monomer-Sequestering Proteins and Actin Filament Capping Proteins

The G-actin–F-actin equilibrium of the resting platelet is principally maintained by two mechanisms that prohibit actin monomer addition to actin filaments (Fig. 3). First, actin subunits not incorporated into filaments complex with the actin monomer-sequestering proteins thymosin β_4 and profilin 1. Second, virtually all actin filament barbed ends are constitutively capped by the high-affinity actin filament capping protein CapZ (Barkalow et al. 1996). Therefore, actin assembly in platelets occurs when actin monomers release from thymosin β_4 and profilin 1 and add to uncapped actin filament barbed ends. Despite these control mechanisms, actin filaments are believed to dynamically turnover in resting platelets.

Thymosin β_4 (human *TMSB4X*, mouse *Tmsb4x*) and profilin 1 (human *PFN1*, mouse *Pfn1*) are two of the most abundant proteins in platelets. Thymosin β_4 forms a 1:1 complex with G-actin, in levels sufficient to account for essentially all sequestered actin monomers in platelets (Weber et al. 1992; Nachmias 1993). It has higher affinity for ATP-bound actin than for ADP-bound actin, suggesting that platelet thymosin β_4 sequesters primarily ATP-bound actin monomers ready to assemble into filaments. The proportion of G-actin bound to thymosin β_4 decreases following platelet activation (Nachmias et al. 1993). *Tmsb4x* deletion leads to partial embryonic lethality due to hemorrhage (Rossdeutsch et al. 2012). It is likely that other thymosins such as thymosin β_{10} compensate for thymosin β_4 loss in mice reaching adulthood. Megakaryocyte-specific *Pfn1* deletion in mice results in mild thrombocytopenia with small platelets due to premature release of platelets into the bone marrow and accelerated platelet clearance (Bender et al. 2014). However, actin assembly is minimally affected by profilin 1 deletion. Instead, *Pfn1*-null platelets contain hyper-stable and misarranged microtubules, revealing an unexpected novel function of profilin 1 as a regulator of microtubule organization.

CapZ (also called capping protein) is a key cellular component regulating actin filament assembly and organization, as it caps the barbed ends of actin filaments, preventing addition and loss of actin monomers. CapZ is a heterodimer composed of α- and β-subunits (Yamashita et al. 2003). The distribution of α-subunits varies among cell types, with platelets expressing both α1 and α2 (Nachmias et al. 1996; Hart et al. 1997). In platelets, the amount of CapZ bound to actin is proportional to that of F-actin (Barkalow et al. 1996). The kinetics of CapZ association with actin closely follows the kinetics of actin assembly and binding reaches a maximum when actin assembly ceases. The observations show that CapZ acts primarily as an actin assembly buffer to maintain actin filament barbed ends capped and inaccessible at rest and to terminate actin assembly in activated platelets by capturing exposed barbed ends. Because CapZ maintains most barbed ends capped in resting platelets (Barkalow et al. 1996), either filament ends must be uncapped, or barbed end nucleation sites must be generated de novo to trigger actin filament assembly. Both mechanisms contribute to actin filament assembly in activated platelets.

The Gelsolin Family

The actin filament severing and capping protein gelsolin (human *GSN*, mouse *Gsn*) is responsible for most of the

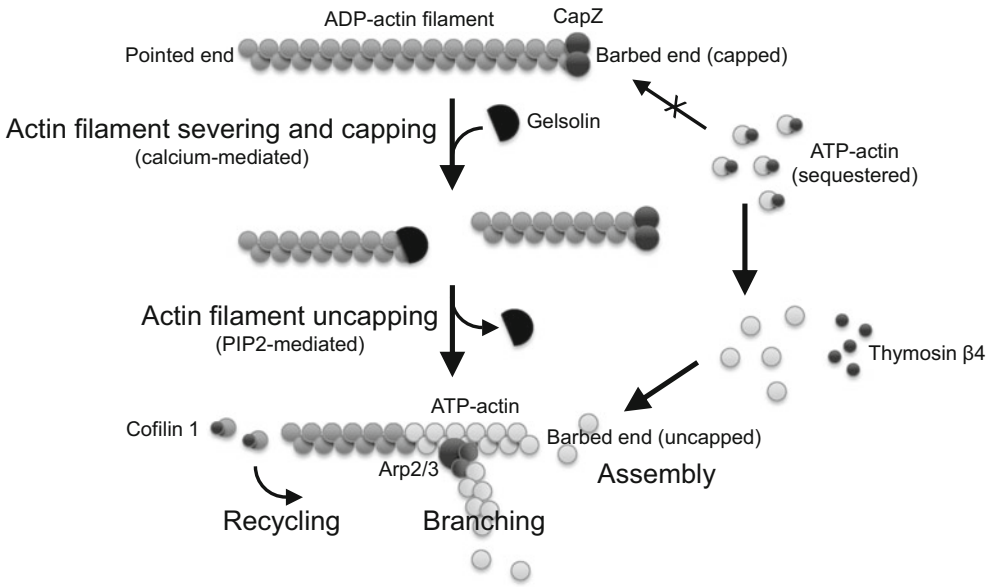

Fig. 3 Regulation of platelet actin assembly. In resting platelets, CapZ caps actin filament barbed ends, and thymosin β_4 sequesters ATP-bound actin monomers, thereby maintaining the large actin pool that drives actin filament assembly. Activation leads to rise of intracellular calcium and the activation of gelsolin. Gelsolin severs cortical actin filaments and caps the barbed ends, thereby inducing platelet rounding. PIP2 is robustly generated at the cytoplasmic surface of the platelet plasma membrane and inactivates gelsolin, thereby leading to the initiation of ATP-bound actin assembly onto exposed barbed ends and actin filament branching by the Arp2/3 complex. Actin filaments are subsequently buffered by CapZ, which recaps the barbed ends and terminates the assembly reaction. Subsequent actin filament treadmilling is stimulated by cofilin 1

actin assembly occurring during platelet activation (Witke et al. 1995; Barkalow et al. 1996). Gelsolin is one of the best-characterized molecules in terms of its effects on actin in vitro. It is activated to bind actin filaments in the presence of micromolar concentration of calcium. Association with actin begins with gelsolin binding to the side of an actin filament, followed by interdigitation into the filament to sever it. After severing, gelsolin remains on the newly formed actin filament barbed end until membrane phosphoinositides, particularly phosphatidylinositol 4,5-bisphosphate (PIP2), mediate its dissociation (Janmey and Stossel 1987).

In resting platelets, the cytoplasmic calcium level is low, and gelsolin is not associated with actin. Following platelet activation, cytoplasmic calcium rises within seconds and activates gelsolin to bind and sever long cortical actin filaments into short ones (Fig. 2) (Lind et al. 1987). Gelsolin severing destabilizes the highly ordered and constrained structure formed between the membrane cytoskeleton and actin filaments cross-linked by FlnA, initiating platelet rounding, before the actin assembly reaction begins. Subsequently, the small guanosine triphosphatase (GTPase) Rac1 is activated and stimulates the synthesis of membrane PIP2 that mediate the dissociation of gelsolin from actin filament barbed ends, thereby promoting actin assembly (Hartwig et al. 1995; Azim et al. 2000; McCarty et al. 2005; Aslan and McCarty 2013). These new ATP-bound actin filaments are preferred for Arp2/3 complex-mediated actin nucleation and branching (Fig. 3) (Falet et al. 2002b). Platelets from *Gsn*-null mice have a severe reduction in their capacity to generate actin filament barbed ends, assemble actin, and spread following platelet activation (Witke et al. 1995; Barkalow et al. 1996; Falet et al. 2000, 2002b; Hoffmeister et al. 2001). *Gsn*-null mice have prolonged bleeding time (Witke et al. 1995), but normal platelet counts and size, indicating that gelsolin is dispensable for platelet production and survival. Gelsolin-mediated actin filament severing can be blocked by vasodilator-stimulated phosphoprotein (VASP) binding to the sides of actin filaments. VASP is a major substrate of protein kinase A in platelets, where its phosphorylation correlates with reduced activation. Consistently, mouse platelets lacking VASP have slightly increased adhesion and spreading (Hauser et al. 1999; Massberg et al. 2004).

Platelets express at least two other actin severing and capping proteins of the gelsolin family: flightless 1 (human *FLII*, mouse *Flii*) and supervillin (human *SVIL*, mouse *Svil*). In platelets, flightless 1 is present in a complex with leucine-rich repeat (in FLII) interacting protein 1 (LRRFIP1), an SNP of which has been associated with altered platelet functions (Goodall et al. 2010). An SNP in *SVIL* has been associated with low supervillin expression in platelets and increased platelet thrombus formation in the shear-dependent platelet function analyzer (PFA)-100 (Edelstein

et al. 2012). Consistent with these observations, *Svil*-null mouse platelets exhibit enhanced platelet thrombus formation at high shear stress, indicating that supervillin plays an inhibitory role in platelet adhesion and arterial thrombosis. The specific molecular details of flightless 1 and supervillin function in platelet actin assembly and remodeling have not yet been elucidated.

The ADF/Cofilin Family

Actin-depolymerizing factor (ADF)/cofilin is a family of actin-binding proteins that regulate both assembly and disassembly of actin filaments. Two distinct mechanisms have been proposed: severing and depolymerization. First, ADF/cofilin proteins can sever actin filaments to create barbed ends without capping, thereby promoting actin assembly. Second, ADF/cofilin proteins can depolymerize actin filaments at their pointed ends, thereby accelerating actin filament turnover in cells, a process called treadmilling (Carlier et al. 1997). ADF/cofilin proteins are primarily regulated by phosphorylation of serine 3 (Ser3), which inhibits their function.

Platelets express primarily non-muscle cofilin 1 (human *CFL1*, mouse *Cfl1*) and ADF (also called destrin; human *DSTN*, mouse *Dstn*). Cofilin 1 is phosphorylated on Ser3 in resting platelets and, therefore, is inactive (Davidson and Haslam 1994; Falet et al. 2005; Pandey et al. 2006). Following platelet activation, cofilin 1 is dephosphorylated and incorporates into the actin cytoskeleton, shortly after the peak of actin assembly occurs (Falet et al. 2005). Ser3 dephosphorylation and activation are maintained by $\alpha_{IIb}\beta_3$-mediated outside-in signals and are transient and reversible in the absence of integrin $\alpha_{IIb}\beta_3$ engagement, such as in platelets isolated from a patient with Glanzmann thrombasthenia expressing low integrin $\alpha_{IIb}\beta_3$ levels (Falet et al. 2005). The observations indicate that cofilin 1 is not essential for the initial polymerization of actin filaments that follows platelet activation, but for actin filament turnover mediated by outside-in signals (Fig. 3).

Cofilin 1-mediated actin filament turnover plays a critical role in the late stages of platelet production by megakaryocytes and in the proper sizing of platelets in the periphery, as mice specifically lacking cofilin 1 in the megakaryocyte lineage develop mild thrombocytopenia with large platelets due to defective platelet production (Bender et al. 2010). Macrothrombocytopenia is severe in mice expressing a germ line mutation in the cofilin 1 partner WD40 repeat-containing protein 1 (WDR1), the vertebrate homolog of actin-interacting protein 1 (AIP1) (Kile et al. 2007). Actin filament assembly and platelet spreading on immobilized fibrinogen are profoundly impaired in the absence of cofilin 1 (Bender et al. 2010). The observations show that cofilin 1 is essential for the maintenance of G-actin–F-actin equilibrium in resting platelets and for agonist-induced actin assembly. By contrast, *Dstn*-null mice lacking ADF have normal platelet counts, size, and actin assembly reaction following activation (Bender et al. 2010).

Actin Nucleation by the Arp2/3 Complex

The Arp2/3 complex plays a major role in the regulation of actin assembly in cells, as it nucleates actin filaments and localizes to the leading edge of crawling cells (Pollard and Borisy 2003). The Arp2/3 complex also initiates the actin-based motility of intracellular pathogenic bacteria such as *Shigella flexneri* and *Listeria monocytogenes*. The Arp2/3 complex is composed of two actin-related proteins, Arp2 and Arp3, and five additional subunits. Arp2 and Arp3 closely resemble the structure of G-actin and serve as nucleation sites for new actin filaments. In vitro, the Arp2/3 complex binds to the side of existing actin filaments to initiate the growth of a new filament at a 70° angle. These observations suggest that the Arp2/3 complex is responsible for generating a branched meshwork of actin filaments and de novo actin filament nucleation at the cell cortex that leads to cell movement. Binding of Arp2/3 complex to ATP-bound actin, as found at uncapped actin filament barbed ends, is preferred (Ichetovkin et al. 2002; Falet et al. 2002b). Therefore, the Arp2/3 complex does not explicitly initiate actin nucleation de novo, but rather amplifies actin filament barbed ends generated by other means, such as gelsolin- or cofilin-mediated severing, thereby exponentially doubling the number of actin filament barbed ends at each branching.

The Arp2/3 complex contributes to the burst of actin assembly that follows platelet activation, associates with the actin cytoskeleton, and redistributes rapidly and uniformly to the lamellar edge of spread platelets (Falet et al. 2002a, b). It is unlikely that the Arp2/3 complex associates to the tip of platelet filopodia, as has been described in one study (Li et al. 2002), because actin filaments in filopodia are bundled, not branched. The Arp2/3 complex contribution to actin filament nucleation in platelets importantly requires free barbed ends generated by gelsolin-mediated severing, capping, and uncapping (Fig. 2) (Falet et al. 2002b). The Arp2/3 complex clusters in marginal actin filament clumps in *Gsn*-null platelets and fibroblasts, consistent with few uncapped ATP-bound actin-containing barbed ends generated in the absence of gelsolin, placing gelsolin function upstream of Arp2/3 complex nucleation in these cells (Falet et al. 2002b).

The Arp2/3 complex is also recruited to sites of clathrin-mediated endocytosis in megakaryocytes and is responsible for the accumulation of clathrin-coated vesicles and F-actin clusters in megakaryocytes lacking the large GTPase dynamin 2 (DNM2) (unpublished observations). DNM2

normally mediates the fission of endocytic vesicles from the plasma membrane (Ferguson and De Camilli 2012). Mutations in DNM2 have been associated with mild thrombocytopenia and neutropenia in patients with Charcot–Marie–Tooth disease (Züchner et al. 2005). Mice specifically lacking DNM2 in the megakaryocyte lineage develop severe macrothrombocytopenia, megakaryocyte hyperplasia, myelofibrosis, extramedullary hematopoiesis, and severe and rapid splenomegaly due to impaired endocytosis in megakaryocytes and platelets (Bender et al. 2015a).

WASp Family and Actin Nucleation-Promoting Factors

Activation of the Arp2/3 complex requires actin nucleation-promoting factors (NPFs), such as WASp family proteins, which integrate signals leading to actin assembly (Pollard and Borisy 2003). WASp (human *WAS*, mouse *Was*) is the protein mutated in Wiskott–Aldrich syndrome (WAS), a rare X-linked recessive disorder characterized by severe immunodeficiency, eczema, and thrombocytopenia. The disease affects most non-erythroid hematopoietic lineages, including lymphocytes, monocytes, neutrophils, and platelets, which are among the most severely affected cells. X-linked thrombocytopenia (XLT) is a milder form of WAS, in which platelets are primarily affected. Platelets from WAS and XLT patients are abnormally small, and circulating platelet counts can be 10 % of normal or lower. The defect is likely due to increased platelet clearance, as WASp deficiency in megakaryocytes induces premature proplatelet formation and platelet production in the bone marrow compartment (Haddad et al. 1999; Sabri et al. 2006).

In platelets, WASp is present in a constitutive 1:1 complex with WASp-interacting protein (WIP; human *WIPF1*, mouse *Wipf1*) (Falet et al. 2009), and *WAS* mutation hotspots map to the WIP-binding region in WASp and disrupt the WIP–WASp complex interaction (Luthi et al. 2003). A homozygous mutation in *WIPF1* has been reported in one patient to cause recurrent infections, eczema, and severe thrombocytopenia, all features of WAS (Lanzi et al. 2012). Cells isolated from the patient have undetectable WASp, but normal *WAS* sequence and mRNA levels. *Wipf1*-null mouse platelets lack WASp, and WIP expression is reduced in *Was*-null mouse platelets, indicating that both proteins are required for the stability of each subunit of the complex (Falet et al. 2009). *Was*-null and *Wipf1*-null mice have mild thrombocytopenia, and their platelets have normal size (Snapper et al. 1998; Zhang et al. 1999; Falet et al. 2009).

The role of the WIP–WASp complex in platelet shape change and actin assembly is unclear, as platelets lacking either WASp or WIP do not show any defect in actin assembly and shape change (Gross et al. 1999; Rengan et al. 2000; Falet et al. 2009), and the Arp2/3 complex redistributes normally to the actin cytoskeleton and to the edge of lamellipodia in the absence of WASp (Falet et al. 2002a). These observations suggest that platelets differ from the other hematopoietic cells affected by WASp deficiency, raising two fundamental questions. First, what is the role of WASp in platelets? Second, what is the identity of the NPFs activating the Arp2/3 complex in platelets? Recent studies have shown that human and mouse platelets lacking WASp contain abnormally organized and hyper-stable microtubules, suggesting an unexpected role of WASp as a regulator of microtubule organization (Bender et al. 2014). WASp also controls the delivery of platelet transforming growth factor-β_1 (TGF-β_1) (Kim et al. 2013) and regulates the formation of specific platelet actin structures, called actin nodules, which likely play a role in the early stages of platelet spreading (Calaminus et al. 2008; Poulter et al. 2015).

Platelets express other WASp family proteins and NPFs unrelated to WASp, which could theoretically activate the Arp2/3 complex. These include the ubiquitous WASp paralog neural WASp (N-WASP), WASp family verprolin homologs 1 (WAVE1) and 2 (WAVE2), cortactin, and hematopoietic lineage cell-specific protein 1 (HS1). An SNP in *WASL* encoding N-WASP has been associated with altered platelet counts (Soranzo et al. 2009; Gieger et al. 2011). However, the role of N-WASP in platelet production and function, particularly in Arp2/3 complex activation, is unclear. N-WASP can be detected in platelet lysates by immunoblot analysis (Shcherbina et al. 2001; Falet et al. 2002a), but its expression appears to be low because platelet lysates fail to initiate the Arp2/3 complex-dependent motility of bacteria expressing *Shigella flexneri* IcsA, which normally recruits and requires N-WASP in host cells (Egile et al. 1999).

WAVE1 (human *WASF1*, mouse *Wasf1*) and WAVE2 (human *WASF2*, mouse *Wasf2*) localize at the edge of lamellipodia and at the tips of filopodia in spread platelets (Kashiwagi et al. 2005). WAVE2 deficiency is lethal by embryonic day 12.5 in mice. *Wasf2*-null mouse megakaryocytes differentiated from embryonic stem cells are severely impaired in terminal differentiation, spreading onto fibrinogen and platelet production (Eto et al. 2007). By contrast, WAVE1 does not appear to be required for platelet production in vivo, as *Wasf1*-null mice have normal platelet counts (Eto et al. 2007), but is critical for platelet spreading and cytoskeletal reorganization downstream of the collagen receptor GPVI (Calaminus et al. 2007). Interestingly, *Wasf1*-null mouse platelets respond normally to stimulation by G-protein coupled receptors, indicating that platelet WAVE1 plays a signaling role in the GPVI signaling cascade, rather than a cytoskeletal role. Early studies have shown that cortactin redistributes to the cortex of spread platelets (Ozawa et al. 1995), similar to the Arp2/3 complex. However, cortactin and its hematopoietic specific paralog HS1

appear to be dispensable for platelet production, spreading, and lamellipodia formation in mice (Thomas et al. 2007; Schnoor et al. 2011).

Based on these observations, N-WASP and WAVE2 appear to be the best candidates for further investigation in their contribution to Arp2/3 complex activation in platelet production and function. N-WASP is believed to activate Arp2/3 complex-mediated actin nucleation activity to induce filopodia formation downstream of the small GTPase Cdc42, whereas WAVE2 orchestrates lamellae spreading downstream of Rac1 (Aslan and McCarty 2013). Rac1 deletion in platelets leads to impaired lamellipodia spreading, as well as to altered responses to GPVI stimulation due to defective phospholipase C-γ2 (PLC-γ2) activation (McCarty et al. 2005; Pleines et al. 2009, 2013). By contrast, platelets lacking Cdc42 display normal filopodia formation, but enhanced secretion and increased aggregation in response to agonist stimulation (Pleines et al. 2010). Platelet-specific Cdc42 deletion also leads to thrombocytopenia, due to impaired DMS formation and platelet production by megakaryocytes (Pleines et al. 2013).

Actin Nucleation by Formins

Formins are another group of proteins regulating actin nucleation (Goode and Eck 2007). Formins are involved in various cellular functions such as cell polarity, motility, and cytokinesis. At cellular levels, formins are required for assembly of stress fibers, cytoplasmic actin networks used for vesicle transport, cytokinetic actin rings, and phagocytic cups. Formins are multidomain proteins that interact with diverse signaling molecules and cytoskeletal proteins. Formins associate with the fast-growing barbed end of actin filaments via their signature formin homology 2 (FH2) domain. Formins initiate filament assembly and remain persistently attached to the barbed end without dissociating, enabling rapid insertion of actin subunits while protecting the end from capping proteins. Formins generate single actin filaments that are typically oriented orthogonally to membranes. Formins have also been shown to directly regulate microtubule dynamics (Chesarone et al. 2010).

Fifteen formin isoforms are present in humans, classified in seven subgroups. The most predominantly expressed diaphanous-related formins are autoinhibited through intramolecular interactions and appear to be activated by the small GTPase RhoA and additional factors. Other classes of formins lack the autoinhibitory and/or RhoA-binding domains and thus are likely to be controlled by alternative mechanisms. Three formins have been characterized biochemically in platelets: diaphanous homolog 1 (DIAPH1; human *DIAPH1*, mouse *Diaph1*), disheveled-associated activator of morphogenesis 1 (DAAM1; human *DAAM1*, mouse *Daam1*), and FH1/FH2 domain-containing protein 1 (FHOD1; human *FHOD1*, mouse *Fhod1*) (Higashi et al. 2008; Thomas et al. 2011). Based on profiling studies, platelets also appear to abundantly express inverted formin 2 (INF2; human *INF2*, mouse *Inf2*). However, its role in platelet formation and function has not yet been investigated.

DIAPH1 and DAAM1 purified from platelet extracts assemble actin in the presence of RhoA, suggesting that they contribute to actin dynamics in activated platelets downstream of RhoA (Higashi et al. 2008). A gain-of-function mutation in DIAPH1 has been associated with dominant macrothrombocytopenia (Stritt et al. 2016). DIAPH1 knockdown increases proplatelet formation by $CD34^+$ cell-derived human megakaryocytes by decreasing their F-actin content, but increasing tubulin polymerization and stability (Pan et al. 2014). Inversely, DIAPH1 overexpression in megakaryocytes increases stress fiber formation. Interestingly, analysis of *Diaph1*-null mice reveals no alteration in platelet counts or platelet hemostatic function in response to stimulation, including spreading and clot retraction (Thomas et al. 2011), although mice lacking platelet RhoA develop macrothrombocytopenia (Pleines et al. 2012). *Diaph1*-null mice develop age-dependent myeloproliferative/myelodysplastic phenotypes, including splenomegaly, fibrotic and hypercellular bone marrow, and extramedullary hematopoiesis in both spleen and liver, suggesting that DIAPH1 acts as a tumor suppressor (Peng et al. 2007). FHOD1 undergoes rapid phosphorylation downstream of ROCK in activated platelets and may therefore be involved in the formation of stress fibers (Thomas et al. 2011). Further studies are required to establish the physiological role of formins in platelet actin dynamics.

Conclusion

The platelet cytoskeleton has two main functions: (1) maintain the discoid shape of the resting platelet and (2) mediate a rapid shape change in response to external stimuli at sites of vascular injury. At rest, specific cytoskeletal structures, such as the spectrin-based membrane cytoskeleton and cytoplasmic actin filaments cross-linked by FlnA or bundled by α-actinins, maintain the unique architecture of the platelet actin cytoskeleton and connect it to the plasma membrane. Actin monomer-sequestering proteins, such as thymosin β_4, and actin filament capping proteins, such as CapZ, prevent the assembly of actin monomers onto the barbed ends of the actin filaments composing the resting cytoskeleton. Platelet activation leads to a rise in intracellular calcium and synthesis of membrane PIP2 to stimulate the activities of actin

regulatory proteins, such as gelsolin and the Arp2/3 complex. The interactions of these cytoplasmic signals and molecules initiate and amplify actin filament growth necessary for platelet shape change.

Platelet Proteomics and its Applications to Study Platelet-Related Disorders

Michela Di Michele, Kris Gevaert, and Kathleen Freson

Abstract

Proteomics is a rapidly evolving research approach in parallel with genomics, utilizing advanced technologies in protein separation, identification, quantification, and bioinformatics. We have reviewed the different proteomic techniques that have been used successfully to analyze platelets in humans over time. Using more advanced technologies, an increasing number of platelet proteins have been identified and this by investigating the resting platelet proteome and that of activated platelets using diverse agonists. It is also possible to analyze platelet subproteomes including that of granules, microparticles, and membrane proteins. Furthermore, experiments can be designed that specifically study changes in the phosphorylation, glycosylation, or palmitoylation profiles of platelet proteins. These studies have generated extensive protein databases of >5000 proteins for platelets under normal physiological conditions that are also useful to study disease. Examples of proteomic studies that were designed to study platelet-related bleeding disorders and cardiovascular diseases, but also other complex disorders where platelets can be used as a model cell, are discussed.

Introduction to Platelet Proteomics

Proteomics is the large-scale study of proteins encoded by a genome under specific conditions and at a given time (Wilkins et al. 1996) and has also been used to study platelets and platelet-related diseases. Because of recent advances, especially in mass spectrometry (MS), proteomics now enables the measurement of multiple properties for thousands of proteins simultaneously, such as their abundance, modifications, subcellular localization, and protein–protein interactions (Larance and Lamond 2015). Platelets are estimated to contain about 5000 different proteins, spanning a wide abundance range and with different post-translational modifications (Burkhart et al. 2012). The platelet proteome is highly dynamic as some proteins are secreted upon platelet activation and the proteome itself changes with age (Cini et al. 2015) or disease state (Macaulay et al. 2005). In addition, the capability of platelets to absorb plasma proteins further increases the proteome variability and complexity. Platelets are anuclear, having no DNA and only limited amounts of mRNA, which makes proteomic research an attractive alternative for gene expression studies. Platelets are readily available in living organisms and in relatively high amounts; therefore proteomes can also be applied to analyze platelets from children starting from small volumes of blood. As for other cell types and organisms, knowledge of the proteome is expected to be more useful than information on the transcriptome as proteins are believed to be the main effectors of gene functions. It has been estimated that the 20,000 human genes translate into one million different proteoforms due to alternatively splicing and posttranslational modifications (Brett et al. 2002). Furthermore, several

studies have revealed a poor correlation between mRNA and protein profiles in lower organisms (Gygi et al. 1999a, b), and this has also been described for platelets (Burkhart et al. 2012; Londin et al. 2014). This discrepancy might be explained by a rapid decay of mRNAs in response to various stimuli and posttranslational protein ubiquitination leading to protein degradation. Moreover, a disease state may be determined by translocation of proteins to different cellular compartments rather than by changes in transcript levels. In addition, several technical issues can explain the imperfect correlation between transcriptomic and proteomic data. For example, the current transcriptomic techniques provide only limited information on alternative splicing, whereas proteomics can detect separate protein isoforms encoded by these variants. Given all these considerations, proteomics represents an efficient tool to gain deeper insights into the molecular mechanisms regulating unknown platelet functions and platelet-related diseases. We, and others, published extensive reviews on the application of proteomics in the field of platelet research, mainly focused on the commonly used methodologies and the key achievements in the elucidation of platelet-related diseases (Di Michele et al. 2012a, b; Zufferey et al. 2012; Rotilio et al. 2012). Here, we summarize recent updates for the main contemporary proteomic strategies for platelet research in humans and the most important studies that applied proteomics to unravel the molecular mechanisms underlying platelets in physiological ("Proteomic Methods Used for Platelet Research" and "Proteomic Strategies to Decipher Platelet Biology") and pathological conditions ("Platelet Proteomics to Gain Insights in Human Diseases").

Proteomic Methods Used for Platelet Research

Gel-Based Proteomics

Gel-based methods, including conventional 2DE (bidimensional electrophoresis) and DIGE (differential in-gel electrophoresis), are commonly used for platelet proteomics. In 2DE, proteins are first separated based on their isoelectric point along a pH gradient by isoelectric focusing and then based on their apparent molecular mass in a polyacrylamide gel by SDS-PAGE (Rogowska-Wrzesinska et al. 2013). Proteins are visualized by in-gel staining, matched in different 2DE gels, quantified, and proteins of interest are excised for further identification by MS. 2DE was first used to study the platelet proteome in the 1970s, identifying some most abundant proteins and membrane glycoproteins (Clemetson et al. 1979) and later for the identification of proteins with changed levels upon platelet storage (Snyder et al. 1987). This method also contributed to generate the proteome reference maps of quiescent platelets (Gravel et al. 1995; Marcus et al. 2000; O'Neill et al. 2002; Garcia et al. 2004a, b), activated platelets (Claeys et al. 2005; Shai et al. 2012), and platelet subproteomes including microparticles (Shai et al. 2012; Garcia et al. 2005), cytosol, and microsomes (Claeys et al. 2005). 2DE holds intrinsic limitations such as the difficulty to analyze hydrophobic, extremely charged, and very small or large proteins, as well as having a limited reproducibility among gels and the presence of multiple proteins in a single spot. Combined with restricted sample loading and the scarce sensitivity of protein stains, all of this hampers the detection of low-abundant proteins. Some of these disadvantages were overcome using DIGE, which allows improved reproducibility, higher quantification accuracy, and reduced time/costs. With DIGE, two samples and one internal standard are loaded together on the same gel after labeling with different fluorescent dyes (Cydye-2, Cydye-3, and Cydye-5), each with specific excitation/emission wavelengths (Unlu et al. 1997). The internal standard is a pool of equal amounts of all the samples used to facilitate accurate spot matching across gels, minimizing inter-gel variability, and allowing to calculate the abundance of each protein spot as a ratio to its corresponding spot in the internal standard, leading to the measurement of subtle changes in protein abundance with high statistical confidence. DIGE has been used to study platelet proteomes under basal or activated conditions (Cini et al. 2015; Baumgartner et al. 2013; Winkler et al. 2008; Veitinger et al. 2012).

Finally, 1D SDS-PAGE can be used in combination with MS in the so-called GeLC-MS approach (Shevchenko et al. 2006). The underlying workflow involves SDS-PAGE, in-gel protein staining, slicing of each lane into discrete gel bands, in-gel protein digestion, peptide purification, and LC-MS/MS analysis. GeLC-MS was successfully used to study human platelet proteomes in resting and stimulated conditions (Piersma et al. 2009; Qureshi et al. 2009; van den Bosch et al. 2014; Ambily et al. 2014), during storage (Dzieciatkowska et al. 2015a; Schubert et al. 2012a; b), or to analyze specific subproteomes including the immunoproteasome (Klockenbusch et al. 2014) and palmitoylome (Dowal et al. 2011).

Gel-Free Proteomics

Gel-based methods are progressively replaced by so-called bottom-up MS-based proteomic methods that analyze peptide mixtures derived from isolated proteomes. These techniques require lower amounts of material, which is particularly important when studying rare platelet-related diseases, platelets from young children, or subproteomes. The first step in gel-free analysis typically consists of digesting the proteome with a specific protease. This is

followed by a chromatographic separation of the obtained peptides coupled to MS for analysis, subsequent data processing, and peptide identification.

The pioneering method is multidimensional protein identification technology (MudPIT) which combines orthogonal peptide separations prior to MS/MS analysis, thereby maximizing sensitivity and resolution (Washburn et al. 2001). The main advantage of MudPIT over gel-based methods is that it largely avoids protein solubilization problems as proteins are cut into peptides that are easier to solubilize. MudPIT was used to analyze the basal platelet proteomes (Finamore et al. 2010), the thrombin-induced secretome (Coppinger et al. 2004), the serine hydrolase subproteome (Holly et al. 2013), and the effects of dysregulated miRNA on thrombocythemic platelets (Xu et al. 2012).

The exponentially modified protein abundance index (emPAI) approach is widely used and assumes that abundant peptides are more often detected, but also considers that bigger proteins and proteins with many peptides in the m/z-range for efficient MS analysis will generate more observed peptides (Ishihama et al. 2005). The emPAI method was successfully employed when studying protein networks associated with platelet glycoprotein VI stimulation (Wright et al. 2011).

Combined fractional diagonal chromatography (COFRADIC) is a gel- and label-free proteomic method (Gevaert et al. 2002). Given its versatility, several COFRADIC protocols were developed, each allowing for the enrichment of a specific set of peptides (Gevaert et al. 2003; Stes et al. 2014; Staes et al. 2011). COFRADIC relies on three steps: (1) a first RP-HPLC fractionation of the digested proteome, (2) a chemical or enzymatic reaction of single or combined peptide fractions that modifies the chemical structure of selected peptides that will then obtain altered chromatographic properties, and (3) a series of RP-HPLC fractionations identical to the first one during which the altered peptides are isolated for LC-MS/MS analysis. COFRADIC was applied for studying the human platelet proteome together with GeLC-MS/MS and MudPIT, revealing that the use of complementary techniques allows for more comprehensive proteome mapping (Martens et al. 2005; Lewandrowski et al. 2009).

Labeling methods rely on the incorporation of stable isotopes, i.e., ^{2}H, ^{13}C, ^{15}N, and ^{18}O by metabolic (SILAC), chemical (ICAT, iTRAQ, or TMT), or enzymatic reactions. In stable isotope labeling by amino acids in culture (SILAC), cells are grown separately in media supplemented with heavy or light labeled essential amino acids, such as lysine and arginine (Ong et al. 2002). Although SILAC is typically only applied to cells that can be expanded in vitro, it was also successfully used for studying platelet proteomes (Kruger et al. 2008; Zeiler et al. 2014). In isobaric tags for relative and absolute quantitation (iTRAQ), quantification occurs using MS/MS spectra rather than MS spectra (Gygi et al. 1999a, b). iTRAQ makes use of an amine-reactive reagent available in different isotopic variants to label peptides at their primary amines. iTRAQ was used to analyze the proteome of human platelets focusing on inter- and intra-biological variations (Burkhart et al. 2012; Vaudel et al. 2012) and platelets stimulated with ADP, thrombin, collagen, TRAP, and/or iloprost (Beck et al. 2014; Cimmino et al. 2015). Furthermore, iTRAQ-based gel-free proteomics, combined with DIGE- and ICAT-based proteome analysis, was applied to detect changes in platelet protein levels during storage of blood products (Thon et al. 2008). Similar to iTRAQ, tandem mass tags (TMTs) employ amine-reactive chemicals to label peptides (Thompson et al. 2003), and up to ten different isobaric tags are available (Werner et al. 2014). TMT labeling was applied to study protein changes in platelets from subjects sensitive or resistant to aspirin (Floyd et al. 2014). Enzymatic labeling is based on peptide labeling with oxygen-18 isotopes (Yao et al. 2001). Stable enzymatic labeling of tryptic peptides in combination with COFRADIC was applied to analyze platelets (Staes et al. 2004).

Proteomic Strategies to Decipher Platelet Biology

General Considerations for Experimental Design of Platelet Proteomic Studies

Most proteomic studies are feasible with about 5 mL of blood allowing the isolation of 10^8 platelets, corresponding to 1 mg of proteins (Burkhart et al. 2012). For comparative proteomic studies, different groups should contain age- and sex-matched donors. Indeed, a DIGE study reported a quantitative variation of 18 % in platelet proteomes of a group of 56–100 years old volunteers, probably due to age differences (Winkler et al. 2008). Also another study detected important differences in the platelet proteome of children and adults using DIGE coupled to LC-MS/MS (Cini et al. 2015). Moreover, higher levels of signaling cascade proteins have been found by 2DE and MS in male compared to female donors (Eidelman et al. 2010). Significant gender differences in platelet proteins have also been detected in a recent study using QconCAT-based MRM, not only in fresh blood from donors but also in apheresis platelet concentrates following varying storage times (Dzieciatkowska et al. 2015b). Finally, inter- and intra-subject variation among the human platelet proteome was measured in four healthy donors and three different blood samples from one donor and revealed that the proteome showed about 15 % of quantitative variation among donors (Burkhart et al. 2012). These studies

highlight the usefulness of including biological replicates in the experimental setup to counterbalance for the intrinsic variability of samples. In addition, also some other factors might be considered when choosing platelet donors, such as medication use (such as aspirin), lifestyle, and dietary habits. Furthermore, cigarette smoking was also found to differentially regulate the levels of several platelet proteins (Della Corte et al. 2012).

Obviously, protocols for sample preparation are also a non-negligible source of variability. For example, the analytical variation of a single sample of platelet proteins within and between four laboratories each using its own 2DE protocol was measured, and the coefficient of variation for each of the matched spots after automatic and subsequent manual matching ranged between 5 and 60 % (de Roos et al. 2008). A 2DE study also revealed changes in the platelet proteome in terms of composition rather than yield depending on the precipitation method used to purify proteins, namely, ethanol versus trichloroacetic acid (Zellner et al. 2005). The type of anticoagulant (acid citrate dextrose, heparin, EDTA, etc.) used for blood collection is of fundamental importance, as these substances can induce changes by interacting with specific platelet proteins (Capila and Linhardt 2002). Particular attention must be given to obtaining highly purified platelet fractions, due to possible contamination mainly from plasma and other blood cells. The origin of plasma proteins found in platelet proteomes, however, is still a matter of debate as it is not clear if they derive from the sample preparation method or are actually located within platelets given their surface-connected open canalicular system and its continuous exchange with plasma components. A shotgun proteome analysis of the cytoplasmic, microparticle, and secreted fractions of TRAP-activated platelets supports the platelet origin of some plasma proteins identified in platelet proteomes, thus excluding methodological artifacts (Veitinger et al. 2012). Concerning contamination with other blood cells, a protocol for isolating highly pure platelets preparations is recommended, leading to platelet preparations with less than 1 leukocyte per 10^6 platelets and less than 1 erythrocyte per 10^4 platelets, beyond <1.5 % by volume of plasma per platelet (Burkhart et al. 2012; Gambaryan et al. 2010). In this context, particularly useful are freely available protein databases of purified blood cells (including T cells, monocytes, neutrophils, erythrocytes, and platelets) obtained by both 2DE and shotgun proteomics, which may be used as references (Haudek et al. 2009).

Proteomics of Resting Platelets

Since the first attempts to characterize the human platelet proteome in the late 1970s by 2DE (Clemetson et al. 1979), a huge number of such proteome studies have followed that have identified a growing number of proteins. A combination of 2DE, immunoblotting, and N-terminal sequencing identified about 25 platelet proteins (Gravel et al. 1995). The cytosolic fraction of platelets was analyzed in a successive study using 2DE combined with MS, leading to the identification of more than 200 proteins (Marcus et al. 2000). Two 2DE studies in combination with improved first dimension separation identified more than 500 and 300 different proteins, respectively (O'Neill et al. 2002; Garcia et al. 2004a, b). COFRADIC gave a further impulse to the development of a detailed platelet proteome map of about 650 platelet proteins, including several proteins not previously detected, and hydrophobic membrane proteins (Gevaert et al. 2003). Another study based on 2DE and shotgun proteomics contributed to the compilation of the platelet proteome in basal conditions by identifying about 100 unique proteins (Finamore et al. 2010). Shotgun proteomics, based on peptide separation by OFFGEL fractionation and RP chromatography coupled to LC-MS/MS detection, was also applied to platelet proteomics and led to the identification of more than 1300 proteins (Krishnan et al. 2011). Finally, the most comprehensive proteome database of human platelets consists of more than 4000 unique (phospho)proteins and has been obtained by iTRAQ and TiO_2 enrichment for the phosphorylated fraction (Burkhart et al. 2012).

Proteomics of Activated Platelets

Upon activation by endothelial cell damage or inflammatory events, platelets release a high number of proteins into the circulation, the so-called platelet secretome or releasate, which is involved in the regulation of primary hemostasis, but also in coagulation, inflammation, angiogenesis, wound healing, and some other processes (Golebiewska and Poole 2015). Numerous proteomic studies have attempted to characterize the platelet secretome using different methods. Moreover, different agonists have been used to activate platelets and induce the protein releasate, such as ADP, thrombin, TRAP, collagen, and arachidonic acid. These agonists have been used alone or in combination, influencing the composition of platelet secretome (Rogowska-Wrzesinska et al. 2013). A concentration step on reverse-phase chromatographic beads of diluted peptide mixtures following in-gel digestion of 2DE-separated proteins and MALDI-TOF-MS analysis was applied to the proteome of platelets activated by thrombin with the identification of several proteins that translocate to the cytoskeleton fraction (Gevaert et al. 2000). In another study, a combination of 2DE and MudPIT resulted in a comprehensive characterization of the secretome of thrombin-activated platelets, leading to more than 300 identified proteins, many of which were

described for the first time in platelets, such as secretogranin III, cyclophilin A, and calumenin (Coppinger et al. 2004). Another MudPIT-based analysis led to the identification of 82 proteins differentially expressed in the platelet secretome upon stimulation with thrombin (McRedmond et al. 2004). In activated platelets, these proteins include chemokines, signaling molecules, and histones, as well as coagulation factors and receptors involved in thrombosis. Another study aimed at characterizing the proteome of thrombin-stimulated platelets using DIGE coupled to MALDI-TOF-MS (Della Corte et al. 2008). By comparing the secretome of unstimulated and stimulated platelets, several differentially secreted proteins were identified, including laminin A, a nuclear protein described for the first time as released by platelets. A recent study using DIGE and LC-MS/MS focused on the difference in the platelet secretome following stimulation with thrombin or collagen (Vélez et al. 2015). Thirty-eight proteins differentially present between these conditions were identified, and this relatively high number of protein differences confirms the influence of the type of agonist used for platelet stimulation on the composition of the secretome. The analysis of the platelet proteome in resting or TRAP-activated conditions by 2DE led to the identification of 31 regulated proteins (Garcia et al. 2004a, b). Among these, eight were not known to be present in platelets, including the adapter downstream of tyrosine kinase 2 (DOK-2). The number of proteins identified in the secretome of TRAP-stimulated platelets dramatically increased when using a GeLC-MS/MS approach, based on 1D SDS-PAGE and LTQ-FT MS with the identification of 716 proteins (Piersma et al. 2009). About 40 % of these proteins were identified for the first time in platelet releasates.

Platelets were also stimulated with less common agonists such as GPIV-activating collagen receptor peptide (CRP) (Wright et al. 2011). In this study, different platelet subcellular compartments were isolated using ultracentrifugation to reduce the overall complexity. The majority of differentially expressed proteins after CRP stimulation were low abundant and involved in signaling. In addition, more than half of the 663 identified proteins were not previously known to be present in platelets. An accurate quantitative proteomic strategy based on stable isotope dimethylation, SCX, and MS analysis was used to compare the platelet secretome following PAR1 or PAR4 stimulation or in resting conditions (van Holten et al. 2014). The differential release of pro- and anti-angiogenic growth factors by PAR1 and PAR4 might be important for the regulation of angiogenesis, though no large differences in protein abundance could be detected that confirmed such a hypothesis.

Some proteomic studies also investigated the effect of different agonists simultaneously on the platelet proteome. 2DE combined with LC-MS/MS was used to identify 144 platelet proteins with changing levels following activation with arachidonic acid, collagen, and thrombin (Majek et al. 2010). A more recent study analyzed the platelet secretome following thrombin and collagen treatment using a reversed releasate approach (Wijten et al. 2013). Contrary to classical studies on platelet secretomes, which may also detect proteins derived from cell lysis, in this case the protein levels in the platelets after stimulation were accurately quantified following stable isotope labeling, assuming that the released proteins are less abundant in the platelet proteome. Importantly, of the about 4500 platelet proteins quantified, only 124 were found to be secreted, spanning a concentration range of $\geq$5 orders. These proteins included several novel low-abundant proteins and well-known proteins such as thrombospondin and von Willebrand factor.

Analysis of Platelet Subproteomes

Platelet Granules

To reduce the complexity of analyzing total proteomes, the isolation of organelles prior to analysis is often used. Organelle isolation can be achieved via density gradient centrifugation, immunopurification, or free-flow electrophoresis (Zufferey et al. 2012). However, assessment of possible contamination from other organelles is recommended prior to analysis using organelle markers via immunoblotting, electron microscopy, or enzymatic assays. Platelets contain three types of secretory granules, alpha granules, dense granules, and lysosomes, each characterized by a different number per platelet, content, morphology, and response to stimuli (Rendu and Brohard-Bohn 2001). The proteome of alpha granules isolated by sucrose gradient ultracentrifugation was extensively characterized by GeLC-MS/MS, leading to the identification of 219 proteins (Maynard et al. 2007). Not surprisingly, the majority of these were already described in platelet secretomes, while 44 proteins were novel. The proteome of dense granules was analyzed using two proteomic methods: 2DE coupled to MALDI-TOF-MS and LC-MS/MS analysis (Hernandez-Ruiz et al. 2007). Overall, 40 proteins were identified, and most of them, such as actin-associated proteins, glycolytic enzymes, and regulatory proteins, were not previously known to reside in these organelles. More recently, a proteomic analysis carried out by subcellular fractionation on a sucrose gradient and MS analysis led to the most comprehensive characterization of the platelet granule proteome, identifying over 800 proteins (Zufferey et al. 2014).

Platelet Microparticles

In the most comprehensive analysis of platelet microparticles so far, almost 600 proteins were identified

(Garcia et al. 2005). About 65 % of these proteins have been described for the first time, suggesting that these organelles have a unique protein composition. The proteome of platelet microparticles was also analyzed in a subsequent study using 2DE and LC-MS/MS, in which the microparticles were separated by gel filtration in four classes based on their size (from approximately 100 nm to greater than 500 nm), revealing major differences in protein composition (Dean et al. 2009). In particular, mitochondrial proteins were mostly present in the largest microparticles, whereas alpha granule proteins were more found in the smallest microparticle fractions. The platelet microparticles proteomes were different depending on the stimulus used to activate platelets as found by another proteomic study using 2DE (Shai et al. 2012). Twenty-six proteins were differentially expressed between shear- and thrombin-activated platelets, mainly involved in signaling pathways. The proteome of microparticles from ADP-stimulated platelets was also extensively characterized by shotgun proteomics (Capriotti et al. 2013). This approach led to the identification of more than 600 proteins, 40 % of which were described in platelet microparticles for the first time.

Platelet Plasma Membrane

Despite a major role for membrane receptors and associated proteins for platelet function, they are relatively poorly represented in proteomics studies. This is mainly due to the characteristics of these proteins, such as their low abundance, hydrophobicity, and the reduced accessibility of trypsin to transmembrane domains, which hamper both gel- and MS-based proteomics. Therefore, specific methods are required to improve plasma membrane protein identification. The first study focusing on the platelet plasma membrane proteome used pre-fractionation over a sorbitol gradient to remove high abundant cytoskeletal proteins and contaminants prior to plasma membrane isolation and GeLC-MS/MS analysis (Moebius et al. 2005). In addition, 1D SDS-PAGE separation was performed both by conventional SDS-PAGE and benzyldimethyl-n-hexadecylammonium chloride/SDS separation to improve protein resolution on gel. Almost 300 proteins could be identified, the majority of which were plasma membrane proteins. In a subsequent study, three different techniques were used for the enrichment of platelet plasma membrane proteins before LC-MS/MS analysis, namely, lectin affinity chromatography, biotin/NeutrAvidin affinity chromatography, and free-flow electrophoresis (Senis et al. 2007). A total of 136 membrane proteins were identified, many of which previously not known as platelet membrane proteins. An interesting comparative analysis of the membrane proteomes from platelets in control and thrombin-activated conditions was carried out by NeutrAvidin affinity chromatography, prior to protein separation by liquid-phase IEF and SDS-PAGE and analysis by FT-ICR MS to identify 88 differentially expressed proteins (Tucker et al. 2009). Another study identified 182 membrane proteins using a different proteomic approach (Qureshi et al. 2009). Membrane proteins were first precipitated via ultracentrifugation, resuspended in a glucopyranoside/guanidium buffer and subsequently analyzed by LC-MS/MS. The most extensive proteomic study on platelet plasma membrane proteins led to the identification of 1282 proteins, which were also relatively quantified via an emPAI-based method (Lewandrowski et al. 2009). The power of this study resides in the use of three different proteomic approaches, GeLC-MS/MS, MudPIT, and N-terminal, methionine, or cysteine COFRADIC, all in combination with aqueous two-phase partitioning.

Proteomics to Analyze Platelet Posttranslational Modifications

Platelet Phosphoproteome

Phosphoproteomics is particularly useful for studying cellular signaling events. 2DE and radioactive labeling were used to identify phosphoproteins upon thrombin activation (Immler et al. 1998). Several protein spots showing a significant increase or decrease in phosphorylation could be detected, in particular different myosin isoforms. Another study was also conducted on thrombin-stimulated platelets, focusing on tyrosine phosphorylation, which plays a central role in platelet activation (Maguire et al. 2002). Proteins containing phosphorylated tyrosine were immunoprecipitated using a monoclonal antibody, separated by 2DE, and the resulting protein spots differentially found between platelets in control and activated conditions were identified by immunoblotting and MALDI-TOF-MS. Further development of modern and more resolving techniques for phosphoprotein/peptide enrichment and MS analysis significantly contributed to shed light on signal-dependent activation responses (Zahedi et al. 2006). For example, two different approaches, treatment with ^{32}P followed by 2DE using different pI ranges and autoradiography or immunoprecipitation coupled to GeLC-MS/MS analysis, led to the identification of 55 phosphoproteins and some in vivo phosphorylation sites (Marcus et al. 2003). In another work, using IMAC-based phosphopeptide enrichment and SCX chromatography coupled to LC-MS/MS, 564 phosphorylation sites belonging to almost 280 proteins were identified in resting platelets (Zahedi et al. 2008). An extensive analysis of the proteome and phosphoproteome of platelets in resting conditions, with particular attention to the integrin signaling pathway, was undertaken by IMAC and GeLC-MS/MS (Qureshi et al. 2009). This led to the identification of more than 1500 proteins, including 262 phosphoproteins. Another strategy for phosphoprotein identification is based on the

enrichment of phosphopeptides via titanium dioxide chromatography and LC-MS/MS after a prior enrichment of plasma membrane proteins in an aqueous two phase (Premsler et al. 2011). In yet another study, protein pulldown using SH2 domains and LC-MS/MS analysis were used to investigate the phosphotyrosine state of platelets upon ADP activation (Schweigel et al. 2013). To study the phosphorylation events mediating platelet activation by collagen, a comparative phosphoproteomic study was carried on phosphotyrosine proteins in resting and CRP-activated platelets (Bleijerveld et al. 2013). This approach was based on immunoprecipitation of phosphotyrosine peptides and stable isotope labeling MS and allowed to identify more than 200 phosphotyrosine sites with an altered phosphorylation status. Also prothrombotic oxidized phospholipids in addition to thrombin were used as agonists for platelet stimulation (Zimman et al. 2014). Here, proteins from stimulated platelets were digested by trypsin, and phosphotyrosine peptides were enriched by immunoprecipitation followed by IMAC. The nonprecipitated proteins were fractionated by SCX, and the resulting fractions further enriched for phosphopeptides using TiO_2 beads. Finally, phosphopeptides were identified and quantified by LC-MS/MS. Interestingly, one study focused on the characterization of the signaling pathways involved in platelet inhibition rather than platelet activation (Beck et al. 2014). Human platelets were treated with iloprost, a stable analog of prostacyclin, which is the most important physiological inhibitor of platelet activation acting on the cAMP/PKA signaling cascade. Using iTRAQ and TiO_2 phosphopeptide enrichment, about 300 phosphopeptides modulated by iloprost were detected.

Platelet Glycoproteome

Studies have shown that platelets possess efficient glycosyltransferase machinery, with more than 200 glycosyltransferases and several substrates (Wandall et al. 2012). The first extensive proteomic study on platelet glycoproteome was performed using concanavalin A affinity chromatography and hydrazide chemistry for enriching glycopeptides, after which they were deglycosylated by N-glycosidase F and analyzed by LC-MS/MS (Lewandrowski et al. 2006, 2009). Concanavalin A, one of the most common lectins in glycoproteomic studies, selectively binds N-glycoproteins. This approach identified 41 glycoproteins and 70 different glycosylation sites. In a subsequent study, the same group focused on the glycosylation sites of platelet membrane proteins (Lewandrowski et al. 2007). The membrane fraction was enriched via aqueous two-phase partitioning in a polyethylene glycol/dextran polymer system, the obtained proteins were digested by trypsin, and the glycopeptides were purified by SCX chromatography prior to N-glycosidase F deglycosylation and MS analysis. By applying this method, almost 150 glycosylation sites on 79 different proteins could be identified, 75 % of which were annotated as plasma membrane proteins. The same group also introduced another strategy for glycopeptide enrichment based on electrostatic repulsion hydrophilic interaction chromatography (Lewandrowski et al. 2008). Importantly, this method might allow resolving different protein isoforms, because of the different interactions of glycopeptides with the stationary phase. By identifying 125 glycosylation sites on 66 different proteins, this work largely contributed to the compilation of an extensive glycosylation site database for human platelet proteins.

Platelet Palmitoylome

Protein palmitoylation, the covalent attachment of long chain fatty acids to cysteines, has an important role in platelet biology, being involved in the regulation of platelet activation and thrombi formation (Sim et al. 2007). A first attempt to characterize the platelet palmitoylome was performed by enriching the platelet membrane protein fraction by acyl-biotinyl exchange chemistry and LC-MS/MS analysis and led to the identification of 215 palmitoylated proteins (Dowal et al. 2011). These proteins included already known palmitoylated proteins, but also 103 new putative palmitoylated ones.

Platelet Proteomics to Gain Insights in Human Diseases

Platelet Proteomics to Study Platelet-Related Bleeding Disorders

Rare inherited platelet-related bleeding disorders are a highly heterogeneous group of disorders that can be caused by abnormal platelet numbers, morphology, and function (Freson et al. 2014). Many genes have been identified as a cause for these disorders, though several patients with an expected platelet-related bleeding disorder still do not receive a genetic diagnosis (Westbury et al. 2015). However, in recent years, next-generation sequencing has offered the potential to improve the diagnosis for such patients. However, in parallel to such genetic studies, proteomics has been used with success to gain insights in such platelet-related bleeding disorders. In 2007, changes in α-granule proteins were quantified for a patient with gray platelet syndrome (GPS) compared to a healthy control (Maynard et al. 2007). GPS is an inherited bleeding disorder caused by a reduced number of α-granules and macrothrombocytopenia. A linear sucrose gradient method was used to isolate α-granules, and proteins were separated by 1D SDS-PAGE and identified by LTQ-FT MS. About 586 proteins were identified, and it was found that soluble, biosynthetic cargo proteins were severely

reduced or undetected in GPS platelets, whereas the packaging of soluble, endocytic cargo proteins was only moderately affected, supporting the defect in α-granule incorporation of proteins synthesized in megakaryocytes. Another bleeding disorder that affects α-granules is Quebec platelet disorder (QPD), characterized by high levels of urinary plasminogen activator (uPA) within platelets. The platelet proteome of four members of the same QPD family was compared to that of two healthy donors using 1D SDS-PAGE gels and LC-MS/MS analysis (Maurer-Spurej et al. 2008). Three α-granule proteins, fibrinogen, multimerin, and thrombospondin-1, were downregulated in patients' platelets, and it was speculated that this was due to degradation by platelet-derived uPA. Combined DIGE and MALDI-ToF/ToF were used to compare the platelet releasate of eight patients with storage pool disease and bleeding symptoms to that of nine unrelated healthy controls (Di Michele et al. 2011). This more advanced technology identified 60 and 14 protein spots that varied in the technical and biological replicate studies, and most proteins are cytoskeleton-related. It was hypothesized that the dense granule defect in these storage pool disease cases might be due to an underlying cytoskeleton defect. A similar proteomic design was used to analyze platelet proteins from patients with dominant macrothrombocytopenia (Karmakar et al. 2015). Patients have altered levels of actin-binding proteins, peroxiredoxin 2, protein disulfide isomerase, and transthyretin that might be associated with the structural changes of their platelets.

Platelet Proteomics to Study Cardiovascular Disease

Arterial thrombosis is a pivotal event in the development of cardiovascular disease, and platelets play a fundamental role in this process. Platelet proteomics has been applied to study this complex disease, and we have selected some examples. The first study was performed in 2008 using 2DE and MS and focused on patients with arterial thrombosis, primarily with ischemic stroke (Arias-Salgado et al. 2008). Most of the differences detected between groups were related to cytoskeletal changes, which supported the idea of preactivated platelets. 2DE and MS analysis of platelets from patients with non-ST segment elevation acute coronary syndrome (ACS) revealed 22 differentially expressed proteins compared to matched cases with chronic ischemic cardiopathy (Parguiña et al. 2010). Most of these proteins are interconnected as part of the network related to cell assembly and morphology and are predicted to participate in platelet activation via $\alpha_{IIb}\beta_3$ or GPVI receptors. Platelet proteins isolated from ACS patients admitted within 24 h of chest pain were compared to these from patients with stable coronary ischemic disease (Lopez-Farre et al. 2011). Different proteins involved in cytoskeleton, glycolysis pathway, and cellular-related antioxidant system were altered in the acute phase of the coronary event as identified via 2DE and MS. The platelet proteome of ST-elevation myocardial infarction (STEMI) patients was compared to that of stable chronic ischemic cardiopathy (CAD) patients again using 2DE and MS (Parguina et al. 2011). This study found 42 differentially expressed proteins with altered major signaling pathways that include proteins related to integrin, integrin-linked kinase, and GPVI signaling. The analysis of a coronary thrombus itself by proteomics using different techniques as 2DE with MS, 1-DE with LS-MALDI MS/MS, and 1-DE with LTQ-Orbitrap identified a total of 708 proteins (Alonso-Orgaz et al. 2014). Some of these proteins were co-expressed with the platelet marker CD41 and pointed out a potential activation of a focal adhesion pathway in platelets during thrombus formation. Proteomics of microvesicles isolated from plasma of STEMI versus CAD patients was performed by DIGE and MS (Vélez et al. 2014). About 102 proteins were identified that correspond to 25 unique differentially expressed proteins that have been linked to inflammation, infarction, and thrombogenesis. The most recent proteomic study used isolated thrombi from STEMI patients during percutaneous coronary intervention at different time points after onset of pain (3 or 6 h) (Ramaiola et al. 2015). Thrombi at 3 h were platelet-rich, while at 6 h leukocyte infiltration was noticed, and proteomic differences between these time points were mainly related to changes in the cell cytoskeletal-associated proteome.

Antiplatelet therapies are widely used to prevent myocardial infarction, stroke, and other cardiovascular events. Platelet proteomics proved also to be useful to study the biological effects of antiplatelet therapy and to study mechanisms of patients' resistance to such drugs. The platelet proteome was analyzed using 2DE for patients with stable angina undergoing percutaneous coronary intervention before angiography, 12 h after clopidogrel, and 24 h after the intervention (Volpi et al. 2012). Protein changes were detected associated with platelet activation and clopidogrel response, and most proteins belong to the cytoskeleton rearrangement, energetic metabolism, and oxidative stress functional classes. Platelet protein expression profiles from aspirin (ASA)-resistant and ASA-sensitive CAD patients were compared using 2DE and MS (Mateos-Caceres et al. 2010). Differences were found for proteins involved in energetic metabolism, cytoskeleton, oxidative stress, and cell survival, which might be due to their different ability to respond to ASA. Pre- and post-aspirin treatment platelet lysate samples (300 mg daily for 28 days) from two ASA-resistant and four ASA-sensitive healthy subjects were analyzed by GeLC-MS/MS (Floyd et al. 2014). Though the

groups presented with no detectable changes in the platelet proteome at baseline, 406 differential proteins were present after aspirin treatment with a marked increase in GPIIIa for ASA resistance. Recently, a manually curated biochemical reaction network of platelet metabolism was constructed using 33 proteomic datasets and 354 literature references (Thomas et al. 2014). The effect of ASA resistance was evaluated using constraint-based modeling, providing evidence for a redirection of glycolytic, fatty acid, and nucleotide metabolism toward eicosanoid synthesis and reactive oxygen species stress as validated by novel proteomic data. The availability of such a network will stimulate data-driven system analysis of platelet metabolism in order to gain insights into pathologies.

Platelet Proteomics to Study Other Disorders

Platelet proteomics has also been used to gain insights in diseases that are linked to platelets, such as for understanding thrombosis risks for phosphomannomutase 2 (PMM2) deficiency, sepsis, deep vein thrombosis (DVT), diabetes and uremia, inflammation in cystic fibrosis, and bleeding in myelodysplastic syndrome (MDS). Some of these proteomic studies are discussed as examples. A subproteomic analysis was performed for patients with the congenital disorder of glycosylation PMM2 that have an increased risk for thrombosis (de la Morena-Barrio et al. 2014). DIGE analysis of the N-glycoproteins however showed no quantitative or qualitative differences between patients and controls. Platelet 2DE profiles of septic patients versus healthy controls resulted in five differentially expressed proteins that include GPIX and GPIIb (Liu et al. 2014). Proteins isolated form plasma-derived microparticles were tagged with iTRAQ reagents and analyzed by 2DE with LS-MALDI MS/MS for nine patients with DVT and six healthy controls (Ramacciotti et al. 2010). The differentially expressed or depleted proteins are expected to influence thrombosis via inflammation, cell shedding, inhibition of fibrinolysis, and hemostatic plug formation. Platelets from 13 diabetic patients were analyzed before and 12 weeks after pioglitazone therapy using DIGE and LS-MS/MS (Randriamboavonjy et al. 2012). More than half of the differentially expressed protein spots identified were known calpain substrates and could be classified as cytoskeletal proteins and signaling molecules. This study suggests that diabetes-induced platelet dysfunction might be due to calpain activation. Platelet proteomics was performed for uremia patients with functional versus dysfunctional platelets as tested by PFA100 (Marques et al. 2010). 2DE and MS analysis showed changes in protein levels that might have occurred at the megakaryocyte level. Shotgun nUPLC-MSE and 2DE were used to compare platelet proteins between cystic fibrosis (CF) patients and healthy controls (Pieroni et al. 2011). CF is caused by mutations in the cystic fibrosis transmembrane conductance regulator that is expressed on platelets and related to changes in inflammation for which the proteomic study provided evidence of changes in integrin signaling. The platelet proteome of myelodysplastic syndrome (MDS) patients was analyzed with DIGE and showed lower levels of proteins that are important for integrin $\alpha_{IIb}\beta_3$ signaling (Fröbel et al. 2013). Impaired platelet aggregation might therefore explain the bleeding complications observed for MDS patients even at sufficient platelet counts.

Less obvious are the platelet proteomic studies that have been designed to unravel disease mechanisms for neuropathologies. However, it is known that platelets do share common characteristics with neurons (Goubau et al. 2013). Again, examples of proteomic studies conducted for Alzheimer's disease (AD), but also for monogenetic neurological diseases, are discussed. The platelet proteome was analyzed by DIGE for 34 AD cases, 13 cases with vascular dementia, 15 Parkinson cases, and 49 healthy controls (Zellner et al. 2012). The study suggested that Mao-B platelet protein levels could be a biomarker for age-related dementia in AD. In addition, the platelet membrane proteome was determined for five AD cases versus controls using 1-DE and LC-MS/MS (Donovan et al. 2013). A total of 144 proteins were altered that represent secretory granule proteins, and it was suggested that platelets may serve as a source of blood-based biomarkers in neuropathologies. DIGE with MS identification was used to analyze platelets and fibroblasts from patients with alternating lemiplegia of childhood (AHC) due to *ATP1A3* mutations (Di Michele et al. 2013). A total of 93 proteins have a different expression of which seven were detected in both cell types, and this included lysosomal protein cathepsin. Functional validation studies showed that AHC might be associated with a defective regulation of apoptosis via the lysosomal cathepsin pathway.

Conclusion

The application of the proteomics and subproteomic approaches described above has provided an invaluable contribution to the elucidation of platelet physiological mechanisms. We have included a figure with the most important items discussed in this chapter (Fig. 1). Moreover, they also provided remarkable insights into the molecular basis underlying platelet-related diseases, though several challenges still remain to be addressed. However, we are confident that the integration of the most recent advances in MS-based techniques in platelet proteomic studies will allow further delineation of the mechanisms implicated in diseases and identify new biomarkers or drug targets.

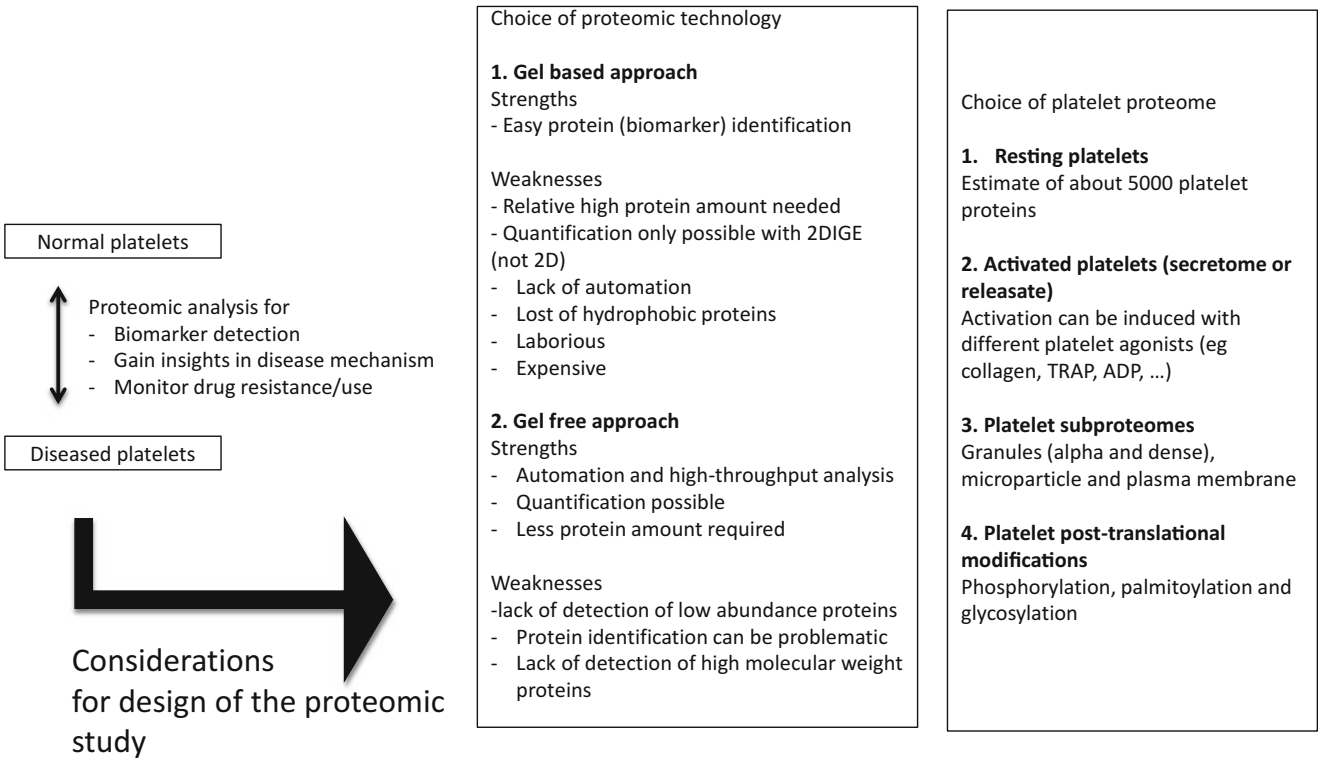

Fig. 1 Overview of proteomic technologies used in platelet research

Take-Home Messages

- Proteomics represents a powerful tool to study platelet proteins and the molecular mechanisms regulating unknown platelet functions and platelet-related diseases.
- Gel-based and gel-free proteomics technologies, both with their own advantages and limits, have been efficiently used to analyze platelets in physiological and pathological conditions.
- The experimental design of platelet proteomic studies should take into account the appropriate controls, technical/biological replicates, and sample preparation protocols.
- Proteomics can be applied to the study of (1) whole platelet proteome (in resting or activated condition); (2) platelet subproteomes (granules, microparticles, plasma membrane); and platelet PTMs (phosphoproteome, glycoproteome, palmitoylome).
- Platelet proteomics has been used to investigate platelet-related bleeding disorders and cardiovascular diseases, but also diseases less obviously linked to platelets.

The Platelet PARs

Amal Arachiche and Marvin T. Nieman

Abstract

The serine protease thrombin is a potent activator of platelets. It binds to two classes of receptors, the GPIb-IX complex and protease-activated receptors (PARs). PARs constitute a family of four G protein-coupled receptors named PARs 1–4 that mediate protease signaling in a wide variety of cells. In this chapter we describe the genomic organization and expression of PARs in platelets from humans and other species. Thrombin is the primary activator of PARs in platelets. We focus on the factors that determine the specificity and rate of cleavage PARs by thrombin, which are the initiating events of thrombin-induced platelet activation. Human platelets express PAR1 and PAR4, which have both overlapping and distinct signaling pathways. These differences have become increasingly important as therapeutics targeting PAR1 and PAR4 are developed. In addition to thrombin-PAR interactions, the activation and downstream signaling of PAR subtypes is influenced by dimerization with one another and other platelet GPCRs. We also discuss the recent identification of genetic variations that impact PAR4 signaling in humans. Finally, we highlight the differences in PAR expression on platelets across species that impact how animal models can be used as preclinical tools.

Key Points

Thrombin signaling in human platelets is mediated by protease-activated receptor 1 (PAR1) and PAR4.

PARs are G protein-coupled receptors that are activated by proteolysis of their N-terminus to expose the tethered ligand.

PAR1 and PAR4 activate overlapping and independent signaling cascades in human platelets.

PARs form homo- and hetero-oligomers that affect their activation and signaling.

Polymorphisms in the PAR4 gene (f2rl3) result in sequence variants with different reactivities, which results in altered responses to PAR4 agonists.

The expression profile of PARs on platelets varies between species, which limits the clinical translation of some animal models.

Introduction

Protease-activated receptors are members of the G protein-coupled receptor (GPCR) superfamily that are widely expressed and signal through multiple G proteins. There are four members of the PAR family of receptors, PAR1, PAR2, PAR3, and PAR4. Here, we describe the expression and activation mechanism of PAR1, PAR3, and PAR4 by thrombin and their roles in platelet signaling. PAR2 is not expressed on platelets and is not discussed in this chapter. We also give a brief overview of the expression profile of PARs in platelet from other species that are frequently used as animal models.

Historical Perspective

In the late 1980s, several laboratories focused their work to solve the enigma of how a serine protease, thrombin, activates platelets. Thrombin is the most potent platelet agonist and plays an important role in thrombus formation and hemostasis. It is generated in the plasma by the prothrombinase complex, which catalyzes the proteolytic activation of the zymogen, prothrombin (FII), to form the active protease, thrombin (FIIa) (Krishnaswamy 2013). Binding sites with three distinct characteristics have been identified for thrombin on human platelets: high-affinity binding sites ($K_d = 0.3$ nM; 50 sites/platelet), intermediate-affinity binding sites ($K_d = 10$ nM; 1700 sites/platelet), and low-affinity nonspecific binding sites ($K_d = 3$ nM; 600,000 sites/platelet) (Harmon and Jamieson 1985). The binding sites are specific to thrombin because prothrombin does not bind to platelets. Originally, two platelet receptors were proposed as potential receptors for thrombin, glycoprotein Ib (GPIb) and glycoprotein V (GPV). However, both GPV and GPIb receptors did not fully explain how platelets response to thrombin. First, platelets from patients with Bernard-Soulier syndrome (BSS), deficient in both GPIb and GPV, respond to thrombin the same as platelets from control individuals. Second, there is no correlation between the cleavage kinetics of GPV by thrombin and the kinetics of platelet activation (Clemetson and Clemetson 1995; Kahn et al. 1999a). Finally, in the early 1990s, protease-activated receptor 1 (PAR1) was identified as the main thrombin receptor on human platelets (Vu et al. 1991a). The cloning of PAR1 lead to the identification of the three other family members (PARs 2–4).

Protease-Activated Receptor 1 (PAR1)

Protease-activated receptor 1 was the first thrombin receptor cloned in 1991 (Vu et al. 1991a). The gene encoding PAR1 (*f2r*) is located in chromosome 5 (5q13). PAR1 has a genomic structure that contains two exons separated by an intron of approximately 15 kb (Kahn et al. 1998a). The *f2r* gene encodes for a 425 amino acid protein with seven transmembrane domains. The general activation mechanism common to all members of the PAR family were largely worked out for PAR1 (Fig. 1). The N-terminal domain of PAR1 is oriented to the extracellular space and contains the recognition site(s) for thrombin. Following cleavage by thrombin at arginine 41 (. . .$LDPR_{41}$/SFLLRN. . .), the new N-terminal exodomain (SFLLRNP. . .) acts as tethered ligand that binds to the second extracellular loop of PAR1. This leads to a conformational change in the receptor, which initiates signal transduction (Nanevicz et al. 1995). The synthetic peptide,

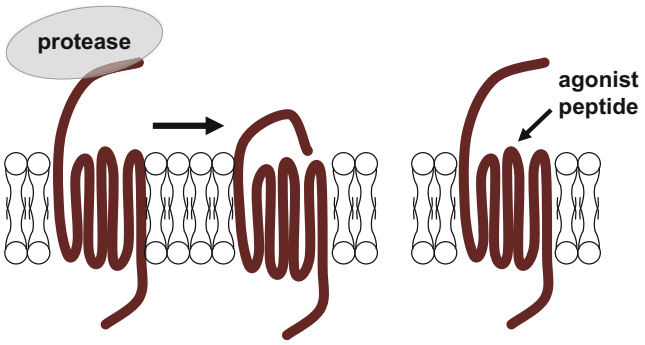

Fig. 1 A schematic of PAR activation by the tethered ligand. The protease binds and cleaves the N-terminal exodomain. The newly formed N-terminus binds to the extracellular loops to initiate downstream signaling events (*left panel*). Experimentally, PARs can be activated via agonist peptides that mimic the cleaved N-terminus (*right panel*). These are often referred to as TRAPs (thrombin receptor-activating peptides)

SFLLRN, mimics the first six amino acids of newly formed N-terminus and can activate PAR1 independent of cleavage (Gerszten et al. 1994). The PAR activation peptides, sometimes referred to as thrombin receptor-activating peptides (TRAPs), have been used experimentally to selectively activate PARs on cells to study the signaling events that are downstream to specific PAR family members. One caveat is that SFLLRN will also activate PAR2. The peptide TFLLRN should be used for cells co-expressing PAR1 and PAR2, such as endothelial cells.

The simplistic view of PAR activation by the tethered ligand is that the N-terminus bends over and activates the receptor by binding extracellular loop 2. However, NMR and mutagenesis studies with the PAR1 exodomain suggest that the N-terminus actually folds back on itself to form a secondary structure that is required for activation (Seeley et al. 2003). It is not known if this is a general mechanism of PAR activation as analogous studies have not been reported for other PAR family members. Although PAR1 was originally identified as the thrombin receptor, it is widely expressed and can be cleaved by multiple proteases to activate distinct signaling pathways through biased agonism (see discussion below) (Koukos et al. 2011; Zhao et al. 2014). It is not known how the alternative cleavage sites influence the secondary structure of the PAR1 N-terminus.

The unique activation mechanism of PARs is irreversible, which prohibits receptor recycling following activation. Following stimulation, PAR1 undergoes desensitization due to receptor internalization (Molino et al. 1997; Brass et al. 1992). A key regulatory step of PAR1 signaling is phosphorylation of the C-terminal tail (Shapiro et al. 2000). More recent studies have also linked PAR1 internalization to ubiquitination and glycosylation (Chen et al. 2011; Soto and Trejo 2010; Russo et al. 2009a; Wolfe et al. 2007).

Protease-Activated Receptor 3 (PAR3)

Protease-activated receptor 3 was cloned in 1997 as the second thrombin receptor and third member of the PAR family (Ishihara et al. 1997). The gene encoding PAR3, *f2rl2*, co-localizes with *f2r* (the PAR1 gene) at chromosome 5q13. It is located at 5′ of *f2r* and separated by less than 25 kb (Schmidt et al. 1996; Kahn et al. 1998a). The common locus of the genes for PAR1 (*f2r*), PAR2 (*f2rl1*), and PAR3 (*f2rl2*) suggests a common ancestral gene for this family of receptors. The genomic organization of *f2rl2* is similar to *f2r*, with one small exon and one large exon. In contrast to *f2r*, the two exons of *f2rl2* are separated by a small intron of approximately 4.5 kb (Kahn et al. 1998a).

The PAR3 mRNA encodes for a 373 amino acid protein, which shares 27 % amino acid sequence identity with PAR1. Similar to PAR1, the N-terminal exodomain of PAR3 has two thrombin recognition sites; the cleavage site is at lysine 38 (. . .LPIK$_{38}$/TFRGAP. . .) and a hirudin-like sequence (FEEFP) that binds thrombin's exosite I (Ishihara et al. 1997; Ayala et al. 2001; Bah et al. 2007). A major difference between PAR1 and PAR3 is that the C-terminal tail of PAR3 is significantly shorter than that of PAR1 (13 versus 51 amino acids). The shorter C-terminal tail likely affects the coupling of PAR3 to intracellular signaling machinery and subsequent signal transduction for platelet activation. PAR3-activating peptide, TFRGAP, does not activate human platelets, *Xenopus* oocytes, or COS7 cells transfected with human PAR3, suggesting that it does not have a signaling function on its own (Andersen et al. 1999; Ishihara et al. 1997). In human platelets, the expression level of PAR3 is substantially lower than PAR1, 150–200 copies versus 1500–2000 copies on the surface, respectively (Brass et al. 1992; Schmidt et al. 1998). It has been difficult to define a functional role for PAR3 on human platelets (Ishihara et al. 1997). In contrast, PAR3 is highly expressed on mouse platelets in which it regulates the sensitivity and response of PAR4 at both low and high thrombin concentrations (Nakanishi-Matsui et al. 2000; Arachiche et al. 2013a). Similar to human platelets, a direct signaling role for PAR3 has not been described.

Protease-Activated Receptor 4 (PAR4)

Protease-activated receptor 4 (PAR4) was the fourth member of PAR family and the third thrombin receptor identified (Xu et al. 1998; Kahn et al. 1998b). In contrast to *f2r* and *f2rl2*, the gene encoding PAR4, *f2rl3*, maps to chromosome 19p12. The *f2rl3* gene is also organized into two exons, but the intron separating the two exons is small (~0.25 kb) compared to other PARs (Kahn et al. 1998a). The expression of PAR4 mRNA was detected in platelets and a number of other human tissues such as the lung, pancreas, thyroid, testis, and small intestine. PAR4 expression was not detected in the brain, kidney, spinal cord, and peripheral blood leukocytes (Kahn et al. 1999b; Xu et al. 1998).

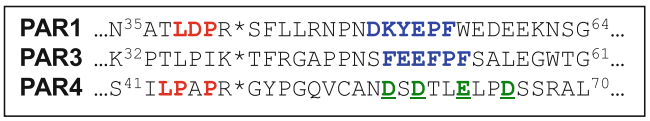

Fig. 2 Schematic diagram of PAR1, PAR3, and PAR4 exodomains. PAR1 and PAR3 primary sequence with amino acids that interact with the thrombin cleavage site highlighted in *red* and the hirudin-like sequence highlighted in *blue*. PAR4 primary sequence with amino acids that interact with the thrombin cleavage site highlighted in *red* and the anionic cluster highlighted in *green* and *underlined*

PAR4 is a protein that is 385 amino acids in length with 27 % and 30 % amino acid sequence identity with PAR1 and PAR3, respectively (Xu et al. 1998). Thrombin activates PAR4 by the cleavage of the N-terminal of PAR4 at arginine 47 (. . .LPAPR$_{47}$/GYPGQV. . .) (Fig. 2). The synthetic peptide (GYPGQV) corresponding to the unmasked amino terminus of PAR4 also activates the receptor. However, peptide library screens demonstrated that the peptide AYPGKF is more potent and is commonly used experimentally (Hollenberg and Saifeddine 2001).

PAR1 has been more extensively studied than PAR4, which has lead to the development of the FDA-approved drug vorapaxar (Baker et al. 2014). However, recently it has been recognized that PAR4 has unique signaling properties that may make PAR4 an attractive target for therapeutics (Kuliopulos and Covic 2003; Young et al. 2013; Mumaw et al. 2014). Further, the identification of PAR4 sequence variants that result in receptors with different reactivities highlights the importance that each receptor contributes to thrombin signaling. Finally, since PAR1 is not expressed on mouse platelets, signaling ascribed to PAR4 in mouse studies need to be interpreted with caution. For example, the C-terminus of mouse PAR4 has properties similar to human PAR1, which affects binding of some antagonists (Aisiku et al. 2015). These differences are discussed below.

Activation of PARs by Thrombin

Much effort has been made to characterize the molecular mechanisms by which thrombin interacts with its substrates. In general, thrombin's interaction with its substrates consists of three parts: (1) it binds via its anionic binding exosite I to a site on some of its substrates termed a "hirudin-like sequence," (2) it binds through amino acids that surround the active site to some amino acids at the P5-P2 positions on the substrate, and (3) thrombin's active site interacts

with the substrate P1-P1′ position. The rate of cleavage of PARs by the activating protease is the rate-limiting step for signaling.

In addition to binding thrombin's active site, PAR1 has a hirudin-like sequence ($D^{50}KYPEK^{55}$) that binds thrombin's exosite I which induces allosteric effects on thrombin, lowering the energy required for PAR1 cleavage (Fig. 2) (Liu et al. 1991; Ayala et al. 2001; Jacques et al. 2000). The importance of the hirudin-like sequence has been confirmed with thrombin exosite mutations as well as PAR1 exodomain mutations (Ayala et al. 2001; Jacques et al. 2000; Vu et al. 1991b; Myles et al. 2001). Further, mutations around the thrombin cleavage site do not dramatically affect the K_m of thrombin cleaving PAR1 due to the exosite I binding region. However, the k_{cat} is reduced sevenfold when Leu^{38} at P4 is mutated to alanine and twofold when Pro^{40} at P2 is mutated (Fig. 2) (Nieman and Schmaier 2007). When PAR1 peptides were co-crystallized with thrombin, structures were solved in which the active site of thrombin interacted with $L^{38}DPR^{41}$ or the exosite I region interacted with $K^{51}YEPF^{55}$. However, none of these structures had the exosite I and the active site simultaneously filled (Mathews et al. 1994). The hirudin-like sequence ($K^{51}YEPF^{55}$) induces a change of conformation when the Ala^{190}-Gly^{197} region of thrombin with the Glu^{192} side chain becomes disordered, helping to accommodate the negatively charged Asp at P3 for PAR1. The crystals in which the active site is filled by the $L^{38}DPR^{41}$ sequence shows that Leu^{38} occupies the aryl-binding pocket formed by Ile^{174} and Trp^{215} as predicted by Bode et al. (1992). The intervening sequence between $L^{38}DPR^{41}$ and $K^{51}YEPF^{55}$ of PAR1 ($F^{43}LLRNP^{48}$) is disordered with no electron density (Mathews et al. 1994). Using the data from the two sets of crystals in Mathews et al. (PDB ID codes 1NRS and 1NRN), Huntington has proposed models for a single PAR1 peptide interacting with thrombin's active site and exosite I simultaneously, which has largely been confirmed by more recent structural studies (Huntington 2005; Gandhi et al. 2010).

PAR4 does not have a hirudin-like sequence (Fig. 2) (Xu et al. 1998). Based on studies with peptides and recombinant exodomains, the primary sites of PAR4 interaction with α-thrombin is at the thrombin cleavage site. In particular, amino acids Leu^{43} at P5, Pro^{44} at P4, and Pro^{46} at P2 are important α-thrombin interaction sites (Cleary et al. 2002; Jacques and Kuliopulos 2003; Nieman and Schmaier 2007). However, individual point mutations at Leu^{43}, Pro^{44}, or Pro^{46} do not influence thrombin binding (i.e., did not influence the K_m) but did reduce the rate of cleavage indicating that Leu^{43}, Pro^{44}, or Pro^{46} are important for orienting PAR4 in the active site of thrombin for efficient cleavage (Nieman and Schmaier 2007). More importantly, these data also suggest that, like PAR1, PAR4 has extended contacts with α-thrombin that minimize the influence of the individual amino acids at the cleavage site (Fig. 1) (Nieman and Schmaier 2007). Earlier work by Jacques and Kuliopulos, using purified exodomains, demonstrates that mutations of the anionic cluster in the PAR4 exodomain (Asp^{57}, Asp^{59}, Glu^{62}, Asp^{65}) (see Fig. 2) decreased the K_m of thrombin binding fourfold from 56 to 208 nM (Jacques and Kuliopulos 2003). Further experiments demonstrate that the anionic cluster stabilizes the interaction with thrombin by slowing the dissociation rate (Jacques and Kuliopulos 2003). These functional data are supported by structural and modeling studies. Ayala et al. showed via molecular modeling using peptides that Leu^{43} may be important for interaction with thrombin residues Leu^{99}, Ile^{174}, and Trp^{215} (Ayala et al. 2001). However, NMR studies with PAR4 peptides by Cleary et al. demonstrate that this leucine is flexible and can interact with thrombin as well as Pro^{44} or Pro^{46} to stabilize secondary structure at the thrombin cleavage site of PAR4 (Cleary et al. 2002). Crystallography studies show that PAR4 interacts with thrombin's gamma (autolysis) loop (Bah et al. 2007).

PAR4 is not an efficient thrombin substrate when expressed on cells alone and requires approximately tenfold more thrombin for activation (Jacques and Kuliopulos 2003; Nieman 2008). However, when PAR4 is co-expressed with PAR1 in heterologous systems as it is on human platelets, the rate of PAR4 cleavage is enhanced six- to tenfold (Jacques and Kuliopulos 2003; Nieman 2008; Arachiche et al. 2013b). The enhanced rate of PAR4 cleavage is similar that first described for the functional interaction between PAR3 and PAR4 on mouse platelets (Nakanishi-Matsui et al. 2000). In this model, thrombin remains bound to the hirudin-like sequence following proteolysis at the cleavage site, which enhances the activation of an adjacent PAR4 (Fig. 3). There are two potential mechanisms for this model. First, the higher-affinity binding site on PAR1 or PAR3 (the hirudin-like sequence) may increase the local concentration of thrombin near the platelet surface to facilitate the activation of PAR4. Alternatively, based on biochemical and structural data with other tight exosite I binders, PAR1's hirudin-like sequence may induce thrombin into the protease conformation with an open active site to facilitate PAR4 cleavage (Huntington 2012; Kamath et al. 2010). The latter model is also supported by structural models of murine thrombin bound to peptides from PAR3 and PAR4 (Bah et al. 2007).

Thrombin Signaling in Human Platelets

The responses of platelets to thrombin stimulation are many and varied. PAR1 and PAR4 cooperate to mediate the full range of thrombin signaling in human platelets by coupling to multiple heterotrimeric G proteins (Kahn et al. 1999b).

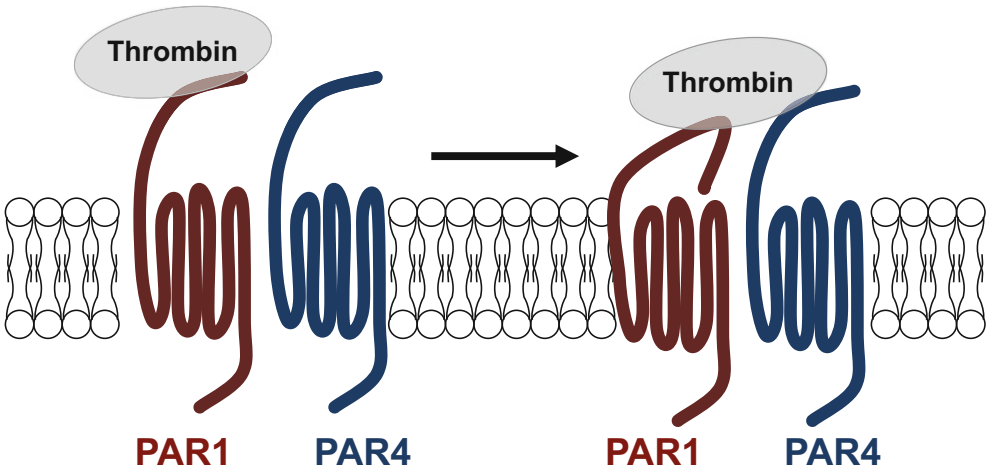

Fig. 3 PAR1 serves as a cofactor for PAR4 activation by thrombin on human platelets. The rate of PAR4 cleavage is enhanced by co-expression of PAR1 (human platelets) or PAR3 (mouse platelets) via the hirudin-like sequence; see text for details

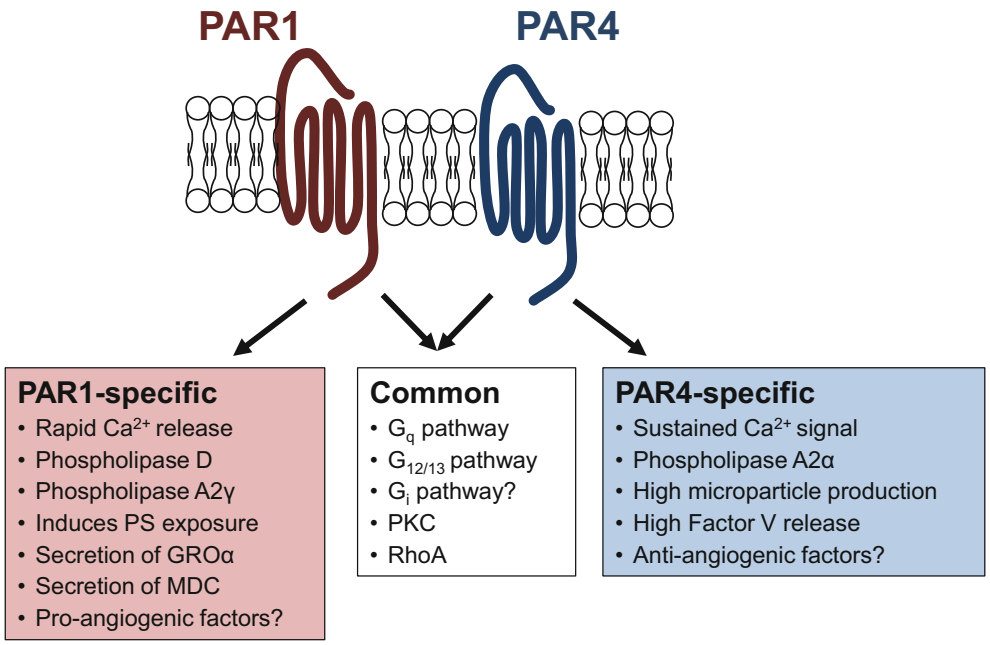

Fig. 4 PAR1 and PAR4 have overlapping and distinct downstream signaling events. PAR1 and PAR4 both signal through multiple G proteins; however, the duration and kinetics of signaling can differ

PAR1 and PAR4 have several overlapping signaling functions, which led to the original hypothesis that PAR4 is a redundant, backup receptor. Several studies have since shown these receptors can activate unique signaling pathways and, in some cases, the same pathways with distinct kinetics (Fig. 4).

Overlapping Signaling Between PAR1 and PAR4

In human platelets, PAR1 and PAR4 both transduce signals through $G\alpha_q$ and $G\alpha_{12/13}$. The activation of $G\alpha_q$ stimulates the formation of inositol triphosphate (IP3) and diacylglycerol (DAG), which induces intracellular calcium mobilization and protein kinase C (PKC) activation, respectively (Hung et al. 1992; Offermanns et al. 1997). This pathway controls a variety of platelet responses including granule secretion, integrin activation, and platelet aggregation in platelets. The activation of $G\alpha_{12/13}$ mediates Rho guanine nucleotide exchange factors and RhoA signaling pathways, which controls platelet shape change (Moers et al. 2003; Huang et al. 2007). $G\alpha_i$ signaling in platelets mediates inhibition of adenylate cyclase activity but also induces platelet shape change, secretion, and calcium mobilization. The direct interaction between PARs and G_i in human platelets is controversial. PAR1 directly couples to G_i in COS7 cells transfected with PAR1 (McCoy et al. 2012) and, in some cases, platelets (Voss et al. 2007). In other studies, PAR1 and PAR4 did not couple directly to G_i. Here, the G_i pathway was mediated by secondary release of ADP, which acts on the G_i-coupled ADP receptor, P2Y12 (Jantzen et al. 2001; Kim et al. 2002, 2006).

Calcium Mobilization

The most dramatic differences between PAR1 and PAR4 signaling in platelets is the kinetics and duration of intracellular Ca^{2+} signaling (Covic et al. 2000; Vaidyula and Rao 2003). Prior to the identification of PAR4, it was recognized that Ca^{2+} mobilization in thrombin-stimulated platelets was different from that of PAR1 agonist peptide-stimulated platelets. Further studies revealed that the PAR1 agonist peptide is a partial agonist of human platelets (Lau et al. 1994). The initial increase in intracellular Ca^{2+} was the same for thrombin and the agonist peptide. In contrast, when platelet was stimulated with the PAR1 agonist peptide in the absence of extracellular Ca^{2+}, the Ca^{2+} flux returned to baseline levels faster and induced a reduced level of lysosome release. Finally, the overall magnitude and duration of the Ca^{2+} signal was greater in thrombin-stimulated platelets (Heemskerk et al. 1997). The identification of PAR4 reconciled these differences when it was demonstrated that there is a distinct wave of Ca^{2+} signaling from PAR4 (Covic et al. 2000). The prolonged Ca^{2+} stimulus associated appears to be required for stable clot formation and full spreading on fibrinogen in response to thrombin in a p38- and ERK1/2-dependent manner (Covic et al. 2002; Mazharian et al. 2007). The proposed mechanism for sustained signaling from PAR4 is that PAR4 is internalized more slowly compared to PAR1. In cultured fibroblast, 50 % of PAR1 is internalized following stimulation compared to 20 % of PAR4 (Shapiro et al. 2000).

Cooperation Between Thrombin and ADP Signaling

PAR1 and PAR4 also synergize with ADP signaling in platelets. One study has shown that PAR4, but not PAR1 signaling to Akt, is dependent on P2Y12, particularly under conditions of limited calcium concentration (Holinstat et al. 2006). A number of other reports have found results suggesting that PAR1 synergizes independently with P2Y12, rather than PAR4 (Resendiz et al. 2007; Wu et al. 2010; Jiang et al. 2013). PAR1 but not PAR4 directly influenced ADP-induced platelet granule secretion and second wave of aggregation. Blocking PAR1 activation by SCH79797 abolished the ATP secretion, $\alpha_{IIb}\beta_3$ activation, P-selectin expression, and the second wave of platelet aggregation associated with partial disaggregation. In contrast, PAR4 antagonist tcY-NH2 had no effect on these responses (Jiang et al. 2013). Furthermore, selective activation of PAR1 by SFLLRN together with collagen enhanced the increase in exposure of procoagulant phosphatidylserine (PS) exposure on the surface of platelets, as simultaneous stimulation of platelets with thrombin and collagen. The selective activation of PAR4 by the agonist peptide, GYPGQV, resulted in less PS exposure on the platelet surface (Andersen et al. 1999). In addition, stimulating platelets with ADP prior to SFLLRN produced a much greater increase in subpopulation of platelets that are PS positive compared to simultaneous stimulation of PAR1/P2Y12 (Shakhidzhanov et al. 2015). In sum, these studies indicate that P2Y12 and PAR1 signaling work in cooperation. Finally, in addition to the interaction of downstream signaling pathways, P2Y12 and PAR4 have a direct physical interaction that influences arrestin recruitment (see below) (Khan et al. 2014; Li et al. 2011).

Membrane Lipids and PAR1–PAR4 Downstream Signaling

PAR1 and PAR4 differentially regulate membrane lipid signaling. The role of sphingolipids has been demonstrated in both platelet function and platelet production (Shrimpton et al. 2002; Zhang et al. 2012b). Sphingomyelin (SM) is one of the major sphingolipids present in the plasma membrane and is hydrolyzed by sphingomyelinase (SMase) enzyme into ceramide and phosphorylcholine. Two types of SMase have been identified in platelets, the lysosomal phosphodiesterase acid SMase (A-SMase) and the membrane-bound neutral SMase (N-SMase); both enzymes regulate mouse and human platelets (Munzer et al. 2014; Chen et al. 2013). Thrombin or PAR4 agonist peptide, but not PAR1 agonist peptide, results in increased association of N-SMase with PAR4 in human platelets. The activation of N-SMase induced the generation of ceramide, which acts as a second messenger to induce the activation of the p38-MAPK-NF-kB signaling pathway in platelets (Chen et al. 2013). Thus far, the role of PAR1 or PAR4 in regulating acid sphingomyelinase (A-SMase) has not been demonstrated.

Arachidonic acid (AA) is another lipid membrane, which plays an important role in platelet function. AA is liberated form glycerophospholipid (GPL) via the action of phospholipase A2 (PLA2) and transformed to thromboxane A2 (TXA2) by sequential action of cyclooxygenase-1 (COX-1) and TXA2 synthase. Thrombin stimulates the generation of thromboxane A2 (TXA2), which, in turn, activates platelets via the thromboxane receptor (TP) and amplifies platelet activation to cause irreversible aggregation. PAR4 stimulation results in significantly greater TXA2 generation compared to PAR1 (Holinstat et al. 2011). Platelets express several PLA_2 isoform, including Ca^{2+}-sensitive 85 kDa cytosolic phospholipase $A_2\alpha$ ($cPLA_2\alpha$), Ca^{2+}-insensitive 14 kDa secretory PLA_2 ($sPLA_2$), and Ca^{2+}-independent PLA2 ($iPLA_2\gamma$). It has been shown that thrombin-induced AA production in human platelets is dependent on $cPLA_2\alpha$ but not $sPLA_2$ (Bartoli et al. 1994).

The platelets from cPLA2α-deficient mice or patient with inherited deficiency of cPLA2α present a decrease in eicosanoid biosynthesis, such as prostaglandins, thromboxanes, and leukotrienes, which alters platelet function (Adler et al. 2008). In addition, mice lacking iPLA2γ present with a prolonged bleeding time and are protected from pulmonary thromboembolism (Yoda et al. 2014). In very recent work, a specific inhibitor of cPLA2α, giripladib, selectively inhibited PAR4 but not PAR1-mediated P-selectin expression in human platelets. However, specific inhibition of iPLA2γ with bromoenol lactone (BEL) significantly reduced P-selectin expression after PAR1, but not PAR4 activation in human platelets (Duvernay et al. 2015). Studies with human platelets show that inhibition of the phosphatidylcholine (PC)-derived phosphatidic acid (PA) formation by phospholipase D (PLD) inhibits platelet activation by PAR1-activating peptide. Thrombin or PAR4-activating peptides are insensitive to this inhibition. Furthermore, PAR1 but not PAR4 signals through phosphoinositide 3-kinase (PI3K) to activate integrin $\alpha_{IIb}\beta_3$ and induce platelet aggregation (Holinstat et al. 2007; Voss et al. 2007).

Granule Secretion and PAR1–PAR4 Downstream Signaling

Human platelets contain three types of storage granules, α-granules, dense granules, and lysosomes. The presence of distinct of α-granules with either pro-angiogenic or anti-angiogenic factors is controversial with studies supporting both selective and random secretion of granule contents. The differential release of pro-angiogenic and anti-angiogenic factors from platelets stimulated with PAR1 versus PAR4, respectively, was first described by Ma and colleagues (2005). The PAR4 agonist peptide stimulated the release of endostatin but suppressed the release of VEGF. In contrast, the PAR1 agonist peptide stimulated the release of VEGF and suppressed the release of endostatin. Curiously, stimulation with thrombin did not release either factor. Other studies also support a differential release of anti-angiogenic versus pro-angiogenic factors that are not due solely to either differential signal strength or kinetics of the respective agonists (Italiano et al. 2008; Chatterjee et al. 2011). Notably, PAR4-induced secretion of SDF-1 and endostatin were PI3K and Akt dependent, while PAR1-induced SDF-1 secretion was not (Chatterjee et al. 2011). PAR1 and PAR4 can also influence the degree of secretion. For example, PAR4 stimulation with the agonist peptide, AYPGKF, enhanced the surface expression of Factor V (1.6-fold) and P-selectin (0.8-fold) compared to PAR1 activation with SFLLRN (Duvernay et al. 2013). PAR4 activation also induced a threefold greater production of platelet microparticles compared with PAR1 activation. The RhoA pathway inhibitor Y-27632 reduced Factor V translocation and microparticle release downstream PAR4 stimulation to levels observed with PAR1 stimulation. These data indicate that PAR4 is mediating these events through the $G_{12/13}$-RhoA signaling axis. PAR4 activation also releases more CD40L from α-granules compared to PAR1. Conversely, PAR1 activation releases more growth-regulating oncogene-α (GRO-α) and macrophage-derived chemokine (MDC), compared to PAR4 (Nguyen et al. 2015).

In contrast, several studies have demonstrated random distribution of proteins within granules and that PAR1 and PAR4 stimulation leads to random release of granule contents from human platelets. A detailed analysis of α-granule proteins with quantitative immunofluorescence co-localization with pair-wise comparisons demonstrates the presence of one type of α-granule with random packing (Kamykowski et al. 2011). An analysis of the rates of secretion of several granules shows that the differences in α-granule release observed between PAR1 and PAR4 are based on the kinetics of granule release due to the strength of the agonist (Jonnalagadda et al. 2012). Furthermore, the RhoA activation downstream $G_{12/13}$ and G_q induced the same level of dense granule release in response to PAR1 or PAR4 activation (Jin et al. 2009). Recent work from van Holten et al. using mass spectrometry (MS)-based quantitative proteomic analysis and enzyme-linked immunosorbent assay (ELISA) shows that PAR1 or PAR4 activation of platelets results in the same α-granule release (van Holten et al. 2014). Finally, it is difficult to conclude if PAR1 and PAR4 induced similar or different protein mobilization, because the controversial results obtained from these studies might be due to the various techniques used to analyze platelet release, differences in agonist concentration, or difference in the number of human platelet samples analyzed.

Biased Signaling of PARs

GPCRs can signal through G protein and arrestin pathways. Biased agonists are those that preferentially activate specific pathways downstream of the receptor (Urban et al. 2007). In contrast, neutral agonists do not discriminate which pathways are activated. Biased signaling downstream of PARs can be mediated by cofactors, alternative cleavage sites, or pharmacologically (Zhao et al. 2014; Lin et al. 2013; Aisiku et al. 2015; Dowal et al. 2011). Studies aimed at understanding and directing the multitude of signaling events have largely been focused in endothelial cells. In this review we will focus on biased signaling as it relates to platelets.

Biased Signaling from PARs in Platelets

Thrombin is a neutral agonist for PAR1 and does not discriminate the downstream pathways that are activated. The first description of a PAR1 ligand that demonstrated specific signaling events in platelets was the activation peptide YFLLRNP (Rasmussen et al. 1993; Bauer et al. 1999). At low concentrations, this version of the PAR1 activation peptide induces shape change through $G_{12/13}$ but does not mediate G_q signaling and, as a result, does not induce full aggregation. Observations such as these opened the possibility of targeting specific pathways downstream of PARs. Since PAR1 activation has many, and sometimes divergent, cellular responses, inhibiting all downstream signaling with an orthosteric inhibitor such as vorapaxar (Zontivity) may not be ideal. An alternative approach that has be pursued by Flaumenhaft and colleagues is to screen for allosteric modulators of PAR1 that spare the cytoprotective signaling of PAR1 while blocking pathways that are detrimental to cell survival (Aisiku et al. 2015; Dowal et al. 2011). Their primary focus has been on PAR1 signaling in endothelial cell; however, the parmodulin compounds also selectively block G_q signaling in platelets. This family of compounds binds to the eighth helix on the cytoplasmic face of the receptor where they alter the interactions between the receptor and the G-alpha subunits.

The traditional role of arrestins is to regulate GPCR trafficking. The reports of arrestin function in platelets have been less straightforward. The internalization of P2Y receptors in an arrestin-dependent manner results in shutting down signaling (Nisar et al. 2012, 2011). In contrast, other reports suggest a direct signaling function of arrestin that promotes platelet activation (Schaff et al. 2012; Li et al. 2011). The specific contributions of arrestins to PAR signaling have been limited to PAR4 (Khan et al. 2014; Li et al. 2011). Recruitment of arrestin-2 to PAR4 is mediated by PAR4-P2Y12 heterodimerization where it has a positive signaling role. In mice that have arrestin-2 deleted, the platelet function is enhanced, and the time to thrombosis is shortened due to increased Src family kinase activation. These data support a direct signaling role for arrestin-2 rather than the expected desensitization of GPCR-mediated signaling that is expected.

Activation PARs by Proteases Other Than Thrombin

In addition to thrombin, several other serine proteases are capable of activating PARs such as factor Xa, plasmin, matrix metalloproteinases 1 and 13, elastase, activated protein C (APC), proteinase-3, granzyme, cathepsin G, and calpain (Zhao et al. 2014). Depending the cleavage site, PARs can be activated or inactivated by these proteases. Further, the alterative cleavage sites can generate novel tethered ligands that initiate specific signaling pathways. The panel of proteases activating PARs has been described for a variety of cell types. Here, we will focus on protease cleavage of PAR1 and PAR4 in the context of platelet function. The reader is directed to recent comprehensive reviews for other contexts (Russo et al. 2009b; Hollenberg et al. 2014; Zhao et al. 2014).

Factor Xa is directly upstream of thrombin in the coagulation cascade and can directly activate PARs (Camerer et al. 2002, 2000; Ruf et al. 2003). Early studies by Sinha et al. show that the pretreatment of platelet-rich plasma with FXa inhibited thrombin-induced platelet aggregation and TXA2 generation (Sinha et al. 1983). One potential caveat is distinguishing between FXa activation of prothrombin (which can subsequently activate PAR1) from direct activation of PAR1 by FXa. However, if the thrombin concentration is increased tenfold over FXa or if FVa is blocked on the surface of platelets using a specific anti-FVa antibody, the inhibition of TXA2 synthesis and platelet aggregation induced by FXa is reversed.

Matrix metalloproteinases (MMPs) are a family of zinc-dependent endopeptidases that are secreted as zymogens and, upon activation, degrade extracellular matrix proteins during tissue repair and cancer invasion (Woessner 1999). Matrix metalloproteinase-1 (MMP-1) directly activates platelets via PAR1. Stimulation of platelets with collagen results in the conversion of the inactive proMMP-1 to active MMP-1. Once activated, MMP-1 is capable of inducing platelet signaling by direct cleavage of PAR1 at a noncanonical site, Asp^{39} ($TLD_{39}PR_{41}SFLLRN$), that is distinct from canonical cleavage site of thrombin at Arg^{41} (Trivedi et al. 2009; Austin et al. 2013). In human platelets, the cleavage of PAR1 at Asp^{39} by MMP-1 induces $G_{12/13}$-Rho, p38 MAPK pathways, and shape change. However, intracellular calcium mobilization and platelet aggregation in response to MMP-1 are less potent than with thrombin (Austin et al. 2013; Trivedi et al. 2009). It should be noted that other cleavage sites on PAR1 have been reported for MMP-1 (Boire et al. 2005; Nesi and Fragai 2007).

The fibrinolytic enzyme plasmin cleaves both PAR1 and PAR4 on platelets. Four cleavage sites have been identified on the PAR1 exodomain (Arg^{41}, Arg^{70}, Lys^{76}, and Lys^{82}) (Kuliopulos et al. 1999). Kuliopulos and colleagues showed that although plasmin is capable of cleaving PAR1 at the canonical thrombin site, the predominant result is inactivation of PAR1 by truncating the tethered ligand at the distal sites. In the presence of a PAR1 inhibitor, plasmin stimulates platelet aggregation and shape change in human platelets via PAR4. Plasmin cleaves PAR4 at canonical thrombin cleavage site Arg^{47} (. . .$LPAPR_{47}$GYPGQV. . .) to generate PAR4 tethered ligand peptide (GYPGQV) (Quinton et al. 2004).

Cathepsin G is a serine protease found in the dense granules of neutrophils and is secreted upon neutrophil activation that cleaves both PAR1 and PAR4. The analysis of the N-terminal exodomain of PAR1 identified three potential cleavage site for cathepsin G: ($TLDPR_{41}SF_{43}LLRN...F_{55}..$). Preincubation of platelets with cathepsin G completely abolish thrombin-induced calcium mobilization (Parry et al. 1996). This is due to cathepsin G cleavage at Phe^{55} which leads to a loss of the PAR1 tethered ligand. Cathepsin G also cleaves PAR4 and induces calcium mobilization in human platelets and in PAR4 transfected fibroblasts (Sambrano et al. 2000). The story in mouse platelets is different. Cathepsin G blocks signaling by low thrombin concentrations by cleaving PAR3 and preventing it from acting as a cofactor for PAR4 (Cumashi et al. 2001). Cumashi and colleagues also showed that cathepsin G does not activate mouse PAR4.

Physical Interactions Between PARs

The molecular organization of GPCRs within the plasma membrane is controversial (Vischer et al. 2015). Homo- and heterodimers of GPCRs may influence signaling and can be thought of as allosteric modulators (Milligan and Smith 2007). The best evidence for a functional interaction between PAR homodimers on platelets is the dominant negative effect of PAR4 sequence variants that have low reactivity, which corroborates molecular studies (Edelstein et al. 2014; de la Fuente et al. 2012). Physiologically, there are examples of PAR heterodimers influencing the rate of activation, downstream signaling, and trafficking of the receptors in a diverse set of environments including platelets, smooth muscle cells, endothelial cells, and podocytes (Fig. 5) (Lin et al. 2013). As discussed above, the coordinated activity between PARs was first described for PAR3 and PAR4 on mouse platelets where PAR3 serves as a cofactor to enhance the rate of PAR4 cleavage by thrombin by approximately tenfold (Nakanishi-Matsui et al. 2000). An analogous mechanism was later demonstrated for PAR1 and PAR4 on human platelets (Leger et al. 2006; Nieman 2008). Each of these cases are dependent on PAR4 heterodimerization with PAR1 (human) or PAR3 (mouse) (Leger et al. 2006; Arachiche et al. 2013a, b).

PAR4, but not PAR1, also forms agonist-dependent heterodimers with another platelet GPCR, the ADP receptor P2Y12 (Li et al. 2011; Khan et al. 2014). The interaction between P2Y12 and PAR4 enhances the recruitment of β-arrestin-2 to PAR4 and mediates sustained signaling through Akt in human platelets. The PAR4-P2Y12 dimerization appears to be important to stabilize platelet plug formation. The interaction interface of the PAR4-P2Y12 heterodimer has been mapped to transmembrane helix 4 of PAR4. A mutation in PAR4 at the heterodimer interface disrupted the interaction with P2Y12 and prevents β-arrestin-2 recruitment and Akt activation (Khan et al. 2014). These data indicate that P2Y12 and PAR1 are competing with each other to interact with PAR4 as both receptors share the same heterodimer interface with PAR4 as well as the PAR4 homodimer interface (de la Fuente et al. 2012; Arachiche et al. 2013b; Khan et al. 2014). These interactions have the potential to not only influence platelet signaling but also how patients respond to therapies (Fig. 5) (Mumaw and Nieman 2014).

In addition to enhancing PAR4 activation, PAR3 can influence PAR4 signaling. PAR3-deficient mice have a 1.6-fold increase in the maximum Ca^{2+} mobilization and an increase in PKC activation but no effect on RhoA-GTP activation compared to platelets from wild-type mice. These results demonstrate that PAR3 regulates PAR4/G_q signaling pathway via a direct interaction with PAR4 indicating that dimerization of PARs may regulate coupling of G proteins to the receptor to influence downstream signaling. In addition to platelets, PAR3 also regulates PAR1 signaling in endothelial cells (McLaughlin et al. 2007; Stavenuiter and Mosnier 2014; Burnier and Mosnier 2013).

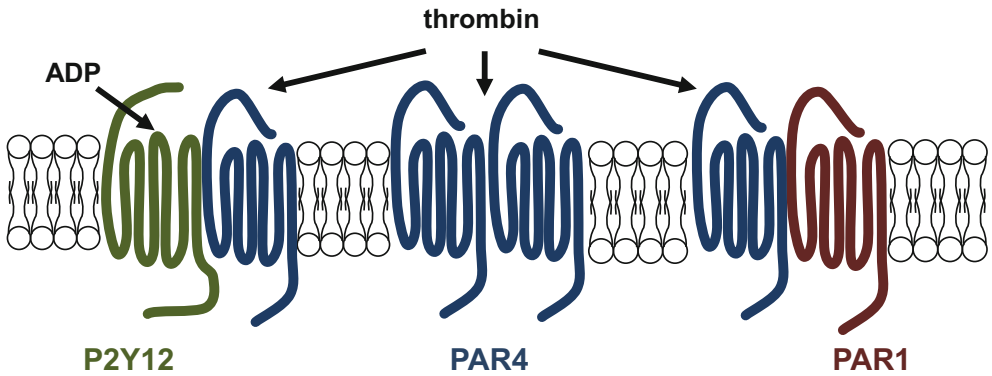

Fig. 5 The physical interaction between PARs. PARs for homo- and hetero-oligomers between PAR family members and other platelet GPCRs. These interactions influence both the rate of activation and signaling. Oligomerization also has the potential to influence the response to therapies. Note: PAR1 and P2Y12 also form homo-oligomers but are not shown in the figure for clarity

Polymorphisms and Sequence Variants

Single-nucleotide polymorphisms have been described for both PAR1 and PAR4. The challenge with SNPs is establishing a direct link from the identified polymorphisms to receptor expression or function and ultimately to a physiological output. One of the first described was a PAR1 polymorphism in an intron that affects PAR1 density on platelets and decreased platelet response to PAR1 agonists in individuals (Dupont et al. 2003). However, in a recent clinical study with 660 patients who underwent percutaneous coronary intervention (PCI), there was no evidence of increased major adverse cardiovascular events (MACE) or bleeding risk correlated with the polymorphism (Friedman et al. 2015).

The heritable interindividual variation in platelet reactivity has been directly linked to PAR4 (Bray et al. 2007; Edelstein et al. 2013, 2014; Tourdot et al. 2014). The Platelet RNA And eXpression 1 (PRAX1) study was designed to examine mRNAs and microRNAs associated with this difference in 154 healthy individuals who self-identify as black or white. In this population, Edelstein et al. showed that the black individuals had increased platelet response to PAR4 stimulation, higher expression of phosphatidylcholine transfer protein (PC-TP), and lower levels of miR-376c (Edelstein et al. 2013). The opposite was observed in the white individuals. Other platelet agonists, including PAR1, were not different between the groups. A second study identified two additional polymorphisms that change amino acids in PAR4 at positions 120 (Ala/Thr) and 296 (Phe/Val) (Edelstein et al. 2014). The polymorphism at 120 is common and is distributed by race. PAR4-120A exhibited a lower reactivity and was found in 81 % of white individuals compared to 37 % of black individuals. In contrast, PAR4-120T was hyperreactive to agonists, resistant to a PAR4 antagonist, and found in 63 % of blacks compared to 19 % of whites (Edelstein et al. 2014). The frequency of Val at 296 was low and had low reactivity regardless of the amino acid at 120 suggesting that it is a dominant negative receptor. The mechanism by which the PAR4 variants elicit their distinct response to affect platelet function is not known. These polymorphisms may change the interaction of PAR4 with the membrane, allosterically alter ligand binding, or influence the transition of the receptor to an active state (Isberg et al. 2014). Structural studies examining the differences between the PAR4 sequence variants are necessary to determine the molecular basis for the differences in reactivity.

Structural Studies on PARs

The platelet field has benefited from the recent advances in membrane protein crystallography (Salon et al. 2011; Zhang et al. 2012a, 2014a, b). Included in this list is the high-resolution crystal structure of PAR1 bound to the antagonist vorapaxar (Zhang et al. 2012a). The general overall structure was similar to many other GPCRs. However, when the PAR1 structure is compared to other class A GPCRs, transmembrane helix 7 was structurally similar to activated receptors, which is surprising for an antagonist bound receptor. Complementary studies are needed to determine if this is a unique feature of PAR1 or if it is specific to the conformation induced by the antagonist vorapaxar. The experimental constraints and sequence modifications required for GPCR crystallography have thus far have prevented a detailed structural analysis of the tethered ligand mechanism (Salon et al. 2011). Recently, Alsteens and colleagues developed a modification of atomic force microscopy to probe the ligand binding site of PAR1 and determined the free-energy landscape (Alsteens et al. 2015). Based on these studies, the authors proposed a two-step binding mechanism where the ligand first interacts in a low-affinity mode and then progresses to a high-affinity mode. Further studies are necessary to determine if the two-step mechanism is shared across the PAR family and how these observations are linked to the NMR studies with the PAR1 exodomain (Seeley et al. 2003). Since PARs are grouped together by their common activation mechanism, it is tempting to use PAR1 as the preferred model to gain structural insight for other PARs. However, PARs share no more sequence identity between family members than other GPCRs in general (34–41 %). There will undoubtedly be specific information regarding activation mechanism that is unique to each PAR as more structural and biophysical data become available.

Species Differences in PARs Expression in Platelets

Animal models are widely used for preclinical studies to examine platelet function and pharmacology in vivo. There are important differences in how platelets respond to thrombin between species (Connolly et al. 1994; Derian et al. 1995). Comparative ultrastructural and functional studies of platelets show differences in the open canalicular system (OCS), cytoskeletal proteins, and regulatory proteins, which may impact the kinetics of dense granule release (Choi et al. 2010; Gruba et al. 2015). The major contributor to species-specific responses of platelets to thrombin is the repertoire of PARs expressed on their platelets.

PAR4 is expressed on the platelets of most species, whereas PAR1 and PAR3 expression is more limited. PAR1 is expressed on platelets from human, monkey, and guinea pig (Fig. 6). PAR3 is expressed on platelets from mouse, rabbit, rat, and dog (Connolly et al. 1994; Derian et al. 1995). Monkey and guinea pig are the only animal models that express both PAR1 and PAR4 on their platelets.

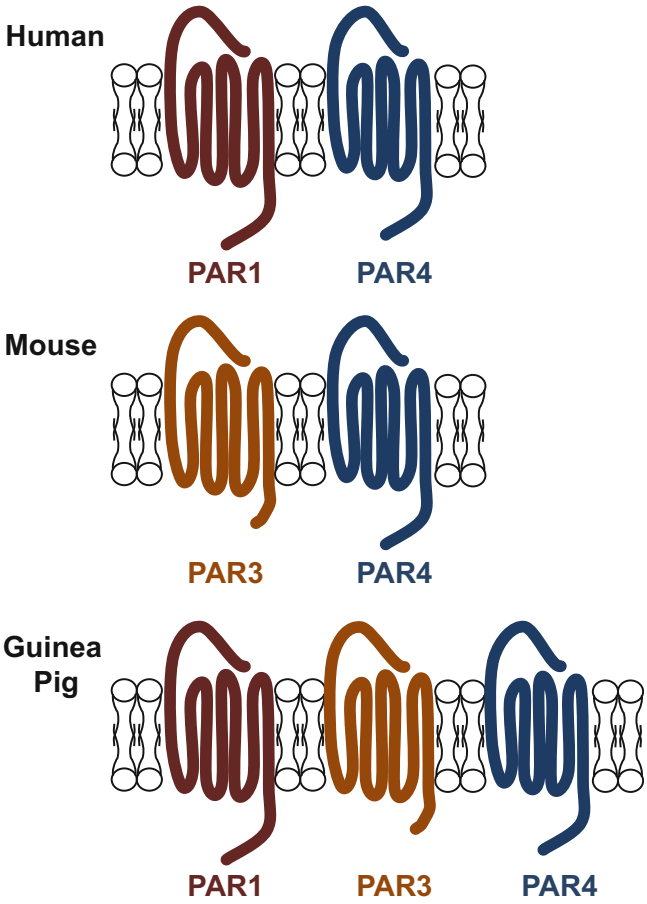

Fig. 6 Species differences in PAR expression on platelets from commonly used preclinical animal models

However, guinea pigs also express PAR3, which makes thrombin signaling more complicated in this animal model (Andrade-Gordon et al. 2001). Platelets from guinea pigs respond tenfold less to SFLLRN in aggregation experiments despite 80 % sequence identity between human PAR1 and guinea pig PAR1 (Kinlough-Rathbone et al. 1993). The high expression of PAR1, PAR3, and PAR4 influences pharmacology experiments. For example, the PAR1 inhibitor RWJ-58259 showed no significant antithrombotic effect in guinea pig thrombosis models in vivo (Andrade-Gordon et al. 2001). Taken together, guinea pigs have limitations as an animal model that need to be considered when evaluating PAR antagonists as potential antithrombotic drugs for humans. Genetically altered mice have been widely used in thrombosis studies to determine the contributions of platelet proteins in vivo. A mouse model with "humanized" PAR expression on their platelets would be an important tool for examining the specific individual contributions of PAR1 and PAR4 in vivo. Mice expressing PAR1 and PAR4 on their platelets would also serve as a convenient preclinical model for antiplatelet agents. To date, these efforts have been unsuccessful (Arachiche et al. 2014).

Take-Home Messages

- Thrombin is a potent platelet agonist that signals via proteolytic cleavage of protease activated receptors (PARs).
- PARs are G-protein-coupled receptors that signal through G_q and $G_{12/13}$ in platelets.
- PAR expression on platelets varies among species; human platelets express PAR1 and PAR4.
- PAR1 and PAR4 have distinct activation and signaling kinetics, which are influence via cooperation between PAR family members.

The P2 Receptors

Béatrice Hechler and Christian Gachet

Abstract

Adenine nucleotides (ADP and ATP) play crucial roles in the physiological process of primary hemostasis and in the development and extension of arterial thrombosis. They act on platelets through three distinct P2 receptors: the $P2Y_1$ and $P2Y_{12}$ receptors, which are G protein-coupled ADP receptors and the $P2X_1$ receptor, a ligand-gated cation channel activated by ATP. Each of these receptors plays a distinct part in platelet activation and thrombus formation and in arterial thrombosis. Due to its central role in the amplification of platelet responses to any stimulus, the $P2Y_{12}$ receptor is a major target for currently used potent antiplatelet drugs. Platelets also express the $P2Y_{14}$ receptor which, however, does not seem to play any part in platelet physiology. Beyond hemostasis and thrombosis, platelets also strongly contribute to acute and chronic inflammatory processes including atherosclerosis, restenosis, endotoxemia, sepsis, and asthma, where these P2 receptors have distinct functions, depending on their roles in platelet function and in other blood and vascular cell types.

Introduction

Extracellular nucleotides serve as intercellular or autocrine messengers regulating numerous physiological and pathological functions including neurotransmission, muscle contraction, bone metabolism, liver glycogen metabolism, cardiac function, vascular tone, inflammation and hemostasis, and thrombosis (Burnstock and Ralevic 2014). Blood platelets were perhaps the first cells to be demonstrated to respond to extracellular nucleotides, when adenosine 5′-diphosphate (ADP) was identified 50 years ago as a small molecule released from erythrocytes which caused platelets to adhere to glass (Hellem 1960; Gaarder et al. 1961) and induced platelet aggregation (Ollgard 1961; Born 1962). The importance of ADP in platelet activation and in hemostasis and thrombosis then became rapidly recognized. Although ADP is itself a weak agonist of platelet aggregation inducing only reversible responses, it is a necessary cofactor for the normal activation of platelets by strong agonists such as thrombin, collagen, or thromboxane A_2 (TXA_2) (Cattaneo et al. 1990; Kinlough-Rathbone et al. 1992; Lau et al. 1994), which induce its release from platelet dense granules where it is stored at a very high concentration.

Stimulation of washed platelets with ADP leads to shape change, reversible aggregation at physiological concentrations of calcium, and finally desensitization (Mustard et al. 1975; Packham and Rand 2011; Gachet 2001, 2008; Gachet and Hechler 2005; Gachet et al. 2006; Hechler and Gachet 2011). Transduction of the ADP signal involves a transient rise in free cytoplasmic calcium, due to the mobilization of internal stores, a secondary store-mediated influx, and the concomitant inhibition of adenylyl cyclase activity (Gachet and Cazenave 1991). In addition, adenosine 5′-triphosphate (ATP) induces an extremely rapid influx of calcium from the extracellular medium in association with platelet shape change (Mahaut-Smith et al. 2004; Sage et al. 1997).

Prior to the molecular identification of the various platelet receptors for ADP and ATP, their intracellular signaling events were thought to be mediated either by a unique

receptor called P2T (Hourani and Hall 1994; Gordon 1986) or by separate entities, one being coupled to the inhibition of cAMP formation (Macfarlane et al. 1983). During the early 1990s, these receptors were progressively identified. They belong to the P2 receptor family and consist of two classes of membrane receptors: P2X ligand-gated cation channels ($P2X_{1\text{-}7}$) and G protein-coupled P2Y receptors ($P2Y_{1,2,4,6,11,12,13,14}$) (Burnstock 2007). Four P2 receptor subtypes are present on blood platelets. These are the two G protein-coupled ADP receptors, $P2Y_1$ and $P2Y_{12}$, and the $P2X_1$ cation channel which is activated by ATP (Gachet 2006). Each of these receptors has a specific function in platelet activation and aggregation, which has implications for their involvement in hemostasis and thrombosis. Platelets also express the $P2Y_{14}$ receptor activated by UDP and UDP-glucose but so far its role, if any, remains elusive (Dovlatova et al. 2008) (Fig. 1).

Biology of the Platelet P2 Receptors

The $P2Y_1$ Receptor

The $P2Y_1$ receptor is broadly expressed in many cells and tissues. Its presence and role in platelets were established by the detection of mRNA in megakaryoblastic cell lines and by pharmacological studies using selective $P2Y_1$ antagonists (Hechler et al. 1998c; Léon et al. 1997). Platelets express approximately 150 $P2Y_1$ receptors per cell (Baurand et al. 2001; Ohlmann et al. 2010), which is very low as compared, for instance, to the thromboxane prostanoid (TP) receptors or the thrombin receptor PAR-1 (1000–2000 receptors/platelet) and probably explains why the signal induced by $P2Y_1$ activation is weak as compared to the signals of other G_q-coupled receptors. ADP is the preferred natural agonist of the $P2Y_1$ receptor, while ATP behaves as an antagonist in platelets

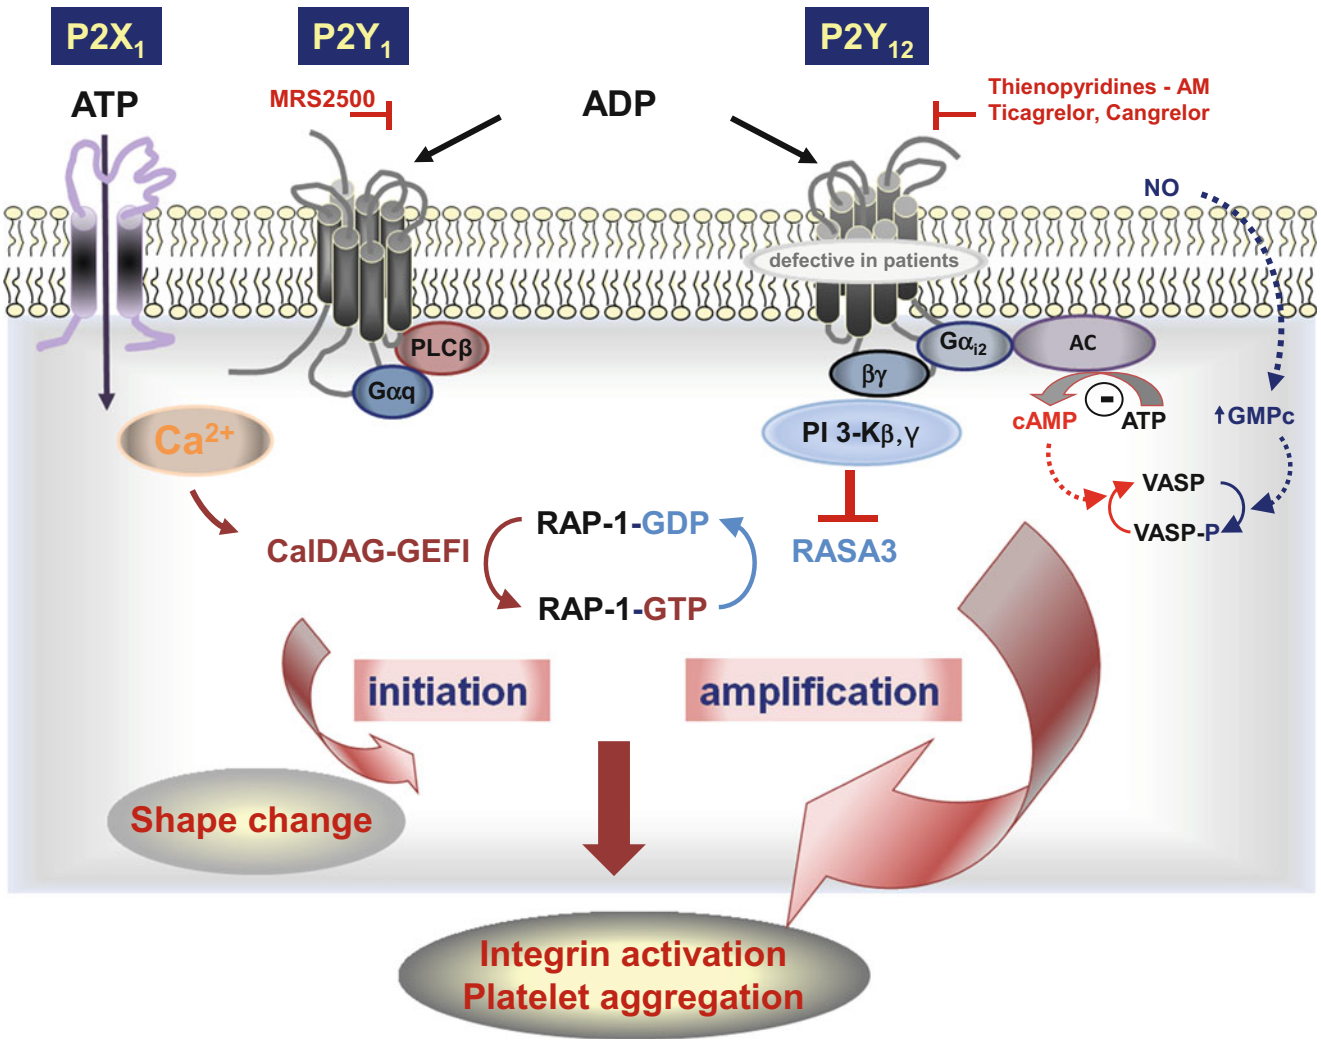

Fig. 1 Schematic illustration of the platelet P2 receptors and their respective role in platelet activation. *AM* active metabolite

(Léon et al. 1997; Hechler et al. 1998c) or as a poor partial agonist in heterologous transfected or reconstituted systems, depending on the receptor density (Waldo and Harden 2004).

The $P2Y_1$ receptor has the classical structure of a G protein-coupled receptor, and its crystal structure was reported recently (Zhang et al. 2014a, b). Its activation leads to the $G_{\alpha q}$-mediated activation of β-isoforms of phospholipase C (PLC) and to a transient increase in intracellular calcium concentrations, mainly through release of calcium into the cytoplasm from intracellular stores and additionally through influx of calcium from the external medium (Sage et al. 1990). These changes in cytosolic calcium concentration support the activation of calcium and diacylglycerol-regulated guanine-nucleotide exchange factor 1 (CalDAG-GEFI) (Crittenden et al. 2004; Stefanini and Bergmeier 2016; Stefanini et al. 2009), leading to rapid and reversible activation of the small GTPase RAP1 and integrin $\alpha_{IIb}\beta_3$ (Franke et al. 1997; Lova et al. 2002). This results in platelet shape change and weak, transient aggregation in response to ADP (Hechler et al. 1998b; Jin et al. 1998; Savi et al. 1998) (Fig. 1). Studies using $P2Y_1^{-/-}$ mice have confirmed its requirement for ADP-induced platelet shape change and aggregation (Fabre et al. 1999; Léon et al. 1999). In addition, the $P2Y_1$ receptor contributes to collagen-induced aggregation (Léon et al. 1999) and is required for collagen-induced platelet shape change when thromboxane A2 (TXA_2) formation is prevented (Mangin et al. 2004).

Platelets activated by ADP become refractory to restimulation, a phenomenon due to desensitization and internalization of the $P2Y_1$ receptor (Baurand et al. 2000, 2005; Hardy et al. 2005), through a mechanism dependent on receptor C-terminal phosphorylation sites, β-arrestin-2 interactions, and protein kinase C (PKC) activity (Hoffmann et al. 2008; Mundell et al. 2006; Reiner et al. 2009).

Overall, the $P2Y_1$ receptor mediates only weak responses to ADP but is nevertheless a crucial factor in initiating the platelet activation induced by ADP or collagen.

The $P2Y_{12}$ Receptor

The $P2Y_{12}$ receptor was cloned in 2001 (Hollopeter et al. 2001; Zhang et al. 2001). Like $P2Y_1$, it belongs to the G protein-coupled receptor family and is activated by ADP, while ATP and a wide range of its triphosphate analogues behave as antagonists (Kauffenstein et al. 2004; Bodor et al. 2003). Platelets express about 400 copies of the $P2Y_{12}$ receptor per cell (Ohlmann et al. 2013). This receptor plays a central role in the amplification of platelet responses to any stimulus, which explains why it is the molecular target of potent antiplatelet drugs including the thienopyridine compounds ticlopidine, clopidogrel, and prasugrel, which are prodrugs, and the direct antagonists ticagrelor and cangrelor (Cattaneo 2011; Michelson 2009). The $P2Y_{12}$ receptor is defective in patients with selective deficiencies of platelet activation in response to ADP (Cattaneo 2011). The tissue distribution of this receptor was long thought to be restricted to platelets and subregions of the brain. Further studies later revealed its expression and functions in microglial cells, vascular smooth muscle cells (VSMCs), dendritic cells (DCs), macrophages, and as yet unspecified leukocytes (Gachet 2012). The $P2Y_{12}$ receptor is responsible for completion of the platelet aggregation initiated by the $P2Y_1$ receptor (Hechler et al. 1998a) and for amplification of the aggregation induced by any other agents. Although ADP itself is unable to trigger secretion from platelet granules, its interaction with $P2Y_{12}$ greatly amplifies platelet secretion (Cattaneo et al. 1997, 2000) and also stabilizes platelet aggregates in vitro (Cattaneo et al. 1990; Eckly et al. 2001; Trumel et al. 1999) and thrombus formation in vivo (André et al. 2003). Conversely, $P2Y_{12}^{-/-}$ mice display a markedly prolonged bleeding time (Foster et al. 2001; Hollopeter et al. 2001), while patients with $P2Y_{12}$ deficiency may exhibit a severe bleeding diathesis (Cattaneo 2011), pointing to a central role of $P2Y_{12}$ in normal primary hemostasis (see below).

The $P2Y_{12}$ receptor activates a $G_{\alpha i2}$ G protein subtype (Ohlmann et al. 1995; Jantzen et al. 2001), which is a critical component of the signaling pathway for integrin $\alpha_{IIb}\beta_3$ activation (Jantzen et al. 2001; Hardy et al. 2004). Thus, $G_{\alpha i2}$ is responsible for the activation of two phosphoinositide 3-kinase (PI3-K) isoforms (PI3-K p110β and p110γ) which regulate $\alpha_{IIb}\beta_3$ activation (Gratacap et al. 2011; Hirsch et al. 2001; Jackson et al. 2005; Li et al. 2003; Martin et al. 2010). The downstream targets of PI3-K activation are the serine-threonine protein kinase B/Akt (PKB/Akt) and the small GTPase RAP1. This sustains $\alpha_{IIb}\beta_3$ activation (Larson et al. 2003; Lova et al. 2003, 2002; Woulfe et al. 2002) and is complementary to the CalDAG-GEFI-mediated rapid and reversible activation of RAP1 (Crittenden et al. 2004; Stefanini and Bergmeier 2016). Sustained activation of RAP1 is caused by downregulation of the RAP1 inhibitor RAP-GAP RASA3 upon stimulation of the $P2Y_{12}$ receptor (Stefanini et al. 2015). In addition, $G_{\alpha i2}$ also inhibits adenylyl cyclase activity and lowers elevated cAMP levels, which itself is not sufficient to cause platelet aggregation but facilitates it (Haslam 1973; Savi et al. 1996; Daniel et al. 1999). One may note that the inhibition of cAMP-dependent protein kinase A (PKA) leads to inhibition of the phosphorylation of the actin regulatory protein vasodilator-stimulated phosphoprotein (VASP) (Geiger et al. 1999). Although this protein does not play a key role in integrin activation, its phosphorylation state is used as a marker of the activation state of the $P2Y_{12}$ receptor, especially to monitor the effects of antiplatelet drugs inhibiting this receptor (Aleil et al. 2005; Mallouk et al. 2012) (Fig. 2).

Upon activation, a substantial fraction of membrane $P2Y_{12}$ receptors are rapidly internalized and recycled to the plasma membrane (Baurand et al. 2005). Whether this process is accompanied by a functional desensitization of $P2Y_{12}$ remains unclear. On the one hand, the $P2Y_{12}$ receptor has been shown to remain functional with conserved ability of

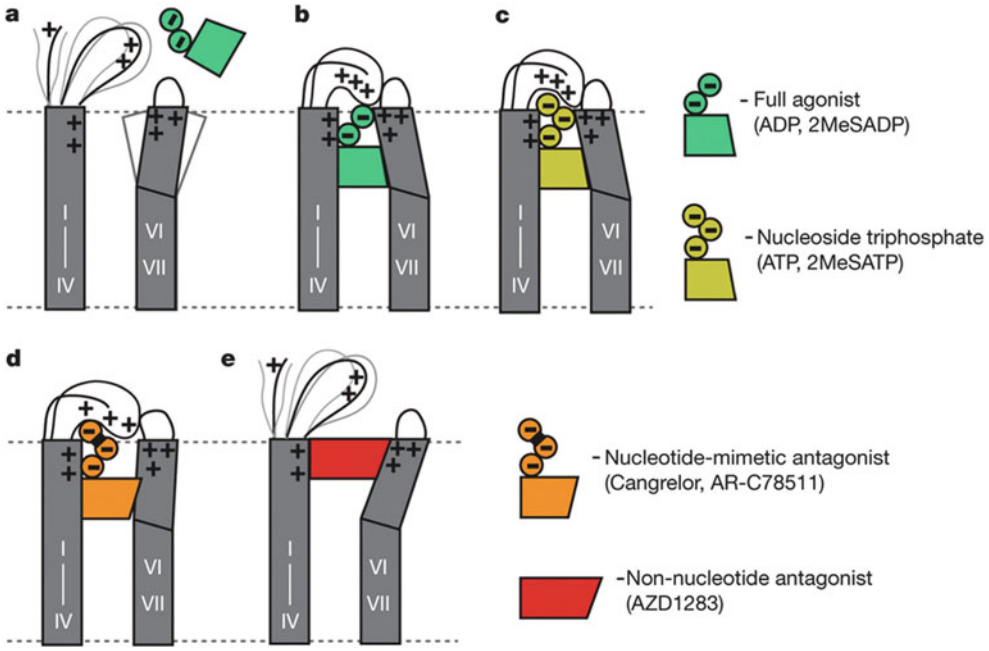

Fig. 2 Schematic illustration of conformational changes in $P2Y_{12}$ receptor extracellular region. (**a**) Unliganded (apo) state of $P2Y_{12}R$ with open entrance to the pocket and partially disordered lid. A number of partially uncompensated positive electrostatic charges among the side chains in the pocket ($R19^{Nterm}$, $K80^{2.60}$, $R93^{3.21}$, $K173^{ECL2}$, $K174^{ECL2}$, $R256^{6.55}$, and $K280^{7.35}$) disfavor formation of the stable closed state. (**b**) The closed state is stabilized by binding of nucleotide agonist (e.g., ADP, 2MeSADP). (**c**) A similar conformation with "lid" closure occurs in 2MeSATP structure and for various docked N^6 unsubstituted nucleoside triphosphate and triphosphate-mimetic ligands. (**d**) A helical reorganization is proposed for some N^6 substituted nucleoside triphosphate and triphosphate-mimetic ligands, especially with bulky N^6 substituents. (**e**) Binding of non-nucleotide antagonist AZD1283 blocks inward movement of helices VI and VII and prevents "lid" closure. ADP to cause amplification of the platelet aggregation induced by other agonists (Baurand et al. 2000, 2005). The in vivo consequence is that under conditions where platelets become refractory to stimulation by ADP, the $P2Y_{12}$ receptor remains functional and is able to promote their reactivity at sites of vessel injury, thus preventing loss of their hemostatic function. On the other hand, it has been reported that $P2Y_{12}$ receptors undergo functional desensitization, through the action of G protein-coupled receptor kinases (GRK) (Hardy et al. 2005; Hoffmann et al. 2008; Mundell et al. 2006). Further studies will be required to solve the apparent contradiction raised by these reports.

Co-activation of the $P2Y_1$ and $P2Y_{12}$ receptors is necessary for a full platelet aggregation response to ADP since separate inhibition of either receptor with selective antagonists results in a dramatic decrease in aggregation (Hechler et al. 1998b; Jin et al. 1998; Savi et al. 1998). However, the $P2Y_1$ and $P2Y_{12}$ receptors are differentially involved in the platelet aggregation induced by other agonists, with $P2Y_{12}$ supporting amplification of these responses and $P2Y_1$ playing only a minor role, except in the case of collagen-induced activation. The $P2Y_1$ and $P2Y_{12}$ receptors are also differentially involved in the procoagulant activity of platelets. Both receptors are indirectly implicated through platelet P-selectin exposure and the formation of platelet-leukocyte conjugates, which leads to leukocyte-tissue factor exposure (Léon et al. 2003, 2004). Nonetheless, only the $P2Y_{12}$ receptor is directly involved in the procoagulant activity of platelets through phosphatidylserine exposure at the surface of the cells (Storey et al. 2000; Léon et al. 2001, 2003).

The $P2Y_{14}$ Receptor

Platelets also express the $P2Y_{14}$ receptor for UDP-glucose (Dovlatova et al. 2008). However, no contribution of this receptor to any platelet function has so far been observed (Dovlatova et al. 2008), and no modulation of thrombosis has been detected using $P2Y_{14}^{-/-}$ mice in various models of arterial thrombosis (unpublished data).

The Platelet $P2X_1$ Receptor

The $P2X_1$ receptor is a ligand-gated cation channel responsible for the fast calcium entry induced by ATP (Mahaut-Smith et al. 2004; Vial et al. 1997). One characteristic of this receptor is that it desensitizes very quickly, thereby hampering the in vitro study of its functions in platelet activation. Furthermore, a lack of potent and selective $P2X_1$ receptor antagonists

has hindered the search for its functional role in hemostasis and thrombosis. Nevertheless, when desensitization of the $P2X_1$ receptor is prevented by addition of high concentrations of apyrase (ATP-diphosphohydrolase EC 3.6.1.5), the selective $P2X_1$ receptor agonist alpha, beta-methylene-ATP (αβMeATP) induces a rapid calcium influx leading to a transient shape change but is unable to trigger platelet aggregation (Rolf et al. 2001) (Fig. 1). These results have been confirmed in $P2X_1^{-/-}$ mice (Hechler et al. 2003). Conversely, overexpression of the human $P2X_1$ receptor in transgenic mice did not result in aggregation or secretion in response to αβMeATP, whereas the calcium influx and shape change were enhanced (Oury et al. 2003). In addition, the $P2X_1$ receptor participates in collagen- and shear-induced aggregation (Cattaneo et al. 2002; Hechler et al. 2003; Oury et al. 2004). Interestingly, the $P2X_1$ component of the calcium signal resulting from activation of GPVI by collagen appears to be resistant to inhibitors of platelet reactivity such as endothelium-released prostacyclin or nitric oxide, which might be relevant to thrombosis when inhibitory endothelial effects remain active (Fung et al. 2012). Recent data indicate a strong contribution of neutrophils to thrombus formation under specific experimental conditions, namely, laser-induced injury of cremaster arterioles (Darbousset et al. 2014), and a key role of the $P2X_1$ receptor in this setting. Whether both platelet and neutrophil receptors are involved in this thrombotic process remains to be assessed.

Genetic Polymorphisms of the $P2Y_1$ and $P2Y_{12}$ Receptors

$P2Y_1$ and $P2Y_{12}$ have been shown to display gene sequence variations which have been proposed to be associated with variable platelet responsiveness to ADP. In $P2Y_{12}$, polymorphisms in the intronic part of the gene have been described with no obvious impact on the coding sequence. Two haplotypes have been identified, H1 and H2, the latter being proposed to be linked to enhanced platelet reactivity to ADP (Fontana et al. 2003a) and to a diminished response to clopidogrel (Staritz et al. 2009; Shalia et al. 2013) and associated with increased risks for peripheral arterial disease (Fontana et al. 2003b) and coronary artery disease (Cavallari et al. 2007). However, these results were not confirmed in latter studies (Bura et al. 2006; Lev et al. 2007; Zee et al. 2008; Ulehlova et al. 2014; Tang et al. 2013; Namazi et al. 2012; Hetherington et al. 2005; Cuisset et al. 2007). A separate single-nucleotide polymorphism of the $P2Y_{12}$ gene (34C>T; rs6785930), located in the coding region of the *P2Y12* gene, associated with an increased risk of ischemic cerebrovascular events in persons with peripheral arterial disease has been described (Ziegler et al. 2005). However, other outcomes, such as premature myocardial infarction (Motovska et al. 2010b), adverse cardiovascular events (Zee et al. 2008; Tang et al. 2013), an increased risk of bleeding (Motovska et al. 2010a), or response to clopidogrel (Ulehlova et al. 2014), were not found to be related to this single-nucleotide polymorphism. In addition, ADP-induced maximal platelet aggregation in healthy subjects was not influenced (Kim et al. 2013). It thus appears that polymorphisms of the noncoding or coding region of the *P2Y12* gene do not have a major impact if any on the receptor function or on the individual responsiveness to clopidogrel.

In $P2Y_1$, a silent polymorphism was identified at position 1622 (A/G), which led to increased platelet aggregation in response to a low concentration of ADP in healthy volunteers carrying the G allele (Hetherington et al. 2005). Again, these results were not confirmed in later studies investigating healthy volunteers (Fontana et al. 2005; Kim et al. 2013) or CAD patients treated with clopidogrel (Sibbing et al. 2006).

Congenital Defects of the Platelet P2 Receptors

Patients with congenital deficiencies of ADP-induced platelet activation experience mild to severe bleeding. To date, only $P2Y_{12}$-deficient patients have been identified, and no $P2Y_1$ or $P2X_1$ deficiency has been observed. Congenital $P2Y_{12}$ receptor defects are autosomal recessive disorders, associated with quantitative or qualitative abnormalities of the receptor. They are characterized by a marked decrease in the number of platelet-binding sites for ADP, due to mutations disrupting the expression of the receptor (Cattaneo 2011; Cattaneo et al. 1992, 2000; Fontana et al. 2009; Hollopeter et al. 2001; Nurden et al. 1995; Shiraga et al. 2005), alterations in the ligand-binding site (Daly et al. 2009), or compromised $P2Y_{12}$ receptor recycling (Nisar et al. 2011; Patel et al. 2014). Other mutations are associated with a normal number of radioligand-binding sites but a dysfunctional receptor (Cattaneo et al. 2003; Lecchi et al. 2015; Remijn et al. 2007).

Platelet P2 Receptors as Targets for Antithrombotic Drugs

Among the three platelet P2 receptors, the $P2Y_{12}$ receptor is a key target for antithrombotic drugs in clinical use, while the $P2Y_1$ and $P2X_1$ receptors are at a preclinical stage of evaluation as potential targets for new antiplatelet agents.

The $P2Y_{12}$ Receptor

The $P2Y_{12}$ receptor is one of the most important targets for antiplatelet drugs and so far the only P2 receptor subtype to be an established target for drugs in clinical use (Gachet

2012). A full chapter of this book is devoted to $P2Y_{12}$ targeting drugs, and we will only summarize some key points. As already mentioned, the $P2Y_{12}$ receptor is targeted by the thienopyridine prodrugs ticlopidine, clopidogrel, and prasugrel and the direct antagonists ticagrelor and cangrelor.

The thienopyridine compounds need to undergo hepatic metabolization to generate active metabolites, which then covalently and selectively bind cysteine residues of the $P2Y_{12}$ receptor, thereby irreversibly inhibiting the receptor and precluding the binding of ADP (Gachet et al. 1995; Mills et al. 1992; Savi et al. 1994). Large-scale clinical trials have demonstrated the beneficial effects of thienopyridines in the prevention of major cardiac events after coronary artery stent insertion and in the secondary prevention of major vascular events in patients with a history of cerebrovascular, coronary, or peripheral artery disease (PAD) (Depta and Bhatt 2015; Franchi and Angiolillo 2015). The second-generation compound clopidogrel was first compared to aspirin in the CAPRIE trial in a very large population of patients with coronary artery disease (CAD), PAD, or stroke and found to be slightly more effective in reducing the combined risk of ischemic stroke, myocardial infarction, or vascular death at a dose of 75 mg/day, designed to ensure 50 % inhibition of the platelet aggregation induced by ADP (CAPRIE-Steering-Committee 1996). The success story of clopidogrel was boosted by its combination with aspirin in a series of trials which clearly established the efficiency of this dual antiplatelet therapy, especially in the setting of percutaneous coronary intervention (PCI). However, clopidogrel was found to display weaknesses with regard to its pharmacokinetic properties, i.e., a slow onset of the effect of the drug which, despite loading doses, requires several hours to achieve optimal inhibition of platelet functions, as likewise a slow offset due to the irreversible nature of its mode of action. Moreover, the important interindividual variability in the response to this drug is still a source of intense debate concerning the monitoring or not of high platelet reactivity during treatment with $P2Y_{12}$ antagonists (Trenk et al. 2013; Cattaneo 2012). Prasugrel is a third-generation thienopyridine compound having a higher efficacy and faster onset of action than clopidogrel. This is due to a change in the molecule and a slightly different metabolic pathway, which result in a better rate of active metabolite generation as compared to clopidogrel (Cattaneo 2010). A large-scale clinical trial, TRITON-TIMI 38, including 13,609 patients planned for PCI demonstrated the overall superiority of prasugrel (60 mg loading dose, 10 mg maintenance dose) over clopidogrel (300 mg loading dose, 75 mg maintenance dose), with a 19 % reduction of ischemic events and in particular a 52 % decrease in stent thrombosis (Wiviott et al. 2007), but with a 32 % increase in major bleeding, including fatal bleeding. Although not really surprising, these results had an important impact on the practices of interventional cardiologists (Bhatt 2009). Thus, despite its limitations and before they were clearly identified, clopidogrel proved that the $P2Y_{12}$ receptor is a very attractive target for antiplatelet drugs. Consequently, extensive research has now led to multiple compounds acting in different ways. Among these, in addition to prasugrel, two new classes of molecules have emerged as alternatives to clopidogrel, namely, the oral direct antagonist ticagrelor and the intravenous short-lived compound cangrelor.

The orally active compound ticagrelor (AZD6140) is a cyclopentyltriazolopyrimidine which is a reversible antagonist of the $P2Y_{12}$ receptor and also has an inhibitory effect on the type 1 equilibrative nucleoside transporter 1 (ENT1), thereby inhibiting adenosine reuptake. The subsequent increased concentration of extracellular adenosine may have pleiotropic beneficial effects in the vasculature (Cattaneo et al. 2014). Ticagrelor (180 mg loading dose followed by 90 mg twice a day) results in profound inhibition of platelet aggregation. Despite its reversible mode of action, complete offset of the effect of the drug requires 3–5 days. Ticagrelor afforded improved cardiovascular outcomes, including a reduction in myocardial infarctions and vascular events, as compared to clopidogrel in the PLATO trial (Wallentin et al. 2009). Moreover, in this study it led to a notable decrease in cardiovascular and total mortality, which was not observed in the TRITON-TIMI 38 trial comparing prasugrel and clopidogrel. The main adverse events associated with ticagrelor are dyspnea and ventricular pauses. Both these adverse events and the beneficial effect on mortality could be related to the additional "adenosine" action of ticagrelor. Cangrelor (ARC69931MX) is an intravenously administered ATP analogue, a $P2Y_{12}$ antagonist with a very short half-life, a very rapid onset of action (3–6 min), and a very short offset (30–60 min). In the CHAMPION-PHOENIX trial comparing the standard care (aspirin plus clopidogrel) with cangrelor added to aspirin plus clopidogrel, cangrelor was clearly of benefit in the prevention of death from any cause, myocardial infarction, and stent thrombosis (Bhatt et al. 2013). Thus, cangrelor has unique properties which make it a drug for acute situations and patients waiting for surgery. It might also be helpful in patients who cannot take oral medication.

The recent resolution of the X-ray structure of the $P2Y_{12}$ receptor revealed the behavior of the receptor depending on the binding of various ligands. Especially it showed that ADP and triphosphate nucleotide antagonists induce a similar closed conformation while the non-nucleotide antagonist AZD1283 (ethyl 6-(4-[(benzylsulfonyl)carbamoyl]piperidin-1-yl)-5-cyano-2-methylnicotinate) impaired the closed conformation by blocking an inward movement of helices VI and VII (Zhang et al. 2014a, b) (Fig. 2). This compound also bound an adjacent binding pocket. These new structural data will no doubt serve as a template for the design of original new $P2Y_{12}$ antagonists acting differently as compared to the existing drugs.

The $P2Y_1$ Receptor

The generation of $P2Y_1^{-/-}$ mice has helped to reveal the key role of this receptor in arterial thrombosis, which may be surprising in view of its apparently modest role in platelet activation. Mice with $P2Y_1$ deficiency display resistance to thrombosis in various models such as systemic thromboembolism induced by infusion of a mixture of collagen and adrenaline (Fabre et al. 1999; Léon et al. 1999) or of tissue factor (Léon et al. 2001) or localized thrombosis after ferric chloride- or laser-induced injury of mesenteric arteries (Lenain et al. 2003). Since the $P2Y_1$ receptor is also expressed by endothelial cells, mice with selective invalidation of $P2Y_1$ in either platelets or endothelial cells have been generated to elucidate the respective contributions of the $P2Y_1$ receptors of these cell types to thrombosis. Thus, mice lacking the platelet $P2Y_1$ receptor only were equally well protected in the model of ferric chloride-induced thrombosis as whole-body $P2Y_1^{-/-}$ mice (unpublished data), indicating that the platelet receptor is probably entirely responsible for the contribution of $P2Y_1$ to thrombosis.

Several selective antagonists of the $P2Y_1$ receptor have been described (Jacobson and Boeynaems 2010) which display various affinities for $P2Y_1$, namely, the adenine nucleotide analogues A2P5P, A3P5P, and A3P5PS (Boyer et al. 1996), MRS2179 (N^6-methyl-2′-deoxyadenosine 3′,5′-bisphosphate) (Baurand and Gachet 2003; Baurand et al. 2001; Boyer et al. 1998; Kim et al. 2003; Léon et al. 2001), MRS2279 (Boyer et al. 2002), and MRS2500 (2-iodo-N^6-methyl-(N)-methanocarba-2′-deoxyadenosine 3′,5′-bisphosphate) (Cattaneo et al. 2004; Kim et al. 2003). The latter displays the highest affinity for $P2Y_1$ and leads to inhibition of thrombosis in treated animals (Hechler et al. 2006). However, due to its limited bioavailability during long-term treatment, new $P2Y_1$ receptor antagonists with an improved pharmacokinetic profile need to be developed. Several novel antagonists derived from non-nucleotide chemical scaffolds have been reported, some of them being active after oral administration (Chao et al. 2013; Costanzi et al. 2012; Hu et al. 2014; Jeon et al. 2014; Morales-Ramos et al. 2008; Pfefferkorn et al. 2008; Qiao et al. 2014, 2013; Thalji et al. 2010; Wang et al. 2013; Yakovlev et al. 2014; Yang et al. 2014). Whether these compounds fulfill the criteria of stability and bioavailability in vivo will require more extensive pharmacological characterization in animal models. A function blocking antibody targeting the $P2Y_1$ receptor, called EL2Ab, has recently been described (Karim et al. 2015). EL2Ab-inhibited ADP-induced platelet aggregation in a dose-dependent manner and prevented occlusive thrombosis, in a similar way to MRS2500, when injected IV 1 h before ferric chloride injury (Karim et al. 2015).

The X-ray crystal structure of the human $P2Y_1$ receptor revealed two distinct ligand-binding sites (Zhang et al. 2015). Thus, the nucleotide antagonist MRS2500 binds to a site at the top of the TM domain between TM6 and TM7 which also involves the N terminus and extracellular loop 2. The non-nucleotide antagonist 1-(2-[2-(tert-butyl)phenoxy] pyridin-3-yl)-3-[4-(trifluoromethoxy)phenyl]urea (BPTU), instead of interacting within the TM bundle, binds to the outside of the receptor at the lipid interface between TM1, TM2, and TM3. This is the first structural characterization of a selective, high-affinity G protein-coupled receptor ligand located entirely outside the helical bundle. Clearly, this $P2Y_1$ crystal structure will open up new possibilities to target novel sites outside the conventional ligand-binding pocket for the development of new $P2Y_1$ antagonists (Fig. 3).

It is worthy of note that inhibition of the $P2Y_1$ receptor results in only moderate prolongation of the bleeding time,

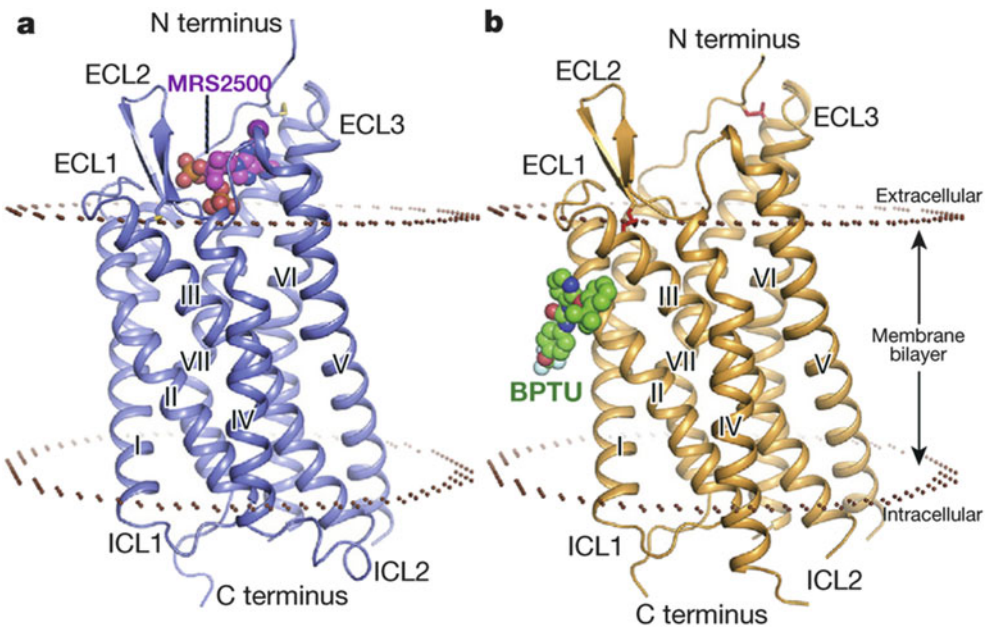

Fig. 3 Structures of the $P2Y_1R$-MRS2500 and $P2Y_1R$-BPTU complexes. (**a**, **b**) Side view of the $P2Y_1R$-MRS2500 (**a**) and $P2Y_1R$-BPTU (**b**) structures. The receptor is shown in *blue* (**a**) and *orange* (**b**) cartoon representation. The ligands MRS2500 and BPTU are shown in sphere representation with *magenta* and *green* carbons, respectively. The disulfide bonds are shown as *yellow* (**a**) and *red* (**b**) sticks. Reprinted by permission from Macmillan Publishers Ltd: [Nature Publishing Group] (Zhang et al. 2015), copyright (2015)

which could be advantageous in terms of safety as compared to inhibition of the $P2Y_{12}$ receptor. Overall, consideration of the role of $P2Y_1$ in experimental thrombosis would provide the rationale for suggesting that this receptor might be a relevant target for new antiplatelet compounds.

The $P2X_1$ Receptor

The important role of this receptor in thrombosis was not anticipated and was only revealed through in vivo evaluation of $P2X_1^{-/-}$ mice. These animals display resistance to the systemic thromboembolism induced by injection of a mixture of collagen and adrenaline and to the localized arterial thrombosis triggered by laser-induced injury of the vessel wall of mesenteric arteries (Hechler et al. 2003). $P2X_1^{-/-}$ mice are also less susceptible to the systemic thromboembolism triggered by tissue factor, i.e., in a thrombin-dependent system (unpublished data). These results were confirmed using the $P2X_1$ antagonist NF449 (Hechler et al. 2005; Kassack et al. 2004). Conversely, increased systemic thrombosis has been observed in mice overexpressing the human $P2X_1$ receptor (Oury et al. 2003). Finally, $P2X_1^{-/-}$ mice exhibit no prolongation of the bleeding time as compared to WT animals, indicating that they conserve normal hemostasis (Hechler et al. 2003). The $P2X_1$ receptor may therefore be considered as a potential target for safe antiplatelet drugs. Here also, however, the current lack of suitable selective chemical tools hampers the preclinical assessment of its relevance as compared to other targets for new antiplatelet drugs.

P2 Receptors in Inflammation

Platelets play an important part in the modulation of various inflammatory responses including chronic responses like atherosclerosis and acute responses such as sepsis, endotoxemia, or allergic asthma (Semple et al. 2011; Gawaz et al. 2005; Idzko et al. 2015). Therefore, in addition to acting as antithrombotics, antagonists and inhibitors of the various platelet P2 receptors could also have anti-inflammatory effects. Moreover, the $P2Y_1$, $P2Y_{12}$, and $P2X_1$ receptors are expressed by cells of the immune system and by vascular cells. Specifically, the $P2Y_{12}$ receptor is present on VSMCs (Harada et al. 2011; Wihlborg et al. 2004), DCs (Ben Addi et al. 2010), and some as yet poorly characterized subtypes of leukocytes (Gachet 2012); the $P2Y_1$ receptor is expressed on vascular endothelial cells, VSMCs, and leukocyte populations including macrophages (Marques-da-Silva et al. 2011), and the $P2X_1$ receptor is present on VSMCs and neutrophils (Lecut et al. 2009; Maître et al. 2015). Thus, these P2 receptors are also directly involved in the modulation of inflammation and in immune responses during thrombus formation, independently of platelet-related processes (Idzko et al. 2014; Ferrari et al. 2015).

The $P2Y_{12}$ Receptor in Inflammation

The platelet $P2Y_{12}$ receptor contributes to inflammatory responses, since reduced levels of circulating inflammatory mediators (TNFα, C-reactive protein), decreased exposure of P-selectin and CD40L, diminished formation of platelet-leukocyte aggregates, and subsequently less tissue factor exposure are observed in mice or patients receiving clopidogrel (Cattaneo 2015; Gachet 2012; Steinhubl et al. 2007). These signaling events are probably responsible for the important role of the platelet $P2Y_{12}$ receptor in restenosis (Evans et al. 2009) and atherosclerosis (Li et al. 2012; West et al. 2014). In the latter case, however, an additional contribution from the $P2Y_{12}$ receptor of VSMCs has been reported, based on studies of $P2Y_{12}^{-/-}$ mice and bone marrow chimeric mice expressing either vessel wall or platelet $P2Y_{12}$ (Li et al. 2012; West et al. 2014). In the particular form of transplant atherosclerosis due to chronic rejection of carotid artery allografts, $P2Y_{12}^{-/-}$ mice and mice treated with clopidogrel displayed reduced neointima formation in the WT grafted vessel with a reduction of infiltrating host-derived smooth muscle-like cells (SMLCs) and leukocytes (Abele et al. 2009; Harada et al. 2011). Nevertheless, in these studies it was difficult to distinguish the effects of the platelet $P2Y_{12}$ receptor from those of the receptor expressed on other cell types, namely, DCs, macrophages, or smooth muscle cells, which have been reported to display $P2Y_{12}$-dependent migration properties (Abele et al. 2009; Harada et al. 2011).

In the context of allergic asthma, platelets are required for the recruitment of inflammatory cells to the lungs and remodeling of the airway wall (Gresele et al. 1982; Idzko et al. 2015). However, divergent results have been reported concerning the role of the platelet $P2Y_{12}$ receptor. On the one hand, the $P2Y_{12}$ receptor did not appear to be involved in allergic inflammation in ovalbumin-challenged mice (Amison et al. 2015). On the other hand, in a mouse model of leukotriene E4 (LTE4)-induced asthma, the platelet $P2Y_{12}$ receptor played an important part, since the pro-asthmatic action of LTE4 was abrogated by platelet depletion or treatment with clopidogrel or in $P2Y_{12}^{-/-}$ mice (Paruchuri et al. 2009). The detailed mechanism remains to be established, although the association of $P2Y_{12}$ with an as yet unidentified coreceptor of the cysteinyl leukotriene family was invoked (Paruchuri et al. 2009). The importance of the $P2Y_{12}$ receptor in asthma is further supported by recent clinical observations. Thus, in a large family-based asthma cohort, $P2Y_{12}$ receptor variants were associated with altered lung function, while in a randomized placebo-controlled trial, prasugrel tended to decrease the

bronchial hyperreactivity to mannitol of patients with allergic asthma (Cattaneo 2015). Obviously, further investigations will be required to clarify the part played by the $P2Y_{12}$ receptor in asthma and to determine whether the discrepancies might be related to differences in the mouse models of allergic inflammation or to the use of $P2Y_{12}$ receptor antagonists versus $P2Y_{12}^{-/-}$ mice.

Recent findings point to a deleterious effect of the platelet $P2Y_{12}$ receptor in LPS-induced endotoxemia or sepsis. Indeed, clopidogrel attenuated inflammation in a rat model of LPS-induced endotoxemia (Hagiwara et al. 2011), while ticagrelor inhibited platelet-neutrophil aggregate formation, neutrophil recruitment, and lung damage in mice subjected to cecal ligation and puncture (CLP), which results in sepsis (Rahman et al. 2014). In sharp contrast, a protective role of the $P2Y_{12}$ receptor has been reported in a slightly different endotoxemia model triggered by repeated administration of LPS on four consecutive days, with $P2Y_{12}^{-/-}$ mice displaying a higher circulating neutrophil count, an enhanced inflammatory state, and more severe lung injury as compared to WT mice (Liverani et al. 2014). However, since platelet consumption was similar in WT and $P2Y_{12}^{-/-}$ mice, the authors suggested the involvement of leukocyte $P2Y_{12}$ receptors rather than the platelet receptor. Alternatively, since healthy untreated $P2Y_{12}^{-/-}$ mice displayed significantly smaller numbers of neutrophils in the spleen and bone marrow, the $P2Y_{12}$ receptor could regulate the cellular composition of the bone marrow and spleen, which might alter their responsiveness to inflammation (Liverani et al. 2014). Further studies will be needed to make all the relevant comparisons between the models, the drugs administered, and/or the use of receptor-deficient mice, in order to better characterize the role of this receptor in various settings and the impact of $P2Y_{12}$ targeting drugs.

Overall, although the data clearly demonstrate the importance of the inflammatory response in the context of arterial thrombosis, it is difficult to distinguish the contribution of the platelet $P2Y_{12}$ receptor from that of the receptor expressed on other vascular and blood cells, in the case of patients treated with any $P2Y_{12}$ targeting drug. Whether these drugs will be used beyond their current indications in atherothrombosis is not known.

The $P2Y_1$ Receptor in Inflammation

The platelet $P2Y_1$ receptor, like the $P2Y_{12}$ receptor, contributes to leukocyte activation and tissue factor exposure through its participation in platelet P-selectin exposure and the formation of platelet-leukocyte conjugates (Léon et al. 2003). These events appear to be important for the contribution of the platelet $P2Y_1$ receptor to leukocyte recruitment to the lung tissue during inflammation of the airways in allergic mice (Amison et al. 2015). However, it is likely that the $P2Y_1$ receptors present on other cell types such as leukocytes or endothelial cells also contribute to this inflammatory process. Thus, the endothelial $P2Y_1$ receptor has been found to play an important pro-inflammatory role through its contribution to the TNFα-induced upregulation of adhesion molecules (P-selectin, VCAM-1, ICAM-1), which occurs in a P38 MAPK-dependent manner and results in the recruitment of monocytes in vitro and in vivo (Zerr et al. 2011). This was confirmed in mice with selective invalidation of the endothelial $P2Y_1$ receptor (unpublished data). In addition, the endothelial $P2Y_1$ receptor contributes to the development of atherosclerosis in $ApoE^{-/-}$ mice (Hechler et al. 2008). This is somewhat paradoxical as endothelial $P2Y_1$ is known to regulate the vascular tone by activating endothelial nitric oxide synthase (Hess et al. 2009; da Silva et al. 2009), a beneficial relaxation mechanism thought to be opposed to deleterious inflammation. The blood pressure was measured in $P2Y_1^{-/-}$ mice, and no difference was found with respect to WT animals (data not shown). The signaling mechanisms underlying these effects are not fully understood but involve the transactivation of surface receptors like the EGF receptor (Buvinic et al. 2007) or tyrosine kinases such as Flt3 (Kalwa et al. 2014). Whether these mechanisms apply to the TNFα receptor remains to be investigated.

The $P2Y_1$ receptor has also been shown to be present on VSMCs, where it contributes to their proliferation and migration in vitro. This could be relevant for the intimal hyperplasia observed in a vein graft model in mice (Liu et al. 2015). In this case, a contribution from the $P2Y_1$ receptors present on platelets and macrophages cannot be excluded. Macrophages would indeed appear to be required, as their depletion abrogated hyperplasia (Liu et al. 2015), while recent data indicated a role of the $P2Y_1$ receptor in the phagocytic and migration activity of macrophages (Marques-da-Silva et al. 2011).

Altogether the $P2Y_1$ receptor could represent an attractive and original target for drugs with multiple sites of action, to treat atherothrombosis and other inflammatory diseases. Nonetheless, a potential side effect of $P2Y_1$ antagonists on vascular tone and blood pressure should be kept in mind.

The $P2X_1$ Receptor in Inflammation

As already mentioned, the $P2X_1$ receptor expressed by neutrophils contributes to thrombus formation in a context of inflammation. This has been shown in a specific model of neutrophil-dependent thrombosis of arterioles triggered by laser injury, where activation of the neutrophil $P2X_1$ receptor appeared to be indispensable for neutrophil recruitment and subsequent fibrin generation at the site of vessel injury (Darbousset et al. 2014).

One may note that the neutrophil $P2X_1$ receptor plays an important part in facilitating the neutrophil chemotaxis

induced by various chemoattractants, possibly by favoring contraction and retraction of the trailing uropod (Lecut et al. 2009). This is in accordance with its recently discovered role in endotoxemia in mice, where the $P2X_1$ receptor was found to be important for neutrophil emigration from venules and systemic inflammation, thereby contributing to tissue damage and mortality (Maître et al. 2015). Whether the platelet and/or neutrophil $P2X_1$ receptor may participate in other conditions of vascular inflammation is an open question.

Conclusion

The effects of adenine nucleotides on platelets are mediated by three distinct receptors, $P2Y_1$, $P2Y_{12}$, and $P2X_1$, each of which plays a specific role in platelet functions and arterial thrombosis. The platelet $P2Y_{12}$ receptor is an established target for antithrombotic drugs, while the $P2Y_1$ and $P2X_1$ receptors constitute attractive targets at a preclinical stage of evaluation. In addition, the platelet P2 receptor subtypes appear to be essential for the development of various pathological processes involving acute or chronic inflammation. The generation of mice presenting tissue-specific deletion of these P2 receptor subtypes will help to define their specific functions under physiological and pathological conditions. New structure-activity studies based on the crystal structures of the $P2Y_1$ and $P2Y_{12}$ receptors should help to discover more suitable antagonists. The perspective exists that these P2 receptors could also represent potential therapeutic targets for the treatment of inflammatory diseases.

Take-Home Messages

- Three distinct P2 receptors are responsible for the physiological effects of adenine nucleotides during platelet activation: the P2Y1 and P2Y12 receptors, which are G protein-coupled ADP receptors and the P2X1 receptor, a ligand-gated cation channel activated by ATP.
- The P2Y1 receptor mediates only weak responses to ADP but is nevertheless a crucial factor in initiating platelet activation by ADP or collagen.
- The P2Y12 receptor plays a central role in the amplification of platelet responses to any stimulus.
- The P2X1 receptor participates in collagen- and shear-induced aggregation.
- The P2Y12 receptor is a major target for currently used potent antiplatelet drugs.
- These three P2 receptor subtypes contribute to acute or chronic inflammation.

Platelet Prostanoids and their receptors

Susanne Fries and Tilo Grosser

Abstract

The prostanoids, which include the prostaglandins (PGs) and thromboxane (Tx)A_2, are a family of locally acting lipid mediators. Two isozymes, cyclooxygenase (COX)-1 and COX-2, of which only COX-1 is expressed in mature platelets, form an unstable intermediate product, PGH_2, from arachidonic acid released from membrane phospholipids. At least nine PG synthases metabolize PGH_2 further to five biologically active prostanoids, which each act through one or more specific G-protein coupled receptor.

These components of the arachidonic acid biosynthetic response pathway all underlie cell-specific regulation and affect platelet biology through a diverse array of signaling events. The primary prostanoid synthesized by platelets is TxA_2, which via the TP receptor acts as an amplification signal to recruit further platelets to a growing blood clot. Patients with genetic defects in the TxA_2 pathway have a mild bleeding disorder, and pharmacological suppression of TxA_2 formation or signaling causes platelet inhibition. Suppression of TxA_2 formation is also the mechanism by which aspirin reduces the incidence of myocardial infarction and stroke. Prostacyclin (PGI_2) acting through the IP receptor is the most potent endogenous platelet inhibitor. It is formed by COX-1 and COX-2 in the vasculature and serves to constrain platelet clotting to the site of vascular injury. The inhibition of COX-2-dependent PGI_2 formation by COX-2-selective nonsteroidal anti-inflammatory drugs (NSAIDs) explains their increased risk of myocardial infarction and stroke. The role of other prostanoids in platelet biology is less established. PGD_2 is synthesized upon platelet activation in a process that involves both platelet COX-1 and plasma PGD synthase. Acting through its inhibitory DP_1 receptor on platelets, it may afford a self-regulating response to thrombogenic stimuli. PGE_2, which is formed in smaller amounts than PGD_2 during clotting, can either enhance platelet activation, via the EP_3 receptor, or inhibit platelet aggregation via the IP or possibly EP_2 or EP_4 receptors. Platelet EP receptor signaling has been hypothesized to play a role in modulating platelet function in fetal and neonatal circulation and in atherosclerosis. Prostaglandin $F_{2\alpha}$ is also formed during platelet activation by various agonists, and higher concentrations inhibit platelets through cross-reaction with other prostanoid receptors.

Prostanoid Biosynthesis

Arachidonic Acid Release The precursor of the prostanoids, arachidonic acid, is released from membrane phospholipids by the phospholipase (PL)A_2 enzymes (Burke and Dennis 2009). Group (G)IVA PLA_2 is the main isoform

expressed in the platelet cytosol (Kramer et al. 1986). Activation by intracellular calcium and/or phosphorylation signals initiates translocation of GIVA PLA_2 to the cell membrane, where it cleaves arachidonic acid from the second carbon of the glycerol moiety of the glycerophospholipids (Channon and Leslie 1990; Lin et al. 1993; Kramer et al. 1996; Canobbio et al. 2004; Garcia et al. 2005). Vascular cells express several additional PLA_2 isoforms including calcium-dependent and calcium-independent forms, and secretory PLA_2s are found in atherosclerotic lesions (Oestvang and Johansen 2006; Alberghina 2010). Arachidonic acid released from the lipid membrane by the PLA_2s is available for prostanoid metabolism by the cyclooxygenases (COXs), which are membrane-anchored proteins (Smyth et al. 2008). Alternatively other lipid mediators in the eicosanoid class may be formed through lipoxygenase, cytochrome P450, or nonenzymatic pathways (Smyth et al. 2010), and free arachidonic acid can be reincorporated into phospholipids (Lands 2000) (Fig. 1).

Cyclooxygenases Conversion of arachidonic acid into the prostanoids PGI_2, TxA_2, PGD_2, PGE_2, and $PGF_{2\alpha}$ involves redox and rearrangement reactions by the COXs and PG synthases (Smith et al. 2011). The COXs first incorporate oxygen into arachidonic acid resulting in the formation of a labile intermediate peroxide, PGG_2, that does not leave the enzyme. In a second step, PGG_2 is reduced to the endoperoxide product PGH_2 (Smith et al. 2000). Hence, the COXs are technically PGH or PGG/H synthases. Their official gene names are prostaglandin-endoperoxide synthase 1 and 2, and their gene symbols are *PTGS1* and *PTGS2*. Catalytic function of the COXs requires dimerization, but only one monomer contains a heme group which acts as an electron source in catalyzing the formation of PGH_2 (Yuan et al. 2006). The other monomer regulates the reaction kinetics allosterically (Zou et al. 2012). COX-1 and COX-2 are highly homologous but metabolize arachidonic acid with distinct kinetics probably due to differential allosteric regulation. Thus, COX-1 is thought to be in a constantly inhibited state which requires high arachidonic acid concentrations to initiate PG biosynthesis (So et al. 1998; Smyth et al. 2005; Smith et al. 2011), while COX-2 is activated in response to much lower substrate concentrations (Chen et al. 1999). This may explain the similar contribution of both isoforms to prostanoid production in the vessel wall, although COX-1 is more abundantly expressed.

COX-2 is more readily inducible by inflammatory stimuli than COX-1 (O'Banion et al. 1992), and it is the major source of PGs mediating pain and inflammation (Smyth et al. 2005). However, COX-2 is also constitutively expressed in many uninflamed tissues (Yamagata et al. 1993; Harris et al. 1994; Breder et al. 1995; Kaufmann et al. 1996; Willingale et al. 1997). For example, both isoforms are coexpressed in uninflamed embryonic and adult blood vessels (Grosser et al. 2002; Ricciotti et al. 2013) and both contribute to vascular formation of PGI_2 (Yu et al. 2012). Mature platelets express only COX-1 (Patrignani et al. 1999). However, megakaryocytes, and immature platelets released in clinical conditions of accelerated platelet turnover, also express COX-2 (Rocca

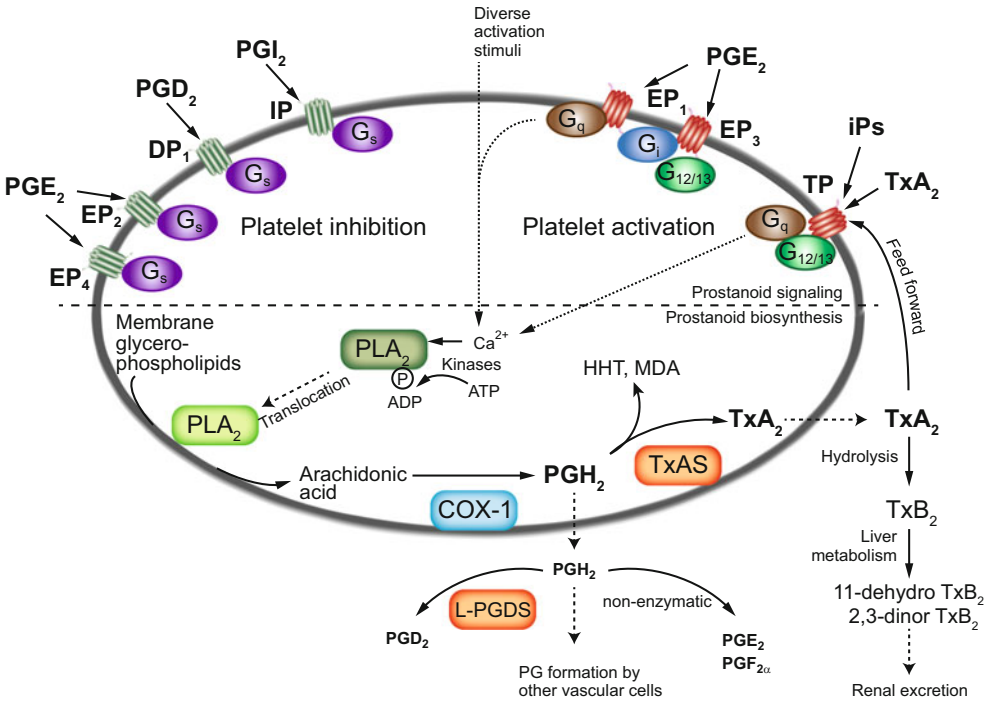

Fig. 1 Prostanoid biosynthesis and signaling in platelets. *Abbreviations*: *PG* prostaglandin, *COX* cyclooxygenase, *PL* phospholipase, *HHT* 12-L-hydroxy-5,8,10-heptadecatrienoic acid, *MDA* malondialdehyde, *iPs* isoprostanes

et al. 2002; Zimmermann et al. 2003). Splice variants of COX-2 mRNA, which would result in non- or dysfunctional proteins if translated, have been detected in mature platelets (Censarek et al. 2007). However, the role of COX-2 protein and RNA variants in platelet development and function is not understood.

Cyclooxygenase Inhibition Most NSAIDs cause substantial inhibition of platelet COX-1 (Chen et al. 2013). However, only a small number of NSAIDs, including naproxen and aspirin, cause sustained platelet inhibition. Aspirin acetylates serine-529 in the substrate-binding channel of the catalytically active COX-1 monomer (Pedersen and FitzGerald 1984). This inactivates the enzyme irreversibly and consequently depresses the formation of TxA_2 (Patrono et al. 2005; Fitzgerald and FitzGerald 2013). Because platelets are anucleate, they have only limited capacity to form new proteins. Thus, platelets exposed to aspirin are inhibited for their lifetime, and new platelets have to be released into the circulation to restore function. Inhibition of platelet COX-1 explains both aspirin's protective effect against thrombotic events and its bleeding complications (Patrono et al. 2005; Patrono 2015). COX-1 acetylation can be monitored as a direct biomarker of the pharmacological response to aspirin using mass spectrometry technology originally developed to quantify posttranslational protein modifications (Li et al. 2014; Patrignani et al. 2014). COX-1 acetylation remains close to maximal for about 2 days after a single analgesic dose (325 mg and above) of aspirin and results in complete inhibition of thromboxane formation and platelet aggregation induced by the COX-1 substrate arachidonic acid (Li et al. 2014). Cumulative inhibition of platelet Tx formation occurs over days when aspirin is administered at low doses (100 mg daily and below). This is the mechanism by which low doses of aspirin lead to platelet inhibition and consequent cardioprotection (Pedersen and FitzGerald 1984).

All other NSAIDs are reversible COX inhibitors. Naproxen is a time-dependent inhibitor with high affinity, slow dissociation kinetics, and a prolonged pharmacological effect (Rosenstock et al. 2001; Capone et al. 2005; Rimon et al. 2010; Li et al. 2014). Its half-life in the circulation is comparatively long and highly variable (ranging from 9 (Palazzini et al. 1990) to 25.7 h (Vree et al. 1993)), so that platelet inhibition following naproxen consumption may be prolonged in some patients. Piroxicam is another very long-acting, but eventually reversible COX inhibitor (Grosser et al. 2011). Naproxen and also shorter-acting NSAIDs, including ibuprofen, may compete with aspirin for access to the arachidonic acid-binding channel and prevent aspirin from acetylating its target serine residue (Catella-Lawson et al. 2001; Rosenstock et al. 2001; Capone et al. 2005; Gladding et al. 2008; Hohlfeld et al. 2008; Galliard-Grigioni and Reinhart 2009; Angiolillo et al. 2011; Anzellotti et al. 2011; Li et al. 2014). This drug-drug interaction results in a form of acquired aspirin nonresponse or "resistance" (Grosser et al. 2013).

Prostanoid Biology

Thromboxane The predominant prostanoid biosynthetic pathway in platelets is the formation of TxA_2. The membrane-bound hemoprotein thromboxane synthase (TxS) rapidly synthesizes large quantities of TxA_2 in response to platelet activation. COX-1-derived PGH_2 formation is the rate-limiting step. TxA_2 is not stored in platelets, and the biosynthetic capacity greatly exceeds the amounts needed to activate platelets (Reilly and FitzGerald 1987). This is consistent with its function as a feed-forward signal in the recruitment of additional platelets to a growing clot (FitzGerald 1991). TxA_2 is rapidly hydrolyzed ($t_{½}$ ~30 s) to the stable and biologically inactive compound TxB_2. TxB_2 is eliminated from the circulation through liver metabolism, resulting in urinary excretion of metabolites including the two most abundant compounds, 11-dehydro TxB_2 and 2,3-dinor TxB_2. A consequence of the excess Tx synthetic capacity is that the concentration-response relationship between COX-1 inhibition and functional platelet inhibition is quite steep (Reilly and FitzGerald 1987). Thus, more than 95 % of the enzymatic capacity of COX-1 must be inhibited before a change in platelet function can be expected. This explains why continuous and almost complete COX-1 inhibition, as is achieved with the irreversible inhibitor aspirin, is cardioprotective, but reversible, partial inhibition with short-acting NSAIDs such as ibuprofen is not.

Thromboxane acts through the TP receptor, which is encoded by a single gene product transcribed into two splice variants, TP_α and TP_β (Narumiya and FitzGerald 2001; Coyle et al. 2002). The TP_α protein is the predominant isoform translated in platelets, although both transcripts are detectable (Habib et al. 1999). In platelets, the TP_α interacts predominantly with G_q and $G_{12}/_{13}$. G_q activates protein kinase C-dependent pathways, which facilitate platelet aggregation, whereas G_{12}/G_{13}-mediated regulation of myosin light chain phosphorylation participates in receptor-induced platelet shape change. In expression systems, differences in G interactions and desensitization characteristics between the splice variants were observed (Vezza et al. 1999; Parent et al. 2001). Under such conditions, TP_α, but not TP_β, may couple to G_h, and TP_α may activate G_s, while TP_β interacts with G_i (Vezza et al. 1999; Parent et al. 2001). Heterodimerization of the TP with

other receptors, such as the IP, may modulate downstream signaling (Wilson et al. 2004).

Deletion of the TP receptor in the mouse prolongs bleeding time, renders platelets unresponsive to TP agonists, and modifies their response to collagen, but not to ADP (Thomas et al. 1998). Similar phenotypes were described in humans with genetically disrupted TP signaling. For example, a mutation in the first intracellular loop of the TP receptor is associated with a mild bleeding diathesis and resistance of platelet aggregation in response to TP agonists (Hirata et al. 1994). The TP undergoes rapid desensitization following its own activation (homologous desensitization), or through other mediators (heterologous desensitization), which terminates the receptor response (Nakahata 2008). This involves TP phosphorylation followed by vesicular internalization and subsequent downregulation of the receptor protein (Nakahata 2008). In addition to TxA_2, isoprostanes (iPs), which are free radical-catalyzed nonenzymatically formed products of arachidonic acid, may activate the TP (Audoly et al. 2000). Prevention of TP activation through iPs despite suppression of TxA_2 by aspirin was the rationale underlying the development of long-acting TP receptor antagonists as platelet inhibitors (Fig. 2). However, early attempts to develop such molecules failed. Persistent and complete platelet inhibition (as is afforded by irreversible acetylation of COX-1 by aspirin) was not achieved due to inadequate pharmacodynamic properties. More recently, the TP receptor antagonist terutroban was found to be similarly effective, but not superior to aspirin in the prevention of stroke (Bousser et al. 2011). Its development was halted in view of the equal efficacy and lower cost of aspirin.

TxS also converts PGH_2 to 12-L-hydroxy-5,8,10-heptadecatrienoic acid (HHT) and malondialdehyde (MDA) (Diczfalusy et al. 1977). HHT activates the leukotriene B_4 receptor type 2 (*BLT2*) and is thought to play a role in wound healing (Liu et al. 2014). MDA, which is produced in approximately equimolar amounts with TxA_2, forms protein adducts that can cause peptide cross-links (Zagol-Ikapite et al. 2015). However, whether this affects platelet function is not known.

Prostaglandin D_2 While PGH_2 is an unstable endoperoxide with a half-life of about 5 min in aqueous solutions (Svensson et al. 1975) and less in plasma where it is bound by proteins (Maclouf et al. 1980), it can act as a substrate for PG synthases expressed in plasma or other cells, a process sometimes referred to as endoperoxide transfer or shift (Mayeux et al. 1989; Boilard et al. 2011). PGD_2 formation during platelet activation relies on such a mechanism. There are two distinct PGD synthases, hematopoietic PGDS (H-PGDS), which is found in mast and other immune cells, and the lipocalin-type PGDS (L-PGDS), which is localized in many tissues and in plasma (Song et al. 2012). Platelets do not express the PGD synthases, but L-PGDS in plasma forms PGD_2 using PGH_2 released during platelet activation (Oelz et al. 1977; Song et al. 2012). PGD_2 signals through two receptors, DP_1 and DP_2, of which DP_1 is expressed in human, but not mouse platelets. DP_1 couples primarily to G_s resulting in adenylate cyclase stimulation and platelet inhibition. DP_2 couples to G_i. The DP_1 expressed in platelets, like the IP (see below), may function as a limiting homeostatic response to thrombogenic stimuli. Thus, combining a DP_1 receptor antagonist, laropiprant (Fig. 2), with niacin to limit the contribution of PGD_2 to the flushing response induced by niacin may have undermined the putative beneficial effect of niacin on cardiovascular risk by increasing platelet activity in the HPS2-THRIVE trial (Song et al. 2012; Song and FitzGerald 2013). While it is unclear if this was the cause of the failure of the HPS2-THRIVE trial to show effectiveness of the niacin/laropiprant combination (Group et al. 2014), the combination product has been withdrawn from the market in countries where it was approved.

Prostacyclin Prostacyclin (PGI_2) is continuously released into the circulation at a relatively constant rate and quickly ($t_{½} < 3$ min) degraded hydrolytically to 6-keto $PGF_{1\alpha}$ (FitzGerald et al. 1981). Like TxB_2, 6-keto $PGF_{1\alpha}$ is subject to liver metabolism, and a major urinary metabolite, 2,3-dinor-6-keto-$PGF_{1\alpha}$, allows monitoring of PGI_2 formation in the organism (Brash et al. 1983). The hemoprotein PGI_2 synthase (PGIS), which catalyzes the isomeric rearrangement of PGH_2 to PGI_2, was originally purified from bovine aorta (DeWitt and Smith 1983) and is constitutively expressed in endothelial and vascular smooth muscle cells (Wu and Liou 2005). COX-1 and COX-2 are also constitutively expressed in the vasculature, and both contribute to the formation of PGI_2 (Ricciotti et al. 2013). Highly controlled clinical studies with COX-2 inhibitors in healthy volunteers showed that 40–60% of the whole body PGI_2 production is COX-2 dependent (Catella-Lawson et al. 1999; McAdam et al. 1999; Fries et al. 2006). Experiments in mice, in which COX-2 was selectively deleted in endothelial or vascular smooth cells or both, identified the vasculature as the predominant source of COX-2-derived PGI_2 formation (Yu et al. 2012). In situations of accelerated platelet-vessel wall interactions such as unstable angina and myocardial infarction, PGI_2 formation is highly upregulated and coincides with platelet TxA_2 release (FitzGerald et al. 1984, 1987). Endoperoxide transfer from platelets to vascular cells may contribute at least partially to this increase in PGI_2 formation. The PGI_2 response is thought to act as a localized negative feedback signal that constrains the thrombus to the site of endothelial injury (Cheng et al. 2002), because PGI_2 inhibits platelet activation through its specific receptor, the IP. The IP is coupled to

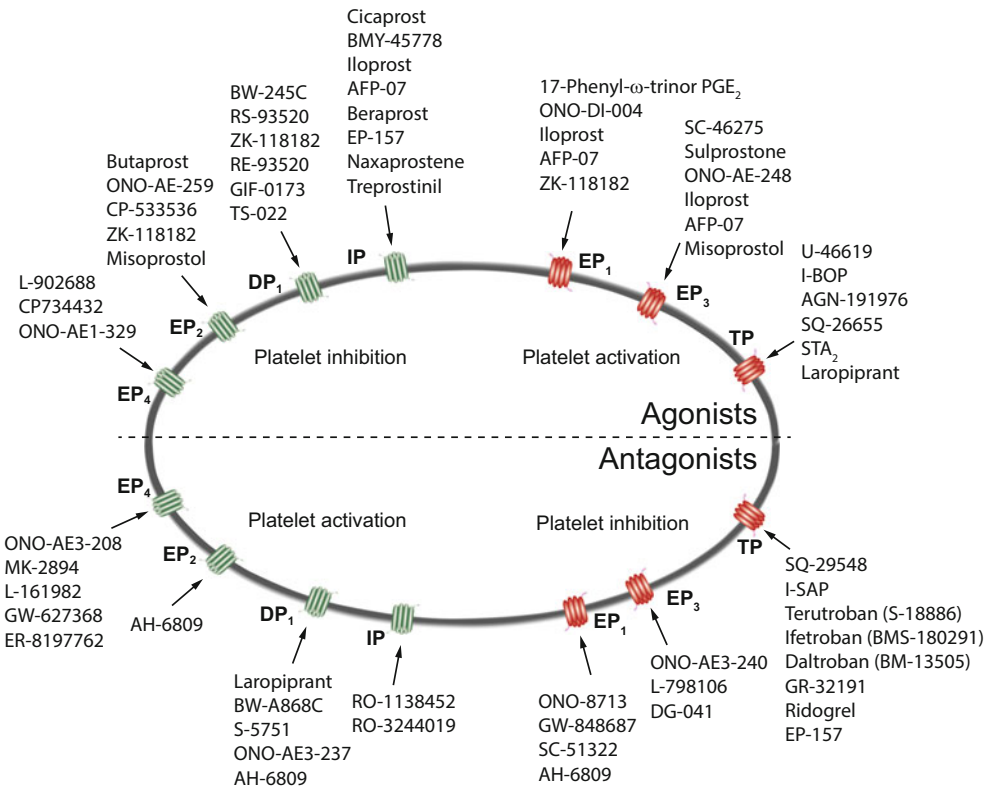

Fig. 2 Prostanoid receptor agonists and antagonists. Prototypic prostanoid receptor ligands and their primary target are listed. Many compounds have limited specificity. Molecules with pronounced effects on multiple prostanoid receptors are shown with multiple receptors. The specificity and potency of prostanoid receptor agonists and antagonists have been reviewed in more detail by Woodward et al. (2011)

G_s-adenylyl cyclase. The resulting cAMP increase activates protein kinase A (PKA), which, among a number of target proteins, deactivates myosin light chain kinase leading to reduced myosin phosphorylation and decreased platelet aggregation. PKA also phosphorylates the vasodilator-stimulated protein (VASP), which regulates fibrinogen binding by modulating the inside-out signaling of the integrin $\alpha_{IIb}\beta_3$, the major fibrinogen receptor in platelets. PGI_2 may also affect the hemostatic system by regulating the expression of thrombin receptors and thrombomodulin (Schror et al. 2010).

Disrupting PGI_2 signaling in mice by deleting its specific receptor, the IP receptor, predisposes to thrombosis in vivo (Murata et al. 1997; Cheng et al. 2002), and various models have been used to demonstrate that perturbation of PGI_2 function augments the thrombotic response. Thus, IP deletion accelerated the thrombotic occlusion of large arteries in response to injury in a gene-dose-dependent fashion (Cheng et al. 2006). Administration of a selective COX-2 inhibitor at doses that reduced PGI_2 formation also resulted in a shortened vascular occlusion time (Cheng et al. 2006). Similarly, genetic disruption of COX-2 or partial genetic disruption, which would be expected to mimic pharmacological inhibition more faithfully than complete knockout, reduced PGI_2 formation and accelerated thrombosis (Cheng et al. 2006; Cryan et al. 2006; Cathcart et al. 2008; Seta et al. 2009). COX-2-derived PGI_2 formation was mapped to the vasculature using tissue-specific deletion of COX-2 in endothelial cells and vascular smooth muscle cells (Yu et al. 2009). Indeed, tissue-specific deletion of COX-2 in vessel wall cells was sufficient to reduce PGI_2 biosynthesis and augmented the thrombotic response in a microvascular laser injury model (Yu et al. 2009). Finally, selective inhibition of COX-2 depressed PGI_2 biosynthesis and predisposed rats and hamsters to platelet activation and arterial thrombosis (Buerkle et al. 2004; Pidgeon et al. 2004). All these observations are consistent with findings from human studies. Thus, polymorphisms in COX-2, PGI_2 synthase, and IP receptor have variously been associated with adverse cardiovascular outcome after angioplasty and hypertension (Arehart et al. 2008; Kohsaka et al. 2008; Lemaitre et al. 2009) and the inhibition of COX-2-dependent PGI_2 formation by COX-2-selective NSAIDs is associated with an increased risk of myocardial infarction and stroke (Grosser et al. 2006, 2010).

Other Prostanoids PGH_2 can spontaneously rearrange to form other prostanoids, and this nonenzymatic process might be the major source of the comparatively small amounts of PGE_2 and $PGF_{2\alpha}$ generated during platelet activation; the E and F synthases are not expressed in platelets nor are they known to be present in plasma in significant amounts. $PGF_{2\alpha}$ may inhibit platelets through cross-reaction with other prostanoid receptors (Armstrong et al. 1985). PGH_2 itself can act as an agonist on the TxA_2 receptor. The role of PGE_2 in platelet function in vivo remains less

clear. In vitro, high PGE_2 concentrations (>10 μM), acting via the IP or, theoretically, the EP_2 or EP_4 receptor, inhibit platelet function (Fabre et al. 2001). Low concentrations of PGE_2, acting via the EP_3, augment submaximal platelet stimulation by other agonists (Andersen et al. 1980; Fabre et al. 2001; Schlagenhauf et al. 2015). Consistent with the latter observation, mice lacking the EP_3 receptor have an increased bleeding tendency and decreased susceptibility to thromboembolism (Ma et al. 2001). Deletion of the enzyme primarily mediating inflammatory PGE_2 formation, the mPGES-1, did not affect thrombogenesis in vivo, probably due to substrate rediversion and augmented formation of PGI_2 (Cheng et al. 2006). Platelet EP receptor signaling has been hypothesized to play a role in modulating platelet function in fetal and neonatal circulation and in atherosclerosis (Tilly et al. 2014; Schlagenhauf et al. 2015).

Take-Home Messages

The primary prostanoid synthesized by platelets is thromboxane (Tx) A, which via the TP receptor acts as an amplification signal to recruit further platelets to a growing blood clot. TP antagonists have been clinically developed as platelet inhibitors but were abandoned in view of the proven efficacy and lower cost of aspirin.

Prostacyclin (PGI) acting through the IP receptor is the most potent endogenous platelet inhibitor. Inhibition of vascular PGI contributes to the prothrombotic adverse effects of cyclooxygenase-2 inhibition by non-steroidal anti-inflammatory drugs.

The role of other prostanoids in platelet biology is less established.

Platelet Genomics

Zongdong Li, Dmitri V. Gnatenko, and Wadie F. Bahou

Abstract

Human platelets are anucleate cells that contain no genomic DNA although they contain both mRNAs and microRNAs derived from precursor megakaryocytes. Nonetheless, genetic variability encompassed within both intronic and exonic sequences are clearly implicated in a wide range of functional parameters known to regulate gene expression and protein function, with concomitant effects on platelet reactivity, volume, peripheral counts, and cellular responsiveness (Hematol Oncol Clin North Am 27:443–463, 2013; Semin Thromb Hemost 39:291–305, 2013; Curr Opin Hematol 19:371–379, 2012). In this chapter, we will review the current status of genetic variations that have been implicated in functional platelet responsiveness, many of which have recently been identified using genome-wide association studies (GWAS) (Genes 5:51–64, 2014; Nat Rev Genet 11:241–246, 2010; Curr Opin Genet Dev 23:339–344, 2013). For synergistic information relevant to platelet genetics, the reader should refer to accompanying chapters on platelet mRNAs (Rowley et al. 2017), platelet noncoding RNAs (Edelstein and Bray 2017), and transcriptomic changes associated with thrombotic risk (Gnatenko et al. 2017).

Many genetic variants have subtle effects and it is likely that complex platelet-related phenotypes associated with cerebro- or cardiovascular risk result from additive effects from multiple loci, contributing to a final common pathway for defective platelet functional and clinical outcome (J Thromb Haemost 5:188–195, 2007; Curr Vasc Pharmacol 9:479–489, 2011; J Thromb Thrombolysis 32:201–208, 2011). Thus, a single subtle effect may be difficult to delineate or consistently reproduce across cohorts. In addition, other confounding variables (e.g., age, sex, body mass index, alcohol consumption, concomitant drugs, nutritional status, and environmental pollutants) may also affect platelet function (Thromb Haemost 105:S60–S66, 2011). Thus, well-defined phenotypes provide the most informative outcomes. Additionally, GWAS with large cohort sizes provide the most robust information relevant for reliable identification of new genetic variations with subtle effect (s) on platelet functional parameters (Fig. 1).

Inherited Genetic Disorders Associated with Platelet Functional Variation

Congenital platelet disorders usually present with mild to severe bleeding typically associated with quantitative changes in platelet counts. While the diagnosis of severe disorders is relatively clear, subtle platelet dysfunction may be much more difficult to interpret, and congenital

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_16

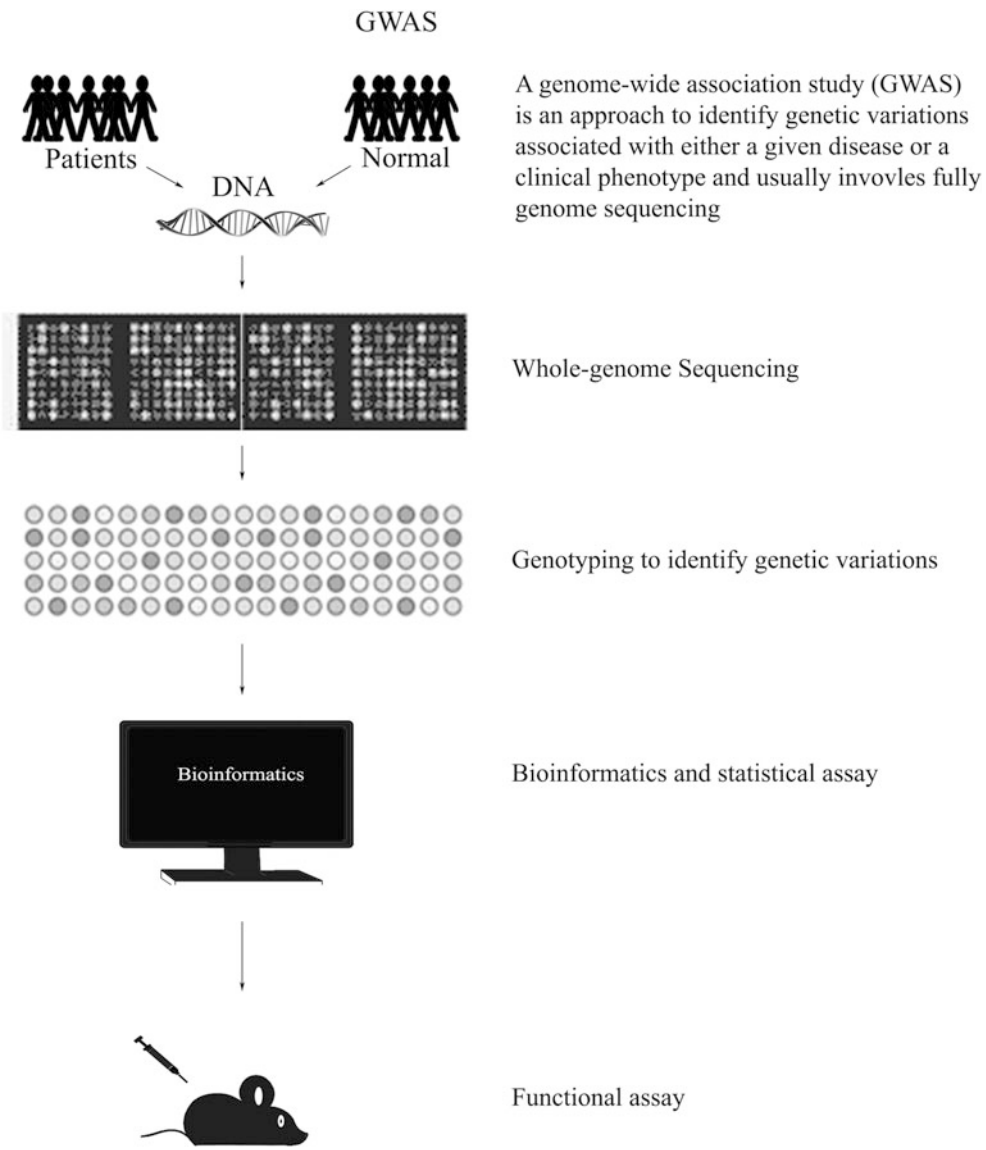

Fig. 1 Genome-wide association studies (GWAS). DNA from patients and normal controls will be used for whole genome sequencing analysis. Single-nucleotide polymorphisms (SNPs) as well as other genetic variations will be compared between two groups in bioinformatics correlation study. Candidate genes will be then tested in functional study

thrombocytopenia may be misclassified as immune thrombocytopenia or ignored because of mild changes in the platelet count. In this section, we provide an update on newly identified genes involved in inherited platelet defects (Table 1). The reader is also referred to well-characterized genetic defects that have been reviewed comprehensively in previous publications (Lambert 2015; Nurden et al. 2012; Israels and Rand 2013; Songdej and Rao 2015). Genes involved in inherited platelet disorders are associated with defects in cell signaling, transcriptional regulation, granule biogenesis, and the cytoskeleton; many patients with these disorders also present with systemic symptoms other than platelet dysfunction.

Cytoskeleton Genetic Disorders

MYH9. *MYH9*-related disorders are an autosomal dominant form of macrothrombocytopenia with giant platelets and platelet counts range from 10 to 136 ($\times 10^9$ L^{-1}) (Kunishima and Saito 2010). In patients with *MYH9*-related disease, more bleeding occurred in patients harboring mutations in the motor domain versus the tail domain of *MYH9*, and 40 % of patients had at least one extra-hematological manifestation such as renal disease, hearing loss, or cataracts (Saposnik et al. 2014).

FLNA. Actin binding protein 280 is coded by *FLNA* on the X-chromosome (Falet 2013). It tethers GP1bα and integrin $\alpha_{IIb}\beta_3$ to the underlying cytoskeleton in platelet,

Table 1 Inherited platelet disorders

Mechanism	Gene	Disorder	Inheritance	Platelet count	Platelet size	Platelet function
Cytoskeleton	MYH9	MYH9 RD	AD	Low	Large	Abnormal
	FLNA	Filaminopathies	X-linked	Low	Large	Mildly affected
	TUBB1	TUBB1 RD	AD	Low	Large	Normal
	ACTN1	ACTN1 RD	AD	Low	Large	Normal
Transcription	FLI1	Paris–Trousseau/Jacobsen	AD	Low, recovers around first year	Large	Mildly affected
	RUNX1	FPD/AML	AD	Moderately low	Normal	Mildly affected
	ETV6	Thrombocytopenia with predisposition to hematologic malignancy	AD	Variable (elevated MCV and predisposition to leukemia)	Normal	Mild to moderate bleeding
	GFI1B		AR	Low (also may have red cell abnormalities)	Large	Moderately affected
Granule	NBEAL2	Gray platelet syndrome	AR	Low	Large	Affected
Signaling	PRKACG		AR	Low	Large	Abnormal
	RBM8A	TAR syndrome	AR	Very low but improves over time	Normal	May be mildly affected
	5′UTR ANKRD26 or ANKRD26	ANKRD26-RD	AD	Moderately low	Normal	Mildly affected/ normal

thereby resulting in disruption of the platelet plasma membrane under high shear. Defects involving *FLNA* have been associated with bleeding and low platelet counts in patient subsets. Recently, mutations of *FLNA* have been associated with an isolated platelet phenotype and the role of *FLNA* in platelet and megakaryocyte has been explored further (Nurden et al. 2011; Begonja and Pluthero 2015).

TUBB1. Tubulin B1 (*TUBB1*) is involved in an autosomal dominant macrothrombocytopenia (Balduini and Savoia 2012; Pecci 2013). A polymorphism in *TUBB1* (rs121918555) has been associated with lack of response to ITP therapy (Kunishima et al. 2014; Basciano et al. 2013). A genome-wide association study of more than 65,000 individuals of European ancestry demonstrated that the *TUBB1* locus was a major determinant of mean platelet volume (Gieger et al. 2011).

ACTN1. Actin-1 (*ACTN1*) mutations were described in six Japanese pedigrees with congenital macrothrombocytopenia after whole exome sequencing (WES) (Kunishima et al. 2013). These families all had autosomal dominant macrothrombocytopenia with platelet counts ranging from 54 to 132 ($\times 10^9$ L^{-1}) and a mean increase in platelet size of 30 % with platelet anisocytosis; increased expression of GPIβ/IX and $\alpha_{IIb}\beta_3$ was thought to be due to increased platelet size. A recent study using WES added more families with *ACTN1* mutations in a large cohort of patients with thrombocytopenia (Westbury et al. 2015).

Transcription Genetic Disorders

FLI1. Paris–Trousseau (Jacobsen) syndrome is an autosomal dominant macrothrombocytopenia (Songdej and Rao 2015; Tijssen and Ghevaert 2013). It is believed that this disease is due to deletion of a portion of the distal portion of long arm of chromosome 11 (11q23.3-24) where the transcription factor Friend of Leukemia Integration (*FLI1*) locus is found. Patients with Paris–Trousseau (Jacobsen) syndrome have giant α granules in a proportion of their platelets (1–5 %) and have a mild bleeding phenotype with mild platelet aggregation defects. In addition, patients with larger deletions of 11q23.3-24 have mental retardation, trigonocephaly, dysmorphic facies, congenital heart disease, and abnormalities of the urogenital and skeletal system (Mattina et al. 2009).

RUNX1. Mutations in Runt-related transcription factor-1 (*RUNX1*) lead to a familial platelet disorder with predisposition to acute myeloid leukemia, and an increased incidence of thrombocytopenia with normal platelet size and platelet dysfunction with abnormal aggregation responses and abnormal secretion (Songdej and Rao 2015; Tijssen and Ghevaert 2013; Owen et al. 2008). Most patients present with mucocutaneous bleeding symptoms: easy bruising, epistaxis, and bleeding after minor surgery or dental challenges, but the penetrance is variable and unaffected family members carrying mutations in involved families are reported (Stockley et al. 2013).

ETV6. Mutations of Ets variant 6 (*ETV6*) have been associated with autosomal dominant thrombocytopenia of varying degree, erythrocyte macrocytosis, and various hematologic malignancies including B-cell acute lymphocytic leukemia, multiple myeloma, chronic myelomonocytic leukemia, T-cell/myeloid mixed phenotype leukemia, refractory anemia with excess blasts, and myelodysplastic syndrome (Zhang et al. 2015; Songdej and Rao 2015; Tijssen and Ghevaert 2013). In addition, several family members were also reported to have skin cancer and colorectal cancer (Noetzli et al. 2015).

GFI1B. Growth factor independent 1B (*GFI1B*) is a transcription factor previously thought to be important in murine erythroid and platelet development (Songdej and Rao 2015; Tijssen and Ghevaert 2013). Mutations in *GFI1B* lead to mild clinical bleeding, red blood cell anisopoikilocytosis, and macrothrombocytopenia, with absent α granules and abnormal aggregation responses (Stevenson et al. 2013).

Granule Biogenesis Genetic Disorder

NBEAL2. Mutations involving myelofibrosis Neurobeachin-like 2 (*NBEAL2*) have been causally identified as the molecular basis for the gray platelet syndrome (GPS) (Freson et al. 2014). *NBEAL2* deficiency results in defective α-granule biogenesis and impaired inflammatory response in a murine model (Deppermann et al. 2013). Granule biogenesis-associated platelet defect usually is a part of a larger syndromic disease such as Hermansky–Pudlak syndrome (mutations in *HPS* genes), arthrogryposis, renal dysfunction, and cholestasis (ARC) syndrome with platelet dysfunction. Many patients with gray platelet syndrome develop stable myelofibrosis (Albers et al. 2011; Kahr et al. 2011; Gunay-Aygun et al. 2011).

Cell Signaling Genetic Disorders

PRKACG. The *PRKACG* gene encodes the γ subunit of cyclic-adenosine monophosphate (c-AMP)-dependent kinase A (PKA) and it is associated with autosomal recessive thrombocytopenia with defects in proplatelet formation and platelet activation (Landolt-Marticorena and Kahr 2014; Nurden and Nurden 2015). These patients have severe macrothrombocytopenia ($5–8 \times 10^9$ L^{-1}) and significant bleeding (Manchev et al. 2014). Genetic sequencing revealed the earlier mutation and biochemical studies confirmed that family members who were homozygous for the mutation had decreased *FLNA* in megakaryocytes and platelets, and increased levels of platelet cAMP; patients who were heterozygous had intermediate levels compared to controls.

RBM8A. Thrombocytopenia absent radii (*TAR*) syndrome is different from congenital amegakaryocytic thrombocytopenia (CAMT). TAR syndrome presents at birth with thrombocytopenia, which typically is associated with skeletal abnormalities and improvement in the platelet count sometime in the first 5 years of life (Klopocki et al. 2007; Fiedler et al. 2012). Proximal microdeletions in 1q21.1 and low frequency noncoding SNPs in the 5′UTR of *RBM8A* (RNA Binding Motif Protein 8A) were identified to be associated with TAR syndrome (Albers et al. 2013). TAR syndrome seems to be due to reduced expression of Y14 (the protein encoded by *RBM8A*) (Albers et al. 2012). Patients with TAR syndrome have very high thrombopoietin levels and impaired phosphorylation of Jak2 kinase that appears to improve with age corresponding to improved platelet counts.

ANKRD26. Recent report shows that the mechanism of thrombocytopenia associated with mutations in the 5′UTR of Ankyrin repeat domain 26 (*ANKRD26*) is due to the loss of appropriate *ANKRD26* silencing and persistent TPO/MPL pathway signaling (Bluteau et al. 2014). *RUNX1* and *FLI1* bind to the 5′UTR region of *ANKRD26* to inhibit the expression of *ANKRD26* in late megakaryocytes. With mutations in 5′UTR of *ANKRD26*, RUNX1 and FLI1 are unable to bind and the expression of *ANDRD26* remains high, resulting a defect in proplatelet formation due to increased signaling through the TPO/MPL pathway (Bluteau et al. 2014).

Platelet Receptor Genetic Polymorphism Affecting Functional Responses

In general, polymorphism involving the three major platelet receptors (ADP receptors, collagen receptors, and fibrinogen receptors) has minimal disease-relevant effects on platelet function (Floyd and Ferro 2012; Williams et al. 2010). However, the correlation between these receptors polymorphism with antiplatelet drug response has also been studied and will be discussed further in the GWAS antiplatelet drug response section (*vide infra*) (Quinn and Topol 2001).

ADP Receptors

P2Y1 and P2Y12 are the two major adenosine diphosphate (ADP) receptors (Fig. 2). Individual variability of ADP-induced platelet aggregation and fibrinogen binding in healthy volunteers and patients has been previously demonstrated. Five different genetic polymorphisms for the P2Y12 gene and two haplotypes H1 and H2 with frequencies

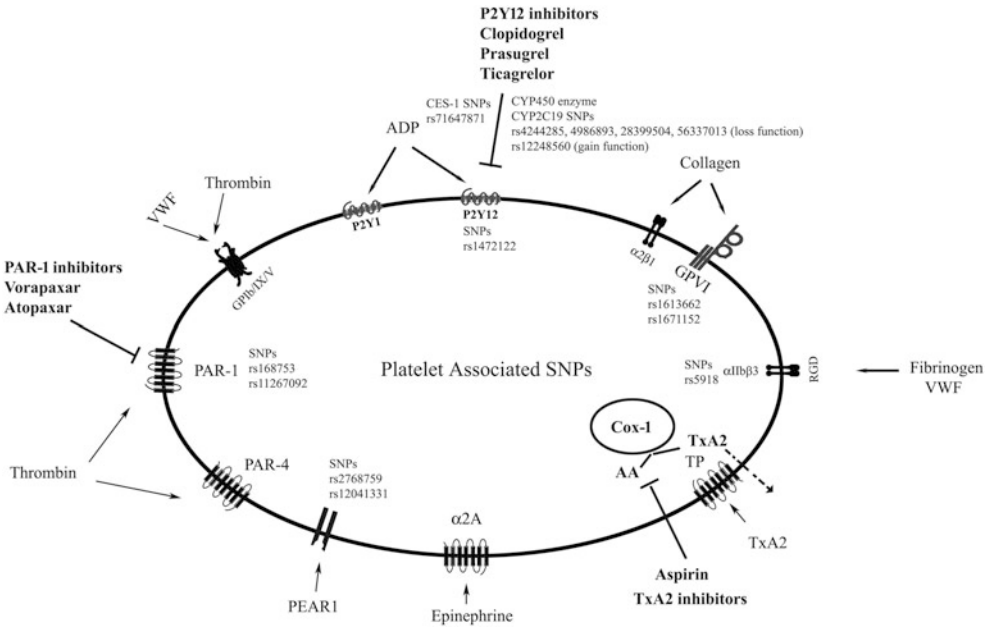

Fig. 2 SNPs studied in antiplatelet drug response. SNPs of platelet receptors and SNPs of enzymes involved in antiplatelet drug metabolism have been studied for the correlation with antiplatelet drug response and some of these SNPs are critical for individual differences of antiplatelet drug response

of 86 % (H1) and 14 % (H2), respectively, have been reported in healthy population (Fontana et al. 2003). In addition, the H2 haplotype was associated with increased prevalence of coronary and peripheral artery disease (CAD, PAD) (Cavallari et al. 2007). In another study, 5 polymorphisms in the P2Y1 gene and 11 in the P2Y12 gene have also been identified (Hetherington et al. 2005). However, in a genome-wide study, none of these polymorphisms were associated with defective platelet function except the *rs1472122* SNP (Jones et al. 2009).

Collagen Receptors

The integrin $\alpha_2\beta_1$ and the platelet-specific receptor GPVI are two major collagen receptors in platelets (Fig. 2). There are three major alleles encoding for the α2 chain; high level expression of α2β1 has been associated with allele 1 (807T/1648G/2531C) while decreased expression of the receptor is associated with other two alleles (allele2: 807C/1648G/2531C; allele 3: 807C/1648A/2531C) (Kunicki et al. 1997). In addition, the 807T allele has been associated with acute myocardial infarction (MI) risk (Santoso et al. 1999; Moshfegh et al. 1999). To date, there is no convincing evidence for thrombotic risk in cohorts associated with polymorphisms of β1 subunit (*ITGB1*). For variants of *GPVI*, the *GPVI* 13254CC genotype has been associated with increased risk of MI and thrombus formation (Croft et al. 2001; Ollikainen et al. 2004). In genome-wide functional studies, the variants *rs1613662* and *rs1671152* have been associated with agonist-induced P-selectin expression, fibrinogen receptor binding, and collagen-induced platelet aggregation, respectively (Jones et al. 2009; Johnson et al. 2010).

Fibrinogen Receptor

Integrin $\alpha_{IIb}\beta_3$ is the major fibrinogen receptor on platelets (Fig. 2). To date, the most intensely studied polymorphic variant of GPIIIa is SNP *rs5918* (Floyd and Ferro 2012). Nonetheless, the role of this variant in innate platelet reactivity and in cardiovascular diseases leads to inconsistent result. While initial studies with small cohort sizes suggested that GPIIIa gene polymorphism may be associated with the risk for developing coronary artery disease and coronary/cerebrovascular thrombosis, subsequent meta-analyses with combined cohort sizes have not been confirmatory (Michelson et al. 2000; Aalto-Setala et al. 2005; Slowik et al. 2004; Ye et al. 2006).

Platelet Genome-Wide Association Studies (GWAS)

Previous candidate gene analyses have mainly focused on genes considered to be important in the function of platelets (a priori) and/or hemostatic disorders, with shortcomings in large-scale studies (Chami and Lettre 2014). Since the majority of platelet SNPs with minor allele frequencies (MAF) (<0.2) and most platelet phenotypes have a small effect size with high interindividual variability, large cohorts and genomic technologies are required to detect rare variants and to elucidate their effects with sufficient statistical power in multivariate analyses and multiple testing to minimize the false discovery rate (FDR). With the advent of next-generation/high-throughput DNA/RNA sequencing, the identification of novel genes associated with platelet dysfunction and thrombocytopenia has become more common. Many new

causes of familial thrombocytopenia and platelet dysfunction have been described in the past few years using these methods (Bunimov et al. 2013; Chami and Lettre 2014). We now discuss recent GWAS with three aspects of platelet biology: platelet volume, platelet count, antiplatelet drug responses, etc.

GWAS: Platelet Counts and Volume

Mean platelet volume (MPV) and platelet count (PLT) are highly heritable and tightly regulated traits. Platelet volume is a marker of platelet function and activation (Azab et al. 2011; Chu et al. 2010; Gasparyan et al. 2011; Lance et al. 2012; Sansanayudh et al. 2014; Vizioli et al. 2009). MPV is increased in certain vascular risk factor states, including hypercholesterolemia and diabetes mellitus, but not essential hypertension. It is increased in acute myocardial infarction, acute ischemic stroke, preeclampsia, and renal artery stenosis. Importantly, an elevated MPV predicts a poor outcome following myocardial infarction, restenosis following coronary angioplasty, and the development of preeclampsia (Bath and Butterworth 1996). Different genetic variants have been associated with MPV and platelet count using candidate gene subsets. Recently, a number of GWAS studies have been reported focusing on these critically important parameters (Table 2).

In one report, 49,094 single-nucleotide polymorphisms (SNPs) that capture variation in ~2100 candidate genes in DNA of 23,439 Caucasians and 7112 African Americans have been studied and strong novel associations between platelet count and a SNP at the tropomyosin-4 (*TPM4*) locus (*rs8109288*) have been found. The data suggests similarities but also differences in the genetic regulation of hematological traits in European- and African-derived populations (Lo et al. 2011). In another GWAS study, it was shown that MPV was strongly associated with three common SNPs: *rs7961894* located within intron 3 of *WDR66* on chromosome 12q24.31, *rs12485738* upstream of *ARHGEF3* on chromosome 3p13-p21, and *rs2138852* located upstream of *TAOK1* on chromosome 17q11.2 and expression analysis indicated a direct correlation of WDR66 transcripts and MPV (Meisinger et al. 2009).

A different GWAS for MPV identified one SNP *rs342293* as having highly significant and reproducible association with MPV in 8586 healthy subjects. Whole-genome expression analysis found that it had a significant association with platelet transcript levels for *PIK3CG*. In addition, the G allele at *rs342293* was also associated with decreased binding of annexin V to platelets activated with collagen-related peptide. The region 7q22.3 is correlated with platelet volume, counts, and function in healthy subjects (Soranzo et al. 2009a). Another GWAS reported 15 out of 22 common variants in 13,943 samples from 6 European population-based studies associated with platelet parameters including MVP and counts (Soranzo et al. 2009b). In a GWAS involving 14,700 Japanese individuals, 5 out of 60 associations are correlated with platelet counts (Kamatani et al. 2010). The largest platelet GWAS to date involves approximately 67,000 individuals with a European background. In this study, 68 independent genomic regions have been identified and that were related to MPV and platelet count (25 and 43 regions for MPV and platelet count, respectively). The 68 reported loci account for about 5 % of variability of platelet count and 10 % of variability of MPV. Replication of selected loci was obtained in cohorts with different ethnic background (Gieger et al. 2011).

In summary, data from various groups and cohorts have identified various SNPs and gene loci to be associated with platelet counts and MPV. However, SNPs and genetic variants identified by one group have not been consistently identified by other groups (Shameer et al. 2014; Oh et al. 2014), limiting firm conclusions relevant to pathogenesis or molecular regulation of MPV; clearly, larger cohorts with more robust controls and molecular validation studies will be required for further insight into molecular regulatory signals controlling platelet size, and how these variants may control functional platelet responses and clinical outcomes (Table 2).

Table 2 GWAS: platelet count and mean platelet volume (MPV)

Cohort size	Platelet count	MPV	Genomic loci	Reference
66,867	56 SNPs	29 SNPs	68	Gieger et al. (2011)
23,439 Caucasians	Caucasian: rs8109288		Caucasian: 1	Lo et al. (2011)
7112 African Americans	African American: rs10876550; rs8109288		African American: 2	
10,048		rs7961894; rs12485738; rs2138852	3	Meisinger et al (2009)
8586		rs342293	1	Soranzo et al. (2009a, b)
13,943	rs11065987; rs11066301; rs210135; rs385893	12 SNPs	16	Soranzo et al. (2009a, b)
14,700	rs739496; rs7775698; rs385893; rs6141; rs5745568		5	Kamatani et al (2010)

GWAS: Antiplatelet Drug Response

The effect of genetic variants on antiplatelet drug responses has been studied for commonly used agents including aspirin, clopidogrel, and prasugrel (Fig. 2). Not surprisingly, these GWAS studies have the same restrictions for large cohort sizes due to small SNP effects and the presence of low-frequency SNP alleles (Meyer et al. 2013; Geisler et al. 2013; Perry and Shuldiner 2013; Zuern et al. 2010; Sabatine and Mega 2014).

Aspirin

The correlation between aspirin resistance and the polymorphisms of cyclooxygenase 1 (*COX-1*), cyclooxygenase 2 (*COX-2*), as well as platelet integrin GPIIIa has been studied with controversies (Freedman 2006; Faraday et al. 2007a, b; Frelinger et al. 2006; Cui et al. 2015). However, SNPs of platelet endothelial aggregation receptor 1 (PEAR1) have been identified in functional genomic and genome-wide association studies. It has been shown that the C allele of *rs2768759* [A/C] located in the promoter region of this gene was associated with lower responsiveness to aspirin measured by collagen- and epinephrine-induced platelet aggregation (Herrera-Galeano et al. 2008). In addition, variant *rs12041331* in intron 1 has been found to account for up to 15 % of variation of platelet function and was strongly linked with agonist-induced platelet aggregation (collagen, epinephrine, and ADP) at baseline and during aspirin treatment (Faraday et al. 2011; Kim et al. 2013; Lewis et al. 2013b).

Clopidogrel

Two steps are required to convert clopidogrel to its biologically active thiol metabolite. The first step, a monooxygenation reaction of the thiophene ring by CYP450 enzymes (i.e., *CYP2B6*, *CYP2C19*) leads to 2-oxo-clopidogrel, a thiolactone metabolite. The second step results in a CYP450-dependent (i.e., *CYP2B6*, *CYP2C19*) oxidative opening of the thiolactone ring of 2-oxoclopidogrel (Sangkuhl et al. 2010). *CYP2C19* is highly polymorphic and the variations include the loss-of-function alleles *CYP2C19* *2,*3,*4, and *5 and the ultra-rapid metabolizer allele *CYP2C19*17 (Zanger et al. 2014; Zanger and Schwab 2013). The effect of *CYP2C19* polymorphisms on the antiplatelet activity of clopidogrel has been studied and a significant impact of *CYP2C19* loss-of-function alleles on enhanced platelet aggregation has been found in clopidogrel-treated patients (Simon et al. 2009; Geisler et al. 2008). Subsequent studies established that patients carrying one or more *CYP2C19* loss-of-function allele (s) have had higher rates of cardiovascular events than noncarriers (Hulot et al. 2006; Trenk et al. 2008; Mega et al. 2009). In a GWAS study, it was confirmed that SNPs on chromosome 10q24 encompassing the *CYP2C18–CYP2C19–CYP2C9–CYP2C8* gene cluster were strongly associated with decreased clopidogrel response. The *rs12777823* variant was nearly in complete linkage disequilibrium with the *CYP2C19*2* variant, accounting for up to 12 % of variability of on-treatment platelet aggregation (Shuldiner et al. 2009).

Carboxylesterase 1 (CES-1) is another enzyme involved in the drug metabolism of clopidogrel. It is involved in the conversion of clopidogrel, its intermediate 2-oxo-clopidogrel, and the final bioactive thiol metabolite into biologically inactive carboxylic acid derivatives. The *G143E* (rs71647871) genetic variant is linked to enzyme function and a recent report has shown a significant association of the *CES-1* G143E SNP allele with higher active metabolite levels and higher inhibition of ADP-induced platelet aggregation (Lewis et al. 2013a). These positive results contrast with those assessing the role of the arylesterase paraoxonase (*PON1*) in clopidogrel bioactivation. In one study, a *PON1* polymorphism (rs662) demonstrated no significant correlation with clopidogrel response (Reny et al. 2012). In addition, the correlation between allelic variants of two distinct platelet receptors (H2 haplotype of *P2Y12* and *PAR1*) and clopidogrel platelet response has also been studied with no reproducible correlation with either allelic system (Angiolillo et al. 2005; von Beckerath et al. 2005; Motovska et al. 2009).

Prasugrel

In contrast to clopidogrel, *CYP450* enzymes are involved in a single step of prasugrel metabolism with a minor contribution from *CYP2C19*. Plasma levels of the active metabolite were not influenced by common genetic variants of *CYP2C19, CYP2C9, CYP2B6, CYP3A5,* or *CYP1A2* (Mega et al. 2009). Recent studies show a significant impact of *CYP2C19* polymorphisms (*2 and *17) on platelet reactivity and the bleeding risk during chronic treatment with prasugrel was influenced by *CYP2C19* genetics (Cuisset et al. 2012). Another study suggests that both clopidogrel and prasugrel therapy may be altered by the *CYP2C19* *2 and *17 alleles (Grosdidier et al. 2013). Taken together, further studies will be needed to definitely establish the contribution of CYP450 genetic variants in prasugrel bioactivation and pharmacokinetic responses.

Ticagrelor

Ticagrelor is primarily metabolized by *CYP3A4/5* enzymes, and *CYP2C19* does not seem to play a relevant role in drug metabolism. To date polymorphisms involving *CYP2C19, ABCB1, P2Y12, P2Y1*, and *ITGB3* demonstrate no consistent effects on inhibition of ADP-induced aggregation by Ticagrelor (Zhou et al. 2011; Tantry et al. 2010; Wallentin et al. 2010).

Thrombin Receptor (PAR1) Antagonists

A limited number of polymorphisms of the *PAR1* receptor gene have been reported in clinical studies. The intervening sequence intronic variation *rs168753* is associated with reduced PAR-1 receptors on the platelet surface and with the response to agonist stimulation; the insertion/deletion variant *rs11267092* has been evaluated for its protective role in venous thromboembolism (Dupont et al. 2003; Arnaud et al. 2000). However, none of these variants have been associated with clinical efficacy of PAR1 antagonist vorapaxar or atopaxar yet.

GWAS: Platelet-Associated Diseases

To date the most intensively studied platelet-associated disease using GWAS is myocardial infarction where platelets play a pivotal role in atherothrombosis (Kathiresan et al. 2009; Ouwehand 2007, 2009). GWAS have also been performed in cohorts with stroke and major depressive disorder (MDD) (Ziegelstein et al. 2009; Wray et al. 2012).

Myocardial Infarction

Platelets play a pivotal role in atherothrombosis after coronary artery plaque rupture, and the extent of platelet response during such an event varies between individuals. To some degree, this variability appears to be genetically controlled. Evidence that the megakaryocyte DNA content correlates with coronary artery atherosclerosis was first suggested by Bath et al. about two decades ago (Bath et al. 1994; Dalby Kristensen et al. 1988). More comprehensive GWAS to correlate different gene loci with MI risk have identified the first 11 risk loci for myocardial infarction (MI) and coronary artery disease (CAD). Studies on quantitative traits provide an alternative approach to identify MI/CAD risk loci (Ouwehand 2007, 2009; Mathias et al. 2010). Nonetheless, specific gene identification, validation, and precise molecular mechanisms for these associations remain ongoing.

Stroke

In a meta-analyses GWAS involved 14,746 African Americans (1365 ischemic and 1592 total stroke cases), genetic variants were examined for validation in METASTROKE and nominal associations ($p < 10^{-6}$) for total or ischemic stroke were observed. Of note, one of these variants (*HPS4*) is implicated in the protein component regulating biogenesis of lysosome-related organelles complexes (BLOC). BLOC complexes are important for the formation of endosomal–lysosomal organelles such as melanosomes and platelet dense granules, and are causally implicated in Hermansky–Pudlak Syndrome (Carty et al. 2015).

Major Depressive Disorder

MDD is a common, complex disorder with a partial genetic component. Adenylyl cyclase (AC) is an enzyme that can regulate the physiologic effects of numerous drugs and hormones through the production of cyclic adenosine-3′, 5′-monophosphate (cAMP). The relationship between platelet AC activity and lifetime diagnosis of major depression among 1481 participants (226 subjects with a history of major depression and 1255 control subjects) has been assessed and it was found that a lower platelet AC activity was associated with MDD (Hines and Tabakoff 2005). However, in another genome-wide association study, no SNPs have been found significantly associated with MDD although gene-based tests suggested a role for adenylate cyclase 3 (ADCY3, 2p23.3) in development of MDD (Wray et al. 2012).

Conclusion and Future Directions

GWAS is a robust and powerful approach to identify novel genes and pathways involved in platelet function under normal or pathological conditions. Although data studying the role of genetic polymorphisms with platelet function and or efficacy of antiplatelet agents is not always consistent, a unifying concept forming a multitude of studies strongly suggest that variability of platelet activation largely depends on genetic inheritance and variability. While many SNPs have been identified and linked to platelet function, delineation of SNP–SNP interactions for optimal gene/phenotypic studies remains an area of critical need and investigation. Furthermore, genetic variations of noncoding regions which incorporate transcription factor binding sites, etc., and epigenetic modifications (such as DNA methylation, histone acetylation, etc.) need to be incorporated into future studies (Freson et al. 2012). Integration of large data sets

incorporating clinical phenotype, functional assays, and high throughput data such as genome sequencing, RNAseq, microarray, and proteomic studies demands advanced bioinformatical solutions (De et al. 2014). In addition, a robust algorithm in statistical studies needs to be developed to prevent misleading false discovery. In theory, these issues should be addressed using integrated systems biology approaches, thereby providing optimal geno/phenotypic data linked to optimal outcomes and tailored antiplatelet interventions.

Take Home Messages

1. Genetic variability of both intronic and exonic sequences is implicated in regulation of platelet reactivity, volume, peripheral counts, and cellular responsiveness. Many genetic variants have subtle effects and a single subtle effect may be difficult to delineate or consistently reproduce across cohorts.
2. Genome-Wide Association Study (GWAS) is a robust approach to identify novel genes and pathways involved in platelet function under normal or pathological conditions. GWAS with large cohort sizes and well-defined phenotypes could provide valuable information to identify new genetic variations with subtle effect(s) on platelet functional parameters.
3. While many SNPs have been identified and linked to platelet function, delineation of SNP–SNP interactions for optimal gene/phenotypic studies remains an area of critical need and investigation. Genetic variations of noncoding regions which incorporate transcription factor binding sites, etc., and epigenetic modifications (such as DNA methylation, histone acetylation, etc.) need to be incorporated into future studies. In addition, a better algorithm in statistical studies needs to be developed to prevent misleading false discovery.

The Platelet Transcriptome: Coding RNAs

Jesse W. Rowley, Bhanu Kanth Manne, and Andrew S. Weyrich

Abstract

Until recently platelets were categorized as simple anucleate cytoplasts that function solely in the hemostatic arena. However, the last decade has demonstrated that platelets have roles beyond primary hemostasis and they possess complex molecular information including a rich repertoire of messenger RNAs (mRNAs). Platelet mRNAs have features that mirror transcripts produced and translated in nucleated cells, and mRNAs for approximately half of the human genome have been identified in this terminally differentiated cell. The study of platelet mRNAs has expanded tremendously with the advent of next-generation RNA sequencing (NGS) and several groups have shown that platelets are capable of translating some megakaryocyte-derived mRNAs into protein. Platelet mRNA profiles have also been used to predict cellular function and platelets are capable of transferring intact mRNAs into microparticles and other cells. This chapter reviews our current understanding of platelet mRNAs and their potential contribution to biological and pathologic processes in humans. Roles for noncoding RNAs are described in Edelstein and Bray (2017).

General Overview of the Platelet mRNA World

Although platelets have been studied for over a century, it wasn't until the late 1980s that Newman and colleagues used PCR-based studies to identify mRNA for GPIIIa in platelets (Newman et al. 1988). These studies set the stage for direct molecular characterization of proteins in healthy subjects and patients with inherited platelet disorders. The subsequent development of microarrays and Serial Analyses of Gene Expression (SAGE) allowed for a broader analysis of mRNAs in platelets. Studies using these techniques revealed that mitochondrial-coded RNAs are abundant in platelets, and that platelets express messages that code for proteins involved in hemostasis, thrombosis, and inflammation (Gnatenko et al. 2003; Dittrich et al. 2006). These studies also showed that platelet mRNAs have long untranslated regions (UTRs) and that messages coding for cytoplasmic polyadenylation elements (CPEs), mRNA localization, and translational control are enriched in the platelet transcriptome (Dittrich et al. 2006).

Microarray, SAGE, and other hybrid-based techniques have recently been supplanted by NGS (Shendure 2008) that enables unprecedented characterization and quantification of the platelet transcriptome (Mortazavi et al. 2008; Costa et al. 2010). Several groups have now employed NGS and shown that most proteins have a corresponding mRNA expressed in human platelets (Rowley et al. 2011; Kissopoulou et al. 2013; Bray et al. 2013; Rowley and Weyrich 2013; Londin et al. 2014; Osman et al. 2015; Cimmino et al. 2015; Eicher et al. 2016; Best et al. 2015). A little over 40 % of mapped long RNA-seq reads correspond to mRNAs of protein coding genes, 32 % correspond to rRNA, and only 6 % map to annotated nonprotein coding loci (Londin et al. 2014). Thus, the majority of the long RNAs (defined as >200 bp, but reads are often detected at >100 bp) in the cell are involved in protein translation. Of

the reads mapping to protein coding genes, the majority map to a handful of genes coding for mitochondrial proteins (Bray et al. 2013), and the remainder map to 7000–10,000 different nuclear-encoded protein-coding genes (Rowley et al. 2011; Bray et al. 2013). The distribution of expression of these transcripts matches that of other cells (Fig. 1). Therefore, the platelet mRNA-ome is complex (Rowley et al. 2011), with more than half of the known human protein coding genes represented in platelets. The remainder of long RNA reads in platelets match to lincRNAs, unannotated intronic and intergenic regions, pseudogenes, and a variety of repeat elements (Londin et al. 2014). Using PTESFinder Pipeline v. 1 (http://sourceforge.net/projects/ptesfinder-v1/), Alhasan and colleagues (2016) have also recently shown that platelets are enriched in noncoding circular RNAs (circRNA), which are resistant to exonuclease degradation. The precise biological/pathologic function(s) of circRNAs in eukaryotic cells is unclear, but focused investigations over the coming years should provide insight into the roles of circRNAs in platelets. Short RNAs (17–200 bp), such as miRNAs, that are detectable by short-RNA sequencing, are also abundant in platelets (Plé et al. 2012a). Short RNAs and other noncoding RNAs are discussed in a subsequent chapter.

As recently reviewed elsewhere (Schubert et al. 2014), the majority of platelet-coding mRNAs appear to be mature

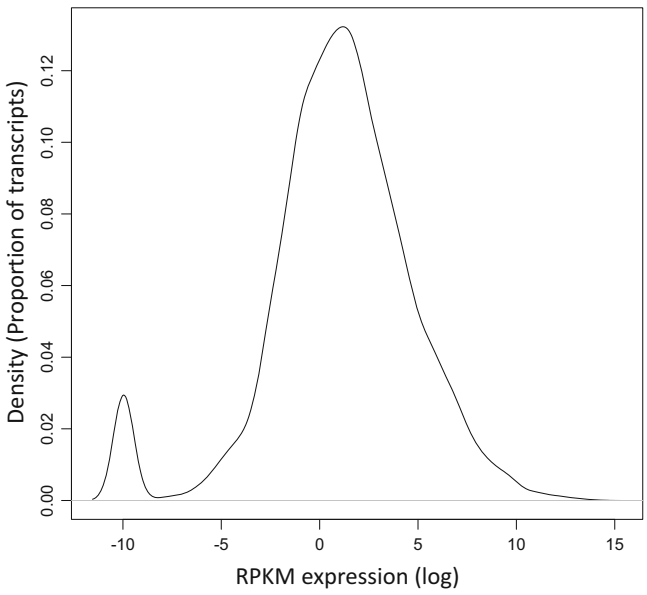

Fig. 1 Distribution of mRNA expression levels in platelets. The histogram depicts the relative levels (on a log scale) of all mRNAs in platelets as measured by RNA-sequencing of poly-A RNA. Note that the distribution is bimodal, similar to what has been described in other cells (Nagaraj et al. 2011). There is a secondary peak of very low abundant transcripts, but the majority of the transcripts follow a normal distribution of expression with a range of expression from low to very abundant

mRNA which are spliced (free of introns), capped, and polyadenylated at their 5′- and 3′-UTRs, respectively. Evidence of capping and polyadenylation comes on several fronts, including deep sequencing data captured by cap-binding proteins (Choi and Hagedorn 2003) or oligo-DT conjugated beads that target poly-A tails (Rowley et al. 2011). Consistent with these features, platelet mRNAs are competent for protein coding when placed in in vitro translation systems and incorporate labeled amino acids into a range of proteins in vivo (Warshaw et al. 1967; Booyse and Rafelson 1967; Shaw et al. 1984; Kieffer et al. 1987). Nevertheless, thus far only 10–20 of the thousands of mRNAs have been specifically demonstrated to be translated in a constitutive or signal-dependent fashion in human platelets (Weyrich et al. 2009; Rowley et al. 2012), including the mTOR-dependent translation of B-cell lymphoma 3 (Bcl-3) following platelet activation (Weyrich et al. 1998). Translation of Bcl-3 mRNA and other messages, including pre-mRNAs for IL-1β (Denis et al. 2005) and Tissue Factor (Schwertz et al. 2006) that are spliced and translated in a signal-dependent fashion, are reviewed elsewhere (Rowley et al. 2012).

The Inheritance of Platelet mRNAs

It is generally believed that most platelet mRNAs are derived from their parent megakaryocytes. Steady-state levels of platelets are maintained by production of new platelets from megakaryocytes and destruction of platelets in the liver and spleen (Mason et al. 2007). Before a megakaryocyte gives birth to platelets, a massive increase in cell growth and DNA synthesis occurs resulting in “mega” cells up to 128 N through repeated endomitotic divisions (Zimmet and Ravid 2000). During the final stages of development, megakaryocytes produce platelets by protruding or fragmenting their cytoplasm (Junt et al. 2007), or during situations of acute platelet need, by rupture (Nishimura et al. 2015). mRNAs are transcribed during the entire process of megakaryocyte development (Raslova et al. 2003), and those transcripts that eventually reach platelets, depending on their stability, potentially come from all stages of megakaryocyte maturation. In the megakaryocyte, as with other cells, precursor RNA is transcribed by RNA-polymerase II. Nascently transcribed RNA is cotranscriptionally loaded (Darnell 2013) with nuclear protein factors that include splicing factors, export signals, and zip code-binding proteins (Buxbaum et al. 2014), for splicing of precursor mRNA into mature mRNA, export from the nucleus (Delaleau and Borden 2015), and trafficking into platelets. Because transcription aborts at or prior to platelet release, gradual loss of mRNA occurs (Alhasan et al. 2016). Young platelets are thought to have more mRNA (Chavda

et al. 1996), increased numbers of ribosomes, and higher synthetic potential (Steiner and Baldini 1969).

Mechanisms by which mRNAs get transferred from megakaryocytes to platelets are unknown. However, there is evidence that mRNAs are differentially sorted rather than randomly distributed into platelets. In this regard, Cecchetti et al. (2011) have shown that matrix metalloproteinase (MMP) and tissue inhibitors of metalloproteinase (TIMP) family members are differentially packaged into platelets. By example, MMP-2 protein is in platelets but its transcript is only found in the megakaryocyte, whereas Timp-2 protein is very low in platelets but the mRNA is abundant. Studies of additional targets and on primary bone marrow or tissue megakaryocytes will help to clarify whether dedicated processes such as zip code-binding proteins direct the majority of mRNA into proplatelets, whether RNA is captured based on its peripheral location, or whether most are simply randomly selected. Attention will also need to be given to transfer of mRNA into platelets to and from other blood cells. Platelets are adept at endocytosis, and numerous investigations have shown that horizontal RNA transfer occurs between cells, including transfer of platelet mRNA to endothelial cells and hepatocytes (Tang et al. 2010; Risitano et al. 2012; Laffont et al. 2013; Clancy and Freedman 2014).

NGS Overview

There are a variety of approaches to measure the expression, individually or globally, of platelet mRNAs. NGS is currently the preferred method of transcriptome-wide studies because it unbiasedly captures a snapshot of mRNA presence, structure, and quantity from a genome at a defined moment in time (Shendure 2008). Here we briefly describe NGS but refer the reader elsewhere to more detailed reviews of this technology and its application to platelets (Wang et al. 2009; Costa et al. 2010; Auer and Doerge 2010; Nekrutenko and Taylor 2012; Schubert et al. 2014).

RNA-sequencing studies include four main steps: RNA isolation, Library Preparation, Sequencing, and Bioinformatic alignment and analysis of expression (Fig. 2). For platelet RNA, common isolation methods including phenol/chloroform-based extraction (TRIzol) or other commercial RNA isolation kits that allow for low abundance RNA isolation are suitable. After total RNA isolation, an RNA selection step targeting the class of RNA of interest is performed. For example, oligo-dT is commonly used to select polyadenyated mRNAs of coding genes. Other strategies, each with their own advantages and disadvantages, include ribosomal RNA removal, pull-down

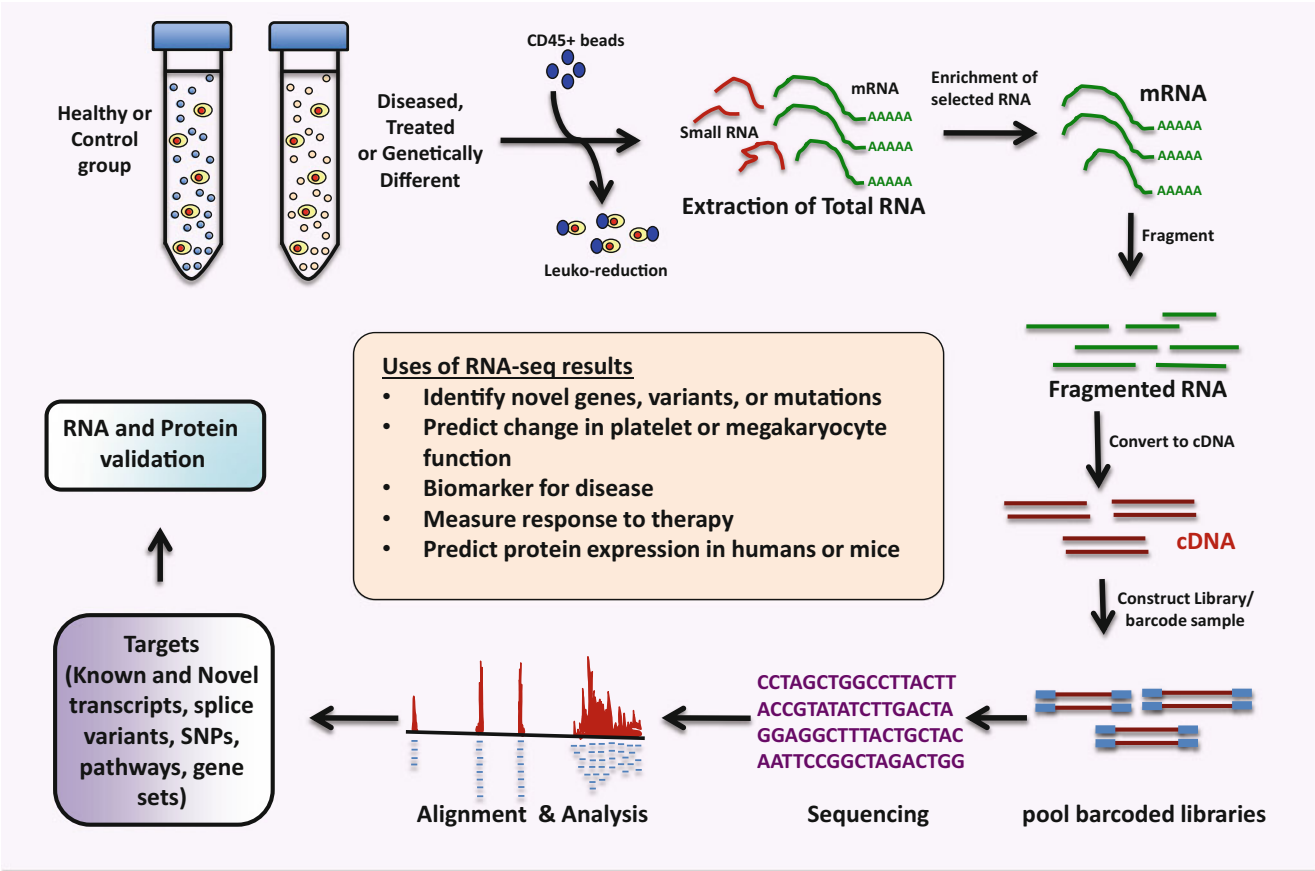

Fig. 2 A schematic overview of the typical workflow for RNA-sequencing studies in platelets

of capped RNA, or capturing of mRNAs associated with a specific RNA-binding protein.

Library preparation procedures vary according to the RNA species, desired analysis, and sequencing technology employed, but often include RNA fragmentation and size selection, adapter addition, cDNA generation, and amplification. Libraries can be prepared to maintain strand information, and therefore both sense and antisense transcripts can be identified from the same RNA pool. Barcodes are often added so that multiple libraries (we commonly pool >8 on an Illumina Hiseq 2000) can be pooled and distinguished bioinformatically. Following library prep, fragments are sequenced by available chemistries and platforms which include Illumina, Roche 454, SOLiD, Ion Proton/PGM, or Pac-bio sequencing. Fragment sequences are processed into the 4 letter nucleic acid code, and each sequence is either aligned to the genome, to the transcriptome, or assembled de novo into a transcriptome (Martin and Wang 2011).

Relative mRNA abundance, or the abundance of mRNA features (splice junctions, UTRs, individual exons or isoforms, etc.), can be quantified by counting the number of reads aligning to mRNA, followed by a normalization step. Estimates of expression based on read counts, RPKMs or FPKMs (reads or fragments per kilobase normalized to a million mapped reads) (Mortazavi et al. 2008), or normalization to reference transcripts such as ActB (Londin et al. 2014) are still commonly employed, although more sophisticated normalization techniques can give more accurate estimates of expression and are preferred for more rigorous statistical analysis (Wagner et al. 2012; Dillies et al. 2013).

As investigators embark on NGS-based studies, they need to keep in mind that bottlenecks can occur at the stage of data analyses. Thus, having a bioinformatics pipeline in place or access to collaborators with experience in managing NGS data is critical. Leukocytes contain >10,000 times more mRNA per leukocyte than a platelet (Fink et al. 2003). Thus, the sensitivity of NGS to detect mRNAs of low expression also requires stringent removal in platelet preparations of leukocytes that can confound data interpretation. Follow-up studies of candidate mRNAs and/or their corresponding protein are usually required to prove the expression and functionality of the target gene in platelets.

Platelet Transcripts as Indicators of Altered Platelet Function

Environmental and genetic factors influence the functional response of platelets. With regards to the environment, aging (Mohebali et al. 2014), diet (McEwen 2014), stress (Suls 2013), exercise (Heber and Volf 2015), obesity (Bhatt 2008; Anfossi et al. 2009; Russo et al. 2010), diabetes (Bhatt 2008), infection (Assinger 2014; De Stoppelaar et al. 2014), heart disease (Béres et al. 2008), immune or inflammatory disease (Herter et al. 2014) are known to alter platelet functional responses. For several of these conditions, platelet mRNA has been used to understand the mechanistic causes of altered platelet function or determine how differences in the platelet transcriptome might influence disease. Because their coded proteins, rather than the mRNAs themselves, are the executors of platelet function, mRNA is used as a surrogate to identify altered proteins, or in some cases to identify altered pathways. This is possible because the mRNA and protein levels in platelets are correlated. A comparison between platelet mRNA measured by RNA-seq and protein levels measured by quantitative proteomics has recently demonstrated this correlation (Rowley and Weyrich 2013). While the extent of the protein–mRNA relationship in platelets is still under debate (Geiger et al. 2013; Londin et al. 2014), the correlation is strong enough to have allowed many groups to successfully validate protein and pathway changes originally identified from mRNA screening. Some examples are highlighted.

CD69 and MRP 8/14 mRNA levels discriminated between STEMI and coronary artery disease (Healy et al. 2006). Protein levels of Myeloid Related Protein 8/14 mRNA correlated with the mRNA level and higher levels of MRP 8/14 predicted cardiovascular risk independent of other risk factors. Later, it was shown that MRP 8/14 is associated with thromboxane-dependent activation (Santilli et al. 2014). Genetic knockout of MRP 8/14 in mice prolonged the time to arterial occlusion, and transfusion of MRP 8/14 sufficient platelets into MRP 8/14 deficient mice decreased time to occlusion (Wang et al. 2014).

Pathway analysis of differentially expressed transcripts in sickle cell disease successfully predicted increased arginase II activity in platelets from diseased individuals (Raghavachari et al. 2007). In another related study, mRNA protein levels of inflammatory cytokines were profiled in patients with sickle cell disease. mRNA and protein for IL-1β, sCD40L, and IL-6 were increased in disease compared to controls (Davila et al. 2015). Lood and colleagues discovered an IFN response signature in the platelet transcriptome, with coordinate protein changes in IFN-regulated proteins such as PRKRA, IFITM1, and CD69 from patients with systemic lupus erythematosus (SLE) (Lood et al. 2010). In addition, COMMD7 and LRRFIP1 were identified as transcripts associated with platelet responsive to ADP or CRP-XL as measured by flow cytometry. When tested for replication of genotyping, LRRFIP1 and COMMD7 harbored single nucleotide polymorphisms (SNPs) potentially associated with MI (Goodall et al. 2010). The functionality of these genes was tested in a laser injury model in zebra fish where Lrrfip1-deficient

zebra fish exhibited a longer time to occlusion and a smaller thrombus size following thrombus induction (Goodall et al. 2010).

Environmentally induced mRNA expression changes in platelets have been identified in several other studies that lack corresponding protein data. Pre- and post glucose infusion studies identified altered insulin response pathways (Rao et al. 2014) and potential differences in mRNA candidates were identified in platelets from STEMI versus non-STEMI individuals (Eicher et al. 2016). Microarray analysis of platelets was also able to distinguish classes of thrombocytosis (Gnatenko et al. 2010) and RT-PCR of mitochondrial transcripts demonstrated an increase in mitochondrial complex I transcripts in older individuals (Merlo Pich et al. 2004). mRNA profiling has been used to identify candidate mRNAs altered in platelets from chronic kidney disease patients where changes in transcript expression were corrected by dialysis (Plé et al. 2012b). One of the altered transcripts was PCTP, an mRNA newly implicated in platelet function (Edelstein et al. 2013) (see later). Differences in these biomarker-based studies set the stage for subsequent examination of protein levels that will help clarify whether the observed changes in transcript expression are linked to altered functional responses in platelets.

Coding mRNA and Genetic Differences in Platelet Function

Genetic differences in the promoters, UTRs, introns, or coding region can influence the mRNA/protein expression level and the function of the product coded by platelet mRNAs. Genetic differences, if found within exons of mRNA are readily detected by RNA-seq (Kahr et al. 2011; Noetzli et al. 2015). Inherited common SNPs, race/ethnicity, gender, and pathological mutations are genetic factors that alter the mRNA content in platelets and dictate platelet function.

One study correlated the expression of Vamp8/endobrevin with platelet reactivity (Kondkar et al. 2010). The level of Vamp8 was related to a SNP in the 3′-UTR thought to alter miRNA binding and regulation of Vamp8 expression. Since Vamp8 is involved in platelet release, this provided a mechanistic explanation to some of the variability observed in platelet reactivity.

To identify transcripts related to racial differences in platelet reactivity, platelet functional responses and platelet mRNA were profiled from 70 black and 84 white subjects in the PRAX-1 study (Edelstein et al. 2013; Simon et al. 2014). Platelet responses to Par4 were higher in blacks than whites, and according to microarray analysis, PCTP mRNA is fourfold higher in blacks than in whites. Differences in PCTP could be attributed to lower miR-376c in blacks. PCTP protein levels were also higher. The role of PCTP protein in potentiating platelet reactivity was further supported by PCTP inhibition and depletion studies. Other relationships between platelet transcript levels; miRNA levels; and a number of demographic, platelet function, and clinical parameters collected as part of the PRAX-1 study (Platelet RNA AND eXpression 1 study) (Simon et al. 2014) can be explored at www.plateletomics.com. For example, the PRAX-1 study identified 129 transcripts differentially expressed by age in platelets and 54 by gender. In addition to age, race, and gender, transcript relationships with BMI; fibrinogen levels; von willebrand factor (VWF); and functional associations with ADP, arachidonic acid, Par4 AP, and Par1 AP can be explored to generate testable hypotheses.

mRNA studies have also been used to identify mutations leading to pathologic changes related to platelet function. Alterations in VWF splicing caused by a synonymous mutation within splicing regulatory regions could not be predicted without careful analysis of mRNA (Pagliari et al. 2013). In this study, mRNA analysis of three unrelated patients with von willebrand disease (VWD2AIIE) uncovered a 159 bp deletion (exon 26) in the mRNA that was not apparent from DNA sequencing. The patients shared a synonymous single nucleotide non-splice site substitution that affected splicing. Other splice site mutations leading to exon skipping in VWD have also been identified (Yadegari et al. 2012; Pagliari et al. 2013).

NGS has also been used to facilitate the discovery and understanding of rare genetic disorders that affect platelet function. Specifically, sequencing of platelet mRNA from patients with Gray Platelet Syndrome (GPS) detected abnormal transcript reads that mapped to neurobeachin-like protein 2 (NBEAL2). Genomic DNA sequencing confirmed the mRNA sequence abnormalities leading to the discovery of NBEAL-2 as the genetic cause of GPS (Kahr et al. 2011). Recent studies also revealed that patients with ETV6 (Ets Variant 6) germline mutations, who have thrombocytopenia and predisposition to lymphoblastic leukemia, display decreased expression of platelet-specific transcripts including significant reduction of mRNAs that regulate cytoskeletal processes (Noetzli et al. 2015). These studies suggest that ETV6, which is known to modulate the activity of other ETS transcription factors, is critical for transcriptional events that occur during platelet formation.

Platelet Transcripts to Monitor Response to Therapy

Aspirin treatment, or treatment with other antiplatelet agents, reduces the risk of primary cardiovascular events in hyperthrombotic states such as diabetes, chronic kidney

disease, coronary artery disease, or secondary cardiovascular events especially after stent placement (Hennekens and Dalen 2014; Park et al. 2015). Resistance to therapy, where platelets demonstrate high reactivity despite treatments, renders pharmacologic therapies less effective or ineffective (Floyd and Ferro 2014). mRNA studies in platelets and whole blood are being used to assess the mechanisms that drive resistance to therapies and as a potential method to screen for nonresponders.

Specific mRNAs differentially expressed in aspirin-resistant platelets have been determined (Fallahi et al. 2013). Regulators of G protein signaling (RGS), critical modulators of platelet function, were specifically analyzed for relationship to aspirin resistance in 39 aspirin-resistant and 50 aspirin-sensitive patients with metabolic syndrome (Mao et al. 2014). Transcripts for RGS2, RGS10, and RGS18 were significantly higher in the aspirin-resistant group. In another study, healthy volunteers were treated for 15 days with aspirin. MRp4 (an efflux transporter that can transport aspirin) mRNA and protein expression were increased by approximately 30 %. Human megakaryocytes grown in aspirin also increased mrp4 suggesting a direct effect of aspirin on platelet MRP4 expression (Massimi et al. 2014).

Another study measured whole blood mRNA levels in aspirin responders and nonresponders pre and post 2 weeks of aspirin treatment (Voora et al. 2013). A discovery cohort identified a gene set, called an aspirin responsive signature (ARS), that associated with aspirin responsiveness in the validation cohort as measured by a composite platelet function score. Although performed on whole blood, 24 of the 60 were platelet specific, and several strongly contributed to the correlation in the gene set, including the transcript ITGA2B. Interestingly, the ARS did not correlate with platelet function score in the absence of aspirin treatment. Furthermore, the ARS, or the expression of ITGA2B itself, was independently associated with the risk for acute MI and death.

The earlier studies demonstrate the promising approach for using mRNA to identify markers and drivers of aspirin or clopidogrel responsiveness. This approach could be used in other antiplatelet drug treatments, or even in therapies where platelets are not the primary targets, but may be involved in drug responsiveness such as the use of fibrinolytics or desmopressin. Considerations for how therapies might affect subsets of platelets, including young versus old platelets, will also be of interest. In this regard, dyes such as thiazole orange have been used to distinguish the immature platelet fraction that is thought to be more "mRNA rich" and individuals with a higher immature platelet fraction are less responsive to clopidogrel treatment (Ibrahim et al. 2012). Furthermore, RNA studies are not limited to mRNA. miRNAs are driving considerable interest in their field because of the ability of a single miRNA to target multiple mRNAs in a pathway. In this regard, miR-223 associates with high platelet reactivity in patients on clopidogrel (Shi et al. 2013).

Platelet Transcripts as Diagnostic Biomarkers of Disease

Although platelets contain some mitochondrial DNA, they lack nuclear DNA, and thus are generally refractory to acute (minutes to hours) transcript changes caused by sudden environmental alterations. Therefore, the total transcript pool in circulating platelets is thought to capture accumulated changes that occur in the ~1000–3000 platelets released from their parent megakaryocyte. As a result, systemic and chronic signals from infection, cancer, or inflammatory disease are more likely to shape the transcriptome of megakaryocytes and, as a consequence, be transferred into platelets. In addition, the accumulated uptake of exogenous RNA (Nilsson et al. 2011), either by direct cellular transfer, or paracrine and endocrine transfer via microparticles, may also alter the platelet transcriptome in disease situations (Clancy and Freedman 2014). Because platelets circulate systemically and are easily obtained, several recent studies have highlighted the potential use of platelet transcripts as biomarkers, even for diseases without apparent platelet etiology.

As an example, Wurdinger and colleagues. (Best et al. 2015) sampled platelets (called Tumor Educated Platelets or TEP) from 55 healthy individuals and 228 cancer patients spanning six different cancers. They included nonsmall cell lung carcinoma, colorectal cancer, glioblastoma, pancreatic, hepatobiliary, breast cancer, none of which are blood-related cancers. Comparing the cancer platelet transcriptome to healthy platelets, this group identified >1400 increased and ~800 decreased transcripts. Samples were subdivided into a training and validation cohort, and using a leave-one-out cross-validation support vector machine algorithm (SVM/LOOCV), 1072 RNAs, including coding mRNAs, were used to classify pan-cancer at a high sensitivity, specificity, and accuracy with high predictive strength. Using the same method, the authors found that platelet transcript signatures were able to accurately classify the origin of different subtypes of tumors, including in metastatic cancers, with high specificity and accuracy. Of note, some of the tumor-differentiating RNAs were transcripts not normally found in platelets (i.e., leukocyte-specific transcripts). It will be interesting to determine whether tumor-differentiating transcripts are from pathologically induced expression in megakaryocytes, transfer of mRNAs from leukocytes to platelets, or from an increased propensity of platelet–leukocyte aggregates in cell isolations collected from cancer patients.

Regardless of the source of the differences in RNA expression, and independent of the impact of these changes to platelet function, the application of a platelet signature is a promising new avenue for a liquid biopsy-based cancer diagnostic and classification.

Another promising diagnostic avenue might be the direct detection of cancer causing mutations in platelets. In the Wurdinger study (Best et al. 2015), mutant KRAS RNA, a mutation common to cancers, was detected in some platelet samples. In another study by the same group (Nilsson et al. 2016), RT-PCR detected EML4-ALK rearrangements in platelet RNA from individuals with nonsmall cell lung cancers. Rearrangements were detected with 65 % sensitivity and 100 % specificity as compared to matched tissue biopsies. Of 77 cancer patients, rearrangements were detected in platelets from 22 patients. The tumor RNA was enriched in platelets compared to plasma, where the rearrangement was only detected in three patients. Because EML4–ALK fusion in cancers is related to progression-free survival, RT-PCR in platelets could be used to serially monitor for EML4–ALK presence and the probability of progression-free survival (Nilsson et al. 2016).

The potential use of platelet transcripts in disease diagnosis and tracking has also expanded to neurodegenerative disorders. Platelets contain many transcripts that are enriched in brain cells, including amyloid precursor protein (APP) (Catricala et al. 2012). RT-PCR analysis of APP mRNA in platelets from Alzheimer's disease (AD) or Frontotemporal Lobar Degeneration (FTLD), indicated upregulation of this mRNA in both diseases, and the level correlated with cognitive impairment in the AD group (Vignini et al. 2013). These studies in cancer and neurodegenerative disorders highlight the possible utility of platelet mRNA as a diagnostic biomarker of disease.

mRNA Profiles in Mouse Platelets

The primary role of platelets to prevent excess bleeding and promote wound healing is shared between human and mouse, and mouse models are often used to understand human platelet function. Understanding similarities and differences between humans and mice is critical for accurate interpretation of murine models of platelet function. For example, thrombin activates human platelets through Par1, but alternatively uses Par3 on mouse platelets (Ishihara et al. 1997; Kahn et al. 1998). Humans respond robustly to platelet activating factor, whereas mouse platelets are not responsive (Karpouza and Vakirtzi-Lemonias 1997). As one might predict, initial RNA-seq comparisons between human and mouse transcriptomes have identified similarities and differences in platelet mRNA expression (Rowley et al. 2011). While the majority of transcripts are expressed at similar levels, several show extreme differences in expression including mRNAs for Par1, Par3, and platelet-activating factor receptor. Thus, mouse models can now be interpreted in the light of molecular expression differences revealed through RNA-seq. Moreover, mRNA profiling can also be used to identify secondary mRNA changes induced by specific mouse genetic knockouts to guide the phenotyping of these animals.

Summary

Characterizing mRNA expression profiles in circulating platelets has emerged as a powerful tool for understanding processes in megakaryocytes and their offspring. It is becoming more appreciated that the transcriptome of platelets is complex and diverse (Fig. 3), and the repertoire of mRNAs expressed by platelets changes in disease. These changes likely reflect differential shuttling of mRNAs from megakaryocytes to proplatelets in pathologic situations, but may also result from horizontal mRNA transfer from other circulating cells.

Determining mRNA expression patterns in platelets is informative on several fronts including: (1) assessment of translation; (2) providing insight into thrombopoiesis; (3) understanding the molecular phenotype and function of platelets from people of different races, gender, and age as well as patients with underlying genetic disorders or acquired diseases; (4) evaluating platelets during storage and their efficacy for transfusion; and (5) predicting the expression of proteins and conservation of genes between mouse and human platelets, which is critical for investigators pondering whether to knock-out or knock-in genes in mice for in vivo appraisal of platelet function. Although powerful, global transcriptome profiling is time consuming, costly, and comes with the difficult task of bioinformatically dissecting the data and determining the next steps of experimental pursuit. The good news is that significant information regarding the platelet transcriptome can be obtained by simply accessing published NGS datasets, and specific genes can be assessed at the candidate level for minimal costs. More sophisticated bioinformatics analyses and advanced NGS-based techniques such as ribosomal footprinting will undoubtedly emerge, and results from these studies will provide new information regarding the megakaryocyte and platelet transcriptome and how mRNA is linked to platelet function in health and disease.

Take Home Messages

- Next-generation transcriptome wide sequencing (RNA-seq) has vastly expanded our current understanding of the platelet transcriptome.

(continued)

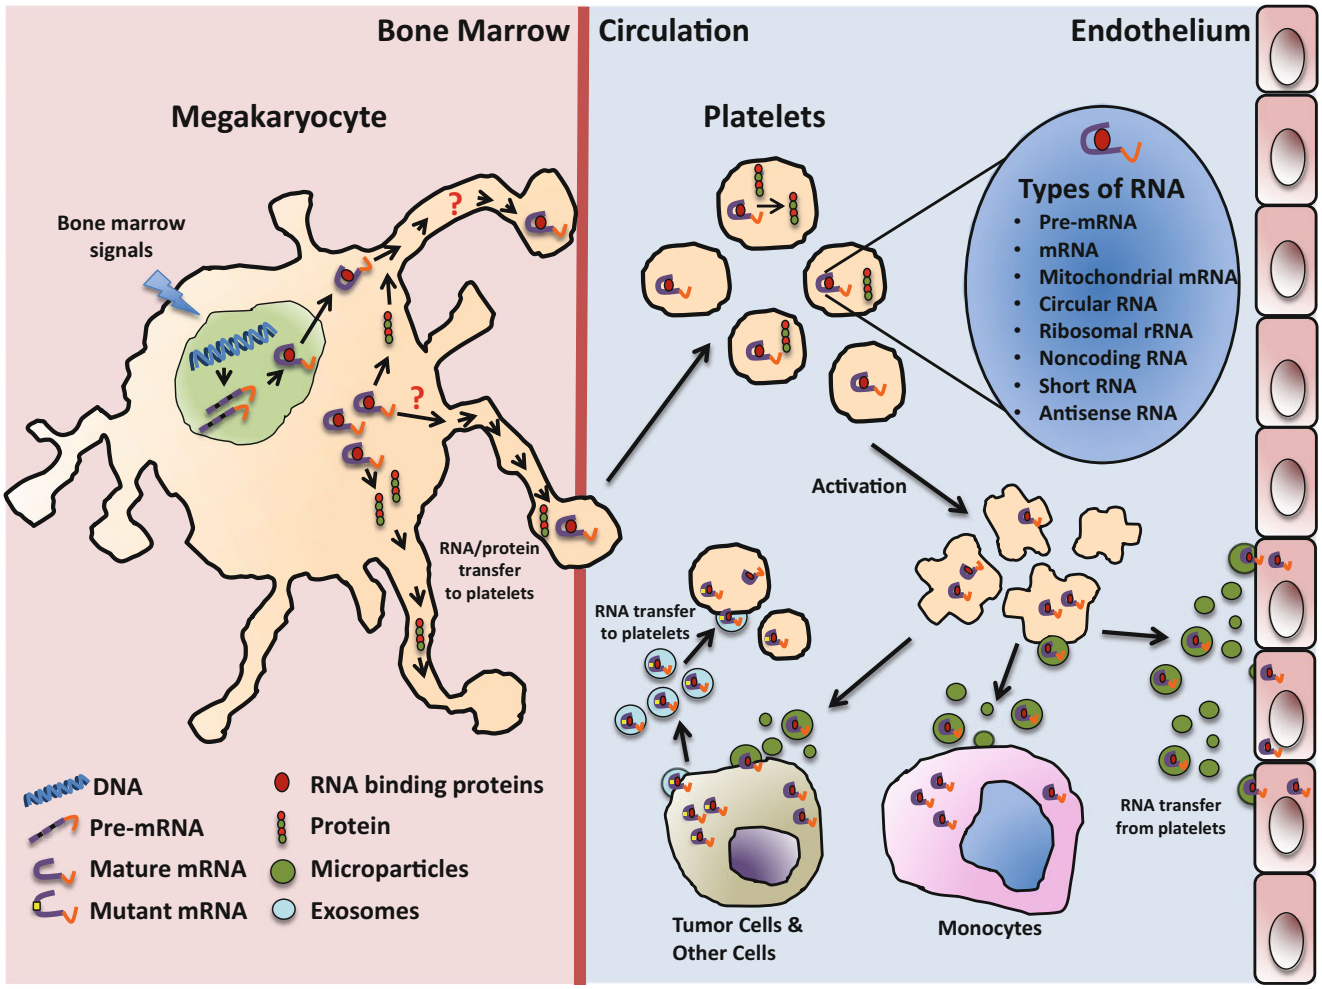

Fig. 3 The fate of platelet and megakaryocyte mRNA. Pre-mRNAs are transcribed in the megakaryocyte where the majority are processed into mature mRNA and exported from the nucleus for translation. Megakaryocyte mRNAs and their protein products are transferred, sometimes differentially, into proplatelets and their platelet progeny, but the mechanisms of transfer are not clear. Depending on the environmental and genetic signals influencing megakaryocyte RNA transcription and turnover at the time of platelet production, different RNAs may be ultimately transported into platelets. Constitutive or signal-dependent translation of mRNA can occur in circulating platelets. Once platelets are released into the circulation their mRNA content (and thereby potential protein production and function) is altered by degradation, by uptake of additional mRNA from other cells, including from tumor cells, or transport of their mRNA to other cells

- The platelet transcriptome is complex, containing all the major RNA subtypes.
- The source of platelet mRNAs is not clear, but most are probably directly captured from megakaryocytes, while others may be transferred into platelets.
- Platelet mRNAs are stable and their mRNA profiles are snapshots of the cumulative transcriptional events that occurred in megakaryocytes.
- Platelet mRNAs code for corresponding proteins, and platelet mRNAs can be used to predict protein and functional differences in health and disease.

- Platelet mRNAs are being used to understand genetic differences in platelet function, including race, gender, and platelet disorders.
- Platelet mRNAs may be used to monitor response to therapy such as aspirin responsiveness.
- Platelet mRNAs may be used as biomarkers of a variety of diseases including metabolic syndromes, infectious diseases, and cancer.
- Mouse platelet mRNA profiles can guide the design and characterization of platelet-related mouse models.

Noncoding RNAs in Platelet Biology

Leonard C. Edelstein and Paul F. Bray

Abstract

Noncoding RNAs (ncRNA) account for the majority of the human cellular transcriptome. Advances in sequencing technologies and analytic approaches continue to identify novel ncRNAs. A large amount of research has investigated the role of microRNAs (miRNAs) in megakaryopoiesis and platelet biology, whereas relatively little is known about other ncRNAs. miRNAs affect basic development and physiology by regulating protein translation, and in doing so miRNAs regulate hematopoiesis and megakaryopoiesis. To date, platelet miRNA studies have focused on their use as biomarkers and as tools for understanding basic mechanisms of megakaryocyte/platelet gene expression, but there is a rapidly expanding appreciation for miRNAs as mediators or modifiers of disease, the potential for platelet miRNAs to affect gene expression in other tissues, and as therapeutic targets.

Introduction

The importance of noncoding RNA (ncRNA) in cell biology has been appreciated since the discovery of transfer RNAs (tRNA) and ribosomal RNAs (rRNAs) and their essential role in protein synthesis. However, the emphasis on small ncRNAs is relatively recent, beginning with the discovery of microRNAs (miRNAs) in the early 1990s. The introduction of next-generation RNA sequencing (RNA-seq) together with sophisticated bioinformatic analyses of large amounts of sequence data without a priori sequence information has led to the discovery of numerous other classes of ncRNAs. In addition to protein synthesis, many aspects of RNA biosynthesis are regulated by ncRNAs including splicing by small nuclear RNAs (snRNAs), rRNA processing by small nucleolar RNAs (snoRNAs), and mRNA translation and stability by microRNAs (miRNAs). ncRNA categories now include PIWI-associated RNAs (piRNAs) that regulate chromatin modification, and small Cajal body-associated RNA (scaRNAs) that modify snRNAs (Cech and Steitz 2014). A common theme among many of these categories is RNA-mediated regulation of RNA processes. This chapter will discuss the likely influence of ncRNAs on megakaryocyte (MK) gene expression and value of understanding ncRNAs in peripheral blood platelets.

miRNAs

MiRNAs are approximately 22-nucleotide regulatory RNAs expressed in multicellular organisms (Bartel 2004). miRBase v21 (June 2014, http://www.mirbase.org/) lists 2588 mature human miRNAs while the GENCODE reference set (v22) derived from ENCODE data lists 4093 (Derrien et al. 2012), although recent data provides strong evidence for more than twice that many (Londin et al. 2015). miRNAs regulate most (>60 %) mammalian protein-coding genes (Friedman et al. 2009). Some miRNAs are expressed ubiquitously, but many are tissue and/or developmental stage specific (Wienholds et al. 2005; Londin et al. 2015).

MiRNA biogenesis has been reviewed in depth elsewhere (Krol et al. 2010) but will be briefly summarized here (Fig. 1). The canonical miRNA pathway consists of pri-miRNAs transcribed from DNA genes by RNA polymerase II, which are then processed into pre-miRNAs in the nucleus by a Drosha RNase-containing complex. After exportation to the cytoplasm Dicer shortens the pre-miRNA into a ~22 nucleotide double-stranded RNA molecule. One strand of this molecule is loaded into the RNA-induced silencing complex (RISC) that contains Argonaute proteins. Guided by the miRNA sequence, the RISC then causes translational inhibition followed by mRNA degradation (Guo et al. 2010; Bazzini et al. 2012; Djuranovic et al. 2012). The impact of miRNAs on gene expression is often to fine-tune and reduce noise in protein expression (Selbach et al. 2008; Baek et al. 2008; Schmiedel et al. 2015). In some cases, as little as a 20 % change in miRNA levels has been shown to produce disease or predispose to malignancy (Alimonti et al. 2010).

miRNAs target multiple mRNAs, and most mRNAs are targeted by multiple miRNAs. mRNA target prediction is a critical aspect of miRNA research, because it is through the targets that miRNA function is achieved. Numerous different miRNA target prediction algorithms are publicly available, including TargetScan, Miranda, PicTar, RNA22, and Microcosm. However, there is a lack of consensus on the optimal prediction method (Rigoutsos and Tsirigos 2011). Often, researchers utilize multiple algorithms that assign different "weights" to various features, such as degree of sequence homology, species conservation, etc., although even this approach has not been validated. Because of false-positive target predictions, it is essential to test in silico predictions in cells.

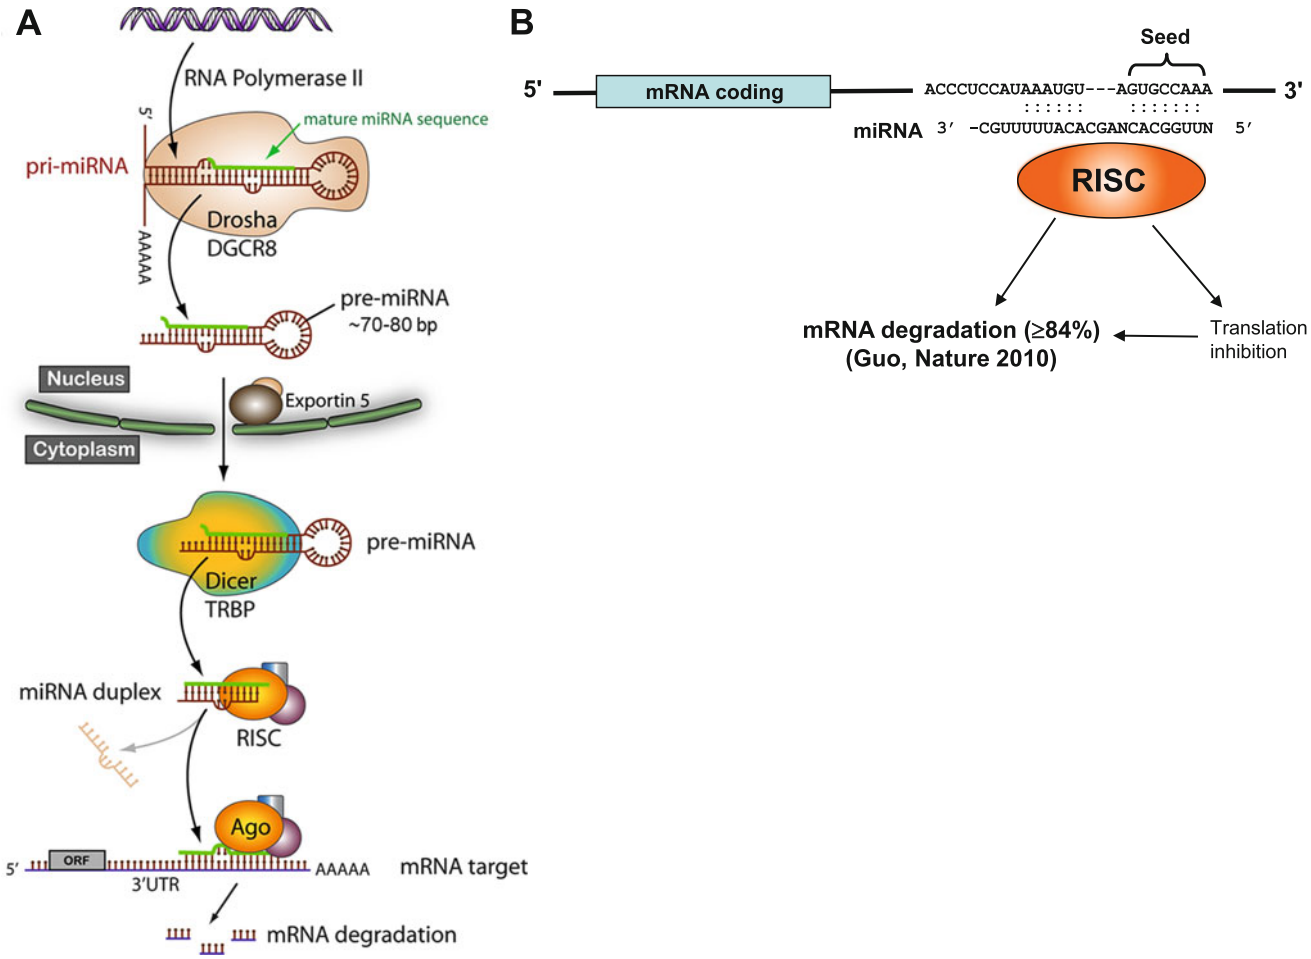

Fig. 1 MicroRNA biogenesis and function. (**a**) The canonical miRNA biosynthesis pathway, described in text. *Drosha* an RNase type III endonuclease, *DGCR8* DiGeorge syndrome critical region 8, *Dicer* another RNase type III endonuclease, *TRBP* TAR RNA-binding protein, *RISC* RNA-induced silencing complex, *Ago* Argonaute 2, *ORF* open reading frame. (**b**) The seed region of the miRNA (bp 2-8) bind to complementary sites on the 3′ UTR of target mRNAs where it predominantly causes a decrease in mRNA levels, but may also inhibit translation. Figure from Edelstein and Bray (2011)

miRNAs and Megakaryopoiesis

The important role of miRNAs in both healthy and malignant hematopoiesis has been thoroughly investigated (Lazare et al. 2014). The function of miRNAs has been studied using a number of techniques including profiling human and mouse $CD34^+$ hematopoietic stem cells differentiated in culture, and genetically manipulating mice and human $CD34^+$ cells, human embryonic stem cells, and transformed cell lines with megakaryocytic properties. These approaches have identified numerous miRNAs that positively and negatively influence megakaryocytic differentiation. Figure 2 summarizes the miRNAs regulating megakaryopoiesis that are described later.

miRNAs Positively Regulating Megakaryopoiesis

miR-150 was one of the first miRNAs identified as regulating megakaryopoiesis (Lu et al. 2008). Different lineages of primary cord blood hematopoietic cells at various stages of differentiation were isolated by flow cytometry and miRNA profiles were determined. *miR-150* was enriched in megakaryocytes as compared to megakaryocyte-erythroid precursors (MEPs). Forced expression in murine bone marrow cells resulted in an increase in colony forming units-megakaryocytes (CFU-MKs). Subsequently, *miR-150,* whose expression increases in response to thrombopoietin (TPO), targets and downregulates *MYB*, a transcription factor that is a negative regulator of hematopoiesis, offering a model of how *miR-150* affects MK development (Emambokus et al. 2003; Barroga et al. 2008).

miR-34a also enhances megakaryopoiesis. *MYB*, as well as *CDK4* and *CDK6,* is targeted by *miR-34a*, a miRNA whose expression level increases during phorbol ester-induced differentiation of K562 cells and TPO-induced differentiation of $CD34^+$ cells. Enforced expression of *miR-34a* in K562 cells enhanced MK differentiation, as measured by cell surface markers (Navarro et al. 2009; Ichimura et al. 2010).

miR-146b increases in phorbol-ester-treated K562 cells and ectopic expression of *miR-146b* in these cells enhanced MK development (Zhai et al. 2014). Platelet-derived growth factor receptor α (*PDGRA*), a negative regulator of megakaryopoiesis, was identified as a target of *miR-146b*.

miR-105 was identified as a positive regulator of megakaryopoiesis in a high-throughput screen in which miRNAs were overexpressed in human embryonic stem cells driven to differentiate into multiple lineages (Kamat et al. 2014).

The earlier megakaryopoiesis-regulating miRNAs were identified using unbiased approaches. In contrast, Chapnik et al. generated a *miR-142* null mouse, specifically because of its known role in hematopoiesis. The mice exhibited reduced MK maturation, proplatelet formation, and thrombocytopenia (Chapnik et al. 2014), supporting *miR-142* as a positive regulator of megakaryopoiesis.

miRNA Negatively Regulating Megakaryopoiesis

By silencing *MYB* in human $CD34^+$ cells, Bianchi and colleagues identified *miR-486-3p* as a target of *MYB*-induced transcription (Bianchi et al. 2015). They further identified

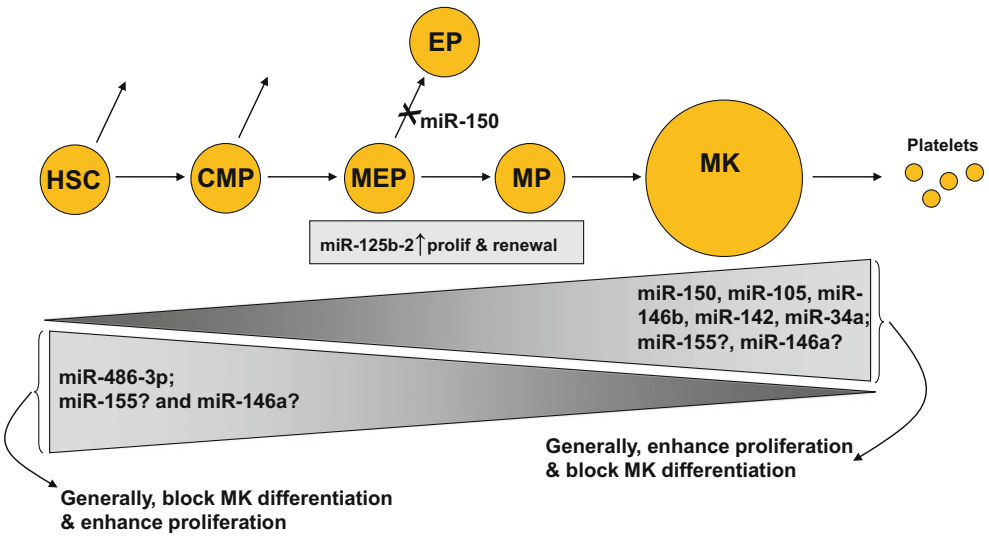

Fig. 2 MicroRNAs and megakaryocytopoiesis. This cartoon summarizes the miRNAs known to participate in megakaryocytopoiesis. Megakaryocytes (MK) originate from self-renewing hematopoietic stem cells (HSC), which differentiate progressively into common myeloid precursors (CMP), megakaryocyte/erythroid precursors (MEP), and MK precursors (MP). The height of the triangles indicates the level of the miRNA, with some miRNAs decreasing during megakaryocytopoiesis, and others increasing. There is conflicting evidence regarding the role of miR-146a and miR-155. Levels of miR-125b-2 do not change during progression from MEP to MP. Figure updated from Edelstein and Bray (2011)

MAF, another transcription factor, as a target of *miR-486-3p*-mediated negative regulation. Overexpression of *miR-486-3p* or silencing *MAF* expression in human $CD34^+$ cells inhibited MK differentiation. Taken together, these studies support an axis in which *miR-150* and *miR-34a* (positive regulators of megakaryopoiesis) target and reduce *MYB* levels resulting in lower levels of its transcriptional target, *miR-486-3p*. Lower levels of *miR-486-3p* result in higher levels of *MAF*, and thus, enhanced megakaryopoiesis.

miRNAs with Complex Effects on Megakaryopoiesis

miR-155 was identified as a hematopoietic stem cell miRNA predicted to target mRNAs critical to hematopoiesis. When transduced into human $CD34^+$ cells, *miR-155* resulted in decreased numbers of CFU-MKs (Georgantas et al. 2007). Identified targets of *miR-155* include the *Ets1* and *Meis1* transcription factors, well known regulators of megakaryocytopoiesis, as well as the chromatin remodeling protein *JARID2* (Romania et al. 2008; Norfo et al. 2014). In contrast to the data indicating that increased *miR-155* decreases megakaryopoiesis, silencing of *JARID2* in human $CD34^+$ cells resulted in increased numbers of MK precursors (Norfo et al. 2014). This data, along with work demonstrating that transfer of hematopoietic stem cells with enforced expression of *miR-155* results in decreased bone marrow MKs, erythrocytes, and lymphocytes but a large number of splenic MKs, suggests that *miR-155* plays a critical role in MK development in a complex manner that depends on the developmental stage (O'Connell et al. 2008).

miR-146a was identified as a transcriptional target negatively regulated by the promyelocytic leukemia zinc-finger (PLZF), a transcription factor known to be involved in hematopoiesis and leukemogenesis. Labbaye et al. reported that *miR-146a* expression decreased in human $CD34^+$ cells induced to differentiate into MKs and that ectopic expression of *miR-146a* in human $CD34^+$ cells inhibited megakaryocytic differentiation, as measured by reduced number of cells with polylobulated nuclei, surface markers, and CFU-MKs (Labbaye et al. 2008). In contrast, Opalinska et al. found that *miR-146a* increased during differentiation and had no effect on megakaryopoiesis (Opalinska et al. 2010). Starczynowski et al. (2010, 2011) reported that the level of *miR-146a* is lower in MK/erythroid precursors in mice relative to hematopoietic stem cells, similar to what Labbaye et al. (2008) found in human cells, but that forced expression in mice had no effect on platelet number, similar to observations by Opalinska et al. (Opalinska et al. 2010; Starczynowski et al. 2011). However, when *miR-146a* was downregulated in mice by decoy targets or anti-miRNA locked nucleic acids (LNA), the CFU-Mk and platelet number increased and the ploidy of the MKs decreased, similar to Labbaye et al. (Starczynowski et al. 2010; Labbaye et al. 2008). Taken together, there is strong evidence that *miR-146a* modifies megakaryopoiesis, but the effects are complex and may differ under different conditions or stresses that have yet to be defined.

The Platelet miRNA Repertoire

Because platelets are more accessible than MKs, more data characterizing the platelet transcriptome has been obtained. Platelets from healthy individuals contain approximately 6000 different protein-coding transcripts (Simon et al. 2014; Londin et al. 2014; Bray et al. 2013; Gnatenko et al. 2003; Rowley et al. 2011) and at least 178 commonly expressed miRNAs (Edelstein et al. 2013). Table 1 lists the highest expressed miRNAs in platelets from healthy subjects (Edelstein et al. 2013; Simon et al. 2014). Many reports over the past several years suggest platelet miRNAs are biologically and clinically relevant as (1) tools to understand platelet physiology and MK gene expression, (2) potential regulators of platelet RNA and protein expression levels, and (3) a source for circulating miRNAs.

Recent work has identified novel platelet-specific miRNAs previously unknown because reference databases did not include RNA-seq of platelet RNA (Londin et al. 2014, 2015). In addition to the 2588 miRNAs listed in miRBase v21, Londin et al. analyzed RNA-Seq data from 1323 samples from 13 different human tissues, including ten platelet samples. They were able to identify 3707 novel miRNAs derived from 3494 precursors. Sixty-eight of these novel miRNAs were detected in all ten platelet samples including 11 which were platelet specific (Londin et al. 2015). Given the large number of predicted targets for each miRNA, these miRNAs may have a significant impact on megakaryocyte/platelet regulation of the transcriptome.

miRNAs in Platelet Physiology and Gene Expression

Because miRNAs often target hundreds of mRNAs, miRNA function is not obvious. Association studies between miRNA levels and cell parameters are a useful approach for beginning to understand potential functional effects of miRNAs. The well-established interindividual variation in platelet number and function, plus the ease of obtaining platelets, makes platelets an ideal system for studying miRNA function in general, and for platelet miRNAs specifically. Although RNA profiling can identify novel regulators of platelet function in healthy and disease conditions, some

[a]Some probes were nonunique and detected multiple species of miRNA. These probes are indicated by listing the detected species in a single row

caution is needed when interpreting the results: (1) Leukocytes contain 60–200 times as much miRNA as platelets (Teruel-Montoya et al. 2014), so proper platelet purification is necessary. Immunodepletion of leukocytes and erythrocytes can result in greater than $1{:}10^6$ leukocyte: platelet ratio, allowing for a more accurate representation of the platelet transcriptome. (2) Because many platelet miRNA levels differ by subject age, race, gender, and medication use (Edelstein et al. 2013; Simon et al. 2014), these variables must be considered in any analyses comparing different groups of subjects. (3) Caution must also be used when assessing platelet miRNA levels and function in transformed cell lines since miRNA expression data has shown that cell line miRNA profiles more closely resemble each other than their postulated cell of origin (Teruel-Montoya et al. 2014).

Kondkar et al. first reported that compared to hyporeactive platelets, *VAMP8* mRNA is more highly expressed in hyperreactive platelets (Kondkar et al. 2010). These investigators showed that *miR-96* levels were inversely correlated with

both *VAMP8* mRNA levels and platelet hyperreactivity, and that *miR-96* regulated *VAMP8* mRNA and protein levels. Subsequently, it was shown that miRNA expression profiles predicted platelet aggregation response (Nagalla et al. 2011). Using a bioinformatics approach, three miRNA:mRNA pairs—*miR-200b:PRKAR2B, miR-495:KLHL5, miR-107:CLOCK*—were identified and validated experimentally. This was the first demonstration of the functional importance of the regulatory subunit of PKA in human platelets.

The Platelet RNA and eXpression 1 (PRAX1) study performed detailed platelet phenotyping, genome-wide genotyping, genome-wide mRNA and miRNA profiling, and tested for multi-omic associations (Edelstein et al. 2013). Platelets from black subjects were discovered to be more responsive to activation through the protease-activated receptor 4 (PAR4) thrombin receptor. A large number of miRNAs and mRNAs were differentially expressed by both self-identified race and PAR4 reactivity (Edelstein et al. 2013). Among the miRNAs differentially expressed by race was the *DLK1-DIO3* cluster of 54 miRNAs. One member of this cluster, *miR-376c*, was shown to regulate phosphatidylcholine transfer protein (*PCTP*), which itself is differentially expressed by race. PC-TP protein was then confirmed as a regulator of platelet PAR4 function. These data are consistent with the possibility that differentially expressed miRNAs contribute to the greater thrombotic risk in blacks as compared to whites (Mozaffarian et al. 2015; Thomas et al. 2010).

Despite the absence of a nucleus, platelets contain mRNA, splice mRNAs, and translate mRNA into proteins relevant to hemostasis and inflammation (Warshaw et al. 1966; Weyrich et al. 2009; Denis et al. 2005). Human platelets also contain functional miRNA processing machinery and miRNAs that are complexed with Ago2 (Landry et al. 2009). There is an increasing body of evidence indicating that inflammatory states enhance platelet mRNA translation into protein (Hottz et al. 2013). Supporting this finding, Corduan et al. reported that upon platelet activation, mRNAs are released from the Ago2:miRNA complex and undergo translation (Corduan et al. 2015). Finally, platelets continue to translate proteins from mRNA under Blood Bank storage conditions (Thon and Devine 2007).

Platelet miRNAs in Disease

Altered miRNA expression has been associated with numerous clinical conditions. Such associations may have value as diagnostic biomarkers or to better understand the molecular pathophysiology of the disease. Because many of these studies utilize blood as the RNA source for profiling, it is important to know which cellular or noncellular component of the blood was used. Extrapolating results from plasma RNA to the cell of origin is only appropriate insofar as the profiles of the individual components are known and if the results are "normalized" to the amount of total RNA assayed. Recently, a formal approach was utilized to determine the absolute quantity of RNA per blood cell (Teruel-Montoya et al. 2014). Although nucleated blood cells have the highest miRNA content per cell (Table 2), because of cell number differences erythrocytes contribute more cellular miRNA to the blood, followed by granulocytes and platelets. Not surprisingly, miRNA expression patterns differ for each lineage (Fig. 3). These lineage differences are important to consider when interpreting disease-circulating miRNA association studies.

Hematologic Disease Starczynowski and colleagues showed that patients with myelodysplasia and deletions of 5q lost *miR-145* and *miR-146a*. They further showed that knockdown of these miRNAs in mouse hematopoietic stems cells caused thrombocytosis, neutropenia, and megakaryocytic dysplasia in a manner dependent upon *miR-145* and *miR-146a* inhibition of tumor necrosis factor receptor-associated factor-6 (Starczynowski et al. 2010). Whereas most other studies have identified disease *associations*, the Starczynowski study is one of the few studies demonstrating a *causal* role for platelet miRNAs in disease pathophysiology.

Polycythemia rubra vera (PV) and essential thrombocytosis (ET) are BCR-ABL negative myeloproliferative neoplasms that are difficult to distinguish from nonclonal conditions due to the variety of causative mutations. A study with PV patients demonstrated higher levels of *miR-26b* in the platelets of patients with PV compared to control subjects (Bruchova et al. 2008). Subsequent work showed that as few as three miRNAs (*miR-10a, miR-148a*, and *miR-490-5p*)

Table 2 Contribution of each cell type to total miRNA content per volume of blood

	Platelet	T-Cell	B-Cell	Granulocyte	Erythrocyte
Total RNA mass, femtogram/cell	2.20	2188.00	1360.00	646.30	0.57
miRNA mass, femtogram/cell	0.05	3.28	3.16	10.23	0.04
miRNA mass, picogram/μl blood	16.90	3.55	0.64	50.24	184.00

Five cell types from five donors were purified and total RNA was extracted. Based on original cell counts, the average total RNA yield on a per cell basis was calculated (row 1). RNA samples were size profiled, the average miRNA-to-total RNA ratio was calculated for each cell type from all subjects, and based on the average total RNA per cell, the average miRNA mass per cell type was calculated (row 2). Row 3 has estimates of the contribution of each hematopoietic cell type to the miRNA content of blood volume using cell miRNA content and cell number per blood volume. Table from Teruel-Montoya et al. (2014)

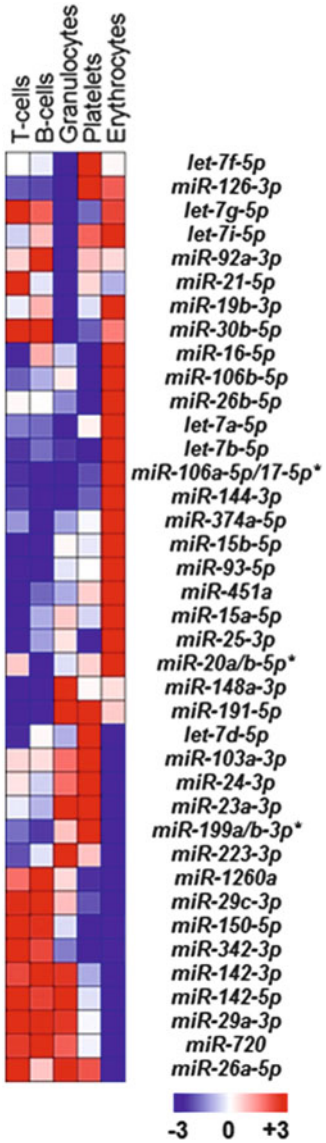

Fig. 3 Peripheral blood cells miRNA profiles. Heatmap is derived from the union of the most abundant miRNAs (39 in total) in each primary blood cell type. Each column indicates the average log-ratio intensity data. *Asterisk* indicates probes with similar and indistinguishable sequence with the nCounter platform. Figure from Teruel-Montoya et al. (2014)

could discriminate ET from normal platelets (Xu et al. 2012). Platelets from a small number of patients with sickle cell anemia were reported to have different platelet miRNA expression profiles than platelets from nonsickle disease subjects (Jain et al. 2013). Unfortunately, none of these clinical association studies considered demographic variables known to alter miRNA expression levels.

Cardiovascular Disease Platelets play a central role in the pathophysiology of acute and chronic cardiovascular disease. Blood cell miRNA profiles were observed to differ between patients having ST-segment elevation MI or non-ST-segment elevation MI with platelet *miR-25-3p* and *miR-221-3p* significantly higher in patients with STEMI than NSTEMI (Ward et al. 2013). A small study of 12 patients with premature CAD and 12 healthy controls identified differentially expressed platelet miRNAs (Sondermeijer et al. 2011). Notably, the majority of studies testing for associations between miRNAs and cardiovascular disease utilize plasma or cardiac tissue, but not purified platelets as an RNA source, and confounding demographic variables altering miRNA levels were not considered. Of potential interest is a report by Zampetaki et al. who prospectively tested for associations between circulating miRNAs and incident MI (Zampetaki et al. 2012). These investigators found *miR-126* levels were positively associated with incident MI, while *miR-223* levels were negatively associated with incident MI. Among circulating blood cells these are the two highest expressed platelet miRNAs, with the former being predominantly of platelet origin (Teruel-Montoya et al. 2014). However, this analysis is confounded by the known high levels of *miR-126* and *miR-223* in endothelial cells and granulocytes, respectively.

Platelet miR-223 in Disease

Generally recognized as the most abundant miRNA in platelets, *miR-223* has been investigated by many groups for its role in disease. While Stratz et al. reported that there was no overall change in the platelet miRNA profile of patients with type 2 diabetes, Elgheznawy and colleagues have reported that *miR-223* is lower in diabetic subjects (Elgheznawy et al. 2015; Stratz et al. 2014). This discrepancy may be due to differences in the presence of antiplatelet medication or experimental approach (profiling vs candidate gene). Elgheznawy et al. also reported that in diabetic platelets, calpain cleaves Dicer, resulting in lower levels of *miR-223, miR-142, miR-143,* and *miR-155*. Coagulation factor XIII-A was identified using proteomic and molecular techniques as a *miR-223* target. Mice deficient in *miR-223* exhibited shorter bleeding times, larger $FeCl_3$-induced thrombi, greater sensitivity to low doses of thrombin, and impaired clot retraction (Elgheznawy et al. 2015). These results differed from Leierseder et al. who reported that *miR-223* deficient mice had no defects in platelet number or function (Leierseder et al. 2013). However, these dissimilarities may be due to differences in assay type and agonist concentration. Platelet *miR-223* expression has also been reported to be lower in subjects with increased on-clopidogrel activity (Shi et al. 2013). And compared to platelets from healthy subjects, platelets from nonsmall cell

lung cancer patients have ten times higher levels of *miR-223* (Liang et al. 2015).

miRNAs in Stored Platelets

Platelets undergo a gradual loss in quality when stored for days at either room temperature or refrigerated (Shrivastava 2009). Attempts to limit bacterial contamination in room temperature-stored platelets include the use of nucleic acid crosslinking agents. Initially, Osman et al. studied the effect of these pathogen reduction systems on miRNA content and found that one of them, INTERCEPT, reduced the levels of 6 of the 11 tested miRNAs. However, neither miRNA crosslinking, nor alterations in synthesis or function was observed (Osman et al. 2015b). In a follow-up study utilizing RNA-Seq, Osman observed 147–800 mRNAs altered by the INTERCEPT system depending on stringency cutoffs (Osman et al. 2015a). Yu et al. measured miRNA levels in platelets 1, 3, and 5 days after apheresis and found ten miRNAs with altered expression levels (Yu et al. 2014). Of these, *miR-326* increased over time and was found to downregulate expression of the antiapoptotic *Bcl-xL*, resulting in apoptosis of the platelets (Yu et al. 2015). Deep sequencing of platelets stored for 1–5 days revealed a gradual loss of the most abundant miRNAs and suggests miRNA profiles might have utility as biomarkers for stored platelet quality (Cox et al. 2015).

miRNA Transfer by Platelet Microparticles

Microparticles are small (0.1–1 μm) vesicles shed by many cell types including platelets upon activation (Italiano et al. 2010). In addition to their protein contents, microparticles also contain miRNAs (Hunter et al. 2008). Notably, microparticles and platelet-like particles are able to transfer miRNAs to other cells types (Hunter et al. 2008; Yuan et al. 2009; Risitano et al. 2012; Gidlöf et al. 2013; Laffont et al. 2013; Pan et al. 2013), raising the possibility that miRNAs released upon platelet activation could regulate gene expression in other cells, such as endothelial, monocytic, neutrophilic, or smooth muscle cells. Platelet microparticle (PMP) engulfment and miRNA delivery to neutrophils have recently been reported to depend on the presence of platelet 12-lipoxygenase and secreted phospholipase A_2-IIA (Duchez et al. 2015).

PMPs have been shown to transfer miRNA to endothelial cells in vitro (Laffont et al. 2013). In addition, PMPs contain functional Ago2:*miR-223* complexes that can regulate *FBXW7* and *EFNA1* expression in endothelial cells. Consistent with the hypothesis that the PMP miRNA profile reflects the parental platelet, thrombopoietin was reported to increase *miR-223* maturation in platelets, leading to higher levels of *miR-223* in PMPs (Pan et al. 2013). This increase in *miR-223* led to decreased *IGF1-R* expression in cultured endothelial cells resulting in apoptosis. After demonstrating that a majority of circulating cell-free *miR-223* is contained in microparticles, Shan et al. injected a locked nucleic acid *miR-223* inhibitor into an atherosclerotic mouse model. This resulted in increased aortic lesion size and increased intimal: medial ratio in a model of carotid artery ligation injury, suggesting PMP *miR-223* has antiatherogenic properties (Shan et al. 2015). Platelet *miR-223* can be delivered to A549 lung cancer cell line where it targets and knocks down *EPB41L3* and increases the invasion capacity in an in vitro assay (Liang et al. 2015).

When Gidlöf and colleagues profiled the miRNA content of platelets from STEMI patients, they found *miR-22, miR-185, miR-320b,* and *miR-425-5p* were reduced in the platelets of patients compared to controls. These miRNAs were even lower in the thrombus as compared to circulating platelets, suggesting platelet activation had led to miRNA release. They further demonstrated that PMP delivered *miR-320b* could repress *ICAM-1* expression in cultured endothelial cells (Gidlöf et al. 2013). Finally, PMPs have been reported as delivering 34 miRNAs to human macrophages including *miR-126-3p*. This results in the downregulation of 367 mRNAs, including the cytokines *CCL4*, *CSF1*, and *TNF* (Laffont et al. 2015). Taken together the evidence for platelet-delivered miRNAs via extracellular vesicles is building, although the ultimate impact of this mechanism on the gene expression of many cell types has yet to be determined.

Circulating miRNAs

miRNAs are found free in both plasma and serum and therefore have the potential to serve as biomarkers for diseases. In general, miRNAs are very biochemically stable and compared to mRNAs have superior performance characteristics as biomarkers for disease activity (Kai and Pasquinelli 2010; Scholer et al. 2010; Lu et al. 2008). This stability in the blood is thought to result from the miRNAs being packaged inside extracellular vesicles such as microparticles, liposomes, or complexed with RNA-binding proteins or high density lipoproteins (reviewed in (Creemers et al. 2012)).

Because platelets contain a significant proportion of the cellular fraction of miRNA in blood and because PMPs are the most abundant microparticle, it is thought that a substantial fraction of circulating miRNAs originates from platelets (Teruel-Montoya et al. 2014; Berckmans et al. 2001). Indeed, miRNA profiles of platelets compared to serum or plasma were shown to exhibit a high degree of correlation, suggesting a platelet origin for many of the circulating

miRNAs (Willeit et al. 2013). Along these lines, circulating levels of miRNAs highly expressed in platelets have been found to be associated with myocardial infarction risk, diabetes, and smoking (Badrnya et al. 2014; Duan et al. 2014; Zampetaki et al. 2012).

Other studies have identified an association between circulating miRNAs and the *intermediate trait* of platelet function. Willeit and colleagues found that plasma miRNA levels were lower in healthy subjects taking antiplatelet medication (Willeit et al. 2013; Yu et al. 2013). Zhang et al. found that reduced circulating *miR-223* levels predicted high platelet function in troponin-negative non-ST elevation acute coronary syndrome patients (Zhang et al. 2014). It was also reported that lower plasma *miR-223* is associated with high platelet reactivity to ADP signaling in patients with coronary artery disease, possibly due to *miR-223* regulation of the $P2Y_{12}$ ADP receptor (Chyrchel et al. 2014; Landry et al. 2009). Finally, circulating *miR-126* was found to correlate with circulating P-selectin levels in diabetic patients and this level was sensitive to aspirin treatment, suggesting a platelet origin (de Boer et al. 2013; Shi et al. 2015).

lncRNAs

Long noncoding RNAs (lncRNAs) are defined as ncRNAs longer than 200 nucleotides. A variety of functions have been assigned to lncRNAs including genomic imprinting, differentiation, cancer progression, and others (reviewed in (Satpathy and Chang 2015)). GENCODE lists 15,931 lncRNAs categorized according to genomic location (long intergenic RNAs (lincRNAs), intronic lncRNAs, and antisense RNAs), length, association with protein-coding genes, and DNA elements (St Laurent et al. 2015). lncRNAs can interact with other nucleic acids through base pairing and also with proteins through secondary RNA structures. Therefore, lncRNAs appear to function through RNA–RNA, RNA–DNA, and RNA–protein associations (Guttman and Rinn 2012). Although a relatively small number of lncRNAs have been well characterized, the vast majority have no known function. Londin et al. detected 192 lncRNAs as present in all ten platelet RNA samples analyzed (Londin et al. 2014). There have been a few reports of lncRNAs regulating erythropoiesis, but megakaryopoiesis is unexplored (Paralkar et al. 2014).

Other Platelet ncRNAs

RNA-seq has been performed on short and long RNA platelet transcriptomes from ten healthy young males (Londin et al. 2014). Approximately 3.5 billion sequence reads were obtained, 40 % of which mapped uniquely to the human genome. About 800 miRNAs and 9000 protein-coding mRNAs were detected in the transcriptomes of *each* of the ten subjects. These mRNAs and miRNAs accounted for only slightly more than half of all of the uniquely mapped sequence reads, suggesting the abundant presence of additional ncRNA transcripts. Detailed bioinformatic analyses revealed ~10,000 non-protein-coding transcripts from mRNA-coding loci, ~1500 pseudogene transcripts, ~200 long intergenic noncoding RNAs (lncRNAs) and abundant signal recognition particle RNAs (srpRNAs), small nuclear RNAs (snRNAs), small cytoplasmic RNAs (scRNAs), and pyknons. Lastly, the platelet transcriptome was rich in a variety of distinct repeat element categories, including DNA transposons, long terminal repeat (LTR) retrotransposons, and non-LTR retrotransposons such as long interspersed elements (LINEs) and short interspersed elements (SINEs). This diverse array of ncRNAs is expected to participate in regulating gene expression, although much work is needed to characterize their effects in megakaryocytes and platelets. Circular RNAs, which have the potential to negatively regulate miRNAs by acting as "sponges," have also been identified in platelets (Alhasan et al. 2015; Hansen et al. 2013; Memczak et al. 2013). Alhasan et al. analyzed platelet RNA-Seq data and identified 3162 genes for which circular transcripts were enriched. In addition, they found the platelets contained more circular RNAs as compared to nucleated cells.

miRNAs as Therapeutics or as Therapeutic Targets

There are numerous diseases caused at least in part by dysregulated miRNA or mRNA expression. The in vivo introduction of pre-miRNAs or mature miRNAs are novel therapeutic approaches to either raise abnormally low miRNA levels or reduce elevated target mRNA levels. Alternatively, undesired miRNA activities can be inhibited by antagomirs or locked nucleic acids (LNAs). Antagomirs are short, complimentary antisense molecules that bind to miRNAs; LNAs are chemically modified oligonucleotides that "lock" the nucleic acid in a conformation which stabilizes the duplexes formed with miRNAs (Kurreck 2003). Another approach is the use of miRNA "decoys or sponges." In this case, single-stranded RNAs with multiple binding sites are used to adsorb the miRNA present in the cell, interfering with its normal function (Ebert et al. 2007). Work done in mouse models of disease demonstrates the potential of using miRNA expression-modifying therapeutics to treat a pathologic conditions, such as cancer (Doebele et al. 2010; Anand et al. 2010; Ma et al. 2010) and cardiac disease (Carè et al. 2007; Thum et al. 2008; Bonauer et al.

2009; Bhagat et al. 2013; Garchow et al. 2011; Rayner et al. 2011a, b; Marquart et al. 2013; Wang et al. 2012; Montgomery et al. 2011). Importantly, LNA-based microRNA inhibition was shown to be effective in reducing viral load in a phase 2 human study of chronic hepatitis C virus infection (Janssen et al. 2013). A long-term, follow-up study observed no long-term safety issues (van der Ree et al. 2014).

The ability of miRNA to inhibit gene expression makes it a useful tool to restrict expression in circumstances where it would cause undesired consequences. Even when tissue-preferential promoters are used to direct transgene expression, off-target and deleterious effects have been observed (Follenzi et al. 2004; Mingozzi et al. 2003). The tissue-preferential expression of miRNAs has been exploited to prevent off-target effects in gene therapy studies of mouse models of hemophilia (Brown et al. 2007). Such a gene therapy approach for hematologic diseases requires knowledge of miRNA levels in different hematopoietic lineages. Teruel-Montoya et al. demonstrated that miRNAs that could be used to restrict transgene expression to a particular blood cell type and that reporter gene expression could be regulated by endogenous miRNA levels in a megakaryocytic cell-specific manner line (Teruel-Montoya et al. 2014). These data established the potential for developing gene therapy vectors that exploit hematopoietic lineage-preferential miRNA expression. In addition, engineering target sites for miRNAs absent in megakaryocytes but present in other hematopoietic cell lineages into a therapeutic transgene could permit megakaryocyte-specific transgene expression in platelet-specific diseases of gene hypofunction.

Blood Bank stored platelets translate protein over time (Thon and Devine 2007) and it is conceivable that the active translation of proteins in stored platelets may contribute to reduced platelet function. An intriguing possibility would be to inhibit the translation of apoptotic and antithrombotic regulatory proteins via introduced miRNAs.

Summary and Future Directions

ncRNAs regulate hematopoiesis and megakaryopoiesis, and platelet miRNAs likely (1) alter platelet gene expression, (2) regulate endothelial cell or other cell gene expression via PMP transfer, (3) serve as important disease biomarkers, (4) define the MK lineage in clonal bone marrow diseases, and (5) serve as tools for understanding basic mechanisms of megakaryocyte/platelet gene expression. Genome-wide association studies have identified intergenic loci where the SNP alters miRNA gene sequence and function (Mencia et al. 2009; Modamio-Hoybjor et al. 2004), and it is likely that additional megakaryocyte/platelet disease-producing genetic variants in miRNA biogenesis will be identified. An enormous number of new miRNAs have been identified by using RNA obtained from multiple cell types (Londin et al. 2014). It will be important to develop commercially available tools for studying these novel miRNAs. Notably, new platelet-specific miRNAs were discovered not in the existing reference database. Exciting possibilities for hematopoietic lineage-restricted transgene expression vectors are possible based on the new knowledge of differentially expressed miRNAs among hematopoietic cells. An increasing number of miRNAs targeting multiple mRNAs that regulate a specific signaling or developmental pathway suggest there are "master-miRNAs" that could be manipulated to affect cell physiology. Ongoing in vivo studies that knock-down or replace defective miRNAs are sure to lead to important laboratory tools and novel human disease treatment approaches. For future platelet miRNA biomarker association studies it will be essential to have appropriate samples sizes and analyses that consider confounding variables known to alter miRNA levels, such as age, gender, race, and medications. Lastly, the non-miRNA repertoire of ncRNAs remains a relatively fledgling field and is sure to yield exciting new insights into megakaryocytes and platelet biology in the very near future.

Implications of Platelet RNA to Vascular Health and Disease

Lauren Clancy and Jane E. Freedman

Abstract

The historical relevance of platelets has focused on their traditional role in the circulation of hemostasis and thrombosis. Recent studies of platelet composition and novel platelet roles in a number of non-hemostatic systemic responses have since broadened our appreciation for the functional capabilities of platelets. One such expansion of our understanding includes the exploration of the platelet's endogenous RNA and its ability to regulate platelet immune and inflammatory processes. RNA profiling of platelet messenger RNA (mRNA) and microRNA (miRNA) revealed distinct expression patterns associated with a number of platelet phenotypes and disease pathologies. A deeper understanding of the genetic material present in platelets endogenously and in disease settings can further elucidate the role platelet RNA plays in thrombosis and the implications of platelet involvement in fields such as cancer, infection, and systemic inflammation.

Introduction

Historical Role of Platelets in Hemostasis

Platelets are vital to the regulation of thrombosis and hemostasis. Upon induction of platelet biogenesis, platelet progenitor cells, megakaryocytes, mature in the bone marrow for 4–5 days (Michelson 2013). Platelet biogenesis occurs when megakaryocytes extend pseudopodia into the blood sinuses of the bone marrow and the force of blood flow sheers fragments off the pseudopodia, resulting in the release of proplatelets and platelets into the bloodstream (Michelson 2013). As platelets move through the bloodstream over the next 7–10 days, they respond to sites of vascular injury (Lackie 2010; Jurk and Kehrel 2005). Receptor recognition, binding, and further platelet activation lead to granule secretion and the initiation of the thrombotic response (Jurk and Kehrel 2005). Vascular and endothelial cells at injury sites need multiple factors to be carefully balanced to bring about normal hemostasis; circulating platelets responding to these sites help maintain this balance. Thrombotic events ensue when the formation of a clot obstructs a vessel.

Alternative Platelet Functions Throughout the Circulation

Platelets' traditional role in hemostasis and their role in the chronic inflammatory disease, atherosclerosis, illustrate the traditional link between platelets and inflammation and have been studied extensively. However, our understanding of platelets and their capabilities has increased alongside our knowledge of platelets' roles in the body's systemic responses. Deeper connections between local inflammation, infection, and cancer progression have all been unearthed in our study of platelet biology. Studies of rheumatoid arthritis sufferers found these patients possess hyperactive platelet microparticles in their joint fluid, linking platelets to local inflammation development (Boilard et al. 2010; Gasparyan et al. 2011). Similarly, platelets have been associated with the systemic response to infection, both viral and bacterial, through their expression of toll-like

receptors (TLRs), especially toll-like receptor 4 (TLR4) and toll-like receptor 7 (TLR7) (Vieira-de-Abreu et al. 2012; Garraud and Cognasse 2010; Semple and Freedman 2010; Beaulieu and Freedman 2010; Shiraki et al. 2004; Andonegui et al. 2005; Cognasse et al. 2005; Aslam et al. 2006; Freedman et al. 2010; Clark et al. 2007; Ma and Kubes 2008; Koupenova et al. 2014). The expression of both these TLRs on platelets allows platelets to act as sentinels in the blood—early sensors detecting foreign pathogens [lipopolysaccharide expressed on Gram-negative bacteria in the case of TLR4 (Andonegui et al. 2005; Clark et al. 2007) and single-stranded RNA viruses in the case of TLR7 (Koupenova et al. 2014)]. Activation of these sensors allows platelets to induce a number of immune responses, including neutrophil recruitment and bacterial removal, neutrophil extracellular trap (NET) formation, and heterotypic aggregate development (Clark et al. 2007; Ma and Kubes 2008; Koupenova et al. 2014; McDonald et al. 2012). Studies regarding cancer progression have found that select oncology patients suffer from coagulation disorders throughout their disease progression (Sabrkhany et al. 2011). These individuals subsequently face a greater risk both of thrombotic events, such as pulmonary embolism and deep vein thrombosis, and of inconsistencies in normal platelet values, such as platelet counts and volume (Tesselaar et al. 2007; Sun et al. 1979). Platelet factors, such as vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF), have been correlated to the required physiological processes for tumor metastasis, such as angiogenesis and chemotaxis (Mohle et al. 1997; Wartiovaara et al. 1998; Heldin and Westermark 1999; Heldin 2013). These correlations, along with the existence of activated platelets in tumor vasculature, suggest that platelets play a role in developing the essential blood supply for tumor growth (Pinedo et al. 1998; Verheul and Pinedo 2000) and furthering tumor cell metastasis (potentially through concealing tumor development from systemic inflammatory reactions) (Jain et al. 2010). An inverse relationship between platelet inhibition and thrombotic events and tumor growth further supports the role of platelets in tumor development (Ibele et al. 1985; Jurasz et al. 2004; Niers et al. 2007; Wang and Zhang 2008). As our understanding of platelet capability expanded from its function in hemostasis to one in moderating systemic inflammation, immune response, and cancer progression, one uncertainty that emerged was how the anucleate platelet is capable of such versatile functions.

Platelet Content

Initial Platelet Content Analyses

As described, platelet biogenesis occurs through the manual fragmentation of megakaryocytes, and thus, platelets do not contain nuclei and are incapable of transcription. Evaluation of platelet contents however revealed that platelets contain all the components required for signal-dependent translation (Fig. 1) including functional ribosomes, signaling proteins, messenger RNAs (mRNAs), and microRNAs (miRNAs) (Zimmerman and Weyrich 2008; Weyrich et al. 2009; Rowley et al. 2011). The mechanism of platelet biogenesis combined with the lack of transcriptional ability in platelets implied that the platelet profile reflected that of their parental cells and was therefore inherently invariable; however, further analysis of this concept disagreed. Megakaryocytes are capable of transcription and altering their own transcriptome, allowing for the potential to similarly produce diverse platelets under different circumstances. Additionally, it was found that megakaryocytes specifically sorted and packaged material into platelets in the final stages of thrombopoiesis (Cecchetti et al. 2011). A study of matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) revealed that though megakaryocytes expressed ten MMP family members at the mRNA level, only seven of these were found in platelets (Cecchetti et al. 2011). Additionally, one of these transcripts not found in platelets, MMP-2, was expressed at the protein level in platelets (Cecchetti et al. 2011). This suggests that megakaryocytes can selectively sort mRNAs into platelets during platelet biogenesis (Cecchetti et al. 2011), so though platelet contents at biogenesis is derived from megakaryocytes, it may not directly reflect the entire profile of the parental megakaryocytes. These findings suggested an evaluation of the platelet transcriptome, and proteome was necessary to better understand the functional capabilities of platelets, especially under specific physiological settings where an altered platelet profile might be present.

Platelet RNA Content

Initial microarray-based studies estimated only 1500–4000 transcripts in healthy human platelets (Bugert et al. 2003; Gnatenko et al. 2003); however, the development of deep sequencing allowed for full detection of 9500 mRNA transcripts (Rowley et al. 2011, 2012; Bray et al. 2013). Platelets also contain various forms of small RNAs, with miRNAs accounting for 80 % of the small RNA expressed (Ple et al. 2012). MiRNAs, small noncoding RNA, utilize distinct sequence recognition of target mRNAs to control mRNA translation, with each miRNA having the potential to recognize many mRNAs simultaneously and thus providing a great amount of concurrent regulation. The presence of megakaryocyte-derived precursor and mature miRNAs as well as the presence of the machinery necessary to perform pre-miRNA processing in platelets led to complementary research evaluating the platelet miRNA profile (Ple et al. 2012; Denis et al. 2005). This profiling of platelets identified

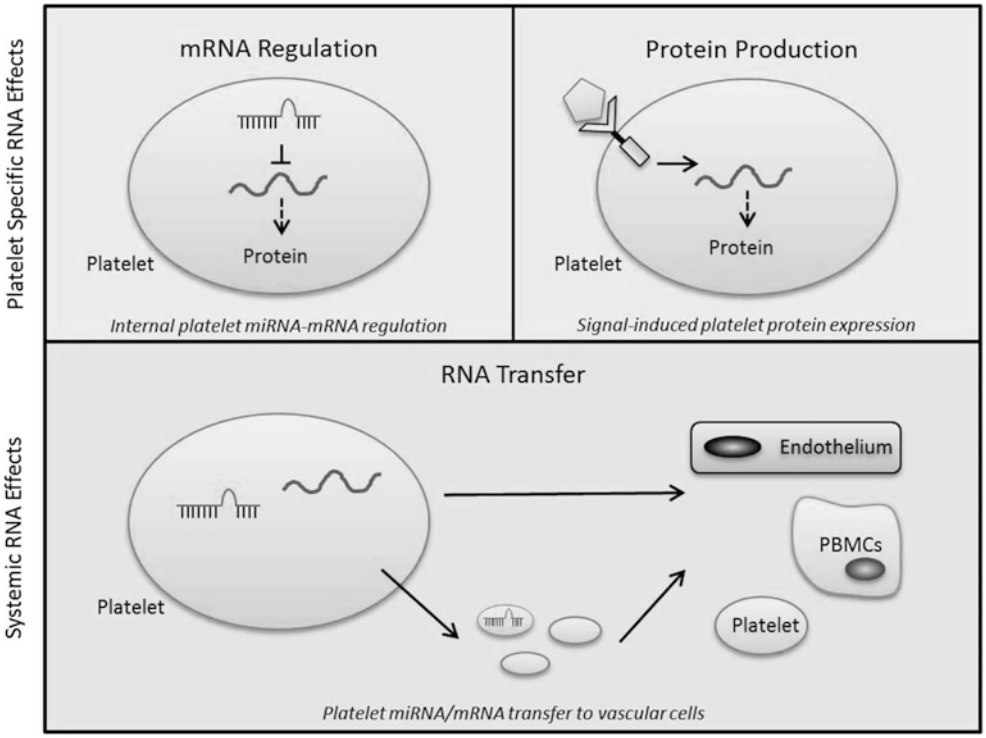

Fig. 1 The role of platelet RNA in the vasculature. Platelets contain broader functions beyond thrombosis including platelet-specific and synthetic RNA functions. Evaluation of platelets reveals that platelets contain all the components required for signal-dependent translation, miRNA–mRNA transcript processes, and functional RNA transfer. Specifically, platelets have the capacity to execute both pre-mRNA processing and protein translation in a signal-dependent manner

532 miRNAs in healthy patient platelets, 40 of which were novel miRNAs, with members of the let-7 family being the most represented (Ple et al. 2012).

Platelet RNA Content and Disease Associations

While initial studies focused on healthy platelet profiling, follow-up focused on correlating platelet RNA profiling to platelet reactivity, species variability, and disease modeling. Differential expression analysis of healthy patient miRNA profiles revealed a correlation between platelet reactivity and miRNA and mRNA expression (Nagalla et al. 2011; Landry et al. 2009). Seventy-four miRNAs were differentially expressed in platelets, with the majority showing increased expression in hyperreactive platelets (Nagalla et al. 2011). This corresponded to an increased differential expression of mRNAs in hyporeactive platelets (Nagalla et al. 2011). Analysis of their findings in hyperreactive platelets to identify differentially expressed increased miRNAs with corresponding decreased target mRNAs revealed 12 miRNA–mRNA pairs, establishing a role for miRNA regulation of mRNA (and thus protein) expression in platelet reactivity (Nagalla et al. 2011). Similarly, an early comparison study between human and mouse platelets evaluated potential roles RNA may play in platelet functional diversity (Rowley et al. 2011). The study identified a large amount of conservation (approximately 4990 transcripts) between species, with 58 % of human platelet transcripts conserved in the mouse platelet profile and 83 % of the mouse profile found in the human profile; however, it also revealed distinct expression variants between the two species which reflected previously described functional differences between human and mouse platelets (Rowley et al. 2011). Specifically, expression of protease-activated receptor (PAR) transcripts in human and mouse platelets directly reflected previously known information about human and mouse platelet signaling (Rowley et al. 2011). This study found the transcript for PAR1, the primary thrombin receptor in human platelets, was expressed in human platelets at 13.5 times the level it is in mouse platelets, and mouse platelets expressed an alternative PAR transcript, PAR3 (Rowley et al. 2011; Darrow et al. 1996; Connolly et al. 1996; Ishihara et al. 1998). This corresponds to and explains previous data showing knockdown of PAR1 in mice having no effect on the mouse platelet thrombin response (Rowley et al. 2011; Darrow et al. 1996; Connolly et al. 1996). Similarly, previous studies showing differential response to platelet-activating factor (PAF) in human and mouse platelets (human platelets responded, mouse platelets did not) are explained by the presence of platelet-activating factor receptor (PTAFR) transcript in only human platelets, not mouse platelets (Rowley et al. 2011; Tsakiris et al. 1999; Terashita et al. 1985). Finally, the presence of CD68 transcript in human platelets and not mouse platelets correlates to CD68 platelet protein expression (Rowley et al. 2011). All together, these studies demonstrate the functional relevance of platelet RNA to platelet reactivity.

The ability of megakaryocytes to alter their transcriptome and preferentially sort platelets led to further evaluation of platelet RNA profiles under various physiological conditions. An abundant amount of correlations exist between platelet RNA expression and physical phenotypes and pathologies. Studies have identified specific differential profiles associated with patient age (129 mRNAs and 15 miRNAs), patient gender (54 mRNAs and 9 miRNAs), and patient race (Simon et al. 2014; Edelstein et al. 2013). Body mass index was significantly ($P < 0.005$) linked to higher expression of 11 of 48 transcripts analyzed in platelets from the Framingham Heart Study, highlighting differential expression of platelet inflammatory transcripts such as intercellular adhesion molecule 1 (ICAM1), S100 calcium-binding protein A9 (S100A9), interleukin 6 (IL6), interleukin 1 receptor 1 (IL1R1), and TLR2 (Freedman et al. 2010).

Similar differential profiles exist under various pathologies as well. Systemic lupus erythematosus (SLE) patients' platelets displayed the type 1 interferon (IFN) gene signature, with increased expression of type 1 IFN-related transcripts (PRKRA, IFITM1, SELP, and/or CD69), especially in patients with a history of vascular disease, myocardial infarction, or arterial or venous thrombosis (Lood et al. 2010). A characterization of sickle cell disease (SCD) is an increased risk of cardiovascular complications specifically linked to increased endothelial damage, inflammation, and platelet activation (Jain et al. 2013). Increased platelet activation directly affects SCD progression through a number of mechanisms, such as creation of microparticles and increased plasma expression of pro-coagulation and adhesion factors (Jain et al. 2013). Coinciding with previous reports linking platelet reactivity to distinct miRNA profiles, a study identified 40 differentially expressed miRNAs (16 upregulated, 24 downregulated) in SCD patient platelets and correlated these patterns to specific miRNA families and resulting regulation of SCD platelet mRNA (Jain et al. 2013).

Unsurprisingly, platelet RNA expression correlations exist for cardiovascular and platelet-related disease as well. RNA comparison of platelets from acute ST-segment elevation myocardial infarction (STEMI) patients and stable coronary artery disease (CAD) patients revealed 54 differentially expressed RNAs, 29 increased and 25 decreased in STEMI patients, with the most significant increased transcripts being CD69 and MRP-14 (Healy et al. 2006). Increased platelet transcript expression of MRP-14 correlated to plasma protein levels of MRP-8/MRP-14, and a prospective case study utilizing the Women's Healthy Study correlated MRP-8/MRP-14 plasma protein levels to incidence of female patients experiencing an initial cardiovascular event (Healy et al. 2006). Thrombocytosis, high platelet counts in the blood, can be differentiated into different classes, specifically essential thrombocythemia (ET), a myeloproliferative disorder, and reactive thrombocytosis (RT) (Gnatenko et al. 2010). Definitive diagnosis of the etiology of thrombocytosis is often difficult, and as the two types' prognoses and associated complications differ, this lack of clear understanding can impede treatment (Gnatenko et al. 2010). RNA sequencing of thrombocytotic patients identified unique RNA profiles of the two phenotypes of thrombocytosis and allowed for selection of an 11-transcript biomarker set which can be used to differentiate RT, ET, and normal patients (Gnatenko et al. 2010). Additional studies by the same group identified a 21-miRNA biomarker set for distinguishing ET patients from normal patients, which could be narrowed to a three-miRNA subset (miR-10a, miR-148a, and miR-490-5p) using statistical analyses (Xu et al. 2012). The identification of these unique mRNA and miRNA signatures to the forms of thrombocytosis may allow for better detection, diagnosis, and treatment in patients. With the presence of unique platelet RNA expression profiles associated with such widespread clinical phenotypes in the realms of disease and inflammation, the study of the functional roles of platelet RNA has developed into an increasingly relevant field of research.

Roles for Platelet RNA

Translational Capacity of Platelet RNA

Initial assumptions centered on platelet RNA being integral to platelet protein production and subsequent platelet alteration in response to their microenvironment (Fig. 1). Platelets have the capacity to execute both pre-mRNA processing and protein translation in a signal-dependent manner (Zimmerman and Weyrich 2008; Denis et al. 2005). It has been demonstrated that lipopolysaccharide signaling in platelets resulted in the processing of pro-IL1β mRNA and the translation and upregulation of IL1β protein, permitting platelet response to bacterial infection (Shashkin et al. 2008). Additionally, platelets possess the ability to process pre-miRNA to mature miRNA, allowing for platelet miRNA regulation of platelet mRNA expression (Denis et al. 2005); this is demonstrated in studies where the existence of a miRNA network affecting expression of the P2Y12 receptor within platelets affected the ability of the platelet to aggregate (Landry et al. 2009). Despite these findings, analysis and comparison of the platelet transcriptome to the platelet proteome revealed that the platelet transcriptome was not completely represented at the proteome level, with estimates ranging from 70 to 90 % coverage (McRedmond et al. 2004; Londin et al. 2014).

Platelet RNA Transfer

Platelets utilize many types of cell-to-cell communication, including direct, moving through the platelet canalicular membrane system, and indirect, discharging microvesicles and exosomes, methods (Risitano et al. 2012; Aatonen et al. 2012; Heijnen et al. 1999; Montecalvo et al. 2012; Valadi et al. 2007; Wahlgren et al. 2012). The possibility of a functional role of platelet RNA being platelet cell communication was hypothesized due to the existence of these cellular communication capabilities and the presence of the unexplained fraction of platelet RNA post-transcriptome-proteome correlation studies. Early research demonstrated platelet RNA transfer through in vitro co-incubation of platelets and vascular cells (Fig. 2), tracking the unique movement of functional platelet-derived transcripts to endothelial and monocyte cells using fluorescence methods and RT-qPCR (Risitano et al. 2012). In vivo infusion experiments utilizing knockout mice supported this phenomenon: transfer of a wild-type TLR2 transcript from wild-type platelets to knockout monocytes was induced through lipopolysaccharide induction of platelet-monocyte interactions (Risitano et al. 2012). These initial findings demonstrated the potential relevance of platelet RNA transfer to elucidating platelet RNA significance.

The role of platelet miRNA in regulating mRNA expression does not account entirely for the functional relevance of platelet miRNA. As mentioned, miRNA have the distinct ability to regulate several target mRNA at once, resulting in potential prolific effects on platelet mRNA levels. This effect can be extended to vascular cells when combined with the phenomenon of platelet RNA transfer. Complimentary to previous analyses of platelet miRNA and their role in STEMI, one study demonstrated that eight miRNAs were significantly downregulated in activated platelets at the thrombus formation of patients with STEMI when compared to the thrombi of non-STEMI patients (Gidlof et al. 2013). Supplementary focus on four of these miRNAs correlated significant increases in their plasma expression to platelet thrombin activation (Gidlof et al. 2013). Additional analysis of STEMI patient peripheral and thrombotic platelets revealed downregulation of these same miRNAs at the site of occlusion as compared to peripheral STEMI or healthy platelets (Gidlof et al. 2013). Further in vitro analysis demonstrated time- and activation-dependent transfer of miRNA from platelets, into platelet-derived microparticles, and then into endothelial cells, utilizing a synthetic exogenous miRNA transfection cell modeling system (Gidlof et al. 2013). This transfer was confirmed in alternative studies analyzing miR-223, the most highly expressed platelet miRNA, and its thrombin-induced release from platelets into platelet-derived microparticles alongside additional confirmation of platelet-derived microparticle uptake by endothelial cells (Laffont et al. 2013). This extension of

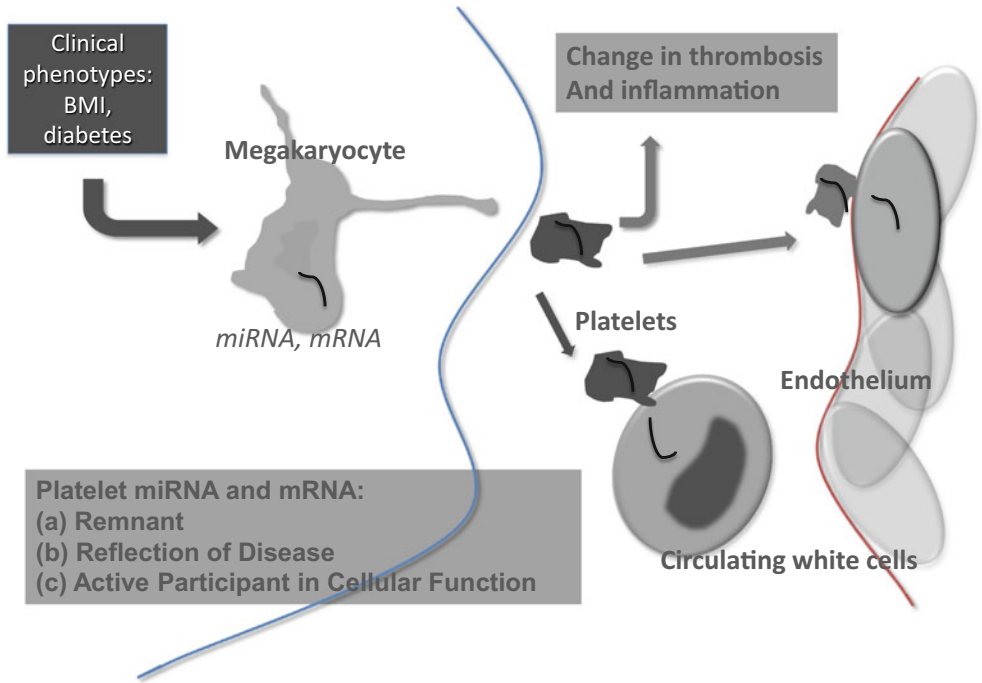

Fig. 2 Platelets and RNA transfer. Platelets play a role in the body's systemic reaction to vascular injury, inflammation, and infection, communicating with other vascular cells by direct transfer of mRNA and miRNA. Research demonstrates that this novel type of cellular communication impacts the recipient cells' phenotypes and may reflect disease states in patients. Different types of RNA may transfer including mRNA and miRNA, and recipients of this transfer process include endothelial cells and white cells

the study of platelet RNA transfer to miRNA transfer further connects platelet RNA to platelet and vascular function.

Integral to the potential relevance of platelet RNA transfer is the capability of platelet RNA to impact its recipient cells through functional regulation, translation, and expression. Three separate labs have confirmed this functional relevance through various modeling systems. The transfer of GFP-labeled vector and its subsequent fluorescent expression from platelet-like particles to monocyte and endothelial cells confirmed the functional relevance of platelet mRNA transfer to vascular cells (Risitano et al. 2012); similarly, the use of targeted luciferase reporter constructs confirmed miRNA transfer and regulation conferred through transfer from platelets to endothelial cells, with one study demonstrating a 30 % downregulation of the targeted mRNA (Gidlof et al. 2013) and another study reporting 44 % downregulation of the target mRNA (Laffont et al. 2013). Similarly, platelet microparticle incubation and subsequent miRNA transfer resulted in >50 % downregulation of miR223-associated endogenously expressed mRNA targets (Laffont et al. 2013). These studies reinforce the notion that platelets—particularly in stimulated environments—can transfer their RNA to other cells of the vasculature and collectively point to a role for platelet transcripts in controlling the expression profiles of other vascular cells. Although the method and in vivo consequences of RNA transfer remain unclear, platelet transcripts seem to play an important role in vascular health beyond traditional clot formation.

Potential Platelet RNA Disease Relevance and Research Applications

As previously outlined, correlations exist between specific platelet profiles and several physiological and disease states. The response of megakaryocytes to their acute environment and pathophysiological alterations in the body may influence the type of platelet produced during thrombopoiesis, with specific platelet transcripts reflecting the overlying condition. New diagnostic and therapeutic tools could arise if the function that these specific transcripts have in the disease state was more fully understood. If these transcripts are specifically sorted by megakaryocytes into platelets in response to a systemic stimulant, it may suggest a role for the transcript in platelet function and disease development which could shed light on the disease itself (such as sorting of a specific signaling transcript into platelets to allow for platelets to respond to a particular form of infection or inflammation occurring systemically). Alternatively, the presence of a specific transcript in platelets under certain conditions or during a disease state may not reflect a role in platelet function and disease development; instead, it may simply represent the upregulation of these transcripts by megakaryocytes responding to stimuli and the subsequent increase in platelet expression due to the mechanism of platelet biogenesis. Though not causally linked to disease development, this scenario still poses advantages to researchers, as platelet transcripts could be used as biomarkers. Conventional biomarker research concentrates on identifying protein biomarkers, but given the availability and accessibility of platelets and the correlation of distinct platelet mRNA and miRNA profiles to physiological conditions, RNA-based biomarkers present in platelets could be utilized to identify disease states, aid research, and develop therapeutic monitoring systems. One such example of therapeutic monitoring has already been described: the use of specific platelet RNA profiling in differentiating the classical phenotypes associated with thrombocytosis. An example of research development through platelet RNA profiling involves gray platelet syndrome (GPS), or platelet alpha-granule deficiency, a bleeding disorder associated with platelets lacking alpha granules (Kahr et al. 2011). GPS platelet RNA sequencing showed abnormal results for a specific transcript, NBEAL2 (Kahr et al. 2011). Further analysis revealed mutations in this gene resulted in abnormal pre-mRNA processing, and this and additional mutations identified in the study were found to be causally linked to disease development (Kahr et al. 2011). Further identification of platelet biomarkers and their correlation to disease states may allow for future development of disease screening, especially relevant for diseases that are difficult to diagnose.

Full elucidation of systemic platelet capabilities fully depends on our total comprehension of the function of platelet RNA. If platelet transcripts directly impact platelet and vascular function through either translational control or RNA transfer, realizing how these transcripts influence disease development will shed light upon both the given disease and possible treatments for it. For example, as described, the correlation between increased presence of MRP-8/MRP-14 protein (and the corresponding increase in MRP-14 transcript) and future cardiovascular events in women (Healy et al. 2006) not only reveals information about the development of cardiovascular disease in women but also potential diagnostic and therapeutic targets. Furthermore, the ability of platelets to transfer RNA to vascular cells also has potential for therapeutic implications. Recent studies have utilized platelet membranes to improve nanoparticle drug delivery (Hu et al. 2015), and once the mechanism and relevance of platelet RNA transfer and its subsequent effect on recipient cells is fully understood, there may be potential to develop platelet RNA transfer into a similar individualized therapeutic delivery system.

Conclusion

The systemic relevance of platelets is no longer limited to their conventional roles in hemostasis and thrombosis. As a result of a number of novel and widespread studies, our understanding of platelet biology has significantly expanded: platelets are now associated with the body's systemic response to vascular injury, inflammation, and infection; our understanding of platelet biology has broadened to include correlations and connections to physiological states, diseases, and cellular communication; and the possibilities for platelet impact on vascular cells' phenotypes and disease and therapeutic development have opened whole new fields of study in platelet functional relevance. Accordingly, a stronger comprehension of platelet RNA transcripts bolsters our understanding of both platelets' conventional thrombotic functions and their nonconventional functions, potentially having extensive implications in a variety of fields.

Take-Home Messages: Implications of Platelet RNA to Vascular Health and Disease

Platelets have a wide variety of RNA including mRNA and miRNA reflecting risk factors and disease.

RNA within platelets is capable of participating in protein production.

MicroRNA in platelets is sensitive to platelet function and may participate in gene expression.

RNA within platelets may be transferred to other vascular cells and participate in regulatory function.

Acknowledgments The authors would like thank Olga Vitseva for preparing the platelet image and to acknowledge Hannah Hoffman and Hannah Iafrati for their assistance in the preparation of this chapter.

GTPases

Lucia Stefanini, Robert H. Lee, and Wolfgang Bergmeier

Abstract

GTPases (GTP hydrolases, GTP-binding proteins) are enzymes that direct various cellular functions, including signal transduction, protein biosynthesis, cell division, and transport of vesicles. They are molecular switches that cycle between two conformational states (Fig. 1): the inactive guanosine-5′-diphosphate (GDP)-bound state and the active guanosine-5′-triphosphate (GTP)-bound-state. In the GTP-bound 'on' state GTPases bind effector proteins and generate cellular responses, until GTP hydrolysis returns the switch to the 'off' state. GTP binding and hydrolysis occur in the highly conserved G domain. GTPases are characterized by low intrinsic GDP–GTP exchange and GTP hydrolysis rates; thus, both processes need to be controlled by guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs) in order for the molecular switch to function at physiologically relevant rates. With few exceptions, GTPases are grouped into two main superfamilies: heterotrimeric G proteins and small GTPases. In this chapter, we will summarize the current state of knowledge about the role of these proteins in the regulation of platelet functional responses, with a particular focus on the tight functional interrelationship between the most well-studied members of the two families.

Heterotrimeric G Proteins

General Aspects

Heterotrimeric GTP-binding proteins, often simply referred to as G proteins, associate with G protein-coupled receptors (GPCRs) in the plasma membrane to relay external signals and convert them into intracellular signaling responses. The G protein heterotrimer is made up of α, β, and γ subunits (Fig. 1A). In humans, there are 16 genes coding for G_α subunits, 5 genes for β subunits, and 14 genes for γ subunits (Milligan and Kostenis 2006). The G_α families ($G_{q/11}$, $G_{12/13}$, G_i, G_s) are grouped based on their structure and functional associations with downstream effectors (Fig. 2). The initial families identified were the cholera toxin-activated, adenylyl cyclase (AC)-stimulating G_s proteins, and the pertussis toxin-sensitive, AC-inhibiting G_i proteins (Milligan and Kostenis 2006). The other major families are the phospholipase C (PLC)-linked G_q proteins (Strathmann and Simon 1990; Taylor et al. 1990) and the RhoGEF-activating

$G_{12/13}$ proteins (Riobo and Manning 2005). The heterotrimeric complex is comprised of the monomeric G_α subunit in association with the β/γ subunit complex, which forms a structurally stable, functional heterodimer (Fig. 1A). Under basal conditions, G_α is GDP bound and has a high affinity for $G_{\beta\gamma}$ and a low affinity for effector proteins, which stabilizes association of the heterotrimer. This interaction serves multiple purposes. It decreases the intrinsic rate of GDP release from G_α, preventing spontaneous GTP binding and activation (Higashijima et al. 1987). It also assists in localizing G_α to the membrane by association with the highly hydrophobic β/γ complex (Evanko et al. 2001), and it prevents signaling by the β/γ complex, which has been increasingly recognized as a critical component of GPCR signaling (see later) (Khan et al. 2013). Upon ligand binding, the GPCR associates with the G_α subunit and induces a conformational change that triggers the release of GDP (Farrens et al. 1996). As GTP is ~10-fold more abundant in the cytosol than GDP, nucleotide-free G_α now binds GTP and dissociates from the $G_{\beta\gamma}$ subunit. The GTP-bound G_α subunit and the $G_{\beta\gamma}$ unit are then free to interact with downstream effectors (Fig. 1A). Thus, the GPCR serves as a GEF for the α subunit of heterotrimeric G proteins. The inactivation of heterotrimeric G proteins depends on GAP proteins, i.e., proteins that increase the rate of GTP hydrolysis. The prototypic GAPs for G proteins are Regulator of G-protein Signaling (RGS) proteins; platelets express several members of this family, which we will review in more detail later. In the case of $G_{q\alpha}$, additional GAP activity is provided by its downstream target phospholipase C PLC-β (Berstein et al. 1992; Harden et al. 2011). However, the contribution of PLC to $G_{q\alpha}$ inactivation has not been evaluated in platelets and will not be discussed in this chapter.

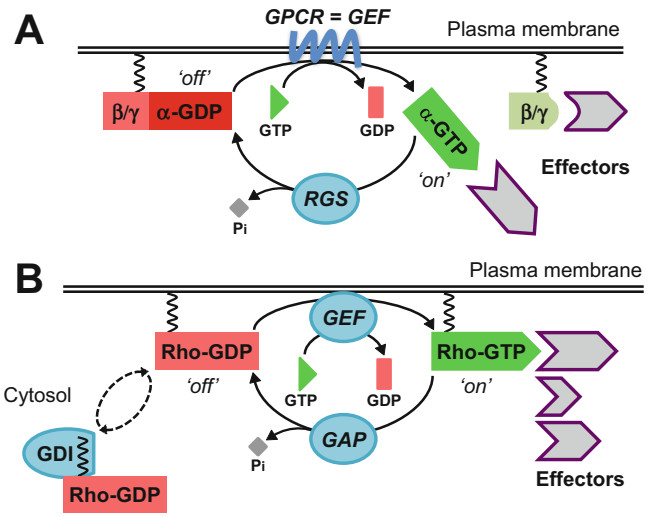

Fig. 1 The GTPase molecular switch. (**A**) Regulation of heterotrimeric G proteins by GPCRs and RGS proteins. Heterotrimeric G proteins are activated by GDP/GTP exchange on their α subunit. This exchange is stimulated by the GPCR, which functions as a guanine nucleotide exchange factor (GEF). GTP loading of the α subunit (*green*) leads to separation of the α and β/γ subunit, which then are free to interact with downstream effectors (*purple*). Inactivation of G_α requires hydrolysis of the γ-phosphate in GTP, a process that is stimulated by RGS (Regulator of G protein Signaling, *blue*) proteins. Inactive, GDP-bound G_α then reassociates with the βγ subunit, completing the inactivation cycle. (**B**) Regulation of the small GTPases by GEFs, GAPs, and GDIs. Small GTPases (RHO is shown as an example) are also activated by GDP/GTP exchange, stimulated by GEFs, and inactivated by GTP hydrolysis stimulated by GAPs (GTPase-activating proteins). In addition to the GDP/GTP switch, the activity of several GTPase families (RHO, RAB, and some RAS) is regulated by GDIs (Guanine nucleotide Dissociation Inhibitor) or GDI-like proteins, which sequester the small GTPases in the cytosol. Active (GTP-loaded) small GTPases are indicated in green, inactive (GDP-loaded) small GTPases are indicated in red, activity regulators are shown in blue, and downstream effectors are in purple. Symbols: GDP (guanosine-5′-diphosphate, green triangle), GTP (guanosine-5′-triphosphate, red rectangle), Pi (inorganic phosphate, gray diamond)

During the course of platelet activation in vivo, primary agonists (thrombin) and released feedback mediators [ADP, thromboxane A_2 (TxA_2)] trigger multiple G-proteins simultaneously, which then act in concert to promote aggregate formation (Broos et al. 2011; Rivera et al. 2009; Stegner and Nieswandt 2011) (Fig. 3). The major GPCRs that mediate G-protein-dependent platelet activation are the thrombin-sensitive protease-activated receptors (PARs), the ADP receptors ($P2Y_1$ and $P2Y_{12}$), and the TxA_2 receptors (TPα and TPβ). GPCRs with less well-characterized contributions to hemostatic plug formation include the serotonin receptor, 5HT-2A, the adrenergic receptor, α2A, and multiple chemokine receptors. Platelet inhibition is achieved through the prostacyclin receptor, IP, also a GPCR. Of the thrombin receptors, human PAR1, PAR4, and mouse PAR4 couple to G_q (Benka et al. 1995; Sambrano et al. 2001; Vaidyula and Rao 2003). These receptors also activate $G_{12/13}$ to induce RhoGEF/RhoA activation and shape change (Klages et al. 1999). The TxA_2 receptor also couples to both G_q and $G_{12/13}$ (Offermanns et al. 1994; Shenker et al. 1991). $P2Y_1$ couples to G_q but not $G_{12/13}$, while $P2Y_{12}$ specifically activates G_i (Jin and Kunapuli 1998). PAR1 can also directly activate G_i (Voss et al. 2007). Initial platelet activation upon exposure to primary agonists (thrombin) is driven by PLC-mediated cleavage of the phospholipid phosphatidylinositol 4,5-biphosphate (PIP_2) to inositol 1,4,5-triphosphate (IP_3) and the second messenger diacylglycerol (DAG). Binding of IP_3 to its receptor on the dense tubular system induces the release of the second messenger Ca^{2+} into the cytosol. Ca^{2+} affects integrin-mediated platelet adhesion by activating CalDAG-GEFI, a guanine nucleotide exchange factor for the small GTPase RAP1 (see later). Just like in other cells, Ca^{2+} is also a critical regulator of a variety of enzymes and cytoskeletal proteins that contain calcium-sensitive regulatory domains (Nesbitt et al. 2003). DAG is best known for its role as an activator of protein kinase C (PKC), which in platelets plays a critical role for the release of the second-wave mediators TxA_2 and ADP (Harper and Poole 2010). Engagement of TPα/β and

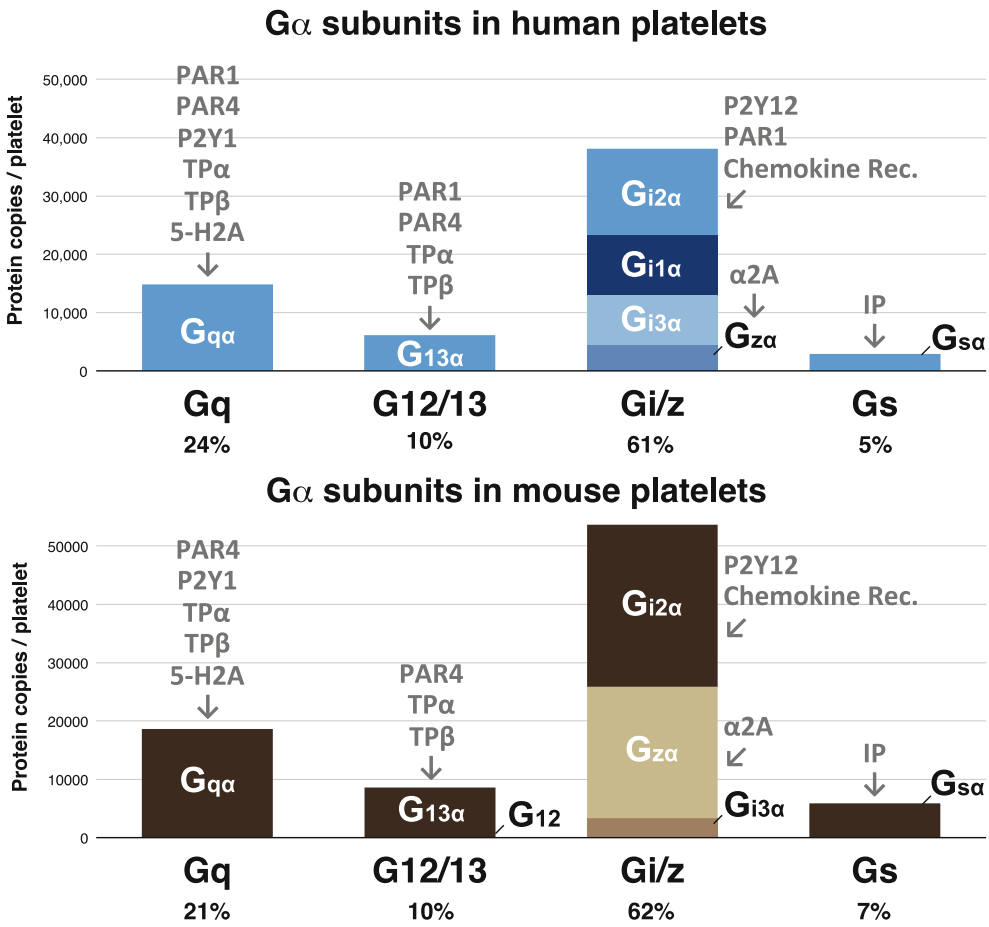

Fig. 2 Expression levels for heterotrimeric G proteins in human and mouse platelets. Graphs show the copy numbers per platelet for the indicated G_α subunits, based on quantitative proteomic analysis; (**top panel**) human (Burkhart et al. 2012) and (**bottom panel**) mouse (Zeiler et al. 2014) platelets. The column height and percentages listed below the columns indicate the relative expression level for each family within the G protein superfamily. Within each column the most abundant isoforms are stacked from top to bottom. G protein-coupled receptors that can activate the respective G proteins are listed in gray

$P2Y_1$ by TxA_2 and ADP, respectively, provides important feedback activation of PLCβ. G_i activation downstream of $P2Y_{12}$ leads to the inhibition of adenylyl cyclase (AC) mediated by $G_{i\alpha}$ and $G_{\beta\gamma}$-mediated activation of phosphoinositide 3-kinase (PI3K). Reduced AC activity leads to lower levels of cyclic AMP and thus reduced negative feedback on platelet activation via protein kinase A (PKA, see later). Signaling downstream of PI3K leads to the inhibition of the RAP1-GAP, RASA3 (Stefanini et al. 2015), and the activation of AKT. Mouse models lacking the major platelet GPCRs have provided valuable information on the role of their associated agonists in hemostasis and thrombus formation. However, the majority of GPCRs couple to more than one family of heterotrimeric G proteins, making it difficult to dissect the phenotype of these mice in regard to the function of individual G proteins (for thorough reviews on platelet GPCRs, see Li et al. 2010; Offermanns 2006). The first section of this chapter will discuss the role of heterotrimeric G protein signaling in platelet activation and thrombus formation, and what we have learned from mouse knockout models and human mutations to put these signaling proteins into the context of bleeding and thrombotic disorders. Key findings from studies in transgenic mouse models and patients with mutations in heterotrimeric G proteins are summarized in Table 1.

Heterotrimeric G Protein Families

$G_{q/11}$ Family

In platelets, G_q is typically the initial heterotrimeric G protein relaying an activation signal upon binding of soluble ligands to GPCRs. Evidence for G_q expression and function was first shown during characterization of the receptors for TxA_2 and thrombin (Hung et al. 1992; Shenker et al. 1991). $G_{11\alpha}$, although expressed in most G_q-expressing tissues, is absent in platelets (Offermanns et al. 1997). G_q signaling is critical for most functional responses in platelets, as it facilitates the activation of PLCβ2/3 and the generation of the second messengers $Ca^{2+}$and DAG. Consistently, platelets from mice lacking $G_{q\alpha}$ exhibit a severe defect in Ca^{2+} mobilization from intracellular stores and in DAG/PKC-mediated granule release in response to thrombin, TxA_2, or ADP. When activated via GPCRs, $G_{q\alpha}$-deficient platelets also show a marked defect in integrin activation and aggregate formation. However, they are able to undergo $G_{12/13}$-mediated shape change upon activation with thrombin or TxA_2 (see later)

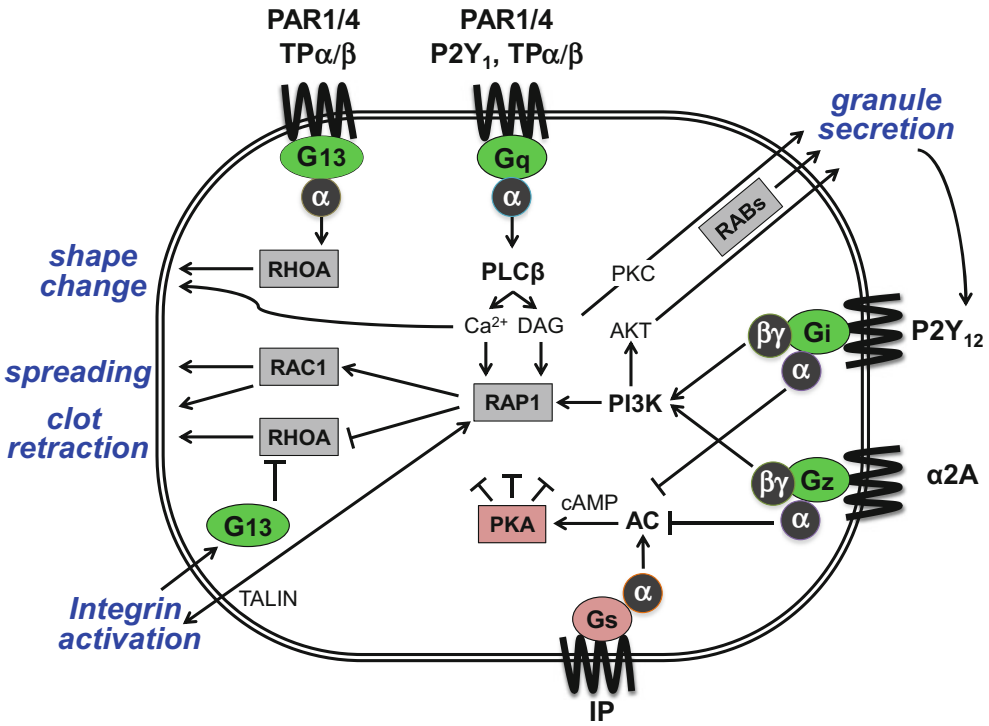

Fig. 3 Heterotrimeric G proteins as key regulators of platelet signaling. This schematic shows the best-characterized interactions between the various G proteins and the main G protein-coupled receptors (GPCRs) on the platelet surface. During the course of platelet activation in vivo, primary agonists (thrombin) and released feedback mediators [ADP, thromboxane (TxA_2)] trigger multiple G-proteins simultaneously, which then act in concert to promote various cellular responses (listed in *blue*). The major GPCRs that mediate G-protein-dependent platelet activation are the thrombin-sensitive protease-activated receptors (PARs), the ADP receptors ($P2Y_1$ and $P2Y_{12}$), the TxA_2 receptors (TPα/β), and the adrenaline receptor (α2A). These receptors activate the indicated heterotrimeric G proteins (*green circles*), leading to dissociation of the subunits and G_α or $G_{\beta/\gamma}$-mediated effects on downstream signaling proteins (figure focused on the interaction with small GTPases, *gray* boxes). Platelet inhibition is achieved through the prostacyclin receptor, IP, and Gs-mediated activation of PKA (*red*). Abbreviations: AC (adenylyl cyclase), Ca^{2+} (calcium ions), DAG (diacyl glycerol), G_q G_{13} G_i (heterotrimeric G proteins), PAR (protease-activated receptor), PI3K (phosphoinositide-3 kinase), PKA (protein kinase A), PKC (protein kinase C)

(Offermanns et al. 1997). A significant defect is also observed when $G_{q\alpha}$-deficient platelets are activated via the collagen receptor, GPVI, a member of the immunoreceptor tyrosine-based activation motif (ITAM) family, likely due to the loss of signal enhancement by the G_q-coupled TP receptor (Packham et al. 1991). Mice deficient in $G_{q\alpha}$ are unable to stop bleeding in a tail clip assay. They are also almost completely protected from collagen/epinephrine-induced thromboembolism (Offermanns et al. 1997) and from thrombosis at the site of severe arterial lesions (Nonne et al. 2005), suggesting a prominent role for G_q signaling in hemostasis and thrombosis. $G_{q\alpha}$-deficient pups also exhibit an increased frequency of intra-abdominal bleeding and perinatal death (Offermanns et al. 1997). Impaired G_q activity is also associated with a bleeding diathesis in humans, and various cellular functions including integrin-mediated aggregation, TxA_2 release, and Ca^{2+} mobilization are markedly impaired in G_q-defective human platelets stimulated via GPCRs (Gabbeta et al. 1997).

G_i Family

Platelets express several G_i family members, including $G_{i2\alpha}$ and $G_{i3\alpha}$. GTP-loaded $G_{i\alpha}$ mediates the inhibition of AC and thus relieves the inhibition of PKA substrates, which include proteins involved in Ca^{2+} mobilization and cytoskeletal rearrangements, as well as small GTPases (Smolenski 2012). $G_{\beta\gamma}$ subunits dissociated from $G_{i\alpha}$-GTP affect platelet activation by associating with multiple effectors including PI3K and PLC. These events are crucial for sustained platelet activation; they are mainly triggered by the binding of the second-wave mediator ADP to its G_i-coupled receptor, $P2Y_{12}$ (Hollopeter et al. 2001; Maayani et al. 2001). The lipid kinase PI3K phosphorylates PIP_2 to phosphatidylinositol 3,4,5-triphosphate (PIP_3), which provides a platform for the binding of proteins that contain a pleckstrin homology (PH) domain to the inner leaflet of the plasma membrane (Lova et al. 2003). These PH domain-containing proteins include AKT, PLC, and BTK, among others (Varnai et al. 2005). In platelets, PI3K-mediated activation of AKT has a well-documented role in granule secretion and cellular adhesion (Kim et al. 2004;

Table 1 Platelet and hemostasis phenotypes in mice and humans lacking components of heterotrimeric G protein signaling

Protein/gene	Platelet phenotype	Hemostasis/thrombosis phenotype	Refs

Woulfe 2010). PI3K signaling also plays a critical role for sustained RAP1 activation, a process required for prolonged integrin activation and the formation of stable platelet aggregates (Cifuni et al. 2008; Stefanini et al. 2015). Specifically, PI3K activity mediates the inactivation of RASA3, a RAP1-GAP that is required to keep circulating platelets in a resting state (see later). $G_{i2\alpha}$ seems to be the predominant $G_{i\alpha}$ protein in platelets. While loss of $G_{i3\alpha}$ in mice has no discernable effects on platelet function, $G_{i2\alpha}$ deficiency leads to impaired ADP-dependent inhibition of AC and reduced platelet activation in response to ADP and low concentrations of thrombin (Jantzen et al. 2001). In vivo, loss of $G_{i2\alpha}$ impairs

the formation and stability of arterial thrombi (Devanathan et al. 2015), a phenotype that is similar to that of mice deficient in $P2Y_{12}$ (Andre et al. 2003). While $G_{i1\alpha}$ has not been detected in murine platelets (Jantzen et al. 2001), it is expressed in human platelets, and decreased expression of $G_{i1\alpha}$ was detected in a patient with reduced ADP- and epinephrine-induced platelet aggregation and a tendency for bleeding (Patel et al. 2003). Patients with mutations in the more highly expressed $G_{i2\alpha}$ and $G_{i3\alpha}$ have not been described. However, the hemostatic effects of $G_{i\alpha}$ inhibition can be observed with pharmacological inhibition of $P2Y_{12}$ by thienopyridines, a widely used class of antiplatelet drugs (Foster et al. 2001; Hollopeter et al. 2001). These drugs act to destabilize thrombus formation by preventing $P2Y_{12}$ activation and G_i signaling. Both $P2Y_{12}$ inhibitors and mutations in $P2Y_{12}$ lead to an increased risk of bleeding in humans and mice (Getz et al. 2014; Hollopeter et al. 2001).

$G_{z\alpha}$, another G_i family member, associates with the adrenergic receptor for epinephrine (α2A) in platelets (Shenker et al. 1991). While epinephrine alone does not cause platelet aggregation, it is able to enhance integrin activation in the presence of other stimuli (Yang et al. 2002). Interestingly, loss of $G_{z\alpha}$ leads to impaired platelet function (Yang et al. 2000) and mice deficient in $G_{z\alpha}$ exhibit a prolonged bleeding time and a reduction in thrombus stabilization, suggesting that the enhancing effect of epinephrine plays a role in vivo during hemostasis (Kelleher et al. 2001; Pozgajova et al. 2006; Yang et al. 2000).

Finally, limited evidence suggests that $G_{i\alpha}$ functionally couples to PAR1 (Voss et al. 2007) and to chemokine receptors in platelets (Abi-Younes et al. 2000). Platelets express a variety of chemokine receptors (Clemetson et al. 2000), but our knowledge of the role of these receptors in platelet function is limited compared to receptors involved in aggregation. Chemokine binding to platelets has a weak activating effect, but can potentiate activation induced by other agonists, similar to what is seen after engagement of other $G_{i\alpha}$-coupled receptors (Schafer et al. 2004; Walsh et al. 2015). G_i signaling by chemokines likely plays a more critical role in chronic vascular disease such as atherosclerosis (Chatterjee et al. 2015; Gleissner et al. 2008), where, for example, reduced platelet expression of the chemokine receptors for SDF-1α, CXCR4, and CXCR7, is associated with lower mortality in patients with coronary artery disease (Rath et al. 2015).

$G_{12/13}$ Family

During adhesion, platelets undergo shape change from their discoid shape in circulation to a flat, expanded cell, increasing the available surface area for binding at the site of vessel injury. Shape change in platelets depends on the rearrangement of the cytoskeleton, formation of new actin filaments for filopodia extension, and outward expansion of the open canalicular system (Bearer et al. 2002). Granules also become centrally localized to facilitate efficient secretion (Fitch-Tewfik and Flaumenhaft 2013). Soluble agonists that can induce shape change include thrombin, TxA_2, and ADP. Stimulation of PAR1, PAR4, or TP induces shape change via direct engagement of $G_{12/13\alpha}$ proteins. Insoluble agonists, such as collagen, indirectly induce shape change by promoting TxA_2 production and release. Platelets express both family members, $G_{12\alpha}$ and $G_{13\alpha}$ (Offermanns et al. 1994). However, $G_{13\alpha}$ seems to be the primary family member functioning in platelets, as no defects in platelet function were observed in $G_{12\alpha}$-deficient mice (Moers et al. 2003). $G_{13\alpha}$-mediated induction of shape change occurs at agonist concentrations below the threshold for aggregation and does not require an increase in the intracellular Ca^{2+} concentration (Rink et al. 1982). $G_{13\alpha}$ couples to RHO-GEFs, such as p115RhoGEF, which activate RHOA (Kozasa et al. 1998). RHOA activates Rho-associated protein kinase (ROCK), which inhibits myosin light chain (MLC) phosphatase and enhances MLC phosphorylation and MLC-dependent contraction to stimulate shape change and granule secretion (Klages et al. 1999). In addition to shape change, $G_{13\alpha}$ contributes to integrin outside-in (Gong et al. 2010) and inside-out (Srinivasan et al. 2015) signaling, as well as TxA_2 generation (Kim et al. 2013a). Consistent with this variety of platelet defects observed in vitro, mice deficient in $G_{13\alpha}$ exhibit a marked impairment in hemostatic plug formation and carotid artery thrombosis (Moers et al. 2003).

G_s Family

As outlined earlier, platelets contain a very sensitive and powerful signaling machinery that facilitates their adhesion to sites of injury under conditions of high shear stress. To avoid unwanted activation, circulating platelets are exposed to inhibitors that are primarily released by the healthy endothelium. The two major inhibitory factors are nitric oxide and prostacyclin (prostaglandin I_2, PGI_2) (Jin et al. 2005). Nitric oxide is able to diffuse across the plasma membrane to directly activate its target, the soluble NO-sensitive guanylyl cyclase (sGC). Activated sGC leads to the formation of cyclic GMP (cGMP), a potent activator of protein kinase G (PKG) (Smolenski 2012). PGI_2 binds to its receptor (IP) on the platelet surface and activates $G_{s\alpha}$, leading to increased activity of AC and cAMP production (Smolenski 2012). While in most cell types cAMP is stimulatory, in platelets cAMP leads to PKA-mediated phosphorylation of multiple proteins and inhibition of platelet activation and adhesion, irrespective of the agonist used to stimulate the cells (Beck et al. 2014). Examples for PKA substrates include small GTPases such as RAP1B, IP_3 receptors, and various actin-binding proteins (Smolenski 2012).

To turn off inhibitory signaling, cAMP is degraded by phosphodiesterases and $G_{s\alpha}$ signaling is turned off by RGS2 (see later) (Smolenski 2012). Loss of PGI_2-dependent $G_{s\alpha}$

signaling in mice lacking the IP receptor leads to enhanced platelet activation, and $G_{s\alpha}$ signaling seems to be particularly important to counteract TxA_2-induced activation (Cheng et al. 2002). In humans, G_s hypofunction leads to platelet hyperreactivity to various agonists, insensitivity to $G_{s\alpha}$ stimulation, and a thrombotic phenotype (Freson et al. 2008). In contrast, a gain-of-function mutation in $G_{s\alpha}$ causes elevated cAMP levels and an increased susceptibility to bleeding (Van Geet et al. 2009). Drugs that increase cAMP levels have inhibitory actions on platelet function and are used clinically in the treatment of stroke (Gresele et al. 2011). However, the reverse is not true; decreasing cAMP levels alone does not induce platelet activation.

Negative Regulation by RGS Proteins

As outlined earlier, stimulation of G_s signaling by mediators released from the healthy vasculature is critical to keep circulating platelets in a quiescent state. At sites of vascular injury, additional negative feedback is required to dampen platelet activation and to prevent uncontrolled thrombus growth. RGS proteins play an important role in this process, as they function as GAPs to promote GTP hydrolysis and terminate G_α signaling. In humans, there are at least 37 genes for RGS proteins, many of which were detected at the mRNA or protein level in platelets (Bodor et al. 2004; Kim et al. 2006). One of the first studies to examine the role of RGS proteins in platelet function was performed using mice expressing a mutant $G_{i2\alpha}$ protein which is unable to interact with RGS proteins. Platelets from these mice show enhanced aggregation and increased platelet adhesion at the site of vascular injury in vivo (Signarvic et al. 2010). Proteomics and biochemical studies have shown that RGS10 and RGS18 are the most highly expressed RGS proteins in human platelets, and that they are involved in regulating platelet activation by thrombin receptors (Burkhart et al. 2012; Garcia et al. 2004; Zeiler et al. 2014). While RGS10 is widely expressed, RGS18 is enriched in platelets and megakaryocytes, as well as other cells of the hematopoietic lineage. Loss of RGS18 in mice leads to platelet hypersensitivity to activation, increased thrombus formation, and mild thrombocytopenia (Alshbool et al. 2015; Delesque-Touchard et al. 2014). The phenotype of mice deficient in RGS10 has yet to be determined. In resting platelets, RGS10 and RGS18 are sequestered in a complex that includes the scaffold protein spinophilin. Upon platelet activation with thrombin or TxA_2, spinophilin is dephosphorylated causing the release of the RGS protein from the complex (Ma et al. 2012). RGS18 also complexes with the scaffold protein 14-3-3. In this complex RGS18 has a decreased affinity for G_α, and the RGS18/14-3-3 complex is upregulated upon activation by thrombin and TxA_2 to promote extended $G_{q\alpha}$ signaling (Gegenbauer et al. 2012). The balance of free and complex-associated RGS18 is tightly controlled to regulate platelet activation both in the absence and presence of receptor agonists, and implicates RGS18 as a potential therapeutic target to control the status of platelet activation. RGS2 has also been reported to play a role in regulating platelet activation by GPCRs. While a mutation in RGS2 in humans causes impaired platelet G_s signaling due to constitutive association between $G_{s\alpha}$ and RGS2, loss of RGS2 in mice had no apparent effect on thrombus formation ex vivo or in vivo, suggesting potential compensation by other family members in mice (Banno et al. 2012; Noe et al. 2010).

Small GTPases

General Aspects

Small GTPases (also known as Small G proteins or Ras-related GTPases after their founding member) form an independent superfamily within the larger class of regulatory GTPases. They are monomers, similar in biochemistry to the heterotrimeric G protein α subunits (Fig. 1), and consist of a highly conserved globular structure of 20–25 kDa that includes two highly flexible motifs (switch regions 1 and 2). These motifs change conformation when GTP is bound and engage the effectors in the cell. The vast majority of small GTPases are posttranslationally modified by lipid anchors (farnesyl, geranylgeranyl, palmitoyl, myristoyl, or acetyl groups) that enable the association to cell membranes.

Small GTPases possess low intrinsic GTP hydrolysis and GDP/GTP exchange activities, thus GDP/GTP cycling needs to be controlled by GEFs and GAPs (Bos et al. 2007; Cherfils and Zeghouf 2013). Some members of this superfamily, such as RHO, RAB, and few RAS GTPases underlie additional regulatory activity by *guanine nucleotide dissociation inhibitors* (GDIs) or GDI-like molecules, proteins that mask the lipid group and sequester the inactive GTPases in the cytosol (Fig. 1B).

In humans, the small GTPase superfamily includes 153 members and is divided into five branches based on sequence and functional similarities (Wennerberg et al. 2005): RAS (cell proliferation, growth, adhesion), RHO (cytoskeletal dynamics), RAB (membrane trafficking), ARF (vesicular transport and actin remodeling), and RAN (nuclear transport and microtubule regulation). Despite the highly conserved structure, variations in sequence, posttranslational modifications, subcellular localization, and upstream regulatory proteins allow this large family to control a wide range of cellular responses. By expressing a defined set of small GTPases (Fig. 4) and upstream regulatory proteins, platelets acquired a unique signaling machinery that is crucial for their role in hemostasis and wound healing. Our understanding of

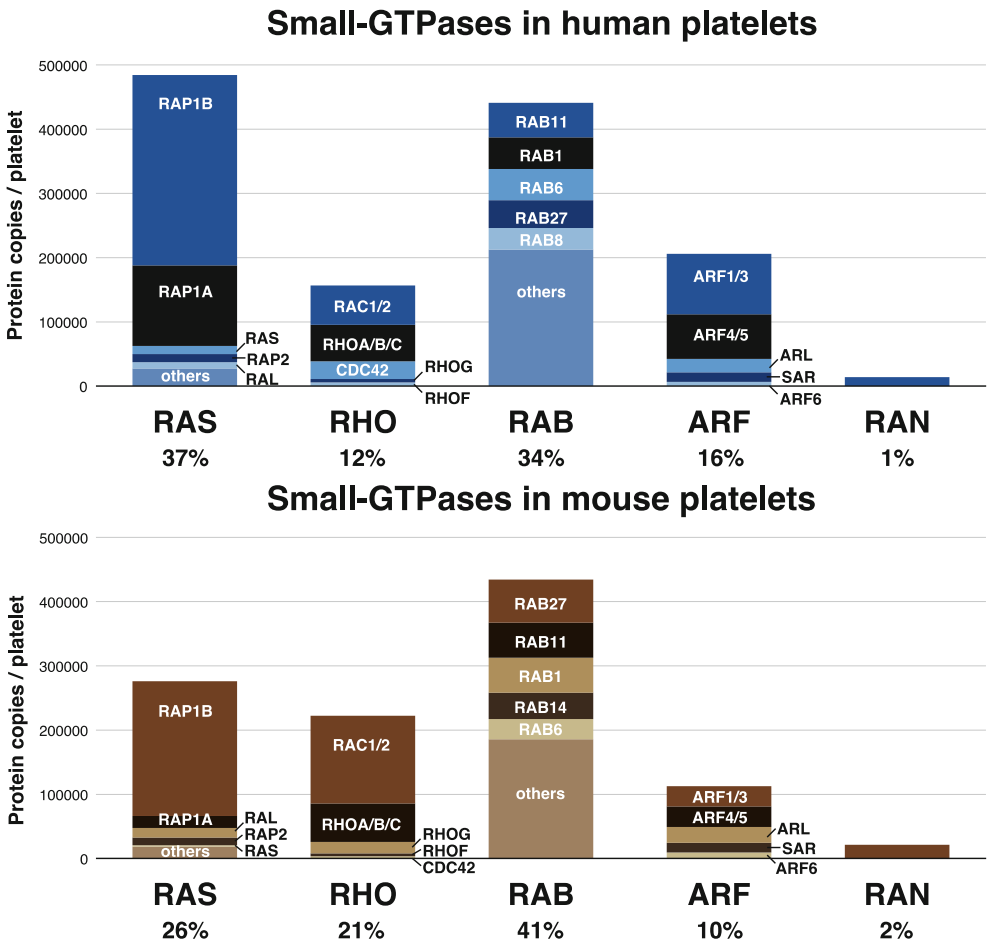

Fig. 4 Expression levels for small GTPases in human and mouse platelets. Graphs show the copy numbers per platelet for the indicated members of the RAS superfamily, based on quantitative proteomic analysis; (**top panel**) human (Burkhart et al. 2012) and (**bottom panel**) mouse (Zeiler et al. 2014) platelets. Each column corresponds to a specific family of small GTPases (RAS, RHO, RAB, ARF, RAN). The column height and percentages listed below indicate the relative expression level for each family within the RAS superfamily. Within each column the most abundant isoforms are stacked from top to bottom

this complex small GTPase signaling network, however, is still incomplete. This part of the chapter summarizes the current state of knowledge about the role of this vast superfamily of proteins in the regulation of platelet functional responses (Fig. 5), with particular focus on the most studied members of the family. Key findings from studies in transgenic mouse models with defects in small GTPase signaling are summarized in Table 2.

Small GTPase Families and Subfamilies

RAS Family

The RAS (*Rat sarcoma*) GTPase family (36 members in mammals) comprises major regulators of cell growth, differentiation, adhesion, and survival and consists of six subfamilies: RAS (cell proliferation, differentiation, and growth), RAP (cell adhesion, exocytosis, cytoskeletal dynamics), RAL (exocytosis), RAD (function unknown), RIT (function unknown), and RHEB (mTOR signaling).

RAP Subfamily

The most highly expressed small GTPases in platelets are members of the RAP subfamily, which are best known for their role in regulating adhesion molecules, the actin cytoskeleton, and MAP kinase cascades. The RAP subfamily consists of five members: two RAP1 proteins (1A and 1B) and three RAP2 proteins (2A, 2B, and 2C), with RAP1A and RAP1B being among the most abundant signaling proteins in platelets (Fig. 4) (Burkhart et al. 2012; Rowley et al. 2011; Simon et al. 2014).

Studies in other cells suggest that RAP1 and RAP2, which share 60 % sequence homology, control distinct cellular responses by signaling through different pools of downstream effectors (Machida et al. 2004; Nonaka et al. 2008; Pannekoek et al. 2013; Taira et al. 2004). Protein and RNA profiling (Burkhart et al. 2012; Rowley et al. 2011; Simon et al. 2014) indicate that platelets express a significant amount of RAP2B (Ohmstede et al. 1990), RAP2C (Paganini et al. 2006), and RAP2A, but RAP2B is the only isoform that has been detected by western blotting (Torti et al. 1993). Compared to RAP1, RAP2 displays a distinct subcellular distribution due to different posttranslational modifications (Canobbio et al. 2008) and in nonstimulated platelets shows elevated GTP loading (Greco et al. 2004; Stefanini et al. 2012), possibly because of a lower

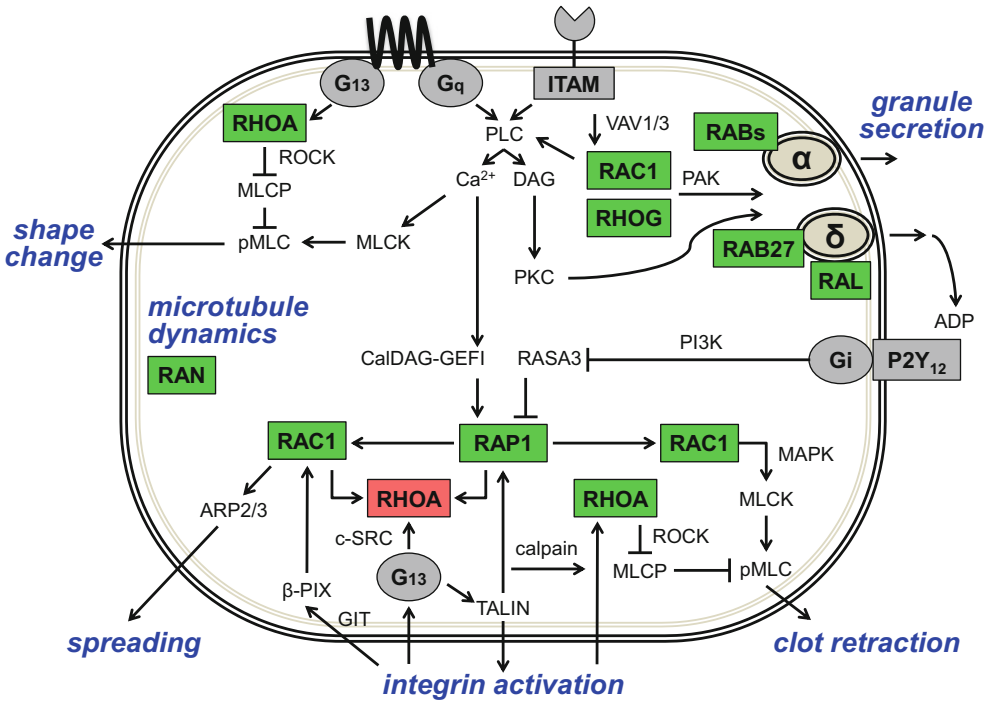

Fig. 5 Small GTPase signaling network in platelets. Active (GTP-loaded) small GTPases are indicated in green, while inactive (GDP-loaded) small GTPases are shown in red. Agonist receptors and heterotrimeric G proteins are shown in gray. Important signaling molecules upstream and downstream of the respective small GTPases are also shown. Abbreviations: α (α-granules), ADP (adenosine diphosphate), ARP2/3 (actin nucleating complex), β-PIX (RAC-GEF), CalDAG-GEFI (RAP-GEF), Ca^{2+} (calcium ions), calpain (calcium-dependent protease), DAG (diacyl glycerol), δ (dense granules), ITAM (immunoreceptor tyrosine-based activation motif-coupled receptors), GPCR (G protein-coupled receptors), G_q G_{13} G_i (heterotrimeric G proteins), GIT (ARF-GAP), ROCK (RHO-associated protein kinases), MAPK (mitogen-activated protein kinases), MLCP (myosin light chain phosphatase), MLCK (myosin light chain kinase), $P2Y_{12}$ (G_i-coupled receptor for ADP), PAK (p21-activated kinase), PI3K (phosphatidylinositide 3-kinases), PKC (protein kinase C), PLC (phospholipase C), pMLC (phosphorylated myosin light chain), RASA3 (RAS/RAP-GAP), c-SRC (tyrosine-protein kinase), TALIN (cytoskeletal protein that mediates RAP1-dependent integrin activation), VAV1/3 (RAC-GEFs)

sensitivity toward GAP-mediated inactivation (Ohba et al. 2000). However, little is known about RAP2 function in platelets and more detailed in vivo studies are lacking.

The high expression of RAP1-GTPases in platelets was recognized in the early 1990s (Kawata et al. 1989; Siess et al. 1990). Subsequent studies established a strong correlation between RAP1 activation and integrin-mediated adhesion upon cellular stimulation (Bos et al. 2003; Caron 2003; Caron et al. 2000; Katagiri et al. 2000; Reedquist et al. 2000). The first genetic evidence confirming a crucial role for RAP1 and its upstream regulator, CalDAG-GEFI, in platelet biology was provided by Shattil and colleagues in engineered murine megakaryocytes (Bertoni et al. 2002; Eto et al. 2002). Shortly thereafter mice deficient in RAP1B (Chrzanowska-Wodnicka et al. 2005) or CalDAG-GEFI (Crittenden et al. 2004) provided definitive proof that integrin activation in platelets is strongly dependent on this signaling pathway. Consistently, both *Rap1b*$^{-/-}$ and *Caldaggef1*$^{-/-}$ mice exhibit a significant defect in hemostasis and a strong protection from experimental thrombosis. These studies also demonstrated that platelet function is more severely impaired in *Caldaggef1*$^{-/-}$ mice compared to *Rap1b*$^{-/-}$ mice, and that the activation of RAP1 and $\alpha_{IIb}\beta_3$ is only partially impaired in *Caldaggef1*$^{-/-}$ platelets. Together, these studies suggested that (1) RAP isoforms other than RAP1B and/or RAP-independent processes contribute to integrin signaling in platelets, and (2) CalDAG-GEFI is not the only regulator of RAP1 activity in platelets.

CalDAG-GEFI is the most abundant RAP-GEF identified in platelets and the only one that has been detected so far by western blotting. Its catalytic activity is regulated by structural rearrangements induced by two EF-hand-binding domains with high affinity ($K_D = 80$ nM) toward Ca^{2+} (Iwig et al. 2013). Consistent with this very high sensitivity toward minor changes in the cytoplasmic Ca^{2+} concentration, platelets from *Caldaggef1*$^{-/-}$ mice (Crittenden et al. 2004) or from patients expressing an inactive CalDAG-GEFI mutant (Canault et al. 2014) fail to aggregate in response to calcium ionophore stimulation and do not respond to threshold doses of physiological agonists. Furthermore, platelets with impaired CalDAG-GEFI function exhibit a delayed activation response to high doses of strong agonists. In vivo,

Table 2 Thrombosis and hemostasis phenotype of mice with defects in small GTPases signaling in platelets

Mouse model	Platelet count/ size	Platelets main features	Secretion	Aggregation	Cytoskeletal dynamics	Thrombosis	Hemostasis	Ref
Rap1b−/−	Normal	Partial integrin activation defect to all agonists	↓ Dense, ↓ alpha	↓ Reduced at LD, normal at HD	↓ Clot retraction, ↓ lamellipodia	↓↓ Nonocclusive 3D thrombi	↑ Bleeding time	Chrzanowska-Wodnicka et al. (2005), Zhang et al. (2011)
Caldaggef1 −/−	Normal	Marked integrin activation defect to most agonists, insensitive to Ca^{2+}, slow activation	↓ Dense, ↓ alpha	↓↓ Abolished at LD, delayed at HD	↓ Clot retraction, ↓ lamellipodia	↓↓↓ 3D thrombi only at low shear rate	↑↑↑ Bleeding time	Crittenden et al. (2004), Stolla et al. (2011a, b), Stefanini et al. (2012)
Rasa3^{hlb}	↓↓↓ Count, ↑↑↑ size	Hyperactivation, short half-life	Normal	↑↑ Independent of $P2Y_{12}$ feedback		Not determined due to severe thrombocytopenia	More stable hemostatic plug	Stefanini et al. (2015)
RhoA$^{fl/fl}$ Pf4Cre^{+}	↓ Count, ↑↑ size	Impaired cytoskeleton-mediated contraction	↓ Alpha	↓ Particularly downstream of G_{13}-coupled receptors	↓ Clot retraction, ↓ shape change	↓↓ Unstable thrombi	↑ Bleeding time	Pleines et al. (2012), Suzuki et al. (2013)
Rac1$^{fl/fl}$ Mx1-Cre^{+} and Rac1$^{fl/fl}$ Pf4-Cre^{+}	Normal	Impaired cytoskeleton-mediated extension, ↓ $PLC\gamma_2$ activation	↓ Dense, ↓ alpha	↓ Particularly downstream of ITAM-coupled receptors	↓ Clot retraction, ↓ lamellipodia	↓↓ Unstable thrombi	↑ Bleeding time	McCarty et al. (2005), Akbar et al. (2007), Pleines et al. (2009), Delaney et al. (2012)
Cdc42$^{fl/fl}$ Mx1-Cre^{+}	↓ Count	Filopodia impaired on FBN and CRP	↓ Dense, ↓ alpha	↓ CRP, COLL, THR	↓ Filopodia, ↓ lamellipodia		↑ Bleeding time	Akbar et al. (2011)
Cdc42$^{fl/fl}$ Pf4-Cre^{+}	↓ Count, ↑ size	Filopodia impaired only on VWF	↑ Dense, ↑ alpha	↑ Enhanced at LD COLL	↓ Filopodia on VWF only	↑ Accelerated thrombus formation	↑ Bleeding time	Pleines et al. (2010)
Rac1$^{fl/fl}$ Cdc42$^{fl/fl}$ Pf4-Cre^{+}	↓↓ Count, ↑↑ size	Aberrant platelet production due to defective microtubule dynamics			↓ Lamellipodia, no microtubules in marginal band		↑↑↑ Bleeding time	Pleines et al. (2013)
RhoG−/−	Normal	Secretion defect in response to CRP	↓ Dense, ↓ alpha	↓ to CRP, rescued by ADP	Normal	↓ Smaller thrombi	Normal	Kim et al. (2013a, b), Goggs et al. (2013a, b)
RhoF−/−	Normal	None	Normal	Normal	Normal	Normal	Normal	Goggs et al. (2013a, b)
Larg−/−	Normal	Agonist-induced RHOA activation not affected	↓ Dense	↓ U46 and PAR4p	Normal	↓ Smaller thrombi only at LD $FeCl_3$		Williams et al. (2015)
Ophn1−/−	Normal	↑ RHOA, CDC42, RAC1 activation	↑ Dense, ↑ alpha	Normal aggregation, ↑ FBN binding	↑ Lamellipodia, ↑ filopodia	↑ Shorter occlusion time	↓ Bleeding time	Fotinos et al. (2015)
Vav1−/− −Vav3−/−		↓ $PLC\gamma_2$ activation		↓ COLL, CRP, RHOD	↓ Spreading on COLL and FBN			Pearce et al. (2004, 2007), Suzuki-Inoue et al. (2006)
P-Rex1−/−	Normal		↓ Dense	↓ Reduced at LD, U46 and THR			↑ Bleeding time	Aslan et al. (2011a, b), Qian et al. (2012)
Rab27b−/− −Rab27a$^{ash/ash}$	Normal	Impaired dense granule number and secretion	↓↓ Dense	↓ COLL and U46			↑ Bleeding time	Tolmachova et al. (2007)

Symbols: increase—↑ mild, ↑↑ moderate, ↑↑↑ severe; decrease—↓ mild, ↓↓ moderate, ↓↓↓ severe
LD low dose agonists, *HD* high dose agonists, *3D* three-dimensional thrombi, *ADP* adenosine diphosphate, *U46* U46619: TxA2 stable analog, *THR* thrombin, *PAR4p* PAR4 agonist peptide, *CRP* collagen related peptide, *COLL* collagen, *FBN* fibrinogen, *RHOD* rhodocytin, *dense* dense granules, *alpha* alpha granules

platelets lacking the sensitivity and speed provided by CalDAG-GEFI fail to form three-dimensional thrombi particularly at arterial shear rates (Stolla et al. 2011b), and *Caldaggef1*$^{-/-}$ mice are strongly protected from ferric chloride-induced carotid artery thrombosis (Stolla et al. 2011a) and collagen- (Crittenden et al. 2004) or immune complex-induced (Amirkhosravi et al. 2014) pulmonary embolism.

Both mouse and human platelets lacking functional CalDAG-GEFI can still undergo slow but sustained RAP1 activation that supports the formation of small and stable three-dimensional thrombi at venous shear conditions (Canault et al. 2014; Stolla et al. 2011a). This CalDAG-GEFI-independent activation of RAP1 and $\alpha_{IIb}\beta_3$ is inhibited by antagonists of PKC, $P2Y_{12}$, and PI3K (Cifuni et al. 2008; Franke et al. 2000; Lova et al. 2002, 2003; Stefanini et al. 2009; Woulfe et al.

2002). PKC contributes to RAP1 activation indirectly, by stimulating granule (ADP) release, and directly by promoting delayed GTP loading of RAP1 via an unknown mechanism. The ADP receptor $P2Y_{12}$ (and probably other $G_{i/z}$-coupled receptors, see earlier) mediates a slow but sustained RAP activation by inactivating the most abundant platelet RAP-GAP, RASA3, in a PI3K-dependent manner (Stefanini et al. 2015). RASA3 is a dual-specificity GAP capable of stimulating the GTPase activity of both RAS- and RAP-GTPases depending on the cellular context (Cullen et al. 1995). It contains a unique PH/Btk domain that binds with high affinity to phosphatidylinositol 4,5-diphosphate (PIP_2) ($K_D = 0.8 \pm 0.5$ μM) and phosphatidylinositol 3,4,5-triphosphate (PIP_3) ($K_D = 0.5 \pm 0.2$ μM), the lipid product of PI3K. This interaction enables RASA3 to localize constitutively to the plasma membrane and to be dynamically regulated in response to agonist-induced PI3K signaling (Cozier et al. 2000). The only other RAP-GAP suggested to play a role in platelets is RAP1GAP2 (Schultess et al. 2005); however, RAP1GAP2 is very weakly expressed in platelets (Burkhart et al. 2012; Rowley et al. 2011; Simon et al. 2014) and genetic evidence confirming its contribution to platelet function is lacking.

While detrimental to hemostatic plug formation, RASA3 is important to maintain circulating platelets in a quiescent state. Genetic deletion (*Rasa3*$^{-/-}$; *Rasa3*$^{fl/fl}$ Pf4-Cre+) (Stefanini et al. 2015) or inactivation (*Rasa3*$^{\Delta GAP}$) (Molina-Ortiz et al. 2014) of *Rasa3* leads to severe thrombocytopenia and high embryonic/perinatal lethality due to impaired vascular development in mice. Thrombocytopenia but normal development was observed in hypomorphic mice with a single point mutation (H794L) in the C-terminal region of RASA3 (*Rasa3*^{hlb}) (Stefanini et al. 2015). Thrombocytopenia in *Rasa3* mutant mice is largely the result of platelet preactivation and impaired platelet survival in circulation (Stefanini et al. 2015), but a defect in platelet production in vitro was also reported (Molina-Ortiz et al. 2014). Interestingly, concomitant deletion of *Caldaggef1* leads to a normalization of platelet lifespan and count in *Rasa3* mutant mice. Thus, a tight regulation of the antagonistic balance between CalDAG-GEFI and RASA3 is critical for both the prevention of premature platelet activation in circulation as well as for hemostatic plug formation.

Beyond their fundamental role in integrin inside-out activation, RAP-GTPases also stimulate thromboxane A_2 generation by signaling through the MAPK ERK (Stefanini et al. 2009) and modulate the actin cytoskeleton through a complex cross-talk with RHO-GTPases (Canault et al. 2014; Stefanini et al. 2012). Platelets with impaired RAP1 signaling also show defects in integrin outside-in signaling (Bernardi et al. 2006; Zhang et al. 2011) and in granule secretion (Stefanini et al. 2012; Zhang et al. 2011). Interestingly, RAP1 was shown to bind directly to granules in platelets (Berger et al. 1994; Nagata and Nozawa 1995) and in other cell types (Maridonneau-Parini and de Gunzburg 1992; Williams et al. 2009), suggesting that it may be controlling secretion not only through the regulation of the cytoskeleton, but also more directly, for instance through the recruitment of RAL-GTPases (see "RAL Subfamily" section). Interestingly, the molecular details for how active RAP1 controls these various cellular functions, including integrin activation, are ill understood. RAP1-GTP-interacting adaptor molecule (RIAM) was suggested to mediate the interaction of RAP1 and TALIN at the β3 integrin cytoplasmic tail (Han et al. 2006; Lee et al. 2009; Watanabe et al. 2008). However, studies in *Riam* knockout mice did not confirm this hypothesis (Stritt et al. 2015; Su et al. 2015).

RAS Subfamily

Ras GTPases have a well-documented role in cell growth, differentiation, and proliferation, cellular functions that are important in megakaryocytes (Matsumura et al. 1998) but not in platelets. Consistently, RAS is expressed in very modest amounts in platelets (Burkhart et al. 2012; Ohmori et al. 1988; Rowley et al. 2011; Simon et al. 2014), where it is activated upon cellular stimulation (Shock et al. 1997). However, it is currently unclear whether RAS plays a role in platelet biology, especially as its activation is not coupled to the activation of ERK MAP kinase (Tulasne et al. 2002), a common downstream target of RAS in other cells.

RAL Subfamily

RAL regulates vectorial targeting of secretory vesicles by direct binding of the exocyst component SEC5 (Moskalenko et al. 2002). In platelets, RAL is activated in a calcium-dependent manner (Wolthuis et al. 1998), and this activation shows strong correlation with the activation of RAP1, a potential upstream regulator. RAL associates with dense granules (Mark et al. 1996) and binds SEC5 upon thrombin stimulation with the same time course as dense granule secretion (Kawato et al. 2008). Further studies need to address the interplay between different branches of the RAS superfamily (RAL, RABs, RHOs, and RAP1) that regulate exocytosis (Novick and Guo 2002) and whether RAL is downstream of RAP1.

RHEB Subfamily

In other cells RHEB is implicated in initiating mTOR (the mammalian target of rapamycin) signaling (Long et al. 2005), a pathway with documented function in platelets (Aslan et al. 2011b; Moore et al. 2014). However, RHEB is not very abundant in platelets and its contribution to cellular activation has not been studied.

RHO Family

RHO (*Ras homologous*) GTPases are best known for their role in the regulation of cytoskeletal dynamics, but they also control

multiple cell signaling pathways. Among the 20 members of the family expressed in mammalian cells, RHOA, RAC1, and CDC42 are the best characterized RHO family members in platelets. However, human platelets also express a significant amount of RHOC, RAC2, RHOG, and RHOF (RIF) (Fig. 4), which may have unique or redundant functions.

RHO

The three highly homologous RHO isoforms, RHOA, RHOB, and RHOC, when overexpressed in cells, induce the formation of stress fibers (Aspenstrom et al. 2004; Ridley and Hall 1992), structures that mediate cell retraction, an inward movement of the membranes and the associated cytoskeleton, opposed to cell spreading. In platelets, the functions of RHO GTPases have been investigated extensively using the clostridial exoenzyme C3 transferase, which modifies and blocks all three isoforms. Furthermore, two independently generated knock-out mouse models (*RhoA*$^{fl/fl}$ *Pf4-Cre*$^{+}$) that lack RHOA specifically in the megakaryocyte lineage have been described (Pleines et al. 2012; Suzuki et al. 2013). *RhoA*$^{fl/fl}$*Pf4-Cre*$^{+}$ mice display macrothrombocytopenia (50 % fewer platelets, 25 % larger volume) and more roundish shape (but normal intracellular morphology) due to aberrant megakaryocyte development and platelet production (Gao et al. 2012; Pleines et al. 2012; Shi et al. 2014; Suzuki et al. 2013). Pharmacological and genetic studies concur that RHO, by orchestrating cytoskeletal dynamics, controls three main platelet responses—shape change (Bauer et al. 1999; Pleines et al. 2012), granule secretion (Jin et al. 2009; Pleines et al. 2012), and clot retraction (Flevaris et al. 2007, 2009; Pleines et al. 2012)—while it is dispensable for integrin inside-out activation and spreading (Leng et al. 1998; Pleines et al. 2012; Schoenwaelder et al. 2002). RHO does not affect actin polymerization (Hartwig et al. 1995; Leng et al. 1998; Pleines et al. 2012), but it regulates how microtubules and actin filaments are organized (Leng et al. 1998; Pleines et al. 2012). The weakening of the cytoskeleton results in an inability to form sustained platelet–matrix interactions under flow (Schoenwaelder et al. 2002), and in smaller and less stable thrombi ex vivo and in vivo. Hence platelet-specific RHOA deficiency in mice causes a bleeding diathesis and protection from experimental thrombosis and cerebral ischemia (Pleines et al. 2012).

Dynamic control of platelet morphology and contractility is achieved through the tight regulation of RHO activity over time (Shen et al. 2013) and the cross-talk with other small GTPases, particularly with RAC1 (Flevaris et al. 2009; Gratacap et al. 2001; Shen et al. 2012) (see "RAC" section). The temporal regulation of RHO is orchestrated by the heterotrimeric G-protein subunit $G_{13\alpha}$ and integrin $\alpha_{IIb}\beta_3$ (see earlier). Stimulation of G-protein receptors coupled to $G_{13\alpha}$, such as the thrombin (PAR) and the thromboxane A_2 (TP) receptors, triggers the early RHOA signaling pathways that mediate shape change and granule secretion (Klages et al. 1999; Moers et al. 2003). Upon integrin engagement, RHOA activity is transiently downregulated in a c-SRC-dependent manner to enable RAC-dependent platelet extension and consequent spreading (early phase of outside-in signaling) (Gong et al. 2010). Once the platelets are firmly attached, CALPAIN cleaves the integrin β3 tail (Kuchay et al. 2012) and relieves c-SRC-dependent RHOA inhibition (late phase of outside-in signaling) thereby allowing platelets to contract (Flevaris et al. 2007). RHOA-powered retractile forces transmitted along the cytoskeleton–integrin–matrix axis to the underlying tissue determine clot retraction.

Very little is known about the molecular identity of the RHOA upstream regulators. p115RHOGEF (ARHGEF1) is activated by $G_{13\alpha}$ and mediates the early RHOA activation, shape change, and secretion (Hart et al. 1998; Huang et al. 2007; Kozasa et al. 1998). LARG (ARHGEF12) and GEF-H1 (ARHGEF2) are RHO-GEFs activated when integrins experience tensional forces (Guilluy et al. 2011), thus they are plausible candidates to mediate the activation of RHO during late outside-in signaling in platelets. However, *Larg*$^{-/-}$ platelets have a very modest phenotype, which seems to suggest a role of LARG downstream of G_{13}-coupled receptors, instead of the integrin (Williams et al. 2015). An important inhibitor of RHO signaling, p190RHOGAP, was not detected by platelet proteomics and transcriptomics analysis. The only RHO-GAPs characterized more in depth in platelets are OLIGOPHRENIN (ARHGAP41) (Bleijerveld et al. 2013; Elvers et al. 2012; Fotinos et al. 2015) and NADRIN (ARHGAP17, RICH1) (Beck et al. 2013; Nagy et al. 2015), but their roles are still not clear since they have broad specificity for RHOA, CDC42, and RAC1. Future studies need to address the contribution of more highly expressed RHO regulators such as p50RHOGAP/ARHGAP1, ARHGAP18, ARHGAP6, and ARAP1. RHO-GDIs are also present in very high levels in platelets (Burkhart et al. 2012; Rowley et al. 2011; Simon et al. 2014), but their role has not been investigated so far.

The best-known downstream effectors of RHO are the Rho-associated protein kinases ROCK1 and ROCK2. These serine/threonine kinases, once stimulated by RHOA/B/C-GTP, phosphorylate many substrates implicated in cell contractility and cytoskeleton remodeling, most notably myosin light chain phosphatase (MLCP) (Bauer et al. 1999; Suzuki et al. 1999) and LIM kinase (LIMK) (Dasgupta et al. 2013). Phosphorylation of MLCP inactivates its phosphatase activity and enables the increase in phosphorylation of myosin light chain (MLC), which in turn triggers myosin IIA ATPase activity and promotes the acto-myosin contractile

response that is involved in platelet shape change, clot retraction, and secretion. Conversely, LIMK, when phosphorylated, is able to inhibit (by phosphorylation) the actin-depolymerizing activity of COFILIN, leading to stabilization of filamentous actin structures, decreased branching, and inhibition of cell extension. Inhibition of both ROCK isoforms with pharmacological inhibitors recapitulates many features of *RhoA*-deficient platelets (Bauer et al. 1999; Calaminus et al. 2007a; Schoenwaelder et al. 2002; Suzuki et al. 1999). However, *Rock1*-deficiency impairs LIMK/COFILIN phosphorylation but not MLCP phosphorylation and shape change (Dasgupta et al. 2013), suggesting that the two isoforms (ROCK1 and ROCK2) may have different functions and that the RHO-dependent contractile response may be under the control of the more abundant isoform ROCK2.

Formins, a large class of multidomain proteins that control both actin polymerization and microtubule stabilization, are another important class of RHO effectors (Faix and Grosse 2006). Platelets have been shown to express mDIA1, DAAM (Higashi et al. 2008), and FHOD1 (Thomas et al. 2011); however, $mDia^{-/-}$ platelets display no functional defects (Thomas et al. 2011).

RAC

RAC GTPases, when overexpressed in cells, stimulate the extension of lamellipodia and cell spreading, an outward movement of the membranes and the underlying cytoskeleton (Aspenstrom et al. 2004; Ridley et al. 1992). Proteomics and transcriptomics studies (Burkhart et al. 2012; Rowley et al. 2011; Simon et al. 2014) suggest that platelets express two of the known RAC isoforms, RAC1 and RAC2, which have both unique and overlapping roles in other hematopoietic cells. The role of RAC2 in platelets has been disregarded because it could not be detected by immunoblotting and its deletion in mouse platelets was inconsequential (McCarty et al. 2005); however, activation of human platelets may depend more on this RAC isoform as they express more RAC2 than murine cells (Burkhart et al. 2012; Zeiler et al. 2014). Germline deletion of *Rac1* is lethal in mice, thus RAC1 functions in platelets have been investigated with inducible ($Rac1^{fl/fl}$ *Mx-Cre*$^{+}$) (Akbar et al. 2007; McCarty et al. 2005) or conditional ($Rac1^{fl/fl}$ *Pf4-Cre*$^{+}$) (Delaney et al. 2012; Pleines et al. 2009) knockout mouse models and two small-molecule inhibitors, NSC23766 (Akbar et al. 2007) and EHT1864 (Pollitt et al. 2010; Stefanini et al. 2012). It is important to note, however, that the specificity of these compounds has recently been questioned (Dutting et al. 2015).

These studies demonstrated that RAC1 controls both cytoskeleton-dependent and cytoskeleton-independent platelet responses, and that *Rac1*-deficient platelets lack the ability to form three-dimensional thrombi under flow ex vivo and in vivo (McCarty et al. 2005). Consistently, *Rac1* mutant mice are protected from thrombosis (McCarty et al. 2005; Pleines et al. 2009) and have prolonged bleeding times (Akbar et al. 2007).

The most notable non-cytoskeletal function of RAC1 is the regulation of PLCγ_2 activity (Piechulek et al. 2005). Platelets lacking functional RAC1 exhibit normal phosphorylation of PLCγ_2, but reduced production of IP_3, impaired intracellular calcium mobilization (Pleines et al. 2009), and impaired PKC activation (Guidetti et al. 2009). Consequently, in the absence of RAC1 the major signaling defect is downstream of ITAM-coupled receptors (Pleines et al. 2009) and integrins (Guidetti et al. 2009), which signal to PLCγ_2. In addition, RAC1 is implicated in the initial signaling steps following GPIb-IX-V stimulation, linking the Src family kinase LYN to MAPK and PI3K/AKT signaling (Delaney et al. 2012).

Besides its role in signaling, RAC1 is best known for orchestrating cytoskeletal dynamics and for inducing cell spreading. Deletion or inhibition of RAC1 in mouse platelets reduces actin polymerization (Hartwig et al. 1995; McCarty et al. 2005), prevents the formation of lamellipodia without interfering with filopodia extension (McCarty et al. 2005), partially impairs both α- and dense-granule secretion (Akbar et al. 2007), and completely inhibits clot retraction (Flevaris et al. 2009) without affecting platelet shape change (McCarty et al. 2005).

It is well established that RAC1 mediates lamellipodia formation through the activation of ARP2/3, a protein complex that nucleates the growth of a new actin filament on the side of an existing filament and, as a result, creates branched actin networks. In platelets, RAC1 and ARP2/3 are enriched in the actin nodules during early spreading (Calaminus et al. 2008; Poulter et al. 2015), and later colocalize at the edge of the fully extended lamellipodia (McCarty et al. 2005). The effectors that link RAC1-GTP to ARP2/3 activation are members of the SCAR/WAVE family. Deficiency of SCAR/WAVE-1 in mice impairs lamellipodia formation on CRP and laminin, but not on collagen or fibrinogen-coated surfaces (Calaminus et al. 2007b). This incomplete spreading defect may be explained by redundant signaling by SCAR-WAVE-2, which is also abundant in platelets. Other major RAC1 (and CDC42) effectors are the serine–threonine kinases of the PAK family. In platelets, RAC1 employs the PAK signaling system to initiate a number of parallel pathways. Pharmacological inhibition of PAKs reduces the phosphorylation of GIT, GEFH1, LIMK, MERLIN, MEK, ERK, AKT, GSK3β (Aslan et al. 2013a, 2013b) and impairs multiple RAC1-dependent platelet responses.

RAC1 orchestrates cytoskeletal dynamics and promotes platelet activation through a complex cross-talk with RHOA and RAP1. The functional relationship with RHOA varies over time (Shen et al. 2012). Upon platelet stimulation,

RHOA-mediated shape change is dependent on G_{13} signaling, while RAC1 activation depends on G_q or ITAM signaling and is required for actin polymerization (Gratacap et al. 2001). Both RHOA and RAC1 positively regulate granule secretion (Flevaris et al. 2009) and generation of PIP_2 (Chatah and Abrams 2001; Gratacap et al. 2001). Upon integrin engagement, during the early phase of outside-in signaling, RAC1 and RHOA have antagonistic functions. RAC1 stimulates actin polymerization, F-actin branching, and lamellipodia extension, while RHOA is turned off to prevent cell retraction and allow spreading (Gong et al. 2010; Pleines et al. 2012). In the final stage of outside-in signaling, after calpain has cleaved the integrin β3 tail, RAC1 and RHOA are both active and have synergistic functions that converge at the level of MLC phosphorylation and lead to platelet-dependent clot retraction. RAC1 increases MLC phosphorylation through the stimulation of the MAPKs ERK and p38 and the activation of myosin light chain kinase (MLCK), while RHOA acts through its effector ROCK to phosphorylate and inhibit MLCP (Egot et al. 2013; Flevaris et al. 2009). Concurrently, there is cross-talk between RAC1 and RAP1, which is critical for full platelet activation (Stefanini et al. 2012). RAC1 promotes RAP1 activation indirectly by stimulating calcium mobilization and ADP secretion, which mediate CalDAG-GEFI activation and RASA3 inhibition, respectively (see earlier). In turn, RAP1-GTP promotes sustained RAC1 activation, which is critical for lamellipodia extension (Canault et al. 2014; Stefanini et al. 2012).

The best characterized RAC-GEFs expressed in platelets are VAV1 and VAV3, which play a crucial and redundant role in the regulation of spreading and in the activation of $PLC\gamma_2$ following stimulation of ITAM-coupled receptors (Pearce et al. 2004; Suzuki-Inoue et al. 2006) or integrin $\alpha_{IIb}\beta_3$ (Pearce et al. 2007). However, VAVs are known to have a broad specificity and the phenotype of *Vav1*/*Vav3*-double knockouts is similar but not identical to the phenotype of *Rac1*-knockouts, suggesting that VAV1/3 may also be modulating other RHO-GTPases. Other potential RAC-GEFs were identified in platelets (Aslan et al. 2011a, 2013a). Among these, P-REX1 does not seem to be a major player since its deficiency in mouse platelets has no effect on spreading (Aslan et al. 2011a) and has a modest effect on aggregation and secretion stimulated by low, but not high, doses of thrombin and U46619 (Qian et al. 2012). β-PIX (ARHGEF7, COOL-1), the most abundant RHO-GEF detected in platelets, and α-PIX (ARHGEF6, COOL-2) could be regulating integrin-induced RAC1 activation (ten Klooster et al. 2006), since they bind GIT1 (Nagy et al. 2015; Sato et al. 2008), an ARF-GAP that translocates to the cytoskeleton upon integrin engagement, but a detailed analysis of their functional importance in platelets is still lacking. TIAM has also been implicated in integrin-dependent RAC1 activation, downstream of a kinase cascade involving SRC, SYK, mTOR kinase, and the ribosome protein S6 kinase (S6K1) (Aslan et al. 2011b); however, this GEF also awaits further investigation. Finally, in addition to the canonical RAC-GEFs, platelets also express several DOCK proteins, which can act as powerful GEFs for RAC and CDC42 (Gadea and Blangy 2014).

RHOG

RHOG shares ~70 % sequence homology with RAC GTPases (Vincent et al. 1992) and, just like these closely related small GTPases, its ectopic expression in cell lines induces lamellipodia formation (Aspenstrom et al. 2004). In platelets, RHOG is rapidly activated in response to either G protein or ITAM-coupled receptor stimulation. However, its deficiency does not affect spreading, clot retraction, and $PLC\gamma_2$ activation, possibly because of redundancy with RAC1. The only defects of $RhoG^{-/-}$ platelets are a decrease in α- and dense-granule secretion and a reduction of SYK, ERK, and AKT phosphorylation, solely downstream of the collagen receptor GPVI. This signaling impairment results in a modest aggregation defect in vitro, which can be rescued by addition of ADP, and reduced thrombus formation but normal hemostasis in vivo (Goggs et al. 2013a; Kim et al. 2013b).

CDC42

In mammalian cells, CDC42 is important for the formation of actively protruding filopodia (Nobes and Hall 1995), the regulation of microtubule dynamics, cell polarity (Etienne-Manneville 2004), cell contraction (Wilkinson et al. 2005), and membrane trafficking (Kroschewski et al. 1999; Osmani et al. 2010). In human platelets, CDC42 is robustly activated in response to thrombin stimulation (Dash et al. 1995) or upon platelet adhesion to collagen (Pula and Poole 2008), but its intracellular distribution and its sensitivity to agonists is distinct from that of RAC1 (Vidal et al. 2002). Moreover, CDC42 is the specific activator of the Wiskott–Aldrich Syndrome protein (WASP), a major regulator of actin polymerization (Pollitt and Insall 2009; Rohatgi et al. 1999) that also binds microtubules (Tian et al. 2000). The role of CDC42 in platelet function was assessed in $Cdc42^{fl/fl}$*Pf4-Cre*+ (Pleines et al. 2010) and $Cdc42^{fl/fl}$*Mx-Cre*+ mice (Akbar et al. 2011). Both mouse models are characterized by a partial macrothrombocytopenia (platelet count 50–80 % of controls) and a mildly prolonged bleeding time. However, the underlying phenotypes are conflicting. Constitutive deletion of the *Cdc42* gene in megakaryocytes ($Cdc42^{fl/fl}$*Pf4-Cre*+) results in platelets with no defect in filopodia formation in suspension or upon adhesion to fibrinogen, in either unstimulated or stimulated conditions.

Reduced filopodia formation is only observed upon platelet adhesion to VWF, suggesting that CDC42 might have a specific role downstream of the GPIb-IX-V receptor. Unexpectedly, these platelets exhibit an increased ATP content and increased secretion of both α- and dense-granules, enhanced aggregation in vitro, accelerated thrombus formation under flow, shorter occlusion time in vivo, and a slightly shorter half-life, suggesting that CDC42 controls granule packing and release (Pleines et al. 2010). Conversely the inducible deletion of the *Cdc42* gene in the hematopoietic system (*Cdc42*$^{fl/fl}$*Mx-Cre+*) leads to reduced filopodia formation on immobilized fibrinogen or collagen-related peptide, an impaired secretion and aggregation response, and diminished phosphorylation of RAC/CDC42 downstream effectors such as PAK1/2 (Akbar et al. 2011). The reasons for these divergent results are currently unknown. Moreover, circulating platelets in *Rac1*$^{fl/fl}$*Cdc42*$^{fl/fl}$ *Pf4-Cre+* mice completely lack microtubule coils in the marginal band and show a dysregulation in granule numbers (Pleines et al. 2013), suggesting that CDC42 might also contribute to granule packing and microtubule organization in the developing megakaryocyte.

RHOF

Recent data suggest the existence of CDC42-independent mechanisms of filopodia formation, involving, among others, the Rho GTPase RHOF (RIF) (Ellis and Mellor 2000). However, *RhoF*$^{-/-}$ mice display no alterations in their platelets and megakaryocytes (Goggs et al. 2013b). Consistent with this, deficiency of the non-branching actin nucleating agent mDIA, which is known to bind RHOF, also has no effect on platelet activation and morphology (Thomas et al. 2011).

RAB Family

RAB (*Ras-related proteins in brain*) GTPases are master regulators of vesicular/membrane trafficking (Stenmark 2009). Thus far 70 members of the RAB family have been identified in humans and platelets express about 40 of them (Fig. 4). There is additional complexity to this family as each RAB protein is suggested to be enriched in a specific membrane microdomain (Chavrier et al. 1990), where it can regulate distinct steps during vesicular/membrane trafficking. These include cargo selection, vesicle budding from a donor membrane, vesicle transport along cytoskeletal tracts (microtubules or actin-filaments), or tethering/fusion to the correct acceptor membrane. Importantly, RABs are also indirectly involved in signal transduction by regulating the exposure/internalization of surface receptors and the translocation of signaling molecules between intracellular compartments.

Proper post-translational modification and localization of RABs is essential for optimal platelet production and function. Mice homozygous for *gunmetal*, a spontaneous, recessive mutation in the *Rab geranylgeranyl transferase* α subunit gene (*Rabggta*), display macrothrombocytopenia, reduced platelet α- and dense-granule contents, and prolonged bleeding times due to the hypo-prenylation of several platelet RABs and their consequent displacement in the cytosolic fraction (Detter et al. 2000; Novak et al. 1995; Swank et al. 1993).

In platelets, the best-studied members of this family are RAB27B and RAB27A, which regulate specifically dense granule number and secretion (Tolmachova et al. 2007). *Rab27b*-deficient platelets exhibit a 50 % reduction in dense granule number and content and a severe, but incomplete, defect in dense granule secretion. As a consequence, these mice display a reduced aggregation response to collagen and U46619 and a bleeding defect that is more severe than that of the gunmetal mouse model (Tolmachova et al. 2007). RAB27A is less abundant than RAB27B in platelets. Its deficiency in humans causes type 2 Griscelli syndrome, a rare autosomal recessive disorder characterized by hypopigmentation and immunodeficiency due to a defect in the release of melanosomes of melanocytes and secretory lysosomes of lymphocytes, organelles that are closely related to platelet dense granules. The mouse model of this disease, a spontaneous *Rab27a* knockout line designated *ashen*, on some genetic backgrounds (on C3H/HeSnJ, but not on C57BL/6J) displays a marginal defect in platelet dense granule secretion and a bleeding tendency (Novak et al. 2002; Wilson et al. 2000). Studies with double-deficient mice (*Rab27b*$^{-/-}$*Rab27a*$^{ash/ash}$) suggest that the two isoforms could be to a certain extent redundant since RAB27A can partially compensate for the secretory defect but not for the reduced granule number of *Rab27b*-deficient platelets (Tolmachova et al. 2007). They also share effectors such as Munc13-4 (Shirakawa et al. 2004), a critical component of the platelet secretory apparatus (Ren et al. 2008). Besides RAB27B, RAB38 has been implicated in dense granule biogenesis (Ambrosio et al. 2012; Ninkovic et al. 2008).

Very little is known about the function and localization of the numerous other platelet RABs and about how they regulate vesicle traffic in platelets. Adding to the complexity, α-granules are ten times more abundant than dense granules and several studies suggest the existence of heterogenous subpopulations, which may be regulated by distinct RAB isoforms. A study dating back to the early '90s has shown that RAB6 and RAB8 are preferentially targeted to the α-granules (Karniguian et al. 1993). More recently, a permeabilized platelet system was employed to show that a RAB-GDI binding RAB4, RAB5, RAB6, and RAB8, but not RAB27, inhibits α- but not dense-granule secretion and RAB4 positively regulates Ca^{2+}-induced secretion of α-granules (Shirakawa et al. 2000). However, more detailed studies are needed to dissect the role of the distinct members of the RAB family in the platelet-specific membrane traffic pathways.

ARF Family

ARF (*ADP ribosylation factor*) GTPases are the founding members of a growing family that includes ARL (*Arf-like*), ARP (*Arf-related proteins*), and the remotely related SAR (*Secretion-associated and Ras-related*) proteins. Members of this family are known to regulate membrane/vesicular trafficking through (1) membrane recruitment of effector proteins that orchestrate vesicle budding; (2) stimulation of enzymes that alter membrane lipid composition, such as phospholipase D and phosphatidylinositol-4-phosphate-5-kinase; and (3) modulation of RHO-GTPases, which in turn regulate the cytoskeleton. Platelets express several members of the ARF family (Fig. 4), but the only member of the family that has been studied in detail is ARF6, which is active (GTP-bound) in resting platelets and rapidly down-regulated upon platelet stimulation with either collagen or thrombin (Choi et al. 2006; Karim et al. 2008). Using a cell-permeant myristoylated peptide that interferes with ARF6-GTP hydrolysis, it was shown that ARF6 down-regulation is critical to enable agonist-induced RHOA, RAC1, and CDC42 (but not RALA or RAP1) activation and the RHO-dependent functional responses required for optimal platelet activation (Choi et al. 2006). ARF6 deficiency in mice interferes with the uptake of fibrinogen through integrin $\alpha_{IIb}\beta_3$, which results in enhanced clot retraction and spreading (Huang et al. 2016). It has also been shown that the ARF-GAP GIT1 constitutively binds the RAC-GEFs, α-PIX (ARHGEF6, COOL-2), and β-PIX (ARHGEF12, COOL-1), and that this interaction is important for their recruitment to the cytoskeleton upon integrin engagement in platelets (Nagy et al. 2015; Sato et al. 2008). The mechanistic basis of the RHO/ARF cross-talk in platelets needs to be elucidated further and a possible avenue of investigation is the study of ARF-GEFs and/or ARF-GAPs with multiple functional domains such as ARAP1, a PIP_3-dependent ARF-GAP that also includes a RHO-GAP domain (Miura et al. 2002).

RAN Family

The RAN (*Ras-like nuclear*) GTPase is the only member of the RAN family in humans. In nucleated cells it is best known for regulating the nucleocytoplasmic traffic of RNA and proteins, but it also orchestrates mitotic spindle assembly by controlling microtubule organization (Li et al. 2003).

In platelets, RAN is quite abundant despite the lack of nuclei (Fig. 4). Deletion of the RAN-binding protein RANBP10 in mice leads to a prolonged bleeding time (Kunert et al. 2009), formation of unstable thrombi in an arterial thrombosis model, attenuated platelet shape change, reduced secretion and aggregation, and impaired marginal band contraction during platelet activation (Meyer et al. 2012), suggesting that RAN in platelets could be regulating microtubule dynamics.

Concluding Remarks

GTPases play a central role in the intracellular signaling required for platelet function. Heterotrimeric G proteins transmit signals from GPCRs, which control both platelet inhibition in circulation and platelet activation at sites of mechanical injury. G_q proteins are critical for the rapid generation of Ca^{2+} and DAG, second messengers that facilitate the near-immediate inside-out activation of integrin receptors on the cell surface and the release of autocrine/paracrine agonists. Proteins of the G_i family are critical to sustain platelet activation and integrin-mediated adhesion. G_{13} proteins are important to facilitate shape change and clot retraction. G_s proteins antagonize the above-mentioned processes by activating PKA, a kinase that down-modulates various signaling pathways. Small GTPases play a crucial role in the integration of stimulatory and inhibitory signals provided by heterotrimeric G proteins. RAP GTPases are critical for integrin activation downstream of G_q and G_i signaling. RHO GTPases are master regulators of the cytoskeleton and thus control shape change, spreading, and clot retraction downstream of G_q and G_{13} signaling. Together with RAB and ARF GTPases, they also control granule secretion. As we learn more about these systems, it is becoming increasingly apparent that (1) signaling by heterotrimeric and small GTPases is very interconnected, and (2) both bleeding and thrombotic complications can often be traced back to disturbances in GTPase signaling. Given their central role in platelet activation, it is also not surprising that antiplatelet therapies used in the clinic target GTPase signaling (Gurbel et al. 2015; Jackson and Schoenwaelder 2003; Smyth et al. 2009). Thus, a better understanding of the unique contributions to platelet activation of the various members of this vast family will be key to the development of improved diagnostics and therapies for cardiovascular disease.

Take Home Messages

- Heterotrimeric G proteins and small GTPases are molecular switches that cycle between the inactive, GDP-bound and the active, GTP-bound state. The GDP/GTP cycle is controlled by GEFs and GAPs.
- Heterotrimeric G proteins are critical for the function of G protein-coupled receptors (GPCRs) that respond to soluble agonists such as thrombin (PAR1, PAR4), ADP (P2Y1, P2Y12), and thromboxane A_2 (TP).
- Platelets utilize G_q, $G_{12/13}$, G_i, and G_s proteins to fine-tune their activation state at sites of vascular injury.

(continued)

- Small GTPases play a crucial role in the integration of stimulatory and inhibitory signals provided by GPCRs.
- The best studied small GTPases in platelets are members of the RAS, RHO, and RAB families, which play crucial roles in integrin signaling (adhesion), cytoskeletal dynamics (shape change, clot retraction), and vesicular trafficking (granule secretion), respectively.
- Interference with GPCR and small GTPase signaling is critical to current and emerging antiplatelet therapies.

Platelet Signalling: Calcium

Alan G.S. Harper and Stewart O. Sage

Abstract

A rise in cytosolic calcium concentration ($[Ca^{2+}]_{cyt}$) is central to platelet activation. Agonists stimulate a rise in $[Ca^{2+}]_{cyt}$ through a combination of Ca^{2+} release from intracellular stores located in the dense tubular system (DTS) and acidic organelles as well as Ca^{2+} entry across the plasma membrane via several channel types. $[Ca^{2+}]_{cyt}$ may be reduced by Ca^{2+} sequestration into the intracellular stores by sarco-endoplasmic reticulum Ca^{2+}-ATPases (SERCAs) and via a H^+-dependent mechanism, whilst Ca^{2+} may be removed across the plasma membrane by plasma membrane Ca^{2+}-ATPases (PMCAs) and by Na^+/Ca^{2+} exchangers (NCXs). Ca^{2+} signals are shaped by differential employment of these basic Ca^{2+} entry and removal processes and by Ca^{2+} buffers present in the platelet cytosol and other cellular compartments. In turn, Ca^{2+} signals can be transduced into a number of platelet responses by an array of effector proteins which may be activated in some cases by Ca^{2+} signals confined to specific cellular microdomains.

Introduction

Human platelets maintain a low resting cytosolic Ca^{2+} concentration ($[Ca^{2+}]_{cyt}$) estimated to be around 50–100 nM. To maintain the resting $[Ca^{2+}]_{cyt}$ against leakage of Ca^{2+} from intracellular stores or across the plasma membrane, or to restore resting $[Ca^{2+}]_{cyt}$ after the generation of Ca^{2+} signals, several Ca^{2+} removal mechanisms are used. Ca^{2+} is sequestered into organelles by sarco-endoplasmic reticulum Ca^{2+}-ATPases (SERCAs) and by a vacuolar H^+-ATPase (vH^+-ATPase), probably coupled to a H^+/Ca^{2+} exchanger. Ca^{2+} is removed across the plasma membrane either by primary active transport via plasma membrane Ca^{2+}-ATPases (PMCAs) and by Na^+/Ca^{2+} exchangers (Fig. 1).

Platelet activation is associated with a rise in $[Ca^{2+}]_{cyt}$, which may reach values of several μM and be associated with oscillations or repetitive spikes in elevated $[Ca^{2+}]_{cyt}$ in individual cells. Stored Ca^{2+} may be released from the dense tubular system and acidic organelles by the second messengers inositol 1,4,5-trisphosphate (IP_3) and nicotinic acid adenine dinucleotide phosphate (NAADP), respectively, and the entry of Ca^{2+} across the plasma membrane may be activated in response to store depletion (store-operated Ca^{2+} entry; SOCE), in response to the second messenger diacylglycerol (DAG) or by direct activation of an ionotropic receptor in the case of ATP acting at the P2X1 receptor. The calcium signals generated by different platelet agonists are shaped not just by the calcium signalling elements recruited but also by the Ca^{2+} buffers in the platelet cytosol.

Many of the basic aspects of platelet calcium signalling have been appreciated for a decade or more. However, many studies have relied on measuring $[Ca^{2+}]_{cyt}$ alone. Such studies are limited by their ability to only monitor the net effect

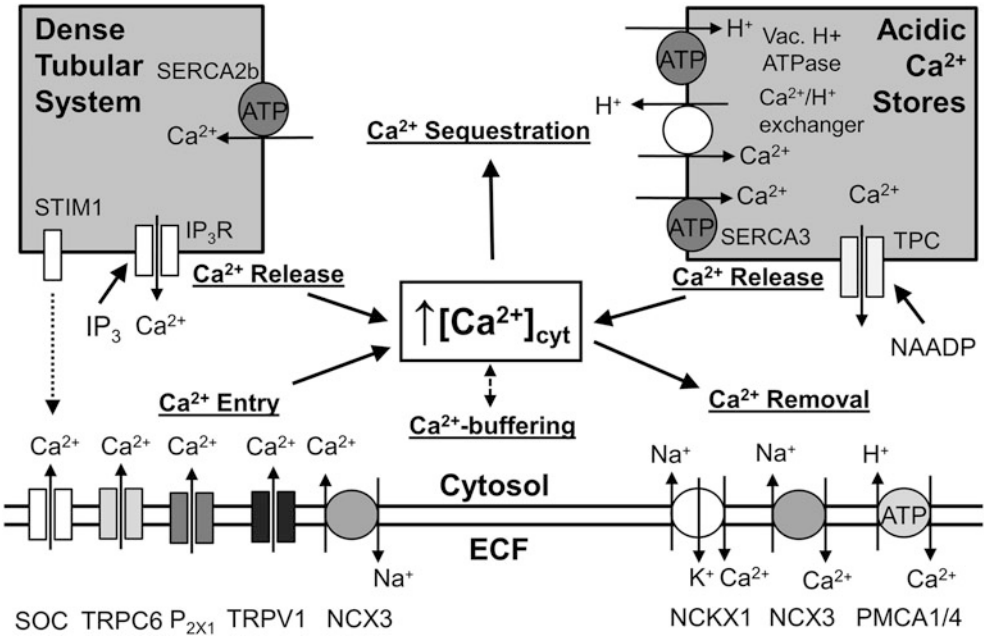

Fig. 1 Summary of the mechanisms that generate and shape platelet Ca^{2+} signals. Ca^{2+} enters the platelet cytosol by entry across the plasma membrane via several channels and possibly by reverse-mode Na^+/Ca^{2+} exchange, as well as by release from intracellular stores and acidic organelles. The Ca^{2+} signal is shaped by various cytosolic Ca^{2+} buffers. Ca^{2+} is removed across the plasma membrane by plasma membrane Ca^{2+} ATPases and forward mode Na^+/Ca^{2+} exchange, and Ca^{2+} is sequestered back into the DTS by SERCA2b and into acidic organelles by SERCA3 and Ca^{2+}/H^+ exchange powered by a V-type H^+-ATPase

of experimental manipulations on the combined actions of the component processes involved in controlling $[Ca^{2+}]_{cyt}$ (Ca^{2+} buffering, sequestration, release, entry and removal) and lack the ability to resolve the source of the Ca^{2+} or the transporters or channels affected. More recent work in human platelets has highlighted the many pitfalls of drawing conclusions as to the molecular pathways involved in eliciting Ca^{2+} signals based solely on measurements of $[Ca^{2+}]_{cyt}$ rather than methods to measure agonist-evoked changes in extracellular and intracellular store Ca^{2+} concentrations ($[Ca^{2+}]_{ext}$ and $[Ca^{2+}]_{st}$, respectively) as well as the platelet pericellular Ca^{2+} concentration ($[Ca^{2+}]_{peri}$), which can be utilised alongside the measurement of agonist-evoked changes in $[Ca^{2+}]_{cyt}$ to improve the interpretation of results compared with simple cytosolic Ca^{2+} measurements alone. Here we summarise current information on platelet calcium signalling, paying particular attention to more recent findings.

Processes That Increase Platelet Cytosolic Calcium Concentration

Release of Stored Ca^{2+}

Most platelet agonists evoke the release of Ca^{2+} from intracellular stores. Two stores are involved, the dense tubular system (DTS; or endoplasmic reticulum (ER)) and acidic stores found in lysosomes and dense granules.

The DTS represents the largest releasable Ca^{2+} store in platelets. DTS Ca^{2+} is released following the formation of inositol 1,4,5-trisphosphate (IP_3). Many agonists, including ADP, platelet activating factor (PAF), thrombin and thromboxane A_2 increase platelet IP_3 levels (Rink and Sage 1990). These agonists activate metabotropic receptors coupled to phospholipase C (PLC) β isoforms 1–3 via a heterotrimeric GTP-binding protein, Gq (Heemskerk and Sage 1994; Boyanova et al. 2012). Additionally, collagen and the low affinity antibody Fc receptor, FcγRII, activate PLC-γ2 via tyrosine phosphorylation (Daniel et al. 1994; Blake et al. 1994). Some studies have implicated PLC-γ_1 in thrombin-evoked responses, although recent data suggest this PLC isoform is undetectable in the platelet proteome (Boyanova et al. 2012). IP_3 releases stored Ca^{2+} in human platelets (O'Rourke et al. 1985) and platelets express all three isoforms of the IP_3-receptor (IP_3RI-III), with the Type I and II receptors being expressed in internal membranes and therefore apparently responsible for IP_3-evoked Ca^{2+} release (Quinton and Dean 1996; El-Daher et al. 2000).

The releasable acidic Ca^{2+} store in platelets is smaller than that in the DTS. The acidic store is released by thrombin acting via protease activated receptor-4 (PAR-4) and glycoprotein (GP) Ib-IX-V, but ADP and arginine vasopressin are apparently without effect on this store (Rosado 2011). The second messenger responsible for releasing Ca^{2+} from acidic stores is nicotinic acid adenine dinucleotide phosphate (NAADP) and this messenger has been shown to release stored Ca^{2+} in permeabilised platelets (López et al. 2006). The collagen receptor GPVI has been reported to elevate NAADP in human platelets and to release Ca^{2+} from the acidic store (Coxon et al. 2012). The identity of the NAADP receptor is a matter of ongoing debate. Much attention has focussed on two-pore channels (TPCs) although conflicting evidence exists (Morgan et al. 2015). Recent work on

platelet dense granules isolated from a megakaryocytic cell line suggests that TPC2 is present in the dense granule membrane and can mediate Ca^{2+} release from this acidic organelle (Ambrosio et al. 2015). Although the agonist-releasable Ca^{2+} pool in the acidic stores is relatively small, it may play an important role in platelet Ca^{2+} signalling by acting to sensitise IP_3Rs and so promote Ca^{2+} release from the DTS, as proposed in the trigger hypothesis demonstrated in other cell types (Galione 2015).

A third known Ca^{2+}-releasing second messenger, cyclic ADP-ribose (cADPR), has been reported to be formed in platelets in response to thrombin but this messenger is without Ca^{2+}-releasing effect in human platelets (Ohlmann et al. 1998).

Ca^{2+} Entry Across the Plasma Membrane

Plasma membrane Ca^{2+} entry channels may be receptor-, second messenger- or store-operated (Sage 1997). In addition, Ca^{2+} may enter cells by Na^+/Ca^{2+} exchangers operating in reverse mode.

Receptor-Operated Channels The only receptor-operated channel identified in human platelets is P2X1 (MacKenzie et al. 1996). This ionotropic receptor is stimulated by ATP and is non-selective, allowing Na^+ as well as Ca^{2+} across the plasma membrane (Sage et al. 1991). Earlier work suggested that this receptor was stimulated by ADP, but it was later shown that the stimulus was the contaminating ATP present in commercial ADP preparations (Mahaut-Smith et al. 2000). The presence of this receptor-operated channel was first suggested on the basis of elevations in $[Ca^{2+}]_{cyt}$ that commenced without discernible latency upon stimulation (Sage and Rink 1987) and was later confirmed in the first patch-clamp recordings from stimulated platelets (Mahaut-Smith et al. 1990). Although P2X1 receptors desensitise rapidly at high agonist concentrations they may be active for tens of seconds at lower levels of stimulation allowing P2X1 receptor stimulation to sustain Ca^{2+} signals evoked by other platelet agonists that stimulate ATP secretion from dense granules (Mahaut-Smith et al. 2011). Ca^{2+} and Na^+ entry via P2X1 receptors also results in membrane depolarisation which may enhance signalling through Gq-coupled receptors such as P2Y1 (Mahaut-Smith et al. 2011). The availability of selective agonists such as α-β-methylene ATP has demonstrated that the rises in $[Ca^{2+}]_{cyt}$ evoked by P2X1 stimulation can result in functional responses including shape change and low levels of $\alpha_{IIb}\beta_3$ activation leading to reversible aggregation, whilst transgenic mouse models indicate a role for P2X1 receptors in amplifying thrombus development (Mahaut-Smith et al. 2011). Although the P2X1 receptor is selective for ATP, it was suggested that a splice variant of this receptor, P2X1del, might mediate P2X1-like responses to ADP (Greco et al. 2001). However, electrophysiological studies indicate that P2X1del does not form functional ion channels and furthermore P2X1del protein is reported to be below the level of detection in human platelets (Vial et al. 2003).

Second Messenger-Operated Channels Second messenger-operated channels (SMOCs) are activated indirectly following the stimulation of metabotropic receptors. The leading candidates for SMOCs in human platelets are channels formed by one or more members of the transient receptor potential canonical sub-family (TRPCs). Human platelets are varyingly reported to express TRPCs 1, 3, 4, 5, 6 and 7 (Hassock et al. 2002; Brownlow and Sage 2005; Liu et al. 2008; Boyanova et al. 2012), with possible associations between TRPCs 1, 4 and 5 and between TRPCs 3 and 6 (Brownlow and Sage 2005). There is conflicting evidence regarding the gating mechanisms of the various TRPC isoforms (Hardie 2007) and at least with TRPC3 the gating mechanism may depend on expression level (Vasquez et al. 2003). TRPCs 3, 6 and 7 are generally regarded as activated by diacylglycerol (DAG; Hardie 2007). In human platelets TRPCs 3 and 6 appear to be responsible for Ca^{2+} entry downstream of DAG formation by PLCs (Hassock et al. 2002; Harper et al. 2013). TRPC6 is reported to be absent from the plasma membrane of resting human platelets and to be inserted upon stimulation by the DAG analogue, OAG, or by thrombin (Harper et al. 2013). Since TRPCs form non-selective cation channels, they gate a substantial Na^+ entry which may result in secondary Ca^{2+} entry by Na^+/Ca^{2+} exchangers (NCXs) operating in reverse mode (Harper et al. 2013).

Another potential SMOC in human platelets may be formed by transient receptor potential vanilloid-1 (TRPV1). TRPV1 has been reported to be expressed in human (Harper et al. 2009; Savini et al. 2010) but not murine platelets (Sage et al. 2014). The TRPV1 agonist, capsaicin, elevates $[Ca^{2+}]_{cyt}$ in human platelets, a response that is inhibited by the TRPV1 antagonists 5′-iodoresiniferatoxin or AMG9810 (Harper et al. 2009). These antagonists reduce rises in $[Ca^{2+}]_{cyt}$ evoked by ADP and thrombin, suggesting a contribution from TRPV1 activation, however the endogenous activator of TRPV1 in human platelets remains to be identified (Harper et al. 2009). Potential candidates include several endovanilloids (Harper et al. 2009), including 12-HPETE, which is produced upon platelet activation (Coffey et al. 2004).

Store-Operated Calcium Entry The phenomenon of store-operated Ca^{2+} entry (SOCE), where depletion of intracellular Ca^{2+} stores leads to the activation of plasma membrane channels permeable to Ca^{2+}, was first described by Putney in 1986. A kinetic study of ADP-evoked rises in $[Ca^{2+}]_{cyt}$ suggested SOCE operated in human platelets since divalent

cation entry was activated temporally coincident with store release (Sage et al. 1990). The existence of SOCE in platelets was confirmed by the use of SERCA inhibitors to deplete intracellular Ca^{2+} stores in the absence of agonist stimulation (Sargeant et al. 1992). In platelets as in other cells the quest to identify the store-operated channel (SOC) proved lengthy. There is now consensus that a highly Ca^{2+}-selective channel (under physiological conditions) is formed by Orai1 and that the Ca^{2+} sensor in the membrane of the endoplasmic reticulum responsible for its activation is STIM1 (Feske et al. 2006; Roos et al. 2005). STIM1–Orai1 coupling has been demonstrated in human platelets (Jardin et al. 2008). Although an essential role for Orai1 in SOCE and thrombus formation has been demonstrated in murine platelets in knock-out studies (Braun et al. 2009), humans with Orai1 mutations affecting channel function do not suffer from major platelet functional defects (Feske 2010).

TRPC1 has also been suggested to play a role in SOCE in human platelets (Rosado et al. 2002), although this does not appear to be the case in murine platelets (Varga-Szabo et al. 2008). There is good evidence to support a role for TRPC1 in SOCE in many other cell types (Cheng et al. 2013). As indicated earlier, TRPCs form non-selective cation channels that are permeable to Na^+ as well as Ca^{2+}. In human platelets, Ca^{2+} store depletion following SERCA inhibition elevates the cytosolic Na^+ concentration, an event blocked by an anti-TRPC1 antibody directed to the pore-forming region of the protein (Harper and Sage 2007). The same antibody reduces the rise in $[Ca^{2+}]_{cyt}$ when Ca^{2+} is added to platelet suspensions following store depletion by SERCA inhibition (Rosado et al. 2002). Although a role for TRPC1 in SOCE in human platelets remains controversial, the presence of this protein in the human platelet proteome allows for this possibility (Boyanova et al. 2012). Although it was suggested that TRPC1 might be activated by conformational coupling to the type II IP_3R, it now appears such coupling is not essential for activation (Harper and Sage 2007). TRPC1 is reported to couple to STIM1 upon Ca^{2+} store depletion in human platelets (Jardin et al. 2008), and this likely serves to activate the channel as reported in other cell types (Cheng et al. 2013).

Processes That Decrease Platelet Cytosolic Calcium Concentration

Ca^{2+} Removal Across the Plasma Membrane

Ca^{2+} is removed across the platelet plasma membrane either by primary active transport via a plasma membrane Ca^{2+}-ATPase (PMCA) or by secondary active transport via Na^+/Ca^{2+} exchangers (NCXs). PMCAs are high affinity Ca^{2+} transporters but have relatively low turnover rates, whilst NCXs have a lower Ca^{2+} affinity but higher turnover rates than PMCAs (Blaustein and Lederer 1999). Consequently, PMCAs are important in the maintenance of resting $[Ca^{2+}]_{cyt}$ whilst Na^+/Ca^{2+} exchangers are more important in the restoration of $[Ca^{2+}]_{cyt}$ after it has been elevated during Ca^{2+} signalling.

Of the four isoforms on PMCA, only PMCA1b and PMCA4b have been detected in human platelets (Martin et al. 2000). PMCA1b expression in human platelets is very low (Pászty et al. 1998), suggesting PMCA4b is the dominant isoform responsible for active Ca^{2+} extrusion (Dean 2010). In platelets the PMCA is subject to several regulatory influences (Dean 2010). The pump is stimulated by Ca^{2+}/calmodulin (Zabe and Dean 2001) and by protein kinase A-dependent phosphorylation (Dean et al. 1997), whilst tyrosine phosphorylation inhibits PMCA activity (Dean et al. 1997), an action that potentiates agonist-evoked rises in $[Ca^{2+}]_{cyt}$ and so platelet functional responses (Bozulic et al. 2007). The PMCA is also modulated by calpain-dependent proteolytic cleavage, with work in vitro and in erythrocytes showing removal of a C-terminal autoinhibitory domain increases activity, whereas further cleavage results in inactivation (Dean 2010). Similar cleavage patterns in human platelets suggest modulation of platelet PMCA by calpain (Brown and Dean 2007).

There are two types of plasma membrane Na^+/Ca^{2+} exchangers: those that exchange Na^+ for Ca^{2+} (NCXs) and those that exchange Na^+ for Ca^{2+} and K^+ (NCKXs) (Lytton 2007). Early functional studies suggested that human platelets possessed an NCKX (Kimura et al. 1993). Messenger RNA for three isoforms of NCKX are reported to be detectible in human platelets (Bugert et al. 2003), however only one study has reported detection of low levels of NCKX1 by Western blotting (Roberts et al. 2012), and others have concluded that NCKX isoforms are absent from the platelet proteome (Boyanova et al. 2012). Low levels of the cardiac NCX isoform, NCX1, have been reported in some Western blot studies (Roberts et al. 2012), whilst others have failed to detect this isoform in human platelets (Harper et al. 2010). A proteomic screen of platelet plasma membrane proteins (Lewandrowski et al. 2009) as well as Western blotting studies (Harper et al. 2010; Roberts et al. 2012) all suggest that NCX3 is the predominant NCX isoform in human platelets. NCX3, like the better studied NCX1, is believed to exchange three Na^+ ions for one Ca^{2+} ion (Lytton 2007). Some early studies concluded that NCXs played little role in influencing $[Ca^{2+}]_{cyt}$ in resting or stimulated platelets (Sage and Rink 1987; Rosado and Sage 2000), however more recent work has provided evidence that forward mode Na^+/Ca^{2+} exchange exports Ca^{2+} across the plasma membrane in resting and thrombin-stimulated human platelets (Roberts et al. 2012). The roles of NCXs in shaping platelet Ca^{2+} signals are complex, with

evidence indicating that these exchangers can promote a rise in $[Ca^{2+}]_{cyt}$ in stimulated platelets. It has been suggested that in collagen-stimulated platelets NCXs transiently reverse to mediate Ca^{2+} entry (Roberts et al. 2012), whilst in thrombin-stimulated platelets there is evidence that NCXs operating in forward mode promote Ca^{2+} recycling via the open canalicular system, supporting the Ca^{2+} signal directly and by promoting the secretion of autocoids from dense granules (Sage et al. 2013) (see section "Signal Magnitude").

Ca^{2+} Sequestration by Intracellular Organelles

Ca^{2+} is sequestered into the main releasable platelet Ca^{2+} store in the DTS by SERCA2b (Enouf et al. 1992), whilst Ca^{2+} is sequestered into the acidic Ca^{2+} stores that are probably located in the dense granules and lysosomes by SERCA3 (Wuytack et al. 1994). SERCA3 shows a much lower sensitivity to thapsigargin than SERCA2b, but is inhibited by 2,5-di-(*t*-butyl)-1,4-hydroquinone (TBHQ) (Cavallini et al. 1995). The acidic Ca^{2+} store membranes also contain a vacuolar H^+-ATPase (vH^+-ATPase), which may be coupled to a H^+/Ca^{2+} exchanger to facilitate Ca^{2+} loading (Sage et al. 2011). Evidence for such a SERCA-independent mechanism of Ca^{2+} sequestration comes from experiments in which the intracellular store $[Ca^{2+}]$ ($[Ca^{2+}]_{st}$) was monitored using Fluo-5 N and $[Ca^{2+}]_{cyt}$ was monitored using Fura-2 (Sage et al. 2011). SERCA2b and SERCA3 were inhibited using high concentrations of thapsigargin (1 μM) and TBHQ (20 μM) and non-acidic Ca^{2+} stores were depleted using the Ca^{2+} ionophore, ionomycin. Since ionomycin is a $Ca^{2+}/H+$ ionophore (Fasolato and Pozzan 1989; Fasolato et al. 1991), it is unable to deplete acidic Ca^{2+} stores due to the absence of a favourable electrochemical gradient for exchange. With SERCAs inhibited, ionomycin caused a rise in $[Ca^{2+}]_{cyt}$ and a fall in $[Ca^{2+}]_{st}$, changes which then gradually reversed indicating Ca^{2+} sequestration in the absence of SERCA activity (Sage et al. 2011). Addition of the pronophore, nigericin, after SERCA inhibitors and ionomycin, caused a further decrease in $[Ca^{2+}]_{st}$ and rise in $[Ca^{2+}]_{cyt}$ which did not reverse over several minutes, indicating that SERCA-independent sequestration was into acidic stores. The nature of the novel SERCA-independent Ca^{2+} sequestration mechanism remains to be identified, but a Ca^{2+}/H^+ exchanger coupled to vH^+-ATPase activity has been suggested on the basis of similarities between platelet dense granules and the acidosomes found in trypanosomes (Ruiz et al. 2004), where such a system operates (Vercesi et al. 1994). Another possibility is that a secretory pathway Ca^{2+}-ATPase may be involved, as found in the dense core vesicles of neuroendocrine cells (Mitchell et al. 2001). A further possibility is that the mitochondrial Ca^{2+} uniporter plays a role (Kirichok et al. 2004). However, the use of antimycin A and oligomycin to inhibit mitochondrial Ca^{2+} uptake does not affect changes in $[Ca^{2+}]_{cyt}$ in platelets treated with thapsigargin and ionomycin (Rosado and Sage 2000).

The SERCA-dependent and pH-dependent Ca^{2+} sequestration mechanisms found in human platelets appear to have different effects in shaping agonist-evoked Ca^{2+} signals (Sage et al. 2011). SERCA inhibition increases the peak of the initial agonist-evoked rise in $[Ca^{2+}]_{cyt}$ and fall in $[Ca^{2+}]_{st}$, whilst blocking pH-dependent Ca^{2+} sequestration using nigericin is without effect on early agonist-evoked changes in $[Ca^{2+}]_{cyt}$ and $[Ca^{2+}]_{st}$, but enhances the later plateau in $[Ca^{2+}]_{cyt}$. Hence pH-dependent Ca^{2+} sequestration into acidic stores appears to commence with some delay after the initial stimulus.

Ca^{2+} Buffering in the Platelet Cytosol

In addition to the Ca^{2+} transport mechanisms detailed earlier, the free $[Ca^{2+}]_{cyt}$ is also influenced by the binding of Ca^{2+} to cytosolic proteins. The intrinsic ability of cellular proteins to buffer agonist-evoked Ca^{2+} signals is often overlooked by many investigators despite the ability of these events to shape the spatiotemporal dynamics of Ca^{2+} signals (Schwaller 2010; Sabatini et al. 2001). However, Ca^{2+} buffering is likely to be essential to the platelet's ability to utilise Ca^{2+} as a second messenger, as influx of Ca^{2+} through a single channel has the potential to deliver a toxic dose of Ca^{2+} to the cell within a split second in the absence of any other systems to restrain Ca^{2+} accumulation (Sage et al. 2013). Estimates of the Ca^{2+}-binding capacity of the platelet cytosol indicate that it is particularly high, with increases in free Ca^{2+} accounting for only around 0.01–0.1 % of all the Ca^{2+} ions entering this cellular compartment (Sage et al. 2013; Valant et al. 1992). These results suggest that Ca^{2+} buffering is likely to play a significant role in modulating platelet Ca^{2+} signal dynamics and the downstream functional responses. Despite this, there has been no study into which molecular targets may underlie this heavy cytosolic Ca^{2+} buffering, although a proteomic study of human platelets has identified a number of candidate Ca^{2+}-binding proteins including calmodulin, S100 proteins, annexins and tubulin (Burkhart et al. 2012) that may be responsible.

Whilst our understanding of the molecular machinery that creates agonist-evoked Ca^{2+} signals in platelets is indebted to the use of fluorescent Ca^{2+} indicators, it is also important to appreciate that the introduction of these compounds artificially increases the Ca^{2+} buffering capacity of the cells. This in turn can markedly alter the spatiotemporal characteristics of any agonist-evoked Ca^{2+} signal (Sabatini et al. 2001). A recent study demonstrated that loading platelets with the commonly used, high-affinity cytosolic Ca^{2+} indicator, Fura-2, could essentially double the Ca^{2+}-binding capacity of the platelet cytosol when compared to

the lower affinity Ca^{2+} indicators, Fura-4F and Fura-FF (Sage et al. 2013). This effect on the buffering capacity of the platelet cytosol could be observed to directly buffer Ca^{2+} signals as well as indirectly interfering with Ca^{2+}-release from intracellular stores (Sage et al. 2013), demonstrating the potential for Ca^{2+} indicators to disrupt normal Ca^{2+} signalling processes. In addition, the introduction of fluorescent Ca^{2+} indicators has also been demonstrated to modulate platelet functional responses to aggregating stimuli (Hatayama et al. 1985; Lanza et al. 1987). Thus, whilst Ca^{2+} indicators may allow us to understand the basic molecular machinery that is responsible for the creation of Ca^{2+} signals, the enhanced Ca^{2+} buffering elicited by their introduction may interfere with the platelet's ability to modulate or respond to this Ca^{2+} signal by interfering with the signal's interaction with its downstream effector molecules. Thus, caution must be taken into account when interpreting the functional responses of platelets loaded with these indicators.

Modulation of Platelet Ca^{2+} Signals

Ca^{2+} signalling systems in cells are strongly non-linear, because in addition to their ability to be activated by agonists, the activity of individual Ca^{2+}-transporting proteins can also be modulated in a time-dependent manner by Ca^{2+}-dependent signalling pathways. In platelets the most studied example of Ca^{2+}-dependent modulation of Ca^{2+} signalling comes from the known role of protein kinase C (PKC) to reduce agonist-evoked rises in $[Ca^{2+}]_{cyt}$ (Lever et al. 2015). However, despite PKC being a well-known modulator of platelet Ca^{2+} signalling, the mechanisms by which it does so have been uncertain, with suggested potential mechanisms including actions on IP_3 production (Rittenhouse and Sasson 1985; Zavoico et al. 1985; King and Rittenhouse 1989; Connolly et al. 1986) to effects on PMCAs and SERCAs (Cavallini and Alexandre 1994; Pollock et al. 1987; Tao et al. 1992). This difficulty in identifying the mechanisms of such modulations relates to the difficulty in studying the effect of a signalling system which has many potential targets when measuring $[Ca^{2+}]_{cyt}$ alone. More recent analysis of the effects of PKC on agonist-evoked Ca^{2+} fluxes into and out of the platelet cytosol has demonstrated a role for Ca^{2+}-dependent conventional PKC isoforms in accelerating Ca^{2+} removal from the cytosol both via an effect on SERCA activity, as well as by indirectly affecting NCX-mediated Ca^{2+} removal via increased Na^+/K^+-ATPase activity (Lever et al. 2015). This ability of PKC to limit agonist-evoked Ca^{2+} signals has been previously shown to play a key role in reducing the development of a procoagulant phenotype in collagen- and thrombin-stimulated platelets (Strehl et al. 2007), thus demonstrating that Ca^{2+}-dependent feedback pathways may play a role in tuning platelet functional responses to physiological stimuli.

In addition to the ability of Ca^{2+} to modulate the generation of its own signal, other physiologically relevant signalling pathways are also able to engage in cross talk with the Ca^{2+} signalling system. These include the ability of endothelial-derived inhibitors such as prostacyclin and nitric oxide to trigger rises in cAMP and cGMP in the platelet which are able to inhibit platelet Ca^{2+} signalling through effects on IP_3-mediated Ca^{2+} release, and possibly via effects on Ca^{2+} entry (for review see Smolenski 2012). In addition to other chemical signals, it has also been shown that shear stress can play a role in upregulating platelet Ca^{2+} signals, both in isolation of other chemical stimuli (Nesbitt et al. 2009) as well as in platelets translocating over surfaces coated with adhesive ligands (Goncalves et al. 2005; Mazzucato et al. 2002).

Controlling Stimulus–Response Coupling of Ca^{2+} Signals in Human Platelets

Calcium Effectors

The central role of Ca^{2+} in mediating platelet activation is through the ability of this second messenger system to translate extracellular signals into functional responses in these cells. The Ca^{2+} signalling system is therefore responsible for triggering and coordinating a range of different processes required for thrombus formation. To mediate this change in platelet activity, the cells require Ca^{2+}-sensitive effector proteins that can translate Ca^{2+} signals into appropriate intracellular responses. Platelets are known to possess a number of such effector proteins: Calmodulin, scinderin, gelsolin and calpain are involved in reorganisation of the actin cytoskeleton and platelet shape change (Paul et al. 1999; Witke et al. 1995; Rodríguez Del Castillo et al. 1992; Croce et al. 1999); CalDagGEFI and CIB1 are involved in integrin $\alpha_{IIb}\beta_3$ activation (Naik et al. 2009; Stefanini et al. 2009); PKC, Munc13-4, SNARE proteins and calpain are involved in granule secretion (Strehl et al. 2007; Golebiewska and Poole 2014; Croce et al. 1999); $cPLA_2$ underlies thromboxane production (Murthy et al. 1995) and TMEM16F is responsible for phosphatidylserine exposure (Mattheij et al. 2015).

The presence of a variety of Ca^{2+}-sensitive signal transduction pathways in one cell requires mechanisms to ensure coordinated activation of these pathways at the correct time and place to produce the desired functional response to any particular extracellular signals. If all the different Ca^{2+}-sensitive processes were fully activated in every platelet then a self-propagating cycle of platelet activation, incorporation into a forming thrombus, secretion of autocrine stimulants and recruitment of additional platelets would lead to uncontrolled thrombus growth, which could eventually occlude the vessel leading to deleterious consequences for the tissue downstream. However, thrombus formation in vivo can be

seen to be a self-limiting process, which does not lead to occlusion of the damaged vessel (Furie and Furie 2008). This suggests that there are a range of regulatory mechanisms that tightly control the ability of Ca^{2+} signals to activate their effector systems. Understanding the systems that prevent excessive activity may provide a valuable asset in devising treatments to prevent excessive blood clotting from occurring (Brass et al. 2011). Recent work has demonstrated that there is heterogeneity in platelet responses during thrombus formation (Munnix et al. 2007; Stalker et al. 2013; London et al. 2006), thus indicating that Ca^{2+}-stimulated processes are able to be differentially activated within the developing platelet aggregate. Whilst this can be explained through spatial control of the physical and chemical stimuli which individual platelets are exposed to when encountering the thrombus (Stalker et al. 2013; Nesbitt et al. 2009; Smolenski 2012), there is still a requirement for the platelet to translate these extracellular signals into a Ca^{2+} signal which can itself be translated into the selective activation of the various Ca^{2+} regulated processes found in these cells. How can individual platelets translate the Ca^{2+} signals they generate to elicit distinguishable phenotypes?

The versatility of Ca^{2+} signalling in cells comes from the ability of cells to selectively decode different agonist-evoked rises in $[Ca^{2+}]_{cyt}$ into specific cellular responses leading to responses over a remarkable range of different timescales (Berridge et al. 2003). The simplest Ca^{2+} signal available in this cellular language is a single Ca^{2+} transient, which can be seen to possess three distinct parameters that can be decrypted by the cell: the signal magnitude, its duration and its subcellular localisation. Previous work in other cells has demonstrated that Ca^{2+}-sensitive effector proteins with different Ca^{2+}-binding affinities and kinetics are able to selectively decode each of these parameters (Dolmetsch et al. 1997).

Signal Magnitude

In platelets, early work identified a role for gradually increasing thresholds of $[Ca^{2+}]_{cyt}$ for the activation of platelet shape change (400–500 nM), serotonin secretion (800 nM) and platelet aggregation (2 μM) (Rink et al. 1982; Hallam et al. 1985). These data establish the potential for the differential Ca^{2+} affinity of effector proteins in mediating these responses in platelets, yet the use of Ca^{2+} ionophores to artificially create Ca^{2+} signals of different amplitude does lead to questions over the physiological relevance of these early studies. Both studies demonstrated that stimulation with physiological agonists such as thrombin and platelet-activating factor could trigger similar responses below the $[Ca^{2+}]_{cyt}$ thresholds defined with ionophores, suggesting that additional regulatory mechanisms were also triggered by agonist stimulation. In addition to other known signalling pathways that may sensitise responses to elevated $[Ca^{2+}]_{cyt}$ (e.g. Paul et al. 1999), it may be that Ca^{2+} microdomains elicited in the vicinity of Ca^{2+}-permeable ion channels play a role in facilitating stimulation of Ca^{2+}-dependent processes in platelets even when the average $[Ca^{2+}]_{cyt}$ reported by fluorescent indicators is relatively low (Parekh 2008).

Signal Duration

The duration of the agonist-evoked rises in $[Ca^{2+}]_{cyt}$ may play an important role in determining important shifts in the functional properties of platelets. Previous work examining platelet interaction with VWF under flow conditions has shown that the duration of Ca^{2+} signalling is crucial in determining the final physiological response of these cells (Nesbitt et al. 2002; Mazzucato et al. 2002). Both of these studies demonstrated that the duration of platelet arrest onto a VWF-coated surface was determined by the length of the Ca^{2+} transient. These transients were not dependent on the presence of extracellular Ca^{2+} and were therefore dependent upon Ca^{2+} release from intracellular stores. In contrast, when the Ca^{2+} signals were prolonged oscillatory responses dependent on Ca^{2+} entry, they led to integrin-dependent, irreversible adhesion and platelet aggregation. This relationship between Ca^{2+} signalling and incorporation within a platelet aggregate was also demonstrated in vivo by van Gestel et al. (2002). This group demonstrated that platelets that were observed to have a sustained increase in their $[Ca^{2+}]_{cyt}$ after binding to the surface of a growing thrombus become stably incorporated within this structure, whilst platelets whose $[Ca^{2+}]_{cyt}$ returned to baseline were found to embolise. Beyond a role in primary haemostatic reactions, prolongation of platelet Ca^{2+} signals has also been demonstrated to play a key role in regulating the blood coagulation process (Heemskerk et al. 2013). Activated platelets create a catalytic surface for the activation of the tenase and prothrombinase complexes through the expression of anionic phospholipids such as phosphatidylserine on the extracellular face of their plasma membrane. Previous work has demonstrated that a large, sustained increase in $[Ca^{2+}]_{cyt}$ is key to the ability of platelets to develop a procoagulant phenotype (Heemskerk et al. 1997; Kulkarni and Jackson 2004; Smeets et al. 1993; Jackson and Schoenwaelder, 2010).

As can be seen from the earlier discussion, prolonged Ca^{2+} signalling in platelets plays a role in determining the rate and extent of both the primary and secondary haemostatic systems that they elicit. Therefore, blocking aspects of the Ca^{2+} signalling system that could elicit a shortening of cytosolic Ca^{2+} signals may be useful for limiting the extent of unwanted platelet aggregation in thrombotic conditions.

A number of signalling pathways are important in eliciting a large, sustained increase in $[Ca^{2+}]_{cyt}$ in agonist-stimulated platelets. These include key roles for store-operated- and receptor-operated Ca^{2+} entry pathways

(Gilio et al. 2010; Harper et al. 2013), autocrine stimulation by the contents of the dense granules (Weiss and Lages 1997; Lages and Weiss 1999) and the activity of Na^+/Ca^{2+} exchangers (Harper et al. 2013; Sage et al. 2013). However, how these systems are coordinated to control the maintenance of agonist-evoked Ca^{2+} signals is less clear. Recent studies have suggested a unified mechanism for prolonging Ca^{2+} signalling via a pericellular Ca^{2+} recycling system. This work has suggested that Ca^{2+} removed from the cell by the NCX can accumulate to a high concentration within the narrow confines of the open canalicular system, such that it can then be recycled back into the cell down its concentration gradient through Ca^{2+}-permeable ion channels and possibly by reverse mode NCX activity, thus prolonging Ca^{2+} signalling directly as well as indirectly through triggering dense granule secretion (Sage et al. 2013; Walford et al. 2015). Further work will be required to define whether this system could be responsible for determining if a platelet adopts proaggregatory and procoagulant phenotypes during thrombus formation under physiological flow conditions.

Subcellular Localisation

In other cells selective activation of Ca^{2+}-sensitive signalling pathways can be achieved through tight spatial coupling of Ca^{2+}-permeable channels and Ca^{2+}-sensitive effectors in specific microdomains of the cell (Rizzuto and Pozzan 2006). Yet the size of the resting platelet is comparative in size or smaller than the spatial spread of elementary Ca^{2+} signals generated through the isolated opening of individual groups of ion channels in other cells (Niggli and Shirokova 2007; Sage et al. 2013). This would seem to suggest that Ca^{2+} signals should always spread throughout the entire platelets. However, Ca^{2+} microdomains may be masked in the tiny platelet volume by the ability of high-affinity, highly diffusible fluorescent Ca^{2+} indicators to act as highly mobile shuttles for rapid transport of Ca^{2+} through the cell (Sala and Hernandez-Cruz 1990). Similar distortions have previously been reported in the spines of Purkinje neurons (Schmidt et al. 2007). In spite of this, previous single cell imaging studies have reported the presence of either localised cytosolic Ca^{2+} microdomains or Ca^{2+} gradients across human platelets (Ariyoshi and Salzman 1996; Tsunoda et al. 1988). In addition, Nesbitt et al. (2009) reported that a localised Ca^{2+} signal was generated that allowed membrane tether formation in adherent platelets, without notable activation of shape change or aggregatory mechanisms. These data suggest that platelets can significantly restrict Ca^{2+} diffusion from the source of entry into the cytosol, and thus use the subcellular localisation of Ca^{2+} signals to selectively activate some Ca^{2+} effectors.

To create localised rises of Ca^{2+} in specific areas would require platelets to localise Ca^{2+}-transporting processes to specific subregions of the cell. This possibility is suggested by a number of previous studies which have shown a key role for the platelet cytoskeleton (Ariyoshi and Salzman 1996, Walford et al. 2015) and lipid raft domains (Brownlow et al. 2004) in facilitating normal agonist-evoked Ca^{2+} signals. Single cell imaging studies have also found evidence for specific subregions of platelets being the sites of Ca^{2+} mobilisation (Heemskerk et al. 2002) as well as Ca^{2+} removal from the platelet cytosol (Sage et al. 2013), suggesting that Ca^{2+}-transporting proteins are inhomogenously located in these cells. In addition to locating Ca^{2+} channels and exchangers in specific regions, platelets would also require cellular mechanisms to restrict the spatial spread of Ca^{2+} through the cytosol to account for the Ca^{2+} microdomains and gradients described earlier. Recent work has suggested that the membrane complex, formed by close association of the open canalicular system with the dense tubular system, may create a suitable cellular architecture to generate such localised Ca^{2+} signals in platelets (Walford et al. 2015). The close association of both the open canalicular system and the dense tubular system at the membrane complex creates a nanojunction, which in other cell types has been shown to play a role in creating a region of the cytosol in which Ca^{2+} concentration can be controlled in isolation from the rest of the cell (van Breemen et al. 2013; White 1972). The possibility that the membrane complex may control platelet Ca^{2+} signalling has been suggested by the identification of a family with a bleeding disorder characterised by the lack of a membrane complex and a defect in thrombin-evoked Ca^{2+} signalling (Parker et al. 1993).

Coincidence Detection

Although individual platelet function may be affected principally by the Ca^{2+} signal within its cytosol, it has also become apparent that the outcome of that signal is also dependent on whether other platelets encountered on the surface of the thrombus are also simultaneously active. Previous work has demonstrated that thrombus growth is dependent on the presence of a coincident Ca^{2+} signal in a neighbouring cell (Nesbitt et al. 2003). Although intracellular Ca^{2+} signalling may facilitate thrombus growth, recent work has also suggested that Ca^{2+} signalling can also upregulate nitric oxide production in platelets, which may work to prevent thrombus growth (Cozzi et al. 2015). Thus, further research will be necessary to understand how these distinct pathways interact to regulate the Ca^{2+}-dependent growth of a thrombus.

Whilst we now have a reasonable understanding of the molecular machinery involved in mediating agonist-evoked rises in $[Ca^{2+}]_{cyt}$, there is still much to learn about how the channels and transporters concerned work to alter the

spatiotemporal patterns of Ca^{2+} signals, how these Ca^{2+} signals regulate downstream Ca^{2+}-sensitive processes and how these systems work alongside other signalling pathways to help regulate both the growth of a thrombus and the patterning of individual platelet responses within it.

Take Home Messages

- A rise in cytosolic calcium concentration ($[Ca^{2+}]_{cyt}$) is central to platelet activation.
- Agonists stimulate a rise in $[Ca^{2+}]_{cyt}$ by releasing Ca^{2+} from intracellular stores and stimulating Ca^{2+} entry across the plasma membrane.
- Stored Ca^{2+} may be released from the dense tubular system (DTS) and acidic organelles by the second messengers inositol 1,4,5-trisphosphate (IP_3) and nicotinic acid adenine dinucleotide phosphate (NAADP), respectively.
- Ca^{2+} entry across the plasma membrane may be activated in response to store depletion (store-operated Ca^{2+} entry; SOCE), in response to the second messenger diacylglycerol (DAG) or by activation of an ionotropic receptor (ATP acting at the P2X1 receptor).
- Platelet activation may increase $[Ca^{2+}]_{cyt}$ from 50 to 100 nM to several μM and result in oscillations or repetitive spikes in elevated $[Ca^{2+}]_{cyt}$ in individual cells.
- Imaging studies have revealed platelet Ca^{2+} signals show subcellular microdomains and the platelet membrane complex may form a specialised nanojunction for Ca^{2+} released by the DTS to be removed into the open canalicular system for subsequent recycling back to the cytosol.
- Platelets Ca^{2+} signals are transduced into function responses by many effector proteins including calmodulin, scinderin, gelsolin, calpain, CalDagGEFI, CIB1, PKC, Munc13-4, SNARE proteins, $cPLA_2$ and TMEM16F.
- Ca^{2+} is removed from the platelet cytosol by sequestration into organelles and removal across the plasma membrane.
- Ca^{2+} is sequestered by sarco-endoplasmic reticulum Ca^{2+}-ATPases (SERCAs) and by a vacuolar H^+-ATPase (vH^+-ATPase), probably coupled to a H^+/Ca^{2+} exchanger.
- Ca^{2+} is removed across the plasma membrane either by primary active transport via plasma membrane Ca^{2+}-ATPases (PMCAs), and by Na^+/Ca^{2+} exchangers.

Platelet Signaling: Protein Phosphorylation

Satya P. Kunapuli, Dheeraj Bhavanasi, John C. Kostyak, and Bhanu Kanth Manne

Abstract

Protein phosphorylation is the main mechanism by which platelet functional responses are regulated. There are myriad protein kinases in the platelet, which are classified by the residue in which they phosphorylate. Protein tyrosine kinases phosphorylate tyrosine residues, while protein serine/threonine kinases phosphorylate serine or threonine residues. Several important signaling cascades are initiated upon platelet activation. Here we will explore the relevance of phosphorylation of specific proteins important to several essential signaling cascades in platelets.

Protein phosphorylation is the major molecular mechanism through which protein function is regulated in response to extracellular stimuli in platelets. Virtually all types of extracellular signals that activate platelets produce most of their diverse physiological effects by regulating phosphorylation of specific phosphoproteins. Although proteins may be covalently modified in many other ways, including acylation (acetylation, myristoylation, isoprenylation), carboxymethylation, tyrosine sulfation, and glycosylation, none of these mechanisms are nearly as widespread as protein phosphorylation. Among the various types of posttranslational modifications, protein phosphorylation is the most important one, regulating the structures and functions of cellular proteins in a wide spectrum of platelet processes, including aggregation, secretion, spreading, and clot retraction. Thus, protein phosphorylation is by far the most prominent mechanism through which platelets regulate their functional responses.

Today, it is believed that one-third of all proteins in the cell are phosphorylated at one time or another, and half of these proteins likely harbor more than 1 phosphorylation site, with phosphorylation at different sites often eliciting quite different cellular responses. Protein phosphorylation events in platelets are regulated by protein kinases. Protein kinases phosphorylate proteins by transferring the γ-phosphate of ATP to tyrosine, serine, or threonine residues. These protein kinases are divided into two groups, tyrosine kinases and serine/threonine kinases, depending on which residue the kinase phosphorylates. Both groups of enzymes are phosphotransferases; they catalyze different reactions to modulate the structures and functions of many cellular proteins in platelets.

Two major mechanisms are involved in receptor-mediated platelet protein phosphorylation. In one of the mechanisms the extracellular signals, or first messengers, regulate protein kinases such as Src Family kinases (SFKs), Syk, or Btk indirectly by acting on plasma membrane receptors such as immunoglobulin-like receptors and GPCRs, thereby regulating the intracellular concentration of a second messenger in platelets. Prominent second messengers, such as Ca^{2+} and diacylglycerol (DAG) in the platelet system, activate protein kinases. The next steps in these pathways are the activation of specific classes of protein serine/threonine kinases (Protein Kinase C) by these second messengers and the subsequent phosphorylation of specific substrate proteins, which leads to platelet activation. In this chapter, we present an overview of the vital role of protein phosphorylation events and their regulation by different protein kinases on platelet function.

Receptor Phosphorylation Regulates Its Function in Platelets

Platelet receptor phosphorylation plays an important role not only in the activation of the receptor but also its regulation. Platelets mainly express two different types of agonist receptors, G-protein-coupled receptors (GPCRs) and tyrosine kinase pathway receptors, both of which are important for platelet activation (Offermanns 2000; Sambrano et al. 2001). There are two different tyrosine kinase-coupled receptors. One is the ITAM (Immunoreceptor tyrosine-based activation motif)-containing receptors, such as the Fc receptor-γ chain (FcRγ) and FcγRIIA, which has the classic YXX (L/I) X_{6-12} YXX (L/I) with two tyrosine residues in its cytoplasmic domain. The other is a hemITAM-containing receptor, such as CLEC-2, which has only one tyrosine residue (YXX(L/I)) in its cytoplasmic domain (Fuller et al. 2007; Underhill and Goodridge 2007). These tyrosine residues in the cytoplasmic domain of FcRγ, FcγRIIA, and CLEC-2 are phosphorylated by Src family kinases when platelets are stimulated with the respective agonists. Using knockout mouse models as well as cell lines which express receptors mutated at these tyrosine residues demonstrates that phosphorylation of these tyrosine residues is important for ITAM and hemITAM receptor activation and downstream signaling (Fuller et al. 2007). However, unlike tyrosine kinase receptors, phosphorylation of GPCRs on serine and threonine residues causes receptor desensitization thereby regulating their activity. Two types of kinases are known to phosphorylate and desensitize the GPCRs in other cells. One type—the second-messenger-dependent kinases, such as cAMP-dependent protein kinase and protein kinase C and protein kinase G—alters the receptor conformation such that the affinity of the receptor for the G protein is greatly reduced and also helps in heterologous receptor desensitization (Kelley-Hickie et al. 2007; Homma and Hanahan 1988). Heterologous receptor desensitization occurs after prolonged activation by one agonist and results in the inability of another agonist to cause activation. The second type of kinase—GPCR kinases (GRKs)—is involved in homologous receptor desensitization. This desensitization is referred to as homologous because only agonist-occupied receptors are substrates for GRKs, ensuring that only those receptors that have been activated will be desensitized. Relatively little is known about the role of GRKs in platelets and megakaryocytes (Kelley-Hickie and Kinsella 2006).

Src Family Kinases

Src family kinases (SFKs) play a central role in mediating the rapid response of platelets to vascular injury (Newman 2009; Senis et al. 2014). This rapid response of platelets to vascular injury is mediated by many tyrosine kinase-linked receptors. Ligand-mediated clustering of these receptors triggers transmission of primary activation signals in platelets. However, none of these receptors have intrinsic kinase activity, so they rely on a family of protein tyrosine kinases called Src family kinases. These kinases are either associated or in close proximity to the tyrosine residues on the receptor cytoplasmic tails in order to phosphorylate the tyrosine residues that mediate platelet activation (Ezumi et al. 1998; Suzuki-Inoue et al. 2002). Activated SFKs are also known to phosphorylate enzymes, adaptors, and cytoskeletal proteins that collectively propagate the signal and coordinate platelet activation, which enhances thrombus growth and stability. SFKs such as Src, Lyn, and Fyn are highly expressed and well studied in platelets and regulate platelet activation by GPVI, CLEC-2, FcγRIIA, GPIb-IX-V, and $\alpha_{IIb}\beta_3$ (Briddon and Watson 1999; Quek et al. 2000; Arias-Salgado et al. 2003; Yin et al. 2008; Chari et al. 2009b). Src and Fyn are primarily regarded as positive regulators, whereas Lyn plays a dual role as a positive and a negative regulator of platelet activation (Fig. 1). All the three SFKs also contribute to G_q- and G_i-coupled receptor signaling (Fig. 2) (Garcia et al. 2005, 2007; Kim et al. 2006; Canobbio et al. 2015). A number of structurally distinct broad-spectrum SFK inhibitors (PP1, PP2, PD0173952) and knockout mouse models have been used to elucidate the contributions of these SFKs to platelet signal transduction and function (Briddon and Watson 1999; Quek et al. 2000; Arias-Salgado et al. 2003; Yin et al. 2008; Chari et al. 2009b). The most well-established functions are summarized in Table 1.

Syk

Syk (spleen tyrosine kinase), a 72-kDa tyrosine kinase was first identified in thymus and spleen (Fluck et al. 1995). The Syk activation process is initiated when SFKs phosphorylate conserved tyrosine residues within ITAMs. These phosphotyrosine motifs are bound by Syk kinases via interaction with the tandem SH2 domains of the kinase. Binding of Syk kinases to ITAM sequences serves both to activate kinase activity and localize the kinase near its substrates (Gibbins et al. 1996). Once bound to the motifs Syk gets phosphorylated at multiple tyrosine residues and becomes active. The individual roles of these tyrosine residues are still not clearly understood. In all cases, it appears that receptor stimulation results in recruitment of Syk to ITAM sequences although the sequence and spacing of ITAMs vary between different receptors. For example, in hemITAM receptor activation, Syk activation is dependent on both SFKs and Tec family kinases (Manne et al. 2015). It was also observed that tyrosine phosphorylation on Syk is differentially regulated in human and murine platelets by protein kinase C isoforms, especially by PKC-β in human platelets

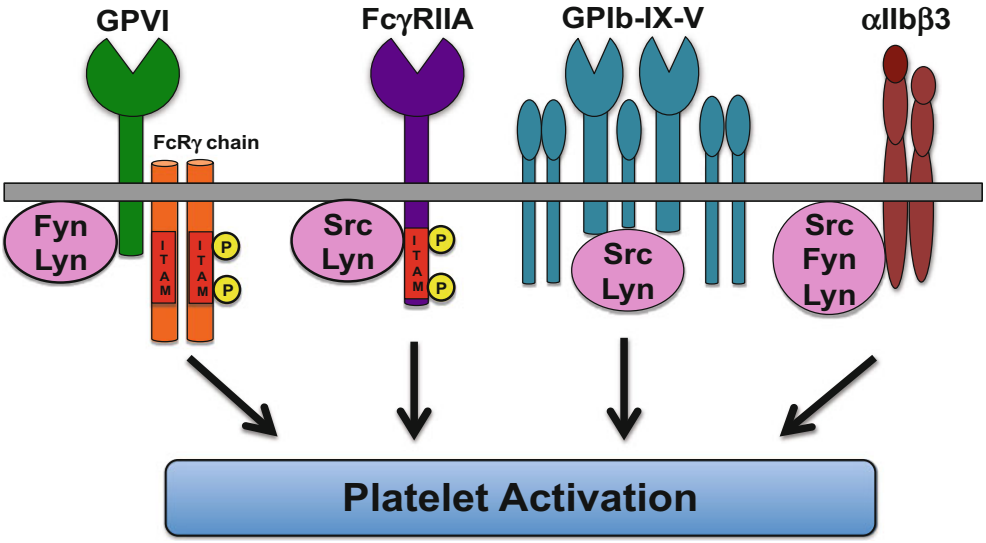

Fig. 1 Role of Src family kinases in platelet activation

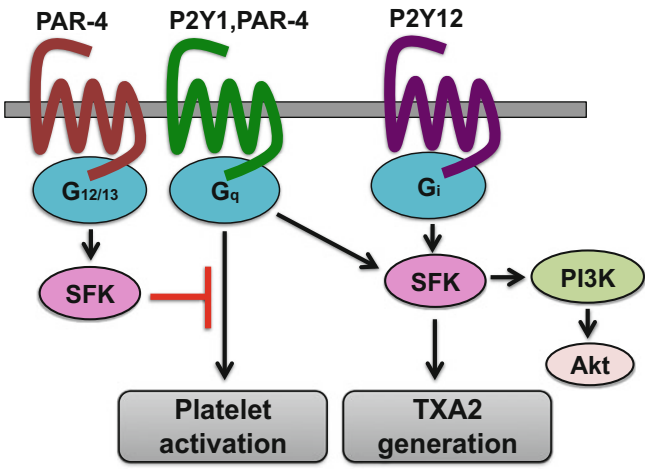

Fig. 2 Role of Src family kinases downstream of G protein-coupled receptors in platelets

Table 1 Functional role of Src family kinases in platelets

Src family kinases	Receptor signaling regulated by SFKs
Src	Positively regulates $\alpha_{IIb}\beta_3$-mediated signaling and functional responses
Fyn	Positively regulates GPVI-mediated signaling and aggregation/secretion
	Potentiation of PAR-4-mediated aggregation
Lyn	Increases $\alpha_{IIb}\beta_3$-mediated spreading
	Delayed onset of GPVI-mediated signaling and aggregation/secretion
	Positively regulates GPIb-IX-V-mediated spreading

(Buitrago et al. 2013). LAT and SLP76 are the major direct downstream substrates of Syk as phosphorylation of both of these substrates is abolished in Syk−/−platelets (Suzuki-Inoue et al. 2006). Recent studies using Syk knockin model confirm a critical role of the N-terminal SH2 domain of a Syk in ITAM and hemITAM signaling (Hughes et al. 2015). This study also shows that the phosphorylation of Syk on Y348 and of the CLEC-2 hemITAM is upstream of auto-phosphorylation of two tyrosine residues, 519/520. $Syk^{-/-}$ platelets were deficient in functional responses with GPVI, CLEC-2, and FcγRIIA (Hughes et al. 2015; Suzuki-Inoue et al. 2006). Interestingly, Syk knockout mice die prenatally due to severe hemorrhaging, also suggesting a role for Syk in maintaining vascular integrity. Recent studies have shown that Syk activation downstream of CLEC-2 plays a crucial role in blood-lymphatic vessel separation and maintenance (Hess et al. 2014; Bertozzi et al. 2010). A number of structurally distinct Syk inhibitors (OXSI2, PRT318, R406) (Bhavaraju et al. 2008; Spalton et al. 2009; Reilly et al. 2011) and knockout mouse models have been used to elucidate the contribution of Syk to platelet signal transduction and function.

Tec Family Kinases

Tec family kinases are known to regulate PLCγ2 in B and T cells (Lewis et al. 2001). The structure of these enzymes shows that, in addition to containing SH2 and SH3 domains, they have a unique pleckstrin (PH) domain, which plays an important role in activation of these kinases by SFKs (Okoh and Vihinen 1999; Mohamed et al. 2009). The Tec family of kinases consists of five different kinases: Bmx, Btk, Itk, Tec, Txk/Rlk (Schmidt et al. 2004). Of these kinases, Btk and Tec are highly expressed in platelets (Atkinson et al. 2003). Activation of Tec family tyrosine kinases occurs downstream of both Src and Syk family kinases in signaling pathways in platelets (Manne et al. 2015). Upon signal initiation, most Tec family kinases translocate to the plasma membrane

through binding of their pleckstrin homology (PH) domain to phosphatidylinositol (3,4,5)-trisphosphate (PIP_3) created by the activation of PI 3′-kinase. At the membrane Tec family kinases become phosphorylated within their activation loop (Tyr 551 in Btk) via either Src family kinases or auto-phosphorylation. Another site that becomes phosphorylated is within the SH3 domain of the kinase (Tyr 223 in Btk). In platelets, Btk and Tec proteins are phosphorylated in response to GPVI and CLEC-2 agonists (Manne et al. 2015; Atkinson et al. 2003) (Fig. 3). The role of Btk in platelets was studied extensively by using platelets from knockout mice and X-linked agammaglobulinemia (XLA) patients, a disease condition in which Btk is dysfunctional (Futatani et al. 2001; Liu et al. 2006). PLCγ2 phosphorylation downstream of GPVI has been show to be regulated by both Btk and Tec kinases (Atkinson et al. 2003). Studies of platelets from mice deficient in Btk and Tec have shown that these proteins are crucial for CLEC-2 signaling, which plays a crucial role in blood-lymphatic vessel separation and maintenance (Manne et al. 2015). Ibrutinib, a Btk inhibitor, is used for treatment in human patients with chronic lymphocytic leukemia (CLL) (Akinleye et al. 2013). Recent phase 3 clinical studies using Ibrutinib showed that a small percent of patients have bruises on the skin, a characteristic of lack of platelet activation (Akinleye et al. 2013). It is also shown that CLL patients treated with Ibrutinib have defects in collagen and vWF-mediated platelet activation, which supports the important role of Btk in platelets (Kamel et al. 2015).

Serine/Threonine Kinases

Serine/threonine kinases catalyze phosphorylation of serine or threonine residues on their target proteins. Protein kinase C, Protein kinase G, Protein kinase A, Protein kinase D, Protein kinase B (Akt), casein kinase, and Erk are some of the ser/thr kinases expressed in platelets.

Protein Kinase C Protein kinase Cs are a subfamily belonging to AGC kinase superfamily. PKC isoforms were first discovered as being activated by diacylglycerol (DAG), a lipid product present in the cell membrane (Mori et al. 1982). PKC isoforms have an N-terminal regulatory domain and a highly conserved C-terminal catalytic domain. PKC isoforms are divided into three subclasses based on their structures and cofactor requirements. A model depicting the structure of PKC isoforms is shown in Fig. 4. Classical PKC isoforms (α, βI, βII, γ) have both C1 and C2 domains and hence depend on calcium and diacyl glycerol (DAG) for their activation; the members of a novel class of PKC isoforms (δ, θ, ε, η) have a C2-like domain that cannot bind calcium and hence are calcium insensitive but require DAG for their activation. Atypical PKC isoforms (ι/λ, ζ) have a C1-like domain that cannot bind DAG and lack a C2 domain. Hence atypical PKC isoforms are both calcium and DAG insensitive but depend on phospholipids for their activation. Among these, PKC isoforms α, β, δ, η, θ, ε and ζ are present in platelets (Crosby and Poole 2003; Murugappan et al. 2004). Under resting conditions, PKC isoforms remain in a closed conformation with the pseudo-substrate-binding domain occupying the substrate-binding site in the C4 domain. Upon platelet agonist stimulation, calcium mobilization and DAG generation lead to translocation and activation of PKC isoforms (Steinberg 2004). Upon activation, PKC isoforms through receptors for activated C kinases (RACKs) localize to their respective substrates and cause substrate phosphorylation and downstream signaling events (Harper and Poole 2010). Dr Mochly-Rosen's group has shown that RACKs are PKC specific and were exploited to design isoform-specific PKC inhibitors (Yedovitzky et al. 1997).

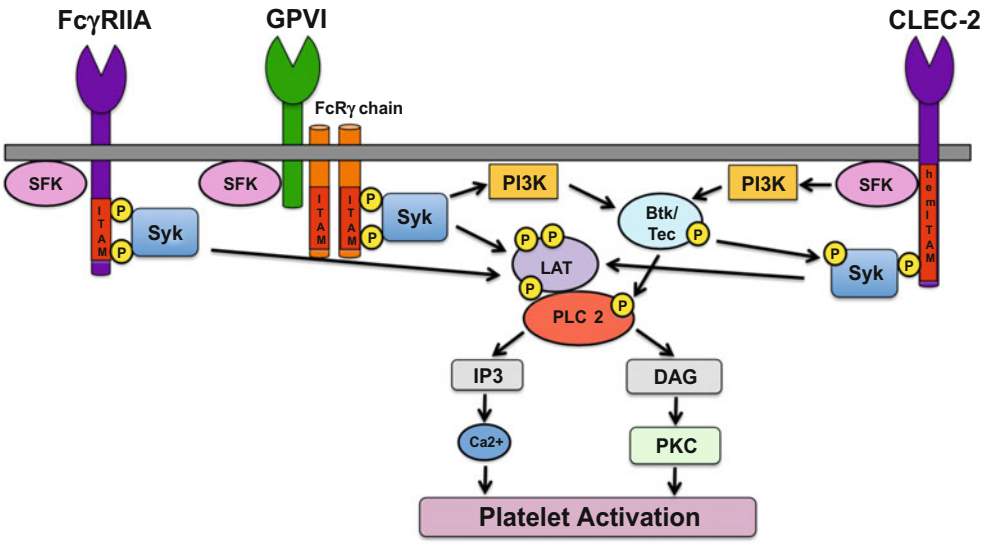

Fig. 3 Role of Syk and Tec family kinases in platelet activation

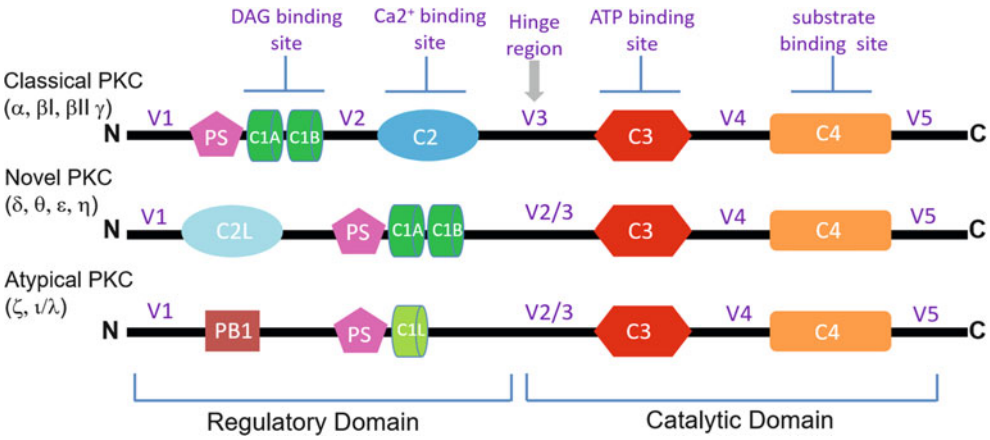

Fig. 4 Model depicting structure of PKC isoforms. *PS* pseudosubstrate domain, *C* constant domains, *V* variable domains; *C2L* C2 like domain, *C1L* C1 like domain, *PB1* Phox and Bem1 domain

PKC isoforms are generally considered active when the threonine residue in their hydrophobic motif gets phosphorylated. Since phosphorylation is the main mechanism through which PKC isoforms are activated, several ATP-competitive inhibitors such as Go6976 (Martiny-Baron et al. 1993), bisindolemaleimide I (Balaban et al. 1999), GF109203X (Toullec et al. 1991), and Ro812230 (Beltman et al. 1996), were used to study their role in vitro and isoform-specific knockout mice were used to study their role in vivo. AEB071, a PKC inhibitor has been shown to have preclinical activity in CLL (El-Gamal et al. 2014) and is currently under clinical trial for treating melanoma (clinicaltrials.gov).

Classical PKC Isoforms PKCα regulates α-granule biogenesis, secretion, dense granule release, and thrombus formation with no defect in hemostasis observed in animals deficient in the enzyme (as shown by tail bleeding times) (Konopatskaya et al. 2009).

PKCβ associates with integrin $\alpha_{IIb}\beta_3$ and regulates platelet spreading on immobilized fibrinogen (Buensuceso et al. 2005). PKCβ also regulates platelet spreading on collagen (Gilio et al. 2010) and is implicated in negatively regulating GPVI-mediated Syk tyrosine phosphorylation in human but not murine platelets (Buitrago et al. 2013). Enzastaurin, a PKCβ inhibitor was shown to have anticancer activity. However, the drug was also shown to potentiate platelet aggregation and growth factor secretion which may be detrimental to patients (Lesyk et al. 2015). It is currently under clinical trials for treating different cancers (clinicaltrials.gov). The role of classical PKC isoforms is depicted in Fig. 5.

Novel PKC Isoforms PKCδ, upon phosphorylation of thr505 in its activation loop, becomes active and is implicated in negatively regulating GPVI-mediated platelet functional responses by associating with SHIP1 and Lyn whereas it positively regulates PAR-mediated platelet responses including granule secretion and thromboxane generation (Chari et al. 2009a). However, PKCδ null mice do not have an in vivo thrombotic defect in $FeCl_3$-induced injury model possibly owing to the fact of opposing effects of PKCδ to different agonists. Besides, PKCδ is also phosphorylated on tyrosine residues downstream of PAR and GPVI receptors (Moussazadeh and Haimovich 1998; Crosby and Poole 2003). Human and mouse PKCδ protein contain 20 and 19 tyrosine residues, respectively. Phosphorylation on tyrosine residues 52, 64, 155, 187 (present in regulatory domain); residues 311 and 332 (present in the hinge region); and residues 512, 523, and 565 (present in catalytic domain) were reported so far (Steinberg 2004). Phosphorylation of PKCδ on Y565 potentiates the activity of the kinase (Hall et al. 2007). Y311 phosphorylation on PKCδ has been implicated in PAR-mediated thromboxane generation (Murugappan et al. 2005) and ADP-induced thromboxane generation (Bhavanasi et al. 2015). Y311-phosphorylated PKCδ has been shown to have lipid-independent kinase activity and this change in cofactor requirements is also accompanied by change in substrate specificity (Bhavanasi et al. 2004, 2015). Studies in RBL-2H3 cells have identified Lyn-dependent phosphorylation of PKCδ at Y332 and that this phosphorylation mediates association of PKCδ with Shc (Leitges et al. 2002) regulating mast cell degranulation indicating that PKCδ could act both as a kinase and as an adaptor. A peptide inhibitor of PKCδ, based on the RACK sequence, was developed and was shown to inhibit reperfusion injury in ischemic heart (Chen et al. 2001; Inagaki et al. 2003) as well as inhibiting platelet function (Chari et al. 2009a).

PKCθ becomes active upon phosphorylation of its thr538 residue in platelets. It is a positive regulator of PAR4-mediated platelet responses (Nagy et al. 2009). The role of PKCθ in GPVI-mediated platelet activation is complicated as it negatively regulates GPVI responses at low concentrations of the agonist but positively regulates GPVI responses at high concentrations of the agonist (Nagy et al. 2009; Harper and Poole 2009). PKCθ null mice have

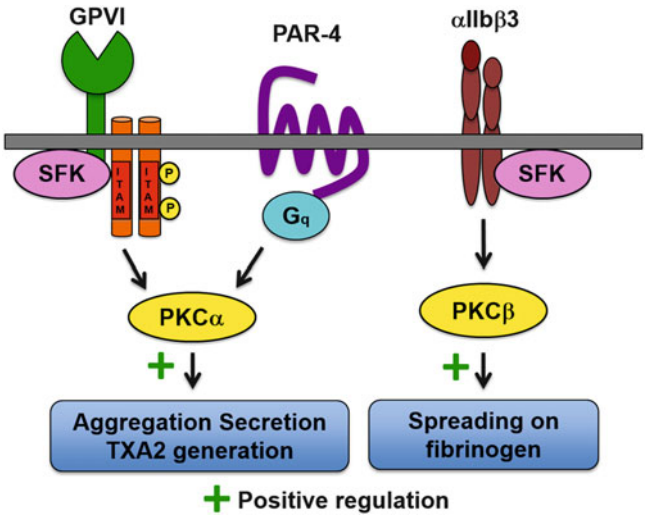

Fig. 5 Role of classical PKC isoforms in regulating platelet activation

delayed thrombus formation in $FeCl_3$-induced injury model and flow over collagen suggesting a role for PKCθ in regulating pathological thrombus formation (Hall et al. 2008; Nagy et al. 2009). PKCθ, upon phosphorylation on its Y90 residue, is also shown to be active in T cells (Liu et al. 2000) and the activity of PKCθ is required for T-cell activation and survival (Sun et al. 2000). PKCθ was also shown to regulate platelet outside-in signaling by being tyrosine phosphorylated but the exact tyrosine phosphorylation site is not known. It regulates platelet spreading on fibrinogen by phosphorylating WASP (Wiskott–Aldrich syndrome protein) interacting protein on ser488 that regulates actin polymerization (Soriani et al. 2006).

Agonist-induced activation of PKCε is measured by its phosphorylation on ser729. PKCε negatively regulates ADP-induced Erk1/2 phosphorylation and subsequent thromboxane generation but contributes little to PAR4- and GPVI-mediated platelet responses. Studies of FeCl3-induced vessel injury in PKCe in PKCε knockout mice have shown that PKCε positively regulates thrombus formation (Bynagari-Settipalli et al. 2012).

PKCη positively regulates ADP-induced aggregation and thromboxane generation. Its activation is measured by phosphorylation on Thr512. Platelet integrin receptor activation dephosphorylates thr512 on PKCη in a PP1γ phosphatase (a serine/threonine phosphatase) dependent manner (Bynagari et al. 2009). The role of novel PKC isoforms is depicted in Fig. 6.

Atypical PKC Isoforms PKCζ is constitutively phosphorylated in human platelets on thr410 and thr560. Thr410, but not thr560, becomes dephosphorylated upon agonist stimulation in an integrin and serine/threonine phosphatase (PP1 and PP2A) dependent manner (Mayanglambam et al. 2011). The exact role of PKCζ and its mechanism of regulation in platelet function are yet to be determined. Table 2 presents some of the platelet functions affected in the absence of PKC isoforms.

PKC isoforms also regulate each other. In cardiomyocytes, PKCε and PKCδ cross phosphorylate each other on their activation loop and hydrophobic domain, respectively, and regulate their activities (Rybin et al. 2003). In platelets, classical PKC isoforms regulate Y311 phosphorylation on PKCδ and subsequent thromboxane generation downstream of ADP receptors possibly through a phosphatase and a tyrosine kinase (Bhavanasi et al. 2015). PKC substrates in platelets that were known to regulate secretion include alanine-rich C-kinase substrate (MARCKs) (Hartwig et al. 1992), platelet leukocyte C kinase substrate (Pleckstrin) (Nishizuka 1988; Tyers et al. 1989), and cytohesin-2 are known to be PKC substrates in platelets that regulate platelet secretion (Elzagallaai et al. 2000) (Lian et al. 2009) (van den Bosch et al. 2014). Identifying and targeting isoform-specific substrates could be beneficial in developing antithrombotic drugs as PKC isoforms could be differentially regulating platelet functions through isoform-specific substrates.

PKC isoforms play an indispensable role in regulating various functions such as thrombosis, heart failure, ischemia–reperfusion injury, metastasis, cell division, development, apoptosis, etc. (Bynagari-Settipalli et al. 2010; Koivunen et al. 2006; Reyland 2007), hence, caution must be exercised while using these PKC inhibitors to treat a specific disease as they might affect other functions of the body. Phosphorylation-specific inhibitors of PKC will hopefully help keep any undesirable side effects under check as compounds that inhibit only specific functions elicited by PKC isoforms could be used based on the disease treated. Currently available inhibitors of PKC are mostly ATP competitive inhibiting the ability of PKC isoforms to phosphorylate their downstream substrates and subsequent signaling responses. However, not all functions of PKC isoforms could be attributed to their catalytic activity as PKC isoforms also exhibit kinase-independent functions in various cells possibly by acting as scaffolds (Goerke et al. 2002; Kim et al. 2012). Hence inhibitors have to be designed in a way that they bind to different domains of PKC isoforms to identify the role played by individual domains of PKC isoforms. Also, inhibitors that inhibit/dissociate interactions between PKC isoforms and different molecules must be designed and studied for their impact in regulating cell functions.

Protein Kinase D Protein kinase D2 (PKD2) is the major isoform present in platelets and gets activated by phosphorylation on ser744 and ser748. It positively regulates agonist-induced platelet dense granule secretion and thrombus formation on collagen under flow (Konopatskaya et al. 2009). PKD2 is also phosphorylated on ser916, an auto-

phosphorylation site by classical PKC isoform α (Konopatskaya et al. 2009), and on ser744 and ser748 by novel PKC isoform δ (Bhavanasi et al. 2011) in platelets.

Protein Kinase G and Protein Kinase A In healthy blood vessels, the endothelium releases nitric oxide and increases cGMP and subsequently cAMP which activate Protein kinase G (PKG) and Protein kinase A (PKA), respectively. These kinases restrict abnormal platelet activation in healthy blood vessels through Vasodilator-stimulated phosphoprotein (VASP) (Haslam et al. 1999; Jensen et al. 2004). VASP negatively regulates platelet function and is a major substrate for PKA and PKG but can also be phosphorylated by PKC. It gets phosphorylated on ser157, ser239, and thr278 (Butt et al. 1994) (Chitaley et al. 2004; Wentworth et al. 2006). PKG was also shown to regulate platelet activation in a biphasic manner consisting of initial stimulatory effect and subsequent inhibitory response (Li et al. 2003). Upon activation, PKA inhibits Rac signaling (Gratacap et al. 2001) and phosphorylation by PKA on thr203 of Gα13 inhibits Rho signaling leading to platelet aggregation (Manganello et al. 2003).

Casein Kinase Casein kinase (CK), another ser/thr kinase has been shown to positively regulate platelet activation including aggregation, secretion, and thromboxane generation. It phosphorylates phosphatase and tensin homolog (PTEN) on ser380, which inactivates PTEN thereby leading to the PI-3 kinase signaling required for platelet activation (Ryu and Kim 2013).

Akt/Protein Kinase B Akt is a 57-kDa serine/threonine protein kinase that is activated via membrane binding of its

PH domain to the phosphatidylinositol 3-kinase (PI3K) products phosphatidylinositol-3,4-bisphosphate (PIP2) and PIP3. As such, membrane translocation of Akt is critical for its activation. Once at the membrane Akt is phosphorylated on threonine 308 via phosphoinositide-dependent kinase 1 (PDK1) and on serine 473 via mammalian target of rapamycin complex 2 (mTORC2). The contribution of each phosphorylation site to the activation of Akt and subsequent effects on platelet reactivity are unknown but worthy of investigation.

There are three isoforms of Akt (Akt1, Akt2, Akt3), all of which are expressed in mouse and human platelets. In mouse platelets, Akt3 appears to be the most highly expressed isoform, but the relative expression of each isoform in human platelets is unknown (O'Brien et al. 2012). It is apparent that each Akt isoform has an independent function, but there is also a good deal of overlap between the isoforms. For instance, deletion of each Akt isoform restricts platelet response to thrombin (Chen et al. 2004; Woulfe et al. 2004; O'Brien et al. 2011). However, only deletion of Akt1 seems to effect collagen-induced platelet activation (O'Brien et al. 2011). Furthermore, Akt1 and Akt3 regulate $\alpha_{IIb}\beta_3$-dependent signaling, but Akt2 is dispensable (O'Brien et al. 2011).

In platelets, Akt is activated by a number of different agonists. However, in each case, Akt activation is dependent on secretion of ADP from dense granules and subsequent activation of the $P2Y_{12}$ receptor. Blockade of the $P2Y_{12}$ receptor using the antagonist ARC69931MX greatly reduces phosphorylation of Akt regardless of the agonist used (Gratacap et al. 2011; Kim et al. 2004, 2009; Cipolla et al. 2013).

Interestingly, translocation of Akt to the membrane, which is necessary for Akt activation, may be mediated by G_q-coupled protease-activated receptors (PAR) (Badolia et al. 2015). Phosphorylation of Akt is greater in human platelets activated with PAR agonists than those activated with ADP. Additionally, Akt translocation is also greater downstream of G_q-coupled receptors. However, inhibition of $P2Y_{12}$ eliminates Akt phosphorylation downstream of G_q while Akt translocation is unperturbed. Therefore, the translocation of Akt appears at least partially dependent upon G_q, while activation of Akt is dependent upon the G_i-coupled $P2Y_{12}$ receptor.

Akt translocation in platelets may be mediated by PAK (Badolia et al. 2015). In human platelets, Akt is constitutively associated with PAK. This association is not altered with PAK inhibition suggesting that the role of PAK is that of a scaffold. PAK has been shown to associate with GTP-bound RAC1 in thrombin-activated platelets. Inhibition of RAC1 in thrombin-stimulated human platelets largely disrupts PAK/Akt translocation to the membrane, suggesting that RAC1 is an important mediator of PAK/Akt translocation.

GSK3β Active Akt is capable of phosphorylating several targets in platelets. One such target is GSK3. Both isoforms of GSK (GSK3α and GSK3β) are expressed in platelets, but expression of GSK3β is predominant (Li et al. 2008). GSK3β is a constitutively active serine/threonine kinase that is negatively regulated by Akt phosphorylation of serine 9 (Cross et al. 1995; McManus et al. 2005). Interestingly, it appears as though Akt3 is the isoform that is predominantly responsible for GSK3β serine 9 phosphorylation (O'Brien et al. 2012). GSK3β appears to be important for platelet function as either GSK3β haploinsufficiency or inhibition causes enhanced platelet reactivity to agonist in vitro and has prothrombotic effects in vivo (Li et al. 2008). Similarly, platelets from GSK3β (as well as GSK3α) constitutively active mutant mice (GSK3α serine 21 and GSK3β serine 9 mutated to alanine) have reduced platelet aggregation and secretion in response to PAR4 agonists (Moore et al. 2013). These studies suggest that GSK3β negatively regulates platelet activity, but the exact mechanisms by which GSK3β exerts its influence are not yet known.

MAPKinases Mitogen-activated protein kinases (MAPK) are serine/threonine kinases that control a variety of cellular functions. There are 3 MAPKs expressed in platelets; p38, extracellular regulated kinase1/2 (ERK1/2), and c-Jun NH2-terminal kinase (JNK). MAPKs are activated by MAPK kinases, which are activated by MAPK kinase kinases downstream of several platelet agonists (Garcia et al. 2005, 2007; Toth-Zsamboki et al. 2003; Flevaris et al. 2009). It has been postulated that ERK1/2 activity is dispensable for primary platelet activation (Borsch-Haubold et al. 1996). However, these experiments were conducted using the MEK (MAPK kinase) inhibitor PD098059 that also inhibits cyclooxygenase and, therefore, thromboxane generation (Borsch-Haubold et al. 1998). It has since been established that ERK is an important regulator of thromboxane generation (Garcia et al. 2005; Shankar et al. 2006).

While ERK1/2 appears to regulate thromboxane generation, another MAPK, p38, appears to play no role in the initial phases of platelet activation, but may regulate outside-in signaling. Phosphorylation of p38 MAPK occurs in response to various platelet agonists (McNicol and Jackson 2003; Schwarz et al. 2000). It has been postulated that p38 is important for platelet granule release. However, the inhibitors used in these studies are known to inhibit cyclooxygenase as well as p38 (Flevaris et al. 2009). Conversely, when a specific inhibitor of p38 is utilized (VX-702) it is apparent that p38 has no role in the initial phases of platelet activation (Kuliopulos et al. 2004). Finally, p38 does appear to be important for platelet outside-in signaling (Flevaris et al. 2009).

Conclusions

Phosphorylations events play a critical role in the regulation of signals that control platelet functional responses. While certain signaling cascades have been thoroughly elucidated and their contributions to regulation of functional events have been understood, the exact role of many phosphorylations, the substrates of the kinases, and the activation and inactivation mechanisms of the kinases are still not clearly understood. Whereas many conclusions regarding the function of a kinase have been based on small molecule inhibitors and knockout mice, these conclusions have limitations. The small molecule inhibitors have nonspecific effects that become apparent as more advances are made in the field. The knockout mice might have other mechanism of regulation of signaling molecules in the progenitor cells that manifests as a platelet functional defect. Hence more studies have to be performed to unequivocally establish the role of a kinase in the signaling cascade and platelet function.

Take Home Messages

- Protein phosphorylation is the chief mechanism behind platelet activation.
- Platelets mainly express two types of surface receptors, GPCRs and Tyrosine kinase Receptors.
- Extracellular signals (via surface receptors) activate a number of intracellular proteins that are regulated by, and modulate other proteins, through phosphorylation.
- Intracellular proteins include tyrosine kinases such as Src family kinases, Syk, and Tec family kinases, as well as serine/threonine kinases like PKC, Akt, and MAPK.

Platelet Adhesion

Elizabeth E. Gardiner and Robert K. Andrews

Abstract

Platelet adhesion is a critical functional component of blood platelets in pathophysiology and a current focus of drugs modulating platelet activity. In this chapter, we discuss platelet adhesion in terms of both basic science and clinical relevance, not only related to thrombosis and haemostasis, but also in terms of inflammation, infection, and immune-related functions of platelets. In particular, a key factor in the initiation and control of platelet adhesion in the healthy or diseased bloodstream is the effect of changes in fluid shear forces, which is also essential in control of expression and regulation of platelet-specific receptors such as glycoprotein (GP) Ib-IX-V and GPVI, and the interactions with their major binding partners, including von Willebrand factor (VWF) and collagen, respectively. It is the nature of human platelets to rapidly become adhesive to various cellular or non-cellular substrates and to secrete an array of prothrombotic and proinflammatory factors, to localize coagulation and neutrophil-mediated inflammation within the vasculature. Understanding the cellular, biochemical, and shear-related mechanisms involved in platelet adhesion can underpin new advances in the diagnosis and therapy of disease.

Introduction

Platelets are produced from megakaryocytes in the bone marrow and circulate in the human bloodstream for 7–10 days, typically at counts of around $200 \times 10^9\,L^{-1}$. Surveillance by platelets of the vasculature for injury or infection or other irregularities triggers rapid functional responses that control haemostasis, wound healing, innate immune, and inflammatory responses. Platelets also play a major role in maintaining vascular integrity, by controlling endothelial cell and barrier function. Central to these coordinated responses is the ability, within seconds to minutes, to adhere and activate, secrete from storage granules, and interact with other vascular factors and cell types. Importantly, these interactions occur even at arterial or at higher pathological flow rates and shear stresses acting against firm platelet adhesion. Some of the key platelet adhesion networks in the vasculature are shown in Fig. 1. These interactions involve: (a) platelet–platelet adhesion (aggregation), (b) platelet adhesion to the subendothelial matrix, (c) platelet adhesion to activated endothelial cells which express prothrombotic and proinflammatory factors, (d) platelet–neutrophil and platelet–monocyte interactions, and a recently discovered mechanism involving (e) glycoprotein (GP) VI-dependent platelet adhesion to polymerized fibrin formed following coagulation. These very recent latter findings are significant in providing a mechanism for GPVI-dependent platelet adhesion and activation without collagen exposure and increasing platelet-dependent thrombin generation (Mammadova-Bach et al. 2015; Alshehri et al. 2015; Chung 2015). All of these

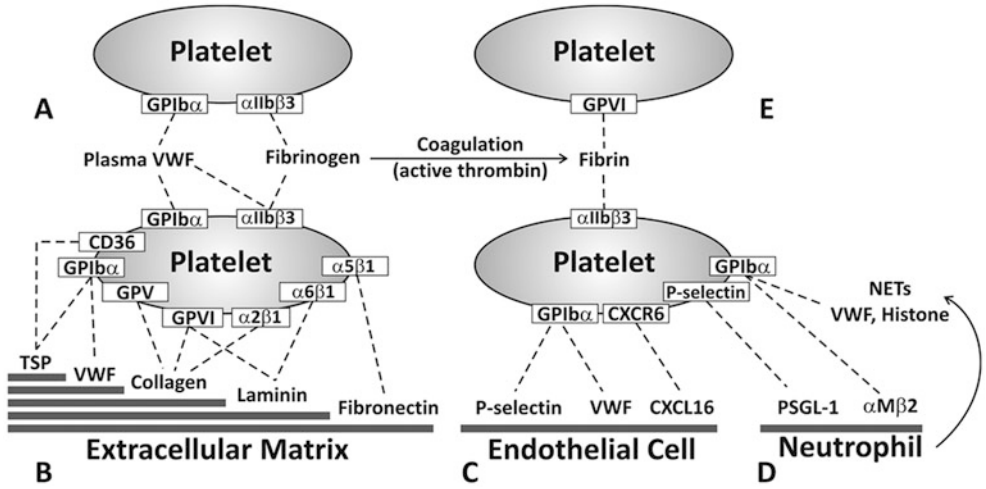

Fig. 1 Platelet adhesion networks. Platelet adhesion in the vasculature involves (**a**) platelet–platelet adhesion (aggregation) mediated by shear-dependent plasma von Willebrand factor (VWF) binding to GPIbα or activated platelet integrin αIIbβ3 binding VWF or fibrinogen, (**b**) platelet–matrix adhesion mediated by receptors on resting or activated platelets for thrombospondin (TSP), VWF, collagen, laminin, and/or fibronectin (**c**) platelet–endothelial cell adhesion mediated by GPIbα binding P-selectin/VWF on activated endothelium or as recently described in atherosclerotic conditions, chemokine-receptor interactions, or (**d**) platelet–neutrophil interactions mediated by P-selectin on activated platelets binding neutrophil P-selectin glycoprotein ligand-1 (PSGL-1), or GPIbα on unactivated platelets binding integrin αMβ2 on activated neutrophils. Platelets also potentially interact with components of DNA-based neutrophil extracellular traps (NETs) including VWF associated via histone. Platelet–monocyte interactions may involve platelet P-selectin, CD40L or GPVI binding monocyte PSGL-1, CD40, or CD147 (EMMPRIN), respectively. (**e**) Recent studies also demonstrate GPVI-dependent platelet adhesion to fibrin generated following coagulation and thrombin generation. Platelet activation/secretion pathways following adhesion are not shown. See the text for details

adhesive interactions are mediated by specialized platelet GP receptors and their counter-receptors or adhesive ligands (Fig. 1). In this regard, human platelets contain several thousand identified proteins and several thousand more predicted by platelet-expressed genes (García et al. 2004a, b; Burkhart et al. 2012). These include secreted, phosphorylated, and other groups of proteins identified by sub-proteome analysis (Senzel et al. 2009; Watson et al. 2005). Supernatants of platelets stimulated to activate metalloproteinase 'sheddases' also contain over a thousand proteins, including 69 membrane protein fragments (Fong et al. 2011). Here we will focus on the function and regulation of some of the key platelet proteins involved in platelet adhesion, focusing on clinically relevant aspects, recent developments, and future therapeutic/diagnostic opportunities.

Platelet–Platelet Adhesion (Aggregation): Introduction of Key Receptors and Ligands

The adhesion of platelets to other platelets leading to formation of clumps or aggregates in plasma or at the vessel wall is covered in detail elsewhere in this edition, but is briefly mentioned here because some of the key receptors that mediate platelet aggregation (Fig. 1a) also play an important role in other adhesive events in the vasculature, and thrombus formation is a critical event in normal haemostasis or thrombotic disease. The stability of a thrombus associated with the vessel wall is also critical in embolization and downstream thrombotic events.

In the absence of vessel wall components, platelet–platelet interactions following stimulation with soluble agonists such as thrombin or ADP are mediated by activation of a platelet-specific β3 integrin, $\alpha_{IIb}\beta_3$, which is constitutively and highly expressed on the resting platelet surface, but in an inactive conformation unable to bind plasma ligands, fibrinogen, or von Willebrand factor (VWF) (Coller 2015; Estevez 2015; Bryckaert et al. 2015). Following platelet activation leading to activation of $\alpha_{IIb}\beta_3$ and ligand-induced $\alpha_{IIb}\beta_3$-dependent signalling, binding of these multivalent adhesive ligands enables platelet–platelet aggregate formation. Exposure of platelets to high supra-physiological shear forces is also an important initiator of platelet aggregation that can occur in the absence of other external agonists or vessel wall factors (section 'Platelet Adhesion to Subendothelial Matrix'). This process is dependent upon platelet GPIbα of the GPIb-IX-V complex binding VWF in a shear-dependent manner, leading to $\alpha_{IIb}\beta_3$-dependent platelet aggregation (Kroll et al. 1996). The GPIbα-VWF interaction is exquisitely regulated, so that even though GPIb-IX-V is constitutively expressed on the platelet surface and VWF is present in normal human plasma, binding of the A1-domain of VWF to GPIbα requires either shear-dependent conformational activation of ligand, receptor, or both, enabling high-affinity interaction sustainable under shear conditions (Yago et al. 2008;

Andrews and Berndt 2008). The binding site for $\alpha_{IIb}\beta_3$ is located in a different domain (C4) of VWF (Bryckaert et al. 2015); the mature VWF subunit (~270 kDa) consists of domains D′-D3-A1-A2-A3-D4-C1-C2-C3-C4-C5-C6-CK and is disulfide-linked to form high molecular weight multimers. VWF is also enabled to bind platelet GPIbα when associated with extracellular fibrillar collagen via the VWF A3 domain (section 'Platelet Adhesion to Subendothelial Matrix') or expressed as high-molecular weight multimers on endothelial cells via endothelial P-selectin (section 'Platelet-Endothelial Cell Adhesion'). The unique properties of these proteins underpin their selective interactions in health and disease.

The GPIb-IX-V complex consists of four type I transmembrane subunits that are all members of the leucine-rich repeat (LRR) family. GPIbα (610 amino acid residues; ~135 kDa; ~20,000 copies/platelet) is the major ligand-binding subunit and is disulfide-linked to GPIbβ and noncovalently bound to GPIX and GPV. GPIbα, GPIbβ, and GPIX are minimally required for surface expression of a functional complex. The ligand-binding N-terminal domain (amino acid residues 1-282) of GPIbα is composed of seven tandem leucine-rich repeats and flanking sequences and contains the binding site for VWF and other ligands (Andrews and Berndt 2012; Gardiner and Andrews 2014a), as discussed in following sections. Within the leucine-rich repeat domain of GPIbα, repeats 2–4 (residues 60–128) play a crucial role in regulating adhesion to VWF under shear conditions (Shen et al. 2000, 2006).

The cytoplasmic tail of GPIbα (~96 residues) contains defined binding sites for filamin (actin-binding protein) of the cytoskeletal actin infrastructure (Cranmer et al. 2011) and for signalling or regulatory proteins, including 14-3-3ζ and the p85 subunit of phosphatidylinositol 3-kinase (PI3K) (Mu et al. 2008, 2010). The cytoplasmic domain of GPIbβ (~34 residues) also contains a binding site for calmodulin, which controls receptor expression and function (Andrews et al. 2001), and a protein kinase A (PKA)-dependent phosphorylation site (Ser166), which controls binding of 14-3-3ζ to the complex (Andrews et al. 2007). Together, these cytoplasmic interactions control normal receptor expression, VWF binding and signalling by GPIb-IX-V. GPV (544 residues, ~82 kDa) contains fifteen LRR domains and mediates platelet adhesion to collagen (Moog et al. 2001). Interestingly, like GPV, the primary platelet collagen receptor GPVI, also forms a noncovalent complex with GPIbα (Arthur et al. 2005). GPV may therefore play a role in regulating GPVI association with GPIb-IX or in regulating binding of thrombin and/or other ligands to GPIbα (De Candia 2012). In this regard, GPIbα acts as a cofactor for thrombin-dependent activation of protease-activated receptor-1 (PAR-1).

One important mechanism regulating surface expression of GPIbα, GPV, and GPVI is metalloproteinase-mediated ectodomain shedding, resulting in the irreversible proteolytic removal of the extracellular ligand-binding domain (Gardiner and Andrews 2014b). Ectodomain shedding of platelet GPIbα near to the outer surface, but N-terminal of the disulfide bond linking GPIbα to GPIbβ, generates a soluble ~130-kDa fragment termed glycocalicin and a membrane-associated remnant fragment that remains bound to GPIbβ/GPIX. GPIbα shedding on human platelets can be mediated by the surface-expressed metalloproteinase, ADAM-17 (Gardiner et al. 2007). Ectodomain shedding of GPV is mediated by thrombin (Berndt and Phillips 1981) or by metalloproteinases (ADAM17 or ADAM10) acting at distinct sites (Gardiner et al. 2007). Shedding of GPVI from human platelets is predominantly, if not exclusively, mediated by ADAM10 generating an ~55-kDa soluble fragment (sGPVI) containing the two extracellular immunoglobulin domains, and an ~10-kDa remnant tail, and is induced by exposure of platelets to high shear stress, activators of ADAM family metalloproteinases, calmodulin antagonists, apoptotic signals, and other triggers (Gardiner et al. 2004, 2007; Al-Tamimi et al. 2012). The cytoplasmic domain of GPVI contains sequences that bind calmodulin (Andrews et al. 2002), an interaction that maintains stable surface expression, and for Src-family kinases involved in GPVI-dependent platelet activation (Suzuki-Inoue et al. 2002). GPVI signalling involves an immunoreceptor tyrosine-based activation motif (ITAM) within the cytoplasmic domain of its co-associated Fc receptor γ-chain (FcRγ, required for GPVI surface expression), and surface density/clustering is an important factor in adhesion and signalling following engagement of GPVI/FcRγ by multivalent ligand due to ITAM cross-talk being prerequisite for activation of Syk-dependent pathways (Chen et al. 2002; Best et al. 2003; Watson 2009; Loyau et al. 2012; Ozaki et al. 2013). Surface clustering of GPIb-IX-V regulates VWF binding (Gitz et al. 2013) and a multimeric ligand is essential for GPIbα-dependent signal transduction (Gardiner et al. 2010), while adhesion of neutrophils via integrin αMβ2 (Mac-1) to immobilized GPIbα extracellular domain is dependent upon a threshold surface density of GPIbα under experimental flow conditions (Kruss et al. 2013).

Platelet Adhesion to Subendothelial Matrix

Understanding the relative role of receptors in platelet adhesion to collagenous extracellular matrix is complicated by a number of factors (Varga-Szabo et al. 2008; Watson 2009; Nuyttens et al. 2011; Cosemans et al. 2013). These include: the possibility of both direct interactions with collagen and indirect interactions with collagen-associated proteins that can occur at different stages of adhesion (Fig. 1b); the relative expression levels and surface density of receptors for collagen and collagen-associated ligands on platelets from different

individuals; the extent of platelet activation and/or the extent to which receptors such as integrins (such as $\alpha_{IIb}\beta_3$, or members of the β1 integrin family) are in an active, ligand-binding state; the cross-regulation between different receptors, where engagement of one receptor leads to upregulation of another receptor such as an integrin (Farndale et al. 2007); the different types of collagen (in the body these include fibrillar types I, II, III, V, XI, non-fibrillar types IX, XII, XIV, XVI, XIX, short chain types VIII, X, basement membrane type IV, triple helix domain types XV, XVIII, membrane-associated types XIII, XVII, and other types VI, VII) and the presentation of different binding motifs (Farndale et al. 2007) in conjunction with the variation in the type and amount of collagen-associated proteins in different vascular beds or atherosclerotic plaque; the relative shear stress and blood flow characteristics which favour, for example, GPIb-IX-V/GPVI binding VWF/collagen at elevated shear rates and integrins or other collagen-binding proteins at lower shear; and also the wider networks between exposed subendothelial matrix and other vascular systems, including endothelial cells and neutrophils which can interact with some of the same platelet receptors (Fig. 1). These are complex but necessary questions in terms of therapeutic agents that target adhesive events and have been addressed over a long period using a range of clinical observations, experimental systems, or models.

Experimental evidence for the relative importance of different platelet receptors may be based on previous studies of human acquired or congenital defects of receptors (GPIb-IX-V, GPVI, α2β1, CD36, and others), changes in expression levels of receptors in human atherothrombotic and other disease (GPVI, α2β1) (Samaha et al. 2005; Gardiner and Andrews 2014c), available mouse knockouts and other animal models of bleeding/thrombosis (Bender et al. 2011), the availability of antibodies and other inhibitors targeting individual receptors, and studies of ex vivo interactions of human platelets with collagen or collagen-related mimetics under various flow conditions (Farndale et al. 2007; Nuyttens et al. 2011). Some important limitations in interpreting these types of studies, therefore, include the types and species of collagen used for ex vivo studies and their potentially different affinity for different receptors, collagen types and receptor binding that occurs in different vascular beds or in atherosclerotic plaque, and key differences between mouse and human platelets/GPVI. For example, important differences between species can include relative expression levels and surface density, sequence differences in the GPVI ligand-binding domain, sequence differences in the cytoplasmic domain which can potentially affect signalling efficiency (Qiao et al. 2010), as well as different (ITAM) receptor profiles where engagement of one ITAM-bearing receptor acts synergistically with other ITAM-bearing receptor to amplify signalling (Bender et al. 2013). In addition, in genetically modified mouse models related to GPVI, there may be effects of the *GP6* gene deletion on other modifier genes which control relative contribution of GPVI to platelet function (for example, by altering extracellular matrix composition) (Cheli et al. 2008). It is, naturally enough, not always clear how well-experimental systems model specific human disease (Libby 2015). In this regard, understanding the range of platelet responses to collagen is necessary for therapeutic targeting and also monitoring changes in receptors such as GPVI as markers of human disease or response to treatment. Some of the most studied interactions between specific platelet receptors and extracellular matrix components are shown in Fig. 1b.

While the precise role of endothelial matrix-platelet receptor interactions in platelet adhesion in health and disease is not entirely certain, it is apparent that platelet GPIbα-VWF and GPVI-collagen engagements are indispensable for initial adhesion of platelets and subsequent activation and aggregation as the wall shear rate increases from low physiological levels (say 150–600 s^{-1}) to higher arterial or pathological levels (say 1500–20,000 s^{-1} or higher). Interestingly, neither GPIb-IX-V nor GPVI are targeted by antithrombotic drugs in current clinical use (Gachet 2015; Metharom et al. 2015), although newer agents involving these receptor-ligand interactions are under development (section 'Therapeutic Targeting of Platelet Adhesion'). Human platelet GPVI preferentially interacts with collagen types I and III; however, in some vascular beds, higher laminin levels potentially compensate for higher levels of collagen type II for example, with less avidity for GPVI. Laminin binding to GPVI and the integrin α6β1 (Inoue et al. 2006; Ozaki et al. 2013) may have functional effects on platelets reminiscent of collagen binding to GPVI and α2β1 (and/or other collagen-binding receptors). Other studies showing that fibrillary fibronectin can support platelet adhesion under flow conditions demonstrate the involvement of multiple receptor-ligand interactions leading to thrombus formation. Platelet adhesion to fibronectin initially involves platelet α5β1 and $\alpha_{IIb}\beta_3$, with subsequent thrombus growth mediated by GPIb-IX-V, GPVI, and Toll-like receptor-4 (TLR-4), the latter potentially via a direct interaction with fibronectin (Maurer et al. 2015). Animal models of atherosclerosis also provide evidence for GPVI-mediated platelet adhesion to atherosclerotic endothelium, by a mechanism involving binding to fibronectin (Bültmann et al. 2010).

Platelet-Endothelial Cell Adhesion

Clearly, the non-adhesion of circulating platelets in the bloodstream with the intact endothelial cell lining of the blood vessel wall is required to maintain the blood flow and prevent vascular occlusion by adherent platelets or

thrombi. This necessitates quiescent platelets and endothelium; however, platelet adhesion to endothelial cells mediated by one or more receptors (Fig. 1c) may be promoted by activated endothelial cells in response to injury, infection, inflammatory response, or other causes. Endothelial cells can rapidly express long strings of highly multimerized VWF from Weibel-Palade storage granules, with high capacity to mediate platelet adhesion via platelet GPIbα (Padilla et al. 2004; López and Dong 2005). Activated endothelial cells also rapidly (within seconds to minutes) express P-selectin stored on secretory granules, and P-selectin is another counter-receptor for GPIbα (Romo et al. 1999). Under chronic inflammatory conditions, endothelial cells upregulate expression of intercellular adhesion molecule (ICAM)-1, which mediates platelet–endothelial cell interactions via fibrinogen bridging ICAM-1 and $\alpha_{IIb}\beta_3$ on activated platelets (Bombeli et al. 1998). Furthermore, as recently described under atherosclerotic conditions, chemokine–receptor interactions involving endothelial chemokine CXC motif ligand 16 (CXCL16) and platelet-expressed CXCR6 mediate platelet adhesion to the human vasculature, promoting platelet-dependent atherogenesis, with these interactions leading to platelet activation and aggregation (Meyer Dos Santos et al. 2015). Other studies of animal models of atherosclerosis also suggest GPVI-dependent platelet adhesion to endothelium, based on inhibition by GPVI deletion and/or blockade by soluble Fc-fusion protein of dimerized GPVI ectodomain (Penz et al. 2005; Bültmann et al. 2010). Platelet–endothelial cell interactions can lead to active thrombus formation, localization of active platelets secreting procoagulant and proinflammatory mediators, and also recruitment of leukocytes. These cellular interactions are also a critical factor underlying thrombotic microangiopathies, often associated with thrombocytopenia, where thrombosis in capillaries and arterioles may follow endothelial injury. An example is thrombotic thrombocytopenic purpura (TTP) featuring larger multimer size of circulating VWF, typically due to abnormal ADAMTS13 activity due to immune or other causes, which can result in increased platelet adhesion at sites of endothelial damage within arterioles/capillaries (Zhou et al. 2010; Zheng 2015). Interestingly, inhibition of platelet GPIbα–VWF adhesion has been investigated as a potential therapeutic treatment for TTP (Feys et al. 2012; Salles and Crawley 2012) and qualitative and quantitative analyses of VWF may aid in monitoring aberrant platelet activation in essential thrombocythemia (Lancellotti et al. 2015).

Platelet–Leukocyte Adhesion

Platelet–leukocyte interactions, involving both direct adhesion and indirect regulation via secreted factors and mediators, are important in health and disease (Seizer et al. 2008; Pawelski et al. 2014; Glezeva et al. 2016; Schrottmaier et al. 2015). Like platelets, polymorphonuclear leukocytes (neutrophils) are rapidly recruited at vascular sites of injury, infection, or inflammation to fulfil their role as defensive cells. Neutrophils activated by pathogenic factors or chemokines become adhesive towards other neutrophils, endothelial cells, and platelets, under conditions of low or high shear stress at inflammatory sites (Simon and Goldsmith 2002). Platelet adhesion to leukocytes is increasingly recognized as part of the proinflammatory role for platelets (Jenne et al. 2013; Rondina et al. 2013; Ed Rainger et al. 2015; Franco et al. 2015; Armstrong et al. 2015) and involves a number of adhesive receptor–ligand interactions (Fig. 1d). On resting platelets, GPIbα can act as a counter-receptor for the β2 integrin, αMβ2, on activated neutrophils (Simon et al. 2000). On resting neutrophils, P-selectin glycoprotein ligand-1 (PSGL-1) can act as a counter-receptor for P-selectin expressed on active platelets. These important P-selectin ligands—GPIbα and PSGL-1—share common structural features, including sialylated mucin-like ectodomains and an anionic sequence rich in sulfated tyrosine residues essential for binding one or more ligands (Andrews et al. 1997). Adhesion of platelets to phagocytic leukocytes may also be involved in platelet clearance in the liver or spleen. In this regard, GPIbα is constitutively shed from platelets consistent with experimental evidence that the spatial density of this receptor is critical for optimal adhesion with neutrophil αMβ2 (Kruss et al. 2013). A change of approximately one order of magnitude in GPIbα density can significantly modulate neutrophil adhesion kinetics. Evidence suggests GPIbα clustering, shedding, or changes in glycosylation/sialic acid are important regulators of platelet clearance (Gardiner and Andrews 2014b). In addition, Ashwell-Morell receptors on hepatocytes that recognize galactose and *N*-acetylgalactosamine on desialylated glycoproteins are implicated in thrombocytopenia associated with the action of desialylating *Streptococcal* neuraminidases in sepsis, and with coagulopathy (Grewal et al. 2008; Grewal 2010; Pawelski et al. 2014). Preventing platelet desialylation, for example by use of therapeutic sialidase inhibitors, may alleviate thrombocytopenia in immunothrombocytopenia associated with anti-GPIbα autoantibodies (Shao et al. 2015; Li et al. 2015).

An alternative, indirect pathway for platelet–leukocyte interactions involves the extrusion from neutrophils of extracellular traps (NETs), electrostatically charged adhesive networks comprised of DNA, associated histones, and secretory granule-derived serine proteases including neutrophil elastase and cathepsin G (Brinkmann et al. 2004). NETs may entrap and limit dispersal of pathogens, following exposure of neutrophils to pathogen-derived stimulatory factors, and may also trigger the intrinsic pathway of coagulation (Martinod and Wagner 2014). NET formation (NETosis) is induced by thrombin-activated platelets adhering to

neutrophils, by a mechanism involving platelet P-selectin and neutrophil PSGL-1, but is defective with platelets from P-selectin-deficient mice (Etulain et al. 2015). Histones also bind VWF (Ward et al. 1997), and VWF is a vital component of NETs (Grässle et al. 2014) providing the opportunity for platelet adhesion to NETs-associated histone/VWF via GPIbα (Fig. 1d). Platelets activated by thrombin or other agonists also induce significant NETosis (Etulain et al. 2015). In turn, activation of platelets leads to release of proinflammatory cytokines and growth factors leading to neutrophil activation and activation of the GPIbα-binding adhesive receptor, αMβ2 (Gardiner et al. 2012; Andrews et al. 2014a).

Finally, platelets adhere to monocytes via platelet P-selectin binding PSGL-1, CD40L binding CD40, GPVI binding CD147 (EMMPRIN), or other mechanisms (Schrottmaier et al. 2015). Importantly, platelets do not only interact with monocytes/endothelial cells at the vessel wall, but platelet-monocyte aggregates are measurable in the circulation, where altered levels are associated with cardiovascular or other disease states (Yong et al. 2011; Pawelski et al. 2014). The cross-talk between platelets, leukocytes, and endothelial cells mediated by direct adhesion or release of soluble mediators is not only integral to maintaining healthy vasculature and is clinically important across a range atherothrombotic and inflammatory disease states, but also points to the potential use of current or new antiplatelet agents targeting adhesive interactions as emerging treatment options.

Platelet–Fibrin Adhesion

GPVI-dependent platelet adhesion to polymerized fibrin formed following coagulation (Fig. 1e) is a recent finding providing a new physiological ligand for GPVI-dependent platelet adhesion and activation without the requirement for collagen or extracellular matrix exposure (Mammadova-Bach et al. 2015; Alshehri et al. 2015; Chung 2015). With some apparent similarity to fibrillar collagen, fibrin is a polymeric molecule with repetitive domains and the capacity to activate platelets by cross-linking GPVI. Fibrinogen is prevalent in normal plasma and can bind $\alpha_{IIb}\beta_3$ on activated platelets, but does not interact with GPVI or other receptors on resting human platelets. Indeed, recent studies on the role of fibrinogen in vascular processes reveal that while fibrinogen supports $\alpha_{IIb}\beta_3$-dependent platelet aggregation, polymerized fibrin is essential for platelet adhesion and occlusive thrombus formation in vivo. Mice expressing a mutant form of fibrinogen that cannot form fibrin uniquely demonstrate the importance of fibrin in preventing excessive bleeding and forming stable occlusive thrombus in a $FeCl_3$ model (Prasad et al. 2015; Litvinov and Weisel 2015). Other studies suggest fibrinogen on the surface of experimentally produced thrombi significantly limits platelet adhesion (Owaynat et al. 2015) and that purified human fibrinogen provides an anti-adhesive coating for biomaterials (Safiullin et al. 2015). However, in the case of intravascular haemolysis, extracellular haemoglobin can interact with the VWF A1 domain and promote GPIbα-dependent platelet adhesion to fibrinogen-coated surfaces, providing an unexpected adhesive mechanism linked to thrombus formation (Da et al. 2015).

Supporting a functional role for platelet GPVI–fibrin adhesion, GPVI-deficiency or anti-GPVI Fab (9O12) compromised thrombin generation and depended on fibrin polymerization, and the Fab 9O12 inhibited platelet adhesion to fibrin at low or high shear rates (Mammadova-Bach et al. 2015). In a separate study, noting that in a $FeCl_3$ injury model, GPVI-deficient mice tend to show initial platelet adhesion but not progression to stable occlusive thrombus, evidence for fibrin binding to platelet GPVI was demonstrated by linking increased tyrosine phosphorylation of GPVI/FcRγ chain and Syk in human or mouse platelets to the presence of active thrombin and fibrinogen under conditions where fibrinogen binding to $\alpha_{IIb}\beta_3$ was blocked (Alshehri et al. 2015). Platelets spread on fibrin but not fibrinogen in a GPVI-dependent manner, accompanied by increased platelet procoagulant activity. These recent studies have renewed interest in the precise location of collagen/extracellular matrix exposure and fibrin formation within thrombi in mouse in vivo models of thrombus formation or human thrombus formation ex vivo, with clear implications for new antiplatelet agents.

Other Forms of Platelet Adhesion

Although not described in detail here, various additional forms of platelet adhesion are also clinically relevant. For example, platelets interact with bacteria and other pathogens (Cox et al. 2011; Morrell et al. 2014; Andrews et al. 2014a), interact with metastatic tumour cells in the circulation (Franco et al. 2015; Li 2015), and can also come in contact with implanted biomaterials such as stents, extracorporeal membrane oxygenation (ECMO), and ventricular assist devices (Murphy et al. 2015), all of which can result in haemostatic complications due to multiple causes. Increased thrombotic or bleeding risk in these diseases clearly involves many of the same receptors that participated in other vascular adhesion events. In addition, there is a newly emerging role for the ITAM-bearing C-type lectin-like receptor on human platelets, CLEC-2, in mediating platelet adhesion to the *O*-glycosylated mucin, podoplanin, expressed on lymphatic endothelial cells and other non-vascular cell types. Platelet CLEC-2 in mice is essential for lymphatic

development as well as for maintaining lymph node stability in adults, and CLEC-2 deficiency results in abnormal lymph node development, blood-lymph mixing, and immune impairment, and for this function, there is a demonstrable requirement for platelet CLEC-2 signalling (Navarro-Núñez et al. 2013; Bénézech et al. 2014). In related model systems, defects in lymphocyte transition at lymph nodes have been observed in mice lacking podoplanin or with antibody-depleted platelet CLEC-2, as well as increased bleeding associated with immunization (Herzog et al. 2013). Recombinant podoplanin supports platelet adhesion and aggregation ex vivo under low (venous) shear conditions in a CLEC-2-dependent manner (Navarro-Núñez et al. 2015). Podoplanin may also be expressed on some tumour cells as they increase motility and migration, and CLEC-2-dependent adhesion to platelets has been implicated in tumour metastasis (Suzuki-Inoue 2011; Astarita et al. 2012).

Therapeutic Targeting of Platelet Adhesion

Antiplatelet drugs in current clinical use mainly target either platelet activation pathways (aspirin), ADP-dependent autocrine activation pathways (P2Y12 antagonists), or the adhesion receptor that mediates platelet aggregation, $\alpha_{IIb}\beta_3$ (Gachet 2015; Metharom et al. 2015). All are associated with variable increased bleeding risk in individuals, or lack of efficacy in preventing thrombosis. It is interesting that the platelet-specific receptors critical for initial platelet adhesion at elevated shear stress, GPIb-IX-V and GPVI, are not currently targeted, although various agents associated with these receptor-ligand pathways have been investigated (Deckmyn et al. 2012; Metharom et al. 2015). These receptors are only expressed on megakaryocytes or platelets. In humans, the rare defects of GPIb-IX-V (Bernard-Soulier syndrome) result in variable bleeding risk, from relatively mild to more severe (López et al. 1998; Andrews and Berndt 2013). In mice, GPIbα also appears to have a far greater contribution to stable arterial thrombosis than VWF (Bergmeier et al. 2006). Rather than completely blocking VWF binding, which would potentially increase bleeding risk, other approaches might involve selective small molecule allosteric inhibitors (Benard et al. 2008), which prevent GPIbα attaining a ligation-competent conformation via structural localization within the leucine-rich repeats and C-terminal flanking sequences (McEwan et al. 2009). Selectivity of GPIbα-targeting inhibitors for individual-binding partners is feasible, based on discriminatory inhibition of one or more ligands by monoclonal antibodies against specific sites within the ligand-binding domain (Shen et al. 2000; Andrews and Berndt 2012).

GPVI has been extensively investigated as a potential antiplatelet target (Zahid et al. 2012; Andrews et al. 2014b; Gawaz et al. 2014; Jiang and Jandrot-Perrus 2014; Jiang et al. 2015). This is due in part to expectations that the bleeding risk may be minimal, based on minimal increase in bleeding in GPVI-deficient mice (Bender et al. 2011) and the evaluation of bleeding severity in humans with congenital or acquired GPVI deficiency (Arthur et al. 2007). One GPVI-related agent is a dimeric form of soluble GPVI ectodomain expressed as a fusion with humanized Fc (Ungerer et al. 2011; Gawaz et al. 2014). Unlike native sGPVI shed from platelets which is monovalent and binds collagen weakly, the bivalent form can inhibit platelet adhesion to collagen. Testing these and other agents, including the Fab 9O12 (Mammadova-Bach et al. 2015), for blockade of GPVI-fibrin interactions is a promising future direction (section 'Platelet-Fibrin Adhesion').

Finally, in addition to targeting platelet adhesion in thrombotic disease, targeting platelet–endothelial cell and platelet–leukocyte interactions can potentially play a role in clinical treatment of inflammatory disease (Simon 2012; Gardiner et al. 2012). Selective targeting of functional sites on GPIbα for VWF, αMβ2, P-selectin, or other ligands (Fig. 1) without increasing bleeding risk may yet be possible, supporting ongoing research in this area.

Summary and Conclusions

Studies reviewed in this chapter reveal some of the diversity and underlying complexity of platelet adhesion pathways, including the diverse receptor–ligand interactions and effects of altered rheological flows, as well as the ongoing worldwide interest and accumulation of literature in this area. Clearly, targeting mechanisms of regulating receptor expression and shedding and/or intracellular signalling pathways associated with receptor engagement discussed elsewhere in this edition could ultimately provide more desirable modes of clinical targeting of platelet adhesion rather than targeting ligand binding. Nevertheless, better understanding of the precise physiological and pathological roles of platelet-specific receptor adhesive function is essential and ultimately can have a major impact on global burden of vascular diseases.

Take Home Messages

The capacity of blood platelets to rapidly adhere to numerous vascular targets underpins the important role of platelets in patho-physiology. This sheer complexity, including multiple ligands, time-dependence, and blood flows, is not only a challenge to define and understand, but also offers an abundance of new avenues to more efficaciously regulate platelet adhesion in future therapeutic applications in human disease.

Acknowledgments We thank the editors for the opportunity to provide this review and our colleagues and coworkers for many helpful discussions. We thank the National Health and Medical Research Council (NH&MRC), Australia, for financial support.

Platelet Shape Change

Joseph E. Aslan

Abstract

Platelets circulate quiescently in a flat, discoid state and undergo specific morphological changes to support granule secretion, integrin activation, platelet–platelet aggregation, adhesion, and contractile processes in the initial stages of the platelet activation program. Dynamic changes in platelet shape have long been associated with platelet activation and hemostatic and thrombotic function. Classical microscopy studies, together with the development of light transmission aggregometry, allowed for an advance of platelet shape change assays as important experimental and clinical tools. Pharmacology efforts have specified how platelet agonists, including thrombin, collagen, and ADP activate G protein-coupled receptors (GPCRs) or ITAM-bearing receptors to increase myosin light chain phosphorylation to drive actomyosin contractions and other dynamic cytoskeletal processes that form the basis for the initiation of platelet shape change. Advances in imaging technologies and molecular tools continue to provide mechanistic insights into platelet shape change as one of the earliest morphological manifestations of platelet activation, a potential biomarker for platelet-based disease states and a powerful tool in basic and translational studies of platelet function.

Introduction

As the primary cellular mediators of hemostasis and thrombosis, platelets respond to physiological cues and other stimuli with precisely regulated changes in cellular shape to support adhesion, spreading, and aggregation in the formation of hemostatic plugs and thrombi. Platelet shape change is ideally described as a transition of platelets from flat, concave discs to a more spherical form, often with pseudopodial protrusions, produced by actomyosin action, and which occur immediately following exposure to an agonist (Hartwig 2006) (Fig. 1). Shape change is considered to be the first readily measurable physiological response of platelets to a given agonist (Kim and Kunapuli 2011), detectable in the initial second of the platelet activation program (Redondo et al. 2006; Gear 1994). In physiological contexts, platelet shape change is initially reversible and can take place independently of other steps of platelet activation to support specific aspects of platelet function such as the centralization of secretory granules, granule release, the formation of filopodial structures and the aggregation of platelets with one another (Kinlough-Rathbone et al. 1976) (Fig. 2).

Platelet shape change can be broadly defined as any detectable alteration of platelet morphology, topology, surface area, volume, surface structure, contractibility, density, membrane ruffling, and blebbing (Frojmovic and Milton 1982). While platelets undergo a number of structural, morphological, and surface changes to support platelet activation, platelet biologists and hematologists historically use the term "shape change" to refer to changes in the manner in which platelets in solution scatter light, as measured by light transmission aggregometry (LTA), or Born aggregometry, in response to

an agonist such as ADP (Rand et al. 2003). The in vitro nature of LTA, often requiring supraphysiological levels of agonist, as well as complexities brought about by changes in light transmission resulting from platelet microaggregate formation and other factors often bring the physiological relevance of shape change as studied by LTA into question (Maurer-Spurej and Devine 2001; Kitek and Breddin 1980). Nonetheless, regardless of the caveats of LTA assays, "extent of shape change" as determined by LTA continues to serve as an important, standardized, and reproducible aspect of the earliest stages of platelet activation (Holme et al. 1998).

Under conditions of physiological shear, platelet shape change allows for a dramatic increase in platelet surface area that assists in recruiting platelets into a growing hemostatic plug or thrombus, where contractile forces generated by shape change also support aggregate consolidation. In vivo, the roles and mechanisms of shape change are less straightforward, as discoid platelets in circulation reversibly change shape as they associate with a vessel wall or with the superficial layers of a growing thrombus, where platelet shape change contributes to platelet aggregate stability (Kuwahara et al. 2002; Maxwell et al. 2007; Stalker et al. 2014). The classical morphological, physiological, and practical aspects of platelet shape have been extensively reviewed (Frojmovic and Milton 1982; Aslan et al. 2012). In this chapter, we present an overview of the platelet shape change process from the perspective of classical platelet studies, current and developing measurement technologies, pharmacological manipulation, physiological regulation, and translational considerations.

Observing and Measuring Platelet Shape Change

Platelet shape change is studied using a variety of techniques to examine individual platelets or platelet populations, fixed at specific stages in the activation process or in real time in response to a given stimulus or in a specific physiological context. Methods to study platelet shape change range dramatically, from simple observations of the swirling properties of a solution of platelets by eye (Bertolini and Murphy 1994), to the latest advances in super-resolution and intravital microscopy technologies (Stalker et al. 2014). As "shape change" historically refers to the initial response of platelets to an agonist as measured by light transmission

aggregometry (LTA), assays that record changes in the light scattering properties of platelet suspensions over time are most commonly used to study shape change and platelet function (Rand et al. 2003). Such LTA studies are often complemented by microscopy analyses of platelet morphology as well as flow cytometry, volume measurement assays, and other methods that measure platelet responses (Allen et al. 1979). It is important to note that sample preparation, temperature fluctuations, and experimental conditions associated with any given shape change assay may impact platelet shape. Methods of platelet isolation, including anticoagulant choice, needle size, and blood draw procedures can also affect platelet shape (Frojmovic and Milton 1982; White 2000). The general health of human donors or model animals, as well as diet, lifestyle, medication use, and potential genetic factors should also be taken into consideration in any rigorous study of platelet morphology and shape change.

Light microscopy observations of platelets dating back to the early 1900s noted that platelets exist in a number of different morphological states and suggested that platelet shape would be associated with specific platelet functions (Ferguson 1934). In the middle of the twentieth century, electron microscopy provided additional clues into how transitions in platelet shape were associated with platelet activation, aggregation, and thrombus formation (Rodman et al. 1962). Studies of platelet shape change were advanced in the 1960s following the development of LTA, or Born aggregometry, which provided a method to follow changes in platelet shape in response to agonists in platelet-rich plasma (PRP) in real time (Michal and Born 1971; Zhou and Schmaier 2005). In LTA assays, light is passed through a glass cuvette containing a stirring suspension of platelets. The presence of platelets in solution causes the passing light to scatter such that a portion of the light is obstructed from passing through. The total light that is transmitted through the cuvette and platelet suspension is recorded and provides a measure of the optical density of the solution. Following the addition of a platelet agonist, platelets eventually clump together to form aggregates, decreasing the optical density of the solution and allowing more light to transmit through. Immediately following the addition of a platelet agonist to the solution, the aggregometry apparatus will typically record an initial, brief ~10 % decrease in light transmission (or, increase in optical density) that precedes platelet aggregation by about 10–30 s (Fig. 3). This decrease in light transmission marks the initial response of platelets to an agonist and denotes the platelet shape change. Figure 3 provides a representative, illustrative example of the shape change as measured by LTA. The degree to which optical density of a suspension of platelets will change can depend on platelet concentration, shape, size, density, suspension media, stirring speed, temperature, and other parameters. Platelet inhibitors and general pharmacological agents such as tirofiban and eptifibatide can be included in the aggregation reaction to allow for studies of shape change independent of aggregation, secretion, and other events (Phillips and Scarborough 1997; Jagroop and Mikhailidis 2008).

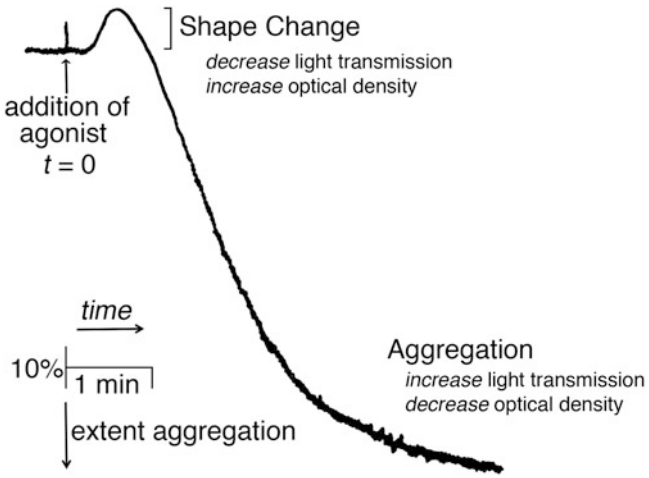

Fig. 3 Platelet shape change as determined by light transmission aggregometry (LTA). Representative aggregation trace of platelets stimulated with agonist at $t = 0$ demonstrating platelet shape change signal as a decrease in light transmission ~1 min following stimulation

In addition to LTA, more advanced light scattering methods that detect specific angles of transmitted light through a platelet solution can be used to more accurately follow platelet shape, size, and volume changes (Maurer-Spurej and Devine 2001; Mindukshev et al. 2012). While early studies of platelet shape change found a profound increase in platelet volume following activation associated with shape change (Mannucci and Sharp 1967), more recent studies suggest that shape change is associated with a small decrease in platelet volume upon activation (Moskalensky et al. 2013). The morphological aspects of shape change have been extensively detailed with a variety of microscopy methods. Atomic force microscopy has also been used to measure the contractile force of individual platelets changing shape (Lam et al. 2011). More recently, intravital microscopy has allowed for a survey of platelet morphology and intracellular signaling in vivo in the dense core as well as the more loosely packed surface of growing thrombus—revealing a complex role for shape change as platelets associate with and assemble into a stable hemostatic plug or thrombus (Stalker et al. 2014).

Maintaining Platelet Shape and Directing Shape Change

The discoid morphology of quiescent platelets is maintained by a careful homeostatic balance of intracellular signaling systems and organized structural elements which preserve

Table 1 Platelet shape change—key facts

Platelet shape change
• denotes the discoid to spheroid transition associated with platelet activation
• is the first readily detectable event of the platelet activation program
• is specifically triggered by platelet agonists
• is reversible, depending on agonist and physiological context
• is commonly observed as a small decrease in light transmission in aggregometry assays
• functionally supports hemostatic plug and thrombus consolidation in vivo
• is generally the result of actin–myosin interactions
• results from signaling events that drive a net increase in myosin light chain phosphorylation
• can occur via calcium-dependent and calcium-independent signaling processes
• has implications in platelet-associated disease states
• is associated with a loss of quality in platelet storage and transfusion

the resting state of the platelet cytoskeleton. Following stimulation, cytoskeletal dynamics support contractile, membrane, and intracellular structural changes in shape as well as secretory and adhesion events of platelet activation. Here we summarize the participation of major cytoskeletal systems in platelet shape change as well as in the maintenance of the resting platelet discoid shape. Contractile events of the actomyosin system—mediated by increases in intracellular calcium as well as calcium-independent RhoA-ROCK signaling—drive the initial stages of shape change to support secretion, aggregation, and other events of platelet activation (Bauer et al. 1999; Paul et al. 1999; Li et al. 2010). Parallel and intersecting intracellular processes promote the severing and reassembly of filamentous F-actin as well as ultrastructural changes of platelet microtubules to commit the platelet shape transition (Table 1).

Myosin Motors, Contraction, and Shape Change

Myosins are a diverse family of actin-based motor proteins that serve critical roles in cellular adhesion, migration, and contraction (Conti and Adelstein 2008). To execute these processes, nonmuscle myosins, made up of myosin heavy chain (MHC) dimers and two pairs of myosin light chains (MLCs), reversibly bind to actin filaments and hydrolyze ATP to generate mechanical force. In the initial moments of the platelet activation program, actomyosin contractions drive an isotropic contraction around the platelet perimeter, resulting in a uniform change in shape to centralize granules prior to secretion and to support other processes in the platelet activation program (Murrell et al. 2015). Myosin ATPase and contractile activity is activated by

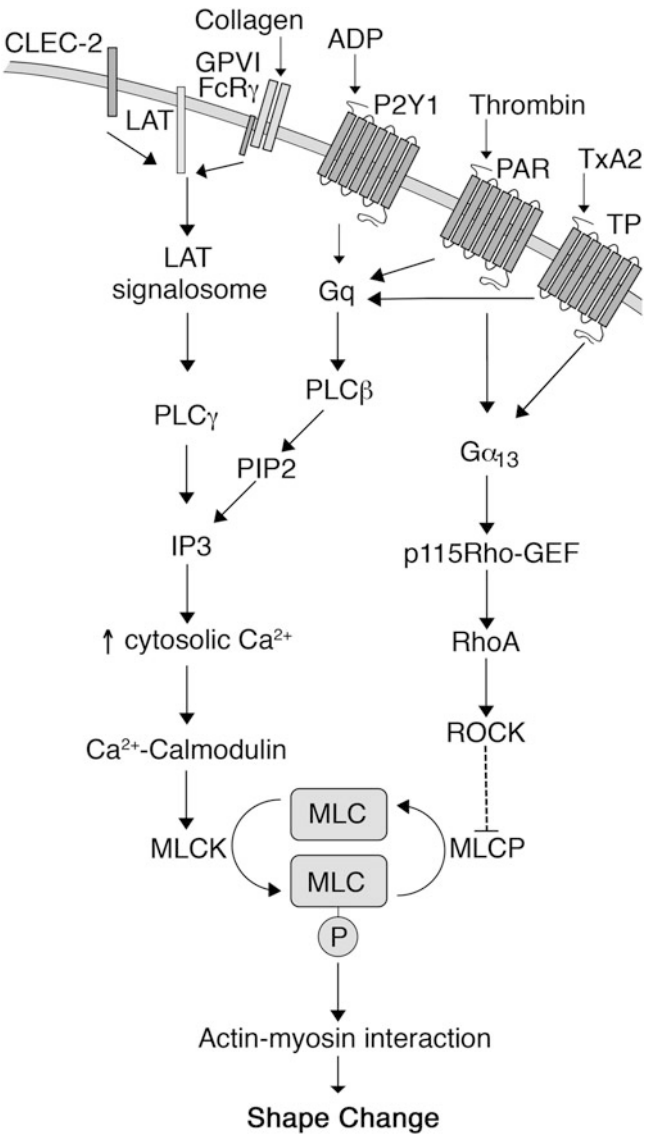

Fig. 4 Essential receptor-ligand signaling systems drive platelet shape change through calcium-dependent and calcium-independent pathways. Upon the stimulation of platelets with GPCR (ADP, Thrombin or TxA2), ITAM receptor (Collagen, ristocetin) or other ligands, PLC-based calcium signaling pathways drive the activation of MLCK or a G_{13}-initiated cascade promotes the inactivation of MLCP. Following a net increase in MLC phosphorylation, myosin associates with actin to generate the contractile basis of the platelet shape change. See text for details

phosphorylation of the myosin light chain (MLC) at Ser_{19}, which serves as a central point of regulation in the initiation of platelet shape change (Daniel et al. 1984; Nachmias et al. 1985) (Fig. 4). Accordingly, platelet shape change is regulated by a net balance of MLC phosphorylation and dephosphorylation, as controlled through calcium-dependent and calcium-independent signaling systems. Following platelet stimulation, increases in platelet cytosolic calcium promote the activation of the calcium calmodulin-

dependent MLC kinase (MLCK), which phosphorylates MLC Ser_{19} to initiate shape change. Shape change can also be triggered independently of cytosolic calcium increases through the activation of Rho kinase (ROCK), which phosphorylates and inhibits the myosin light chain phosphatase (MLCP) to result in a net increase in MLC Ser_{19} phosphorylation, contraction, and shape change.

Platelets express the nonmuscle myosin heavy chain isoform gene *MYH9*, which encodes the nonmuscle myosin heavy chain IIA. Inhibition of myosin II ATPase activity with blebbistatin—which blocks myosin–actin interactions (Kovacs et al. 2004)—inhibits platelet shape change (Johnson et al. 2007). Mouse platelets with *MYH9* deletions have impaired contractile shape change and hemostatic defects in vivo (Leon et al. 2007). Interestingly, mouse *MYH9*-null platelets have normal aggregation, secretory, and spreading capabilities, but have defective stress fiber formation associated with impaired thrombus formation under flow over collagen. Similarly, different mutations in patients with *MYH9*-related disorders are associated with a number of phenotypes—including an absence of shape change (Canobbio et al. 2005) as well as cytoskeletal abnormalities, disorders of platelet function, and platelet production (Althaus and Greinacher 2009).

Actin Filaments

Actin—the most abundant protein in platelets—comprises well over 10 % of the total platelet proteome and has central roles in platelet activation and function. In resting platelets, a network of cross-linked F-actin associates with a filamentous membrane skeleton made up of spectrin and filamin, linked to the platelet plasma membrane by the glycoprotein receptor GPIb to give structural integrity and flexibility to the characteristic discoid platelet shape (Hartwig and DeSisto 1991). Concomitant with actomyosin contractions, a complete change in platelet shape requires the disassembly of the membrane skeleton, a disruption of resting platelet actin filaments, and ultimately assembly of new actin structures characteristic of activating platelets (Hartwig 2006). Despite well-established roles for actin in filopodia formation and platelet aggregation, the roles of the actin cytoskeletal system in the initial moments of platelet activation and shape change are less clear. Agents that disrupt the actin cytoskeleton such as latrunculin A and cytochalasins prevent platelet pseudopodia formation and inhibit shape change (Patscheke and Worner 1978; Woronowicz et al. 2010; Maurer-Spurej and Devine 2001; Casella et al. 1981). Immediately following platelet stimulation, the spectrin-rich actin membrane cytoskeleton is reorganized by actin-severing proteins, including gelsolin, which interacts with, severs, and caps actin filaments to prevent elongation in a calcium-dependent manner. The severing activities of gelsolin, together with the release of the capping protein adducin from the spectrin–actin cytoskeleton help to remodel the resting platelet membrane cytoskeleton to contribute to changes in platelet shape in the platelet activation program (Hartwig 2006; Barkalow et al. 2003). Mouse platelets lacking gelsolin expression have higher resting levels of F-actin content and display hemostatic defects and inhibited shape change responses (Witke et al. 1995; Falet et al. 2000). Similarly, platelets from patients with hereditary gelsolin Asp187Asn-related amyloidosis show abnormal shape change (Kiuru et al. 2000). Studies of platelets null for the expression of cofilin, another actin-severing protein associated with shape change, suggest that cofilin does not have an essential role in shape change but contributes to later events in platelet activation (Bender et al. 2010). Platelet gelsolin activity is held in check by the vasodilator-stimulated phosphoprotein VASP, which dampens platelet activation and shape change by stabilizing actin and preventing severing by gelsolin (Bearer et al. 2000). Experiments that take advantage of blocking antibodies suggest that the actin-nucleating Arp2/3 complex may support actin remodeling events in platelet shape change (Li et al. 2002) in a manner independent of the Arp2/3 activator WASp (Falet et al. 2002; Oda et al. 2005).

Microtubules and Marginal Band Dynamics

A circumferential, marginal band of microtubules surrounds the inner periphery of discoid platelets and is one of the most notable ultrastructural features of the platelet observed by electron microscopy (White 1968). The microtubule marginal band is a major platelet structural element that confers the discoid shape of resting platelets. Microtubule depolymerization with pharmacological agents such as nocodazole and colchicine or cold treatment reversibly transitions discoid platelets to a spherical shape—a process referred to as spherocytosis (White and Rao 1998). However, microtubule stabilization with taxol does not prevent shape change, suggesting that the marginal band is important to the maintenance of resting platelet shape rather than the platelet shape change process (White and Rao 1983), especially given the rapid kinetics of shape change relative to changes in marginal band state. The marginal band is composed of 8–12 dynamic microtubules that continuously polymerize from multiple assembly sites in both directions around the circular marginal band (Patel-Hett et al. 2008). These microtubules are polymers made up of dimers of α-tubulin and β-tubulin monomers. About one half of the tubulin content in resting platelets can be found as polymerized tubulin in the microtubule marginal band (Steiner and Ikeda 1979). Nearly 90 % of the β-tubulin in

platelets is β1-tubulin, a megakaryocyte/platelet-specific β-tubulin isoform (Italiano et al. 2003). β1-tubulin content is required for marginal band integrity, as depletion, mutation, or disruption of β1-tubulin causes platelet sphering. Despite sphering, β1-tubulin-null mouse platelets preserve normal hemostatic platelet function. Interesting, Q43P mutation of β1-tubulin is associated with platelet spherocytosis as well as decreased sensitivity to platelet agonists in humans and may be thromboprotective in men (Freson et al. 2005). Microtubule-associated regulatory proteins such as RanBP10, an activator of the Ran GTPase, also associate with β1-tubulin and have roles in microtubule assembly and in maintaining platelet discoid shape (Kunert et al. 2009), and platelet shape change (Meyer et al. 2012). Genetic abnormalities in the X-linked megakaryocyte transcription factor GATA1 impact the expression of a number of megakaryocyte and platelet-specific genes, including β1-tubulin, and can alter resting platelet shape and shape change response to agonists (Hughan et al. 2005).

Studies of marginal band and microtubule dynamics have suggested a number of potential fates for the marginal band in platelet shape change. As the marginal band is not readily resolved by EM following platelet stimulation or cold treatment, it was initially hypothesized that a breakdown or depolymerization of the microtubule band supported platelet activation (White and Krivit 1967). Later EM and fluorescence microscopy studies suggested that the marginal band condenses to form a smaller, tighter ring as platelets activate and contract to change shape in the disc to sphere transition (White and Burris 1984). More recent studies that bring together fluorescence 3D confocal microcopy, pharmacological, and cell biological methods suggest a more integrated model based on the continual polymerization of the marginal band in both directions, as mediated by microtubular motor proteins kinesin and dynein (Diagouraga et al. 2014; Sadoul 2015). In this model, microtubules of the marginal band continue to polymerize as platelets activate and change shape. In the initial stages of activation and shape change—or following mild stimulation—the expanding marginal band folds in on itself into a coiled-coil microtubule structure, resembling the seam of a tennis ball. A similar marginal band morphology has been reported in platelets lacking profilin1 which have abnormally organized, hyperstable microtubules (Bender et al. 2014). Without further stimulation, this coiled-coil band eventually finds its way back to a ring shape, reverting the platelet to a discoid shape. As platelet stimulation and activation proceeds, the continuously polymerizing microtubules of the coiled-coil divert from their two-dimensional circular path to eventually form a new, flat, more compressed microtubule ring in the activated, smaller, spherical activated platelets. As tubulin polymerization continues, microtubules may eventually enter extending protrusions to support platelet filopodia formation, aggregation, and spreading. Similar microtubule twisting-based shape change mechanisms occur in nonmammalian, nucleated thrombocytes to mediate hemostasis (Lee et al. 2004).

Agonist-Receptor Systems as Initiators of Shape Change

Platelet agonists engage their respective receptors to set forth intracellular signaling cascades that drive platelet hemostatic responses, especially shape change. Following shape change, platelets release additional factors such as ADP or thromboxanes that serve a positive feedback role in amplifying platelet activation localized at sites of injury. Platelet shape change occurs rapidly in response to primary and secondary platelet agonists which signal for a rapid reorganization of the platelet cytoskeleton through calcium-dependent and calcium-independent pathways (Fig. 4).

Collagen, GPVI/FcRγ and ITAM-Based Signaling

Following vessel rupture, circulating platelets are activated by basement membrane collagen through binding to the glycoprotein receptor GPVI as well as integrin $\alpha_2\beta_1$, which supports platelet adherence to sites of injury (Clemetson and Clemetson 2001). Upon ligand binding and dimerization, GPVI recruits the Src family tyrosine kinases Fyn/Lyn to phosphorylate and couple to the FcRγ chain complex (Dutting et al. 2012). Phosphorylation of the FcRγ immunoreceptor tyrosine-based activation motif (ITAM) sets forth the activation of Syk, establishing formation of the LAT signalosome, which transduces signals for shape change in response to a variety of collagens (Jarvis et al. 2002; Nieswandt et al. 2000). Studies of collagen and GPVI in platelet shape change make use of GPVI-specific agonists, notably collagen-related peptide (CRP) and GPVI-dimerizing antibodies as well as genetic models that specify roles for GPVI together with FcRγ chain complex in the shape change initiated by collagen (Nieswandt and Watson 2003; Nieswandt et al. 2001). Roles for ITAM-bearing proteins in platelet shape change and platelet function have also been advanced by studies of the snake venom toxin rhodocytin, which triggers platelet shape change and activation through the ITAM-contain ing C-type lectin receptor CLEC-2 (Suzuki-Inoue et al. 2011).

Thrombin and PARs

Following shape change, granule secretion, and the exposure of phosphatidylserine (PS) on the outer leaflet of the plasma

membrane, platelets provide a surface for the generation of thrombin (Bevers et al. 1982), a multifunctional serine protease locally generated at sites of vascular injury which serves as a potent platelet agonist as well as the primary effector protease of the coagulation cascade (Stalker et al. 2014; Monroe et al. 2002). Thrombin activates platelets via the proteolytic cleavage of protease-activated receptors (PARs), G protein-coupled receptors (GPCRs) coupled to G_q and $G_{12/13}$ to trigger shape change, as well as the secretion of secondary platelet activators (ADP, TxA2, serotonin) that further potentiate platelet shape change and localized platelet activation (Coughlin 2000). Of the four PAR family members, PAR1 and PAR4 are expressed by human platelets; mouse platelets express PAR3 and PAR4. PAR1 responds to low-dose thrombin while higher concentrations are needed for PAR4 stimulation. Studies of thrombin and PARs in platelet shape change have been facilitated by selective PAR agonist peptides as well as mouse models of PAR deletions and other signaling mediators downstream of PARs (Sambrano et al. 2001; Wu et al. 2002). For example, the PAR-1 agonist peptide TRAP-6 (SFLLRN) promotes platelet shape change and full platelet activation of human platelets while the PAR-1 interacting peptide YFLLRNP selectively stimulates PAR-1 to elicit shape change independent of calcium mobilization (Rasmussen et al. 1993; Otterdal et al. 2001).

ADP, ATP and the Purinergic P2 Receptors

The platelet purinergic P2 receptors $P2Y_1$, $P2Y_{12}$, $P2X_1$ bind to nucleotides, notably ADP as well as ATP to support platelet activation (Kahner et al. 2006). ADP plays a critical role in platelet activation, hemostasis, and thrombus progression (Born 1985). On its own, ADP is a relatively mild platelet agonist, inducing reversible shape change and weak aggregation; however, the release of ADP from platelets serves an important role in amplifying and reinforcing platelet responses to and within a growing thrombus. After binding to ADP, $P2Y_1$, a G_q-coupled GPCR, promotes the release of calcium from internal stores to result in platelet shape change (Moers et al. 2004). Selective agonist, pharmacological inhibitor and genetic studies have confirmed that $P2Y_1$ is required for calcium mobilization and platelet shape change in response to ADP. ADP also binds to the G_i-coupled GPCR $P2Y_{12}$, well known as the target of clopidogrel and other antiplatelet agents, which couples ADP binding to $G\alpha_i$ activation to inhibit adenylyl cyclase activity, cAMP production, and PKA activation, which serves an inhibitory role in platelet activation and shape change (Offermanns 2006). While the combined efforts of $P2Y_1$ and $P2Y_{12}$ are required for complete platelet activation and aggregation in response to ADP, $P2Y_{12}$ is not required for shape change; $P2Y_{12}$-null platelets undergo shape change but have impaired aggregation in response to ADP. A third platelet purinergic receptor, $P2X_1$, is a ligand-gated, receptor-operated calcium channel that allows for the influx of extracellular calcium into platelets in response to ATP binding. Stimulation of platelets with $P2X_1$-specific agonists leads to increases in cytosolic platelet calcium and reversible shape change (Rolf et al. 2001). Like other P2 receptors, $P2X_1$ has roles in amplifying signals of platelet activation in combination with signals from other agonists and receptors such as collagen and shear-induced aggregation (Varga-Szabo et al. 2009).

Thromboxanes, TP, and Other Prostanoid Receptors

Platelets synthesize and release thromboxane (TxA2) to serve as a short-lived, locally restricted positive feedback activator of platelets (Offermanns 2006). TxA2 binds to the thromboxane receptor TP, a prostanoid GPCR coupled to G_q and G_{13}, resulting in shape change and platelet recruitment to a growing hemostatic plug. In vitro studies of TxA2 take advantage of U46619, a stable, synthetic TP agonist. In vivo, TxA2 is produced from arachidonic acid by COX-1, a well-known target of low-dose aspirin, and thromboxane synthase. Accordingly, aspirin inhibits shape change and aggregation in response to arachidonic acid and is an effective agent in the prevention of arterial thrombosis; however, aspirinated platelets maintain hemostatic functionality and maintain shape change response to a variety of other agonists (Dejana et al. 1980).

Other prostanoid receptors mediate inhibitory effects on platelet shape change and activation (Breyer et al. 2001). Prostacyclin (PGI2) and prostaglandin E1 (PGE1) bind to their own prostanoid GPCRs to increase adenylyl cyclase and cAMP levels in platelets, resulting in platelet inhibition (Best et al. 1977). cAMP activates AKAP-anchored PKA (Raslan et al. 2015), which phosphorylates and inhibits RhoA and RhoA-ROCK2-MLCP signaling, MLC phosphorylation, and shape change (Aburima et al. 2013). Nitric oxide (NO) inhibits platelet shape change through a similar PKA-based mechanism (Jensen et al. 2004).

Other Ligand-Receptor Systems

The activation of several other receptor-ligand systems triggers platelet shape change and shape change-related processes in platelets (Offermanns 2006). CD40 ligand, which binds to the CD40 receptor, activates platelets and shape change, offering a link between inflammation and thrombosis and a connection of platelet shape change in

inflammatory processes (Inwald et al. 2003). Serotonin binds to platelet 5HT-2_A receptors to promote shape change and to enhance the platelet hemostatic response (De Clerck and Herman 1983). Interestingly, epinephrine binds to α2A-adrenergic receptors to support weak platelet aggregation in the absence of a classical shape change (Siess et al. 1984). Interactions of platelets with VWF via the GPIb/V/IX complex cause shear-dependent, cytoskeletal-mediated changes in shape through calcium signaling which support increased rolling velocity (Fig. 5) (Mangin et al. 2003; Maxwell et al. 2006). The interaction of platelets with surface immobilized ligands such as fibrinogen, which promotes actin remodeling through activation of the integrin $\alpha_{IIb}\beta_3$, causes shape change-like processes as platelets attach to such surfaces, forming filopodial extensions and spreading through actin-rich lamellipodial sheets (Fig. 6) (Aslan and McCarty 2013). Integrin $\alpha_{IIb}\beta_3$ signaling is mediated by the ITAM-bearing platelet Fc receptor, FcγRIIa, which also transduces signals to support shape change-like platelet activation (Boylan et al. 2008). While these events are closely related to shape changes and occur in the initial steps of platelet activation by GPCRs and other receptors (Haimovich et al. 1993), critical mediators of platelet activation via integrin $\alpha_{IIb}\beta_3$, including talin (Nieswandt et al. 2007), kindlin3 (Moser et al. 2008), and Rap1 are not required for platelet shape change (Chrzanowska-Wodnicka et al. 2005).

Signaling the Platelet Shape Change

Intracellular signaling pathways downstream of platelet GPCRs, integrins, glycoprotein receptors, and ITAM-bearing receptors support specific facets of the platelet activation program, including platelet shape change (Li et al. 2010). Ultimately, these receptor signaling systems activate both calcium-dependent and calcium-independent pathways to drive changes in platelet shape through the control of myosin light chain phosphorylation and actomysosin contractions that initiate shape change (Fig. 4).

Intracellular Calcium and Phospholipase Signaling

Changes in platelet intracellular calcium concentration have long been known to signal several aspects of platelet function, including platelet shape change (Rink et al. 1982). Early studies demonstrated that the calcium ionophore A23187, which transports divalent cations across cell membranes into the cytoplasm and releases calcium from internal stores, promotes platelet shape change (White et al. 1974). Likewise, EGTA and BAPTA-AM, which chelate intracellular calcium released from intracellular stores during platelet activation, delay shape change kinetics (Bauer et al. 1999). Increases in intracellular calcium levels typically first come about through mobilization of calcium from intracellular stores, followed by another more dramatic increase in intracellular calcium store operated calcium entry (SOCE) mechanisms (Rink et al. 1982; Varga-Szabo et al. 2009). While SOCE provides the majority of cytosolic calcium increases in platelet activation, mobilization from stores alone is sufficient to activate platelets and elicit shape change.

Calcium-centric platelet activation events, including platelet shape change, are strongly tied to the activation of phospholipases PLCβ and PLCγ, which are activated by Gq and ITAM signaling, respectively. PLCs may also be regulated by PI3K/Akt to change the kinetics of intracellular platelet calcium signaling and shape change (Chen et al. 2004). PLC enzymes catalyze the conversion of the inner leaflet plasma membrane phospholipid phosphatidylinositol 4,5-trisphosphate (PIP2) to inositol 1,4,5-trisphosphate (IP3) and 1,2-diacylglycerol (DAG), which serve as second messengers in a number of intracellular signaling processes. After generation from PIP2, IP3 binds to IP3 receptors in the platelet endoplasmic reticulum (ER) membrane to promote the release of calcium from the ER. The ER, also known as the dense tubular system (DTS) in platelets, is the primary store for calcium in platelets (Gerrard et al. 1978) and serves a major role in shape changes mediated by intracellular calcium (Jardin et al. 2008). Nonetheless, the release of calcium from other organelles may contribute to platelet intracellular calcium increases (Lopez et al. 2006). Ultimately, following IP3-mediated release from intracellular stores, cytosolic calcium binds to calcium–calmodulin to activate MLCK, which then phosphorylates MLC to drive actin myosin interactions and shape change (Hathaway and Adelstein 1979) (Fig. 4). Following IP3-trigered release of calcium from the ER/DTS, store-operated extracellular calcium entry (SOCE), mediated by the intracellular calcium sensor stromal interaction molecule 1 (STIM1) and the plasma membrane channel protein Orai1 drive a major influx of extracellular calcium (Varga-Szabo et al. 2009). While SOCE has a major role in raising intracellular calcium in platelets, many aspects of platelet function, including shape change, are preserved in platelets lacking STIM1 or Ora1, suggesting that IP3-mediated release from the ER is sufficient for shape change and other functions. Given the kinetics of SOCE relative to rapid shape change and platelet activation, SOCE is more likely to support roles in thrombus stability, as shown in genetic studies of STIM1 and Ora1knockout mice (Varga-Szabo et al. 2011) and intravital studies of calcium flux in platelets in growing aggregates (Maxwell et al. 2007). Similarly, continued IP3 formation via synthesis of PIP2 by PIP5KI has roles in the stabilization of platelets in aggregates but is not required for an initial shape change (Wang et al. 2008).

RhoA-ROCK Signaling and Calcium-Independent Shape Change

The Ras homologous Rho GTPases cycle between inactive GDP-bound and active GTP-bound states to serve as signaling switches in a number of cytoskeletal process, including platelet shape change (Aslan and McCarty 2013). RhoA signaling, mediated by the Rho-activated kinase (ROCK), plays a requisite role in the calcium-independent platelet shape change downstream of G_{13}-coupled receptor activation (Pleines et al. 2012). The finding that $G\alpha_q$-null platelets fail to mobilize calcium, yet still change shape in response to certain agonists such as thrombin and U46619 ultimately allowed for the characterization of PLC- and calcium-independent mechanisms of platelet shape change (Offermanns et al. 1997). Related studies of $G\alpha_{13}$ and RhoA knockout mice as well as ROCK inhibition have likewise established that PLC- and calcium-independent platelet shape change occur through a G_{13}-RhoA-ROCK-MLCP signaling axis (Paul et al. 1999; Bauer et al. 1999).

Following the activation of G_{13}-coupled GPCRs, including TP and PARs, $G\alpha_{13}$ activates the Rho guanine nucleotide exchange factor p115RhoA-GEF, promoting RhoA-GTP formation and ROCK activation (Fig. 4) (Hart et al. 1998). Active ROCK phosphorylates and inhibits MLCP to drive a net increase in MLC phosphorylation, actomyosin contraction, and platelet shape change in a PLC- and calcium-independent manner (Watanabe et al. 2001). ROCK can also be activated through caspase cleavage in apoptosing cells (Coleman et al. 2001)—including apoptotic platelets—to promote contraction, membrane blebbing, and other cellular phenotypes common to apoptotic cells and activating platelets (Leytin 2012; Aslan and Thomas 2009). Activation of intrinsic, mitochondrial apoptotic pathways in platelets promotes shape change-like responses through ROCK in a caspase-dependent manner (Schoenwaelder et al. 2011; Kile 2014). ROCK similarly has a role in platelet

PS exposure, which also serves as a classic marker of apoptosis associated with blebbing (Dasgupta et al. 2013). Beyond the RhoA–ROCK–MLCP–MLC axis, roles for Rho GTPase family members such as Rac1 in shape change are less established. Rac1, which promotes actin polymerization through WAVE, Arp2/3, and PAK activation, plays an essential role in platelet lamellipodia formation and thrombus stabilization (McCarty et al. 2005). Interestingly, as a component of the LAT signalosome, the Rac1 GEFs Vav1/3 contributes to shape change in ITAM signaling, as discussed later (Pearce et al. 2004; Suzuki-Inoue et al. 2006). This role for Vav may in part be explained by Rac1-mediated PLCγ2 activation and calcium mobilization downstream of GPVI or CLEC-2 engagement (Pleines et al. 2009).

ITAM Signaling and Tyrosine Phosphorylation

Following phosphorylation by Src tyrosine kinases Lyn/Fyn, ITAM-bearing receptors GPVI/FcRγ and CLEC-2 activate Syk to establish the LAT signalosome, consisting of LAT, SLP-76, Vav1/3, PLCγ2, BTK/Tec, and other proteins (Suzuki-Inoue et al. 2006). Calcium mobilization and shape change in response to GPVI and CLEC-2 stimulation requires the activities of several of these signaling mediators, including Syk (Spalton et al. 2009), LAT (Pasquet et al. 1999), SLP-76 (Falet et al. 2000), Vav1/3 (Pearce et al. 2004), and BTK/Tec (Atkinson et al. 2003). The Src kinase inhibitor PP2, which prevents Syk activation downstream of GPVI or CLEC-2, also blocks shape change in response to stimulation of these ITAM-coupled receptors (Polanowska-Grabowska et al. 2003; Severin et al. 2011). Conversely, inhibitors of Src kinases can potentiate platelet shape change downstream of GPCR activation, as specific Src family members such as Fyn may serve negative feedback roles to dampen calcium signaling in response to GPCR agonists (Kim and Kunapuli 2011), suggesting a complex relationship between tyrosine phosphorylation and platelet shape change (Senis 2013; Severin et al. 2012; Senis et al. 2014).

Clinical and Translational Considerations

Platelet Storage

From a translational perspective, platelet shape change is a topic of high relevance to efforts aimed at preparing and banking platelets for transfusion. Stored platelets lose their characteristic resting discoid shape, undergoing cytoskeletal changes, forming pseudopods and shedding microparticles, characteristic of an activated phenotype referred to as the "platelet storage lesion" (Shrivastava 2009). This deleterious effect on platelet quality stems from a combination of factors as platelets remain outside of the circulation, including pH changes, mechanical stress, activation by secreted factors, and metabolic abnormalities (Maurer-Spurej and Chipperfield 2007). Moreover, platelet storage requires subphysiologcial temperatures (ideally between 20 and 24 °C) that result in calcium mobilization, actin assembly, marginal band alterations, and shape change associated with platelet activation (Hoffmeister et al. 2001, 2003; Winokur and Hartwig 1995). Understanding the molecular, metabolic, and physiological bases of shape change may allow for tools to improve the quality and shelf life of stored platelets. Advances of platelet shape assays may provide important quality controls in storage situations. Shape change-based diagnostics may also help to ensure that platelets have normal hemostatic function prior to transfusion or other clinical uses.

Platelet Shape Change in Disease

Given the early role of shape change in the platelet activation program, it is surprising that shape change is not been better developed as a diagnostic marker or therapeutic target for hemostatic and thrombotic complications associated with disease. Here we highlight instances of how shape change may provide insights into the progression, manifestation, and understanding of platelets in disease contexts. In addition to the roles of platelets in the atherothrombotic events of acute myocardial infarction (Badimon et al. 1986), platelet shape change may have roles in atherogenesis, as circulating, activated platelets may exacerbate the progression of atherosclerosis (Huo et al. 2003). In the context of cardiovascular disease, circulating platelets may become activated by oxidized low-density lipoprotein (LDL), which binds to CD36 to drive shape change and platelet activation through both calcium-dependent and calcium-independent mechanisms (Wraith et al. 2013). Atheromatous plaques can also promote platelet shape change through GPVI activation (Penz et al. 2005). Moreover, platelets from hypertensive subjects show an increased propensity to change shape via calcium signaling mechanisms (Erne et al. 1985).

Classic inherited rare platelet disorders are also associated with specific shape change phenotypes, and shape change plays an important role in the diagnosis of such disorders (Diz-Kucukkaya 2013). Platelets from patients with Glanzmann thrombasthenia lack expression of integrins and fail to aggregate but still have detectable shape change. Shape change abnormalities have been described in patients with Bernard–Soulier syndrome (Milton et al. 1985). There is also a common absence of

shape change in patients with Wilson's disease (Owen et al. 1976). Myosin serves a central role in platelet shape change, and *MYH9*-related platelet disorders provide a key example of shape change phenotypes in platelet abnormalities; individuals with a variety of different *MYH9*-related disorders have moderate bleeding tendencies associated with a loss of platelet shape change (Althaus and Greinacher 2009). As the RUNX1 transcription factor mediates the expression of MYL9, mutations in RUNX1 are associated with similar shape change phenotypes (Jalagadugula et al. 2010). Shape change abnormalities are also described in cases of Gray platelet syndrome (Nurden and Nurden 2007) and Hermansky–Pudlak syndrome (Fujimura et al. 1990).

The developing roles of platelets in a number of chronic conditions suggest that assays of shape change may serve as tools in the diagnosis, monitoring, and treatment of conditions associated with inflammation (Semple et al. 2011; Boilard et al. 2012), bacterial infection (Reddi et al. 2015; Fitzgerald et al. 2006), exposure to air pollution (Alshehri et al. 2015), and metabolic disease (Porta et al. 1980). The roles of platelets in tumor metastasis as well as the thrombotic events associated with cancer suggest a role for shape change in understanding platelet–cancer interactions (Menter et al. 2014). Differences in platelet morphology and shape change that occur with aging also provide a potential avenue for future studies.

Conclusions and Future Perspectives

Shape change represents a nearly instantaneous, readily visualized functional response of platelets to a number of stimuli in hemostatic, thrombotic, and other physiological processes. Studies of platelet shape change, through a combination of microscopy, LTA, and other methods, have provided a number of key insights into the fundamental molecular and cellular mechanisms that initiate and regulate platelet function. Through the use of pharmacological and genetic tools, a molecular definition of shape change has begun to emerge, as the phosphorylation of myosin light chain, through calcium-dependent and calcium-independent signaling routes, appears to ultimately gate the decision of platelets to change shape in the platelet activation program. However, while myosin phosphorylation has a central role in the contractile basis of platelet shape change, other cytoskeletal elements, namely, actin filaments and continuously polymerizing microtubules, can also influence platelet shape change and shape change-like behaviors through mechanisms which are less clear. Future studies of the crosstalk between myosin, actin, and tubulin cytoskeletal elements as well as their coregulation by intracellular signaling systems in platelets will help to provide a more complete molecular definition of platelet shape change in the context of the platelet activation program (Sadoul 2015).

Throughout the history of platelet studies, the majority of findings regarding platelet morphology and shape dynamics have come from static, microscopic observations or from semiquantitative LTA measurements of platelets in solution under nonphysiological conditions, defining platelet shape change from an ex vivo perspective. In vivo, studies of platelets null for the expression of key shape change mediators, including MYH9, suggest that shape change has a contractile role in thrombus consolidation and stability rather than in initiating platelet–platelet contacts and aggregation (Canobbio et al. 2005; Leon et al. 2007). A better understanding of the mechanisms and physiological relevance of platelet shape change will come about as the phenomenology of shape change is better detailed in vivo in the context of a growing hemostatic plug or thrombus where secondary platelet agonists function in specific concentration gradients to drive shape changes in aggregate incorporation and consolidation.

Despite some practical and experimental limitations, the analysis of platelet shape dynamics via light transmission aggregometry will likely remain in the platelet research and clinical laboratory toolkit for its ease of use and wide availability. However, a number of other developing, light scattering-based techniques have the potential to more readily provide greater physiologically relevant measurements of the shape change (Mindukshev et al. 2012), particularly in whole blood samples. While such technologies are not likely to replace standard light transmission aggregometry in the near future, the possibility of incorporating light scattering and other optical tools into flow cytometers and other microfluidics platforms to provide systems-level shape and size measurements of platelet populations is intriguing. In addition to light scattering-based approaches to measuring platelet shape, developing microscopy tools will always provide a powerful complement to shape change measurements, and advances in quantitative microscopy acquisition and analyses have the potential to add to data collection and statistical descriptors of resting and activating platelet populations (Kraus et al. 2010, 2014; Phillips et al. 2012). Moreover, as intravital and super-resolution microscopy technologies develop, it will be more readily possible to observe and measure changes in platelet morphology in vivo in the circulation as platelets interact with the superficial layers of a growing thrombus or with a plaque-laden arterial wall. Ultimately, similar approaches will also provide a more coherent, physiologically relevant role for platelet morphological dynamics in classical hemostatic and thrombotic contexts as well as oncological, inflammatory, metabolic, and other disease states.

The Migration of Platelets and their Interaction with Other Migrating Cells

Eleonora Petito, Stefania Momi, and Paolo Gresele

Abstract

Platelets, beyond their well-described role in haemostasis and thrombosis, act as inflammatory cells playing an active role in several inflammatory conditions. As observed with other inflammatory cells platelets can migrate in vitro, either randomly or in the direction of a chemotactic agent, and in vivo, into inflammed tissues in response to different stimuli. In this chapter we will summarize the current knowledge about the mechanisms that regulate platelet chemotaxis, the evidence for the ability of platelets to migrate in vitro and in vivo, and the mechanisms by which platelets influence chemotaxis of other cells.

Introduction

It is now well established that platelets act as inflammatory cells and contribute to both innate and adaptive immune response through several mechanisms, like pathogen binding, trapping and killing, direct modulation of leukocyte and endothelial cell activation, leukocyte recruitment, and activation of antigen presenting cells (APC) (Czapiga et al. 2004; Jenne et al. 2013; Semple et al. 2011; Vieira-de-Abreu et al. 2012) (also see Slaba and Kubes 2017). Platelets are therefore the most abundant circulating cell type (150–400,000/μL) with an immune function and participate in host defence against parasites, bacteria and viruses. Moreover, increasing evidence shows that platelets play a pathogenic role in several chronic inflammatory disorders including atherosclerosis, allergic inflammation (asthma, rhinitis and eczema), chronic obstructive pulmonary disease, rheumatoid arthritis and inflammatory bowel disease.

Several structural and biochemical characteristics allow platelets to act as inflammatory cells (Heijnen and Korporaal 2017; Slaba and Kubes 2017), probably because they retain some functions of their phylogenetic ancestor, the amoebocyte, the unique nucleated cell with defensive and haemostatic functions circulating in the haemolymph of invertebrates (Momi and Wiwanitkit 2017).

One of the crucial functions of "bona fide" inflammatory cells is their ability to migrate through tissues. Platelets display a number of attributes compatible with the ability to migrate: they express receptors for adhesive proteins and chemokines, contain and release matrix metalloproteinases (MMPs) required for extracellular matrix (ECM) degradation, and have the cytoskeletal and enzymatic machinery required for cell locomotion.

In this chapter, we will summarize the in vitro and in vivo evidence of platelet migration in response to chemotactic stimuli and of the role of platelets in tissue recruitment of other cells, including leukocytes and cancer cells.

Chemotaxis is the active movement, or migration, of a cell in the direction of a chemotactic gradient. It is a central event in several physiologic processes, such as embryonic development, tissue repair, angiogenesis and immune response, and the abnormal chemotaxis of the cells contributes to many pathologic conditions, like chronic inflammation, autoimmunity and metastasis. Cell locomotion is a complex and multistep process by which an extracellular chemotactic gradient is detected by a specific cell receptor, a signal is translated to the cell's

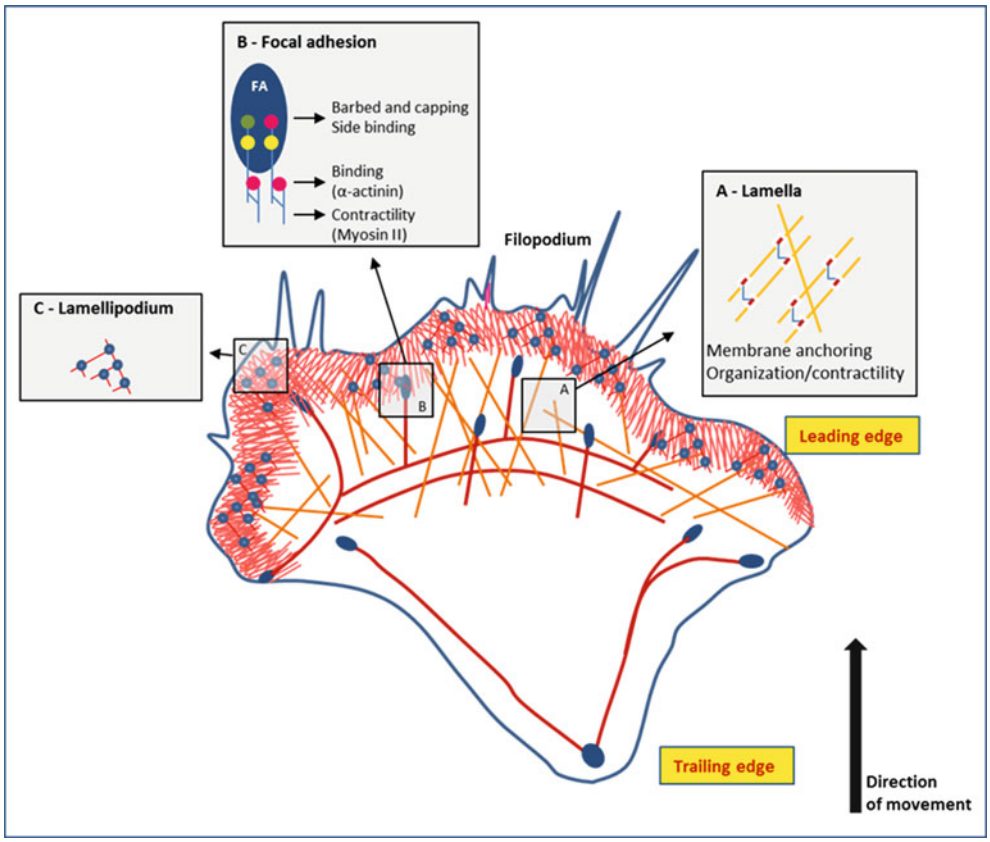

Fig. 1 Cellular polarization. Structural and functional asymmetry of a migrating cell consisting of a leading edge at the front in the direction of movement and a trailing edge at the rear associated with a cytoskeletal organization

motile apparatus and an intracellular functional and structural asymmetry is generated allowing the cell to move towards the detected chemoattractant. Cell polarization is crucial for chemotaxis and consists of the formation of two cellular compartments, the leading edge at the front and the trailing edge at the rear. At the leading edge the cell extends a protrusion, a lamellipodium or filopodium, in the direction of the chemotactic stimulus, which establishes new adhesion sites with the substratum, while at the trailing edge the cell contracts, adhesion sites detach and the uropod, a protrusion at the rear of the cell, retracts. In each of these steps several proteins and intracellular signaling pathways are involved and a fundamental role is played by the cytoskeleton and its ability to rapidly assemble and disassemble (Fig. 1) (Charest and Firtel 2007; Germena and Hirsch 2013; Jin 2013; Raftopoulou and Hall 2004).

Structural Characteristics Ascribing to Platelets the Ability to Migrate

Platelets possess all the structural characteristics required for chemotaxis. They express on their surface several functional chemokine receptors, such as CCR1, CCR3, CCR4, CXCR1, CXCR4, CXCR6, CXCR7 and CX3CR1 (Abi-Younes et al. 2000, 2001; Borst et al. 2012; Chatterjee et al. 2014; Clemetson et al. 2000; Kowalska et al. 1999, 2000; Postea et al. 2012; Rath et al. 2014; Schafer et al. 2004; Suttitanamongkol and Gear 2001; Wang et al. 1998) and other receptors involved in leukocyte migration, like Toll-like receptor 4 (TLR4) and formyl peptide receptors (FPR) (Andonegui et al. 2005; Cognasse et al. 2005; Czapiga et al. 2005).

Platelets possess the central components of chemotaxis-related intracellular signaling, and in particular phosphatidylinositol 3-kinase (PI3K) and phosphatase and tensin homologue deleted on chromosome 10 (PTEN) that regulate the production and cellular localization of phosphatidylinositol 3,4,5-trisphosphate (PIP3), which is crucial for the generation and maintenance of cell polarity (Van Keymeulen et al. 2006), and the Rho family of small GTPases that activate a plethora of effector molecules modulating actin cytoskeleton dynamics (Germena and Hirsch 2013; Worthylake and Burridge 2001; Yan and Jin 2012).

Platelets contain a cytoskeletal framework that allows cell movement. The discoid shape of platelets is maintained by a membrane skeleton that coats internally the plasma membrane, composed by a network of actin filaments, spectrin, adducin, and actin-associated proteins, and by a rigid cytoplasmic scaffold made of actin and filamin A. Actin-associated proteins and filamin A link the platelet cytoskeleton to integrins. Platelet activation induces changes

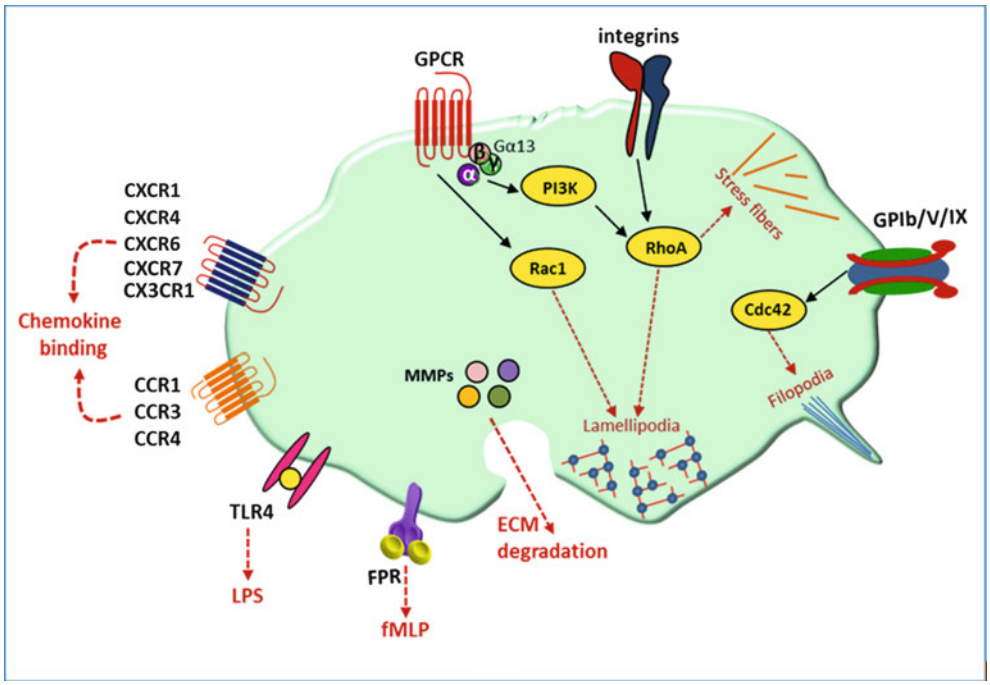

Fig. 2 Structural characteristics ascribing to platelets the ability to migrate. Platelets express on their surface several receptors triggering chemotaxis. Platelets possess the main components of chemotaxis-related intracellular signalling, involved in cell polarization and cytoskeletal re-organization. Platelets contain and release upon activation different MMPs involved in the ECM degradation required for their passage through the basement membrane

in the cytoskeletal organization with the formation of focal adhesion complexes, dynamic structures linking integrins to the actin cytoskeleton and which together with stress fibres contribute to a contractile response (Goggs et al. 2015; Hartwig 2006).

Platelets contain, and release upon activation, several MMPs, including MMP-1, -2, -3, and -14 (Seizer and May 2013; Busti et al. 2010), which may accomplish the extracellular matrix degradation required for the passage of migrating cells through the basement membrane (Fig. 2).

Platelet Migration: Studies In Vitro

The first in vitro observations on the ability of platelets to migrate date back to the early 70s. Before then, platelets were considered cell fragments passively drifting in the circulation until a contact with an area of damaged endothelium stopped them. The motion of platelets occasionally observed under a light microscope was considered as passive diffusion or Brownian movements, i.e. a temperature-dependent, erratic, not directional movement of particles smaller than 4–5 μm observed in colloidal suspensions (Chamot and Mason 1947).

The first studies on platelet migration in vitro assessed the optimal conditions to study platelet movement showing that several factors, such as temperature, pH, anticoagulant, platelet concentration and buffer composition, influence this process (Lowenhaupt et al. 1977; Nathan 1973; Valone et al. 1974) (Table 1).

Methods

Lowenhaupt and Valone were the first to study platelet migration (Lowenhaupt et al. 1973, 1977; Lowenhaupt 1978; Valone et al. 1974). Lowenhaupt adapted the capillary tube migration chamber previously described by George and Vaughan for the study of macrophage migration (George and Vaughan 1962). This consisted of an incubation chamber with a capillary tube immobilized at the bottom. The incubation chamber was composed of a stainless steel slide (75 × 25 × 3 mm) with a center hole 20 mm in diameter and one side sealed by a siliconized glass slide to form a dish and two small channels connecting it to the edge of the slide (Fig. 3a). A siliconized micro-hematocrit capillary tube, fire-sealed at one end, was filled with platelet-rich plasma (PRP) (300,000 platelets/μL) and centrifuged for 5 min. The capillary tube was then cut at the meniscus between platelet poor plasma (PPP) and the platelet pellet and secured to the bottom of the incubation chamber. The chamber was then filled with autologous PPP, covered with a siliconized cover glass and incubated at 22 °C for 18 h in a CO_2 incubator in order to maintain pH between 7.2 and 7.4. To investigate platelet chemotaxis, in the same incubation chamber, a thread-like piece of collagen or a fine-collagen-packed capillary tube was placed at a distance of about 5–6 mm from the platelet-packed capillary tube. The end point was the area of platelet migration out of the capillary tube visible by a stereomicroscope and measured with a planimeter (Lowenhaupt et al. 1973).

Table 1 Methods used to study platelet migration in vitro and optimal experimental conditions

Parameter	Optimal condition	Method	References
Temperature (°C)	22	Capillary tube[a,b]	Lowenhaupt et al. (1973, 1977, 1982) and Lowenhaupt (1978)
		7-compartment chamber[a]

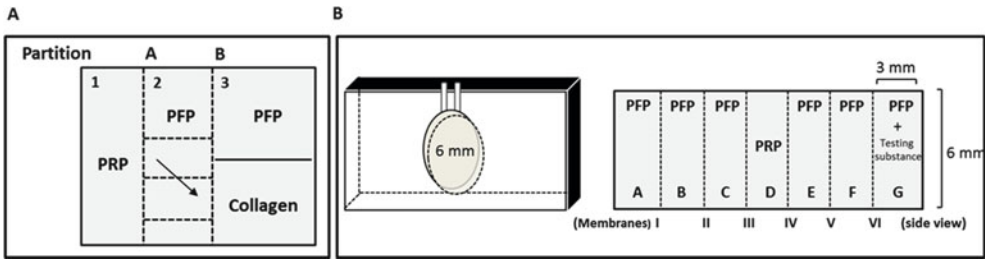

Fig. 4 (**A**) Diagram of the micromaze. PRP is placed in compartment 1, PFP in compartments 2 and 3 and collagen suspended in PFP in compartment 4. (**B**) Seven-compartment chamber. (*sx*) A basic unit of the seven-compartment chamber. (*dx*) The linearly connected 7-compartment chamber showing contents in each compartment

Valone instead studied platelet migration by adapting the Boyden chamber initially developed for the study of leukocyte chemotaxis (Boyden 1962) (Fig. 3b). This is a perspex chamber composed of two compartments separated by a filter membrane 100 μm thick with pores of 8 μm size. A platelet suspension in standard buffer (0.005 M KH_2PO_4, 0.005 M Na_2HPO_4, 0.1 M NaCl, 0.2 g/100 mL glucose and 0.5 g/mL gelatin) (100,000/μL) was placed in the upper compartment and buffer medium in the lower compartment. After 3 h of incubation the filter was removed, washed, fixed in 10 % formalin, stained, cleared and mounted on a glass slide. Platelets migrated into the filter were counted in 10 high-power fields by phase-contrast microscopy at a fixed level (40–70 μm from the top of the filter) (Valone et al. 1974).

Directional migration of platelets towards a chemotactic gradient was also studied with the micromaze method (Lowenhaupt 1978) or the 7-compartment chamber using indium^{111}-oxine-labeled platelets (Lowenhaupt et al. 1982). The micromaze is a chamber formed by four compartments connected by thin slits to permit cell passage between compartments; collagen was placed in compartment 4 (Fig. 4a). Platelet movement was visualized by an inverted phase-contrast microscope by following the leading edge of the platelet mass or by viewing the passage of individual platelets between compartments through the slits: time-lapse image sequences were taken at fixed intervals (Lowenhaupt 1978). The 7-compartment chamber consists of seven identical compartments linearly connected and separated by Nucleopore or Millipore filters of different pore size (III and IV 3 μm, II and V 1 μm, I and VI 0.45 μm); collagen was placed in compartment G (Fig. 4b). Gel-filtered platelets were labeled with ^{111}In-oxine, resuspended in autologous platelet-free plasma (PFP) and filtered through two sterile nylon mesh filters to remove aggregates. Platelet chemotaxis was expressed as a ratio of the radioactive counts of the two-end compartments (Lowenhaupt et al. 1982).

More recently platelet chemotaxis has been studied using several further modifications of the original Boyden chamber, namely:

1. The NeuroProbe 96-well ChemoTx microplate, with the upper and lower compartments separated by a 2 μm pores filter. After 2 h of incubation, platelets migrated into the lower compartment were counted by light microscopy (Czapiga et al. 2005).
2. The Nucleopore single wells, with the upper and lower compartments separated by a 3 μm pore size filter, loaded with murine or human PRP. After 1.5 or 3 h incubation, respectively, filters were stained and platelets were counted at various depths below the filter surface (0–100 μm for murine and 40–70 μm for human platelets) (Pitchford et al. 2008).
3. The transwell inserts, with a polyethylene terephthalate (PET) membrane with 0.4 μm pores. Platelets were added in the upper compartment, allowed to migrate

for 8 h and then counted in the lower compartment by flow cytometry (Kraemer et al. 2010).

Horizontal migration of platelets has been studied in a delta T culture dish placed on a microscope with a heated stage and platelet movements were recordedbefore and during the addition of either fMLP or PBS (as a control) every 5 s for 15 min (Czapiga et al. 2005), or in a migration chamber consisting of a fibrinogen-coated slide with a central spot of low-melting agarose containing the chemotactic agent and platelet movement were recorded using a polarization microscope for 3 h (Kraemer et al. 2010).

The assays used to study platelet migration are summarized in Table 1.

Chemotactic Agents

Platelets can detect an extracellular chemotactic gradient and move along this gradient. The first platelet chemotactic agent to be described has been collagen. Various types of collagen (bovine, equine, human from skin or from achilles tendon) elicit platelet chemotaxis, although with different potency. Only native collagen, and not heat-denatured or dinitrofluorobenzene-treated collagen, induces platelet chemotaxis. Interestingly, the structural features of collagen required for platelet aggregation, i.e. the fibrillar structure, are not required for chemotaxis. Collagen-induced platelet chemotaxis does not require a direct contact with platelets, given that migration was still observed when a filter impermeable to the large polymerized collagen molecules was interposed between platelets and the stimulus. Thus, the generation of "chemotaxins", low molecular weight substances produced by the interaction between collagen and plasma, was postulated (Lowenhaupt 1982). Platelets migrated in the direction of collagen for a long distance (3000 times their diameter, i.e. 6 mm) in a very short time (15 min) (Lowenhaupt 1978).

Formyl peptides, cleavage products of bacterial and mitochondrial proteins, induce platelet chemotaxis via binding to formyl peptide receptors (FPR), seven transmembrane receptors coupled to Gαi stored in α-granules and expressed on the platelet surface after activation (Czapiga et al. 2005). Platelet movement towards fMLP at a velocity of 13.07 ± 1.10 μm/min has also been recorded in time-lapse (Czapiga et al. 2005).

Recently, platelet chemotaxis towards a conventional chemokine of the CXC family, CXCL12 or stromal cell-derived factor-1α (SDF-1α), has been shown (Kraemer et al. 2010). This chemokine induced platelet migration upon binding to its specific receptor CXCR4 expressed on platelets, given that the CXCR4-receptor antagonist AMD3100 inhibits it. Platelets also trans-migrate through an IL-1β-activated layer of human umbilical vein endothelial cells (HUVEC) in the direction of SDF-1α (Kraemer et al. 2010). In time-lapse studies platelets accumulated around the source of SDF-1α after 3 h, with a speed of migration variable depending on the number of focal adhesion contacts. In the early stages of migration (fast migration: 200 μm/3 h) platelets have only few focal adhesion contacts, while their number increases as migration speed slows down (Kraemer et al. 2010).

Molecular Mechanisms Regulating Platelet Migration

Platelet migration is an active, energy-consuming process that requires viable and metabolically intact platelets. Infact, fixation with formalin or pre-treatment with iodoacetic acid (IAA) and sodium fluoride (NaF), which interfere with the glycolytic pathway, with 2,4-dinitrophenol (DNP), which uncouples oxidative phosphorylation, and with 6-aminonicotinamide, which suppresses the hexose monophosphate shunt, blocks platelet migration (Valone et al. 1974; Lowenhaupt et al. 1977). As expected cytochalasin B, which disrupts actin filaments, inhibited migration, while colchicine, which interferes with the polymerization of microtubules, did not (Lowenhaupt et al. 1977).

Platelet migration triggered by SDF-1α is mediated by PI3K, given that the PI3K inhibitors wortmannin and LY294002 significantly inhibited it. PI3K phosphorylates Wiskott-Aldrich syndrome protein (WASP) that induces the rearrangement of the actin cytoskeleton (Kraemer et al. 2010). Downstream signaling linking PI3K to platelet migration involves the serum- and glucocorticoid-inducible kinase 1 (SGK1), known to be involved in endothelial cell and monocyte/macrophage migration (Borst et al. 2015; Zarrinpashneh et al. 2013). The importance of SGK1 in platelet migration seems to be connected to its ability to regulate the actin cytoskeletal architecture in fact WASP and vinculin, two proteins interacting with actin, are SGK1-sensitive. WASP activates the Arp 2/3 complex that binds actin, thus inducing its polymerization, and vinculin is an actin-binding protein that, when phosphorylated, stabilizes the focal adhesions (Kraemer et al. 2010; Schmidt et al. 2012). SGK1-deficient platelets show impaired migration, reduced WASP activation and enhanced vinculin phosphorylation (Schmidt et al. 2012).

Platelet migration is dependent on the increase of intracellular Ca^{2+} via the Ca^{2+} channel Orai1, the pore forming unit of the store-operated Ca^{2+} entry (SOCE) channel, and on K^+ efflux via the Ca^{2+}-activated K^+ channel SK4 (Schmidt et al. 2011).

Platelets adhering to a fibrinogen-coated surface and then exposed to high shear conditions ($1500\ s^{-1}$) undergo

polarization, cytoskeletal reorganization with increased WASP phosphorylation and redistribution of intracellular focal adhesion kinases (FAK) to areas of dynamic focal adhesions, and migration in the direction of flow at a speed of approximately 10 μm/h (Kraemer et al. 2011).

Platelet Migration in Disease

Platelet migration has also been studied in disease conditions and/or in response to various pathologic stimuli. Duquesnoy in 1975 described a platelet migration inhibition (PMI) assay to detect antibodies in serum directed against the human leukocyte antigen (HLA) and the platelet-specific antigen Pl-A1 (Duquesnoy et al. 1975), or alloantibodies against platelets in platelet-transfused patients (Levine and Brubaker 1983). This assay was a modification of the capillary tube chemotaxis chamber used by Lowenhaupt et al. (1973) and it tested the capacity of antibodies to inhibit platelet migration by mixing control PRP with patient's serum. The sensitivity of the PMI test was reported to be comparable or even greater to that of several other methods used for the detection of platelet antibodies, such as the platelet lysis assay, complement fixation, platelet aggregometry and platelet factor-3 release (Duquesnoy et al. 1975; Levine and Brubaker 1983).

Platelets from allergic asthmatic subjects, but not from healthy donors, concentration-dependently migrated in vitro in response to the specific sensitizing allergen and in response to a monoclonal anti-human IgE antibody. In asthmatic subjects allergen-specific IgEs, produced upon previous contact with the allergen and bound to the platelet high-affinity receptor for IgE, FcεRI, bind the allergen inducing the cross-linking of contiguous receptors thus triggering platelet chemotaxis (Pitchford et al. 2008). The same phenomenon is triggered by an anti-IgE antibody that, binding to contiguous Fc portions of FcεRI-bound IgEs, induces the cross-linking of the receptors. The crosslinking of IgE receptors on platelets was previously shown to trigger other platelet functional activities, such as cytotoxicity (Polack et al. 1991), oxygen radical formation (Vargas et al. 1999) and release of chemokines (Hasegawa et al. 2001; Klouche et al. 1997). Migration of platelets from ovalbumin (OVA)-immunized mice in response to the sensitizing allergen was also demonstrated (Pitchford et al. 2008).

Platelet Chemotaxis: Studies in Animal Models

Studies in animal models confirm the ability of platelets to migrate into inflammed tissues. Extravascular accumulation of platelets in bronchial tissue and in lungs, associated with bronchospasm, has been observed by electron microscopy or

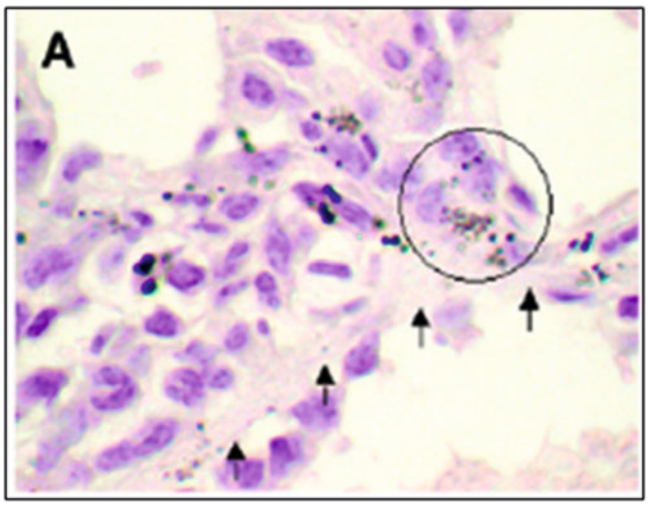

Fig. 5 Individual platelets (*arrows*) migrated in lung parenchyma after mouse allergen challenge. Reprinted with permission of the American Thoracic Society. The American Journal of Respiratory and Critical Care Medicine is an official journal of the American Thoracic Society

by the accumulation of ^{111}In-oxine-labelled platelets in guinea pigs and baboons after intravenous challenge with platelet-activating factor (PAF) and other platelet agonists, like ADP or collagen. The penetration of platelets in tissue was not the consequence of blood extravasation, as no other blood cells were concomitantly found (Arnoux et al. 1988; Lellouch-Tubiana et al. 1985; Page et al. 1984; Robertson and Page 1987). The presence of platelets in skin accompanied by neutrophils was also described after the intradermal injection of PAF in rats (Pirotzky et al. 1984).

Platelets have also been detected in bronchoalveolar lavage (BAL) fluid of mice with chronic allergic airway inflammation (Pitchford et al. 2004) and from rabbits with experimental asthma, following allergen-challenge (Coyle et al. 1990).

Platelets from OVA-immunized mice were observed to migrate out of blood vessels after allergen inhalation and to localize in lung parenchima, directly underneath the airways (Fig. 5). Platelet influx in tissue preceded leukocytes and was largely independent of the latter (Pitchford et al. 2003, 2005). Platelet migration into inflammed lung was shown to be mediated by the binding of allergen to FcεRIγ-bound allergen-specific IgEs on the platelet surface (Pitchford et al. 2008), a phenomenon previously described for other inflammatory cells such as eosinophils, basophils and mast cells (Ishizuka et al. 2001; Orida et al. 1983; Svensson et al. 2004).

Transendothelial migration of platelets into the skin of guinea pigs induced by the subcutaneous injection of fMLP was demonstrated by serial electron-microscopy of thin tissue sections (Feng et al. 1998b). In that study it was shown

that platelets crossed endothelial cells not at the level of interendothelial cell junctions, which remained closed. However, platelets have been demonstrated to extend pseudopods suggesting active diapedesis. Moreover, single platelets enclosed within endothelial cytoplasmic vacuoles, generally located close to interendothelial cell junctions, were observed and the platelet-containing vacuoles were observed to open to the abluminal surface whereupon platelets were discharged into the underlying basal lamina. Following transmigration across the basal lamina, platelets were found free in dermal connective tissue, together with neutrophils and other white cells. Interestingly, migrating platelets did not display the ultrastructural features of a release reaction, suggesting that conventional platelet activation is not required for platelet migration (Feng et al. 1998b).

The mechanism of transmigration observed in this model, i.e. that platelets cross undamaged endothelium by a process similar to pinocytosis, has been previously described for neutrophils (Feng et al. 1998a). This mechanism does not necessarily apply to all stimuli-inducing diapedesis and active migration through interendothelial cell junctions may also take place (Laitinen 1993; Marchesi 1966).

Platelet translocation into the Disse spaces of the liver and their active penetration into hepatocytes have been reported by immunostaining for 5-hydroxytryptamine (5-HT), a sensitive method to detect platelets in tissue as platelets contain large amounts of 5-HT, and by electron microscopy (Nakamura et al. 1998). Platelets in the Disse spaces of lipopolysaccharide (LPS)-treated mice were in contact with Kupffer cells (hepatic macrophages) (Nakamura et al. 1998; Yamaguchi et al. 2006). This process seems to involve biochemical pathways different from those involved in aggregation, given that anti-platelet agents, including aspirin, did not prevent hepatic platelet accumulation (Nakamura et al. 1998).

In a murine model of corneal abrasion, diapedesis of platelets out of vessels was demonstrated with accumulation of platelets in the limbus where they actively contribute to corneal nerve regeneration. The accumulation of platelets was mediated by P-selectin (Li et al. 2011), an adhesion molecule that also plays a role in the accumulation of platelets in glomeruli in a murine model of glomerulonephritis (Zachem et al. 1997). Activated platelets, alone or together with neutrophils, were found by immunofluorescence within glomeruli of rats with nephritis induced by the selective perfusion of the renal artery with the lectin concanavalin A (Zachem et al. 1997).

In a model of ligation of intestinal arteries in mice, green fluorescent protein (GFP)-labeled platelets were observed in areas of post-ischemic inflamed tissue, where they could function as pilot cells that guide the invasion of other inflammatory cells. This mechanism was mediated by SDF-1α involving signalling through PI3K and activation of SGK-1 (Kraemer et al. 2010). Furthermore, SGK-$1^{-/-}$ mice showed decreased platelet transmigration into the ischemic intestinal vascular wall (Schmidt et al. 2012).

Platelet Chemotaxis: Studies in Humans

Despite the difficulty in detecting platelets in tissue using histology with conventional staining techniques, due to the small dimensions and the lack of a nucleus, observations using electron microscopy and/or immunological staining confirm the ability of platelets to transmigrate into tissues in humans with inflammatory conditions.

Platelets were found in BAL of patients with allergic asthma following allergen challenge without the concomitant presence of erythrocytes, confirming active diapedesis and not passive transfer due to blood extravasation, with some degranulated platelets and free granules in the lavage (Metzger et al. 1985, 1987). Platelet aggregates have also been observed in the lamina propria of the microvasculature of lungs of asthmatic subjects by transmission electron microscopy during late-onset airways obstruction following allergen provocation, in apposition to areas of bronchial smooth muscle, underneath the epithelium, and in areas of eosinophil infiltration (Beasley et al. 1989).

Extravascular platelets, colocalized with leukocytes, have been detected by immunofluorescence in surgically excised nasal polyps from patients with aspirin-exacerbated respiratory disease (AERD), a chronic inflammatory disorder characterized by nasal polyposis and asthma triggered by the ingestion of aspirin (Laidlaw and Boyce 2012).

Platelets were also identified by immunohistochemistry in brain tissue sections from patients with multiple sclerosis with active demyelinating plaques and by confocal immunofluorescent microscopy in a chronic active type 1 lesion (active inflammation and demyelination) (Langer et al. 2012).

Electron microscopy of the synovium of patients with rheumatoid arthritis (RA) showed platelet thrombi obliterating the lumen of vessels and platelets were observed in the vicinity of gaps between endothelial cells of the joint vasculature (Schumacher 1975). Positive staining for $\alpha_{IIb}\beta_3$ outside the vasculature was detected using immunohistochemistry of the synovium from patients with RA, representing either platelets or platelet-derived microparticles (PMPs) (Konttinen et al. 1989; Palmer et al. 1986). Moreover, platelets, platelet aggregates and platelet-leukocytes complexes have been shown in the synovial fluid of patients with RA suggesting active migration into extravascular sites (Endresen 1981; Endresen and Forre 1992; Farr et al. 1984; Ginsberg et al. 1978; Yaron and Djaldetti 1978).

Platelet Contribution to the Chemotaxis of Other Cells

Platelets influence the migration of other cells by releasing soluble chemotactic mediators, by liberating PMPs, or by direct contact with the involved cells (Fig. 6).

Platelet lysates enhanced cell migration of several hepatocellular carcinoma cell lines (Carr et al. 2014) and fibroblasts (Carducci et al. 2016; Senior et al. 1983), and adherent activated platelets stimulated the migration of murine embryonic endothelial progenitor cells (EPC) (Langer et al. 2006).

Platelets contain and release upon activation several soluble mediators influencing cell migration (Table 2). Among them chemokines, which represent a significant fraction of the platelet α-granules content, are released upon platelet activation and mediate the recruitment of several cells to sites of inflammation, including leukocytes, cancer cells and hematopoietic cells, thus favouring neointima formation and atherosclerosis, vessel repair and regeneration after vascular injury (Gleissner et al. 2008). CXCL4/platelet factor 4 (CXCL4/PF4), the first member of the chemokine family discovered in platelets and the most abundant platelet chemokine (Deuel et al. 1977), and CXCL7/neutrophil-activating peptide-2 (CXCL7/NAP-2) purified from supernatants of thrombin-stimulated platelets induce neutrophils to undergo firm adhesion on an endothelial cells monolayer in a concentration-dependent manner. CXCL7 also stimulates neutrophil transendothelial migration (Petersen et al. 1999; Schenk et al. 2002). Furthermore, CXCL7 and CXCL5/epithelial neutrophil-activating protein 78 (ENA-78), secreted by activated platelets upon contact with tumor cells, induce

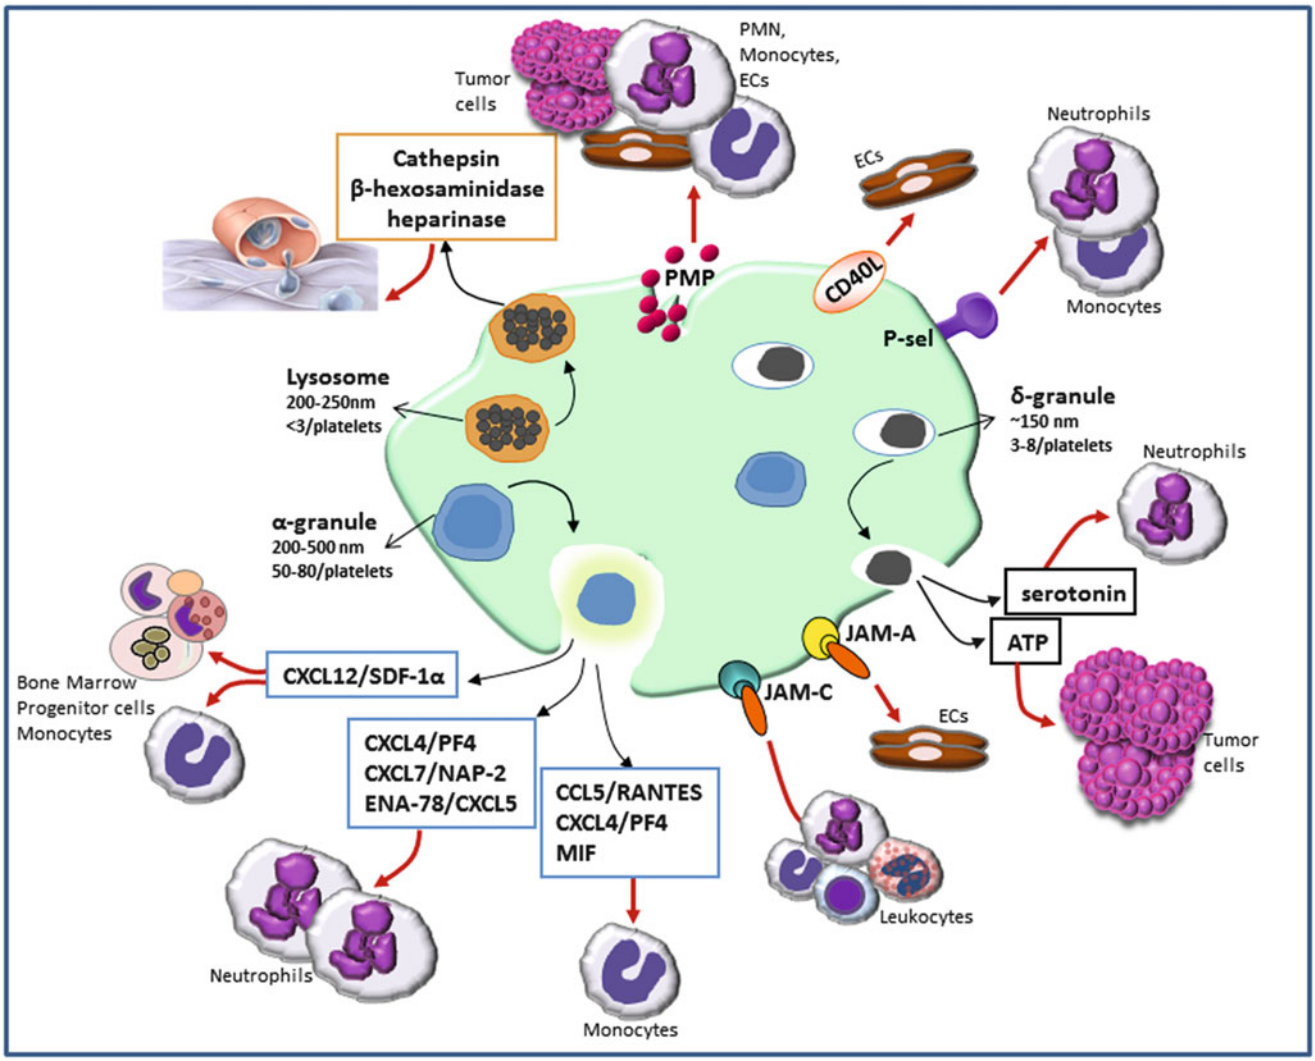

Fig. 6 Platelet contribution to the chemotaxis of other cells. Platelets play an active role in the induction of chemotaxis of other cells by releasing, upon activation, soluble mediators contained in their granules (α, δ and lysosomes), by liberating PMPs, and by expressing surface receptors favouring cell–cell interactions

Table 2 Soluble platelet-derived inflammatory mediators and platelet surface proteins that modulate cell migration

Soluble platelet-derived mediators	Responding cells
α-granules	
CXCL4/PF4	Neutrophil firm adhesion on the endothelium
CXCL7/NAP-2	Neutrophil firm adhesion on the endothelium and trans-migration
	Formation of the early metastatic niche
CXCL12/SDF-1α	Adhesion and migration of bone marrow progenitor cells
	Monocyte adhesion and chemotaxis
CXCL5/ENA-78	Neutrophil migration
	Formation of the early metastatic niche
CCL5/RANTES	Monocyte adhesion on the endothelium and recruitment
MIF	Monocyte arrest on the endothelium and chemotaxis
Dense granules	
Serotonin	Neutrophil and T-cell recruitment
ATP	Tumor cell transendothelial migration and metastasis
Lysosomes	
Cathepsin, heparinase, β-hexosoaminidase	Cell diapedesis by remodeling the inflammed tissue
PMPs	Neutrophil and monocyte adhesion to the endothelium
	Chemotaxis and invasion of breast and lung cancer cells
	Chemotaxis of hematopoietic stem/progenitor ($CD34^+$) and various myeloid and lymphoid cells
Platelet surface proteins	
CD40L/CD154	Endothelial cell activation
CD40	T cell recruitment
P-selectin	Monocyte and neutrophil rolling and adhesion to the endothelium
JAM-A	Platelet adhesion to the endothelium
JAM-C	Firm adhesion of leukocytes on adherent platelets

granulocyte migration and guide the formation of the early metastatic niche (Labelle et al. 2014). Activated platelets are a major source of CXCL12/SDF-1α (Chatterjee and Gawaz 2013). Platelet-derived CXCL12 supports adhesion of CD34+ human progenitor cells (PCs) under static conditions and facilitates the rolling and firm adhesion of CD34+ cells onto platelets adhered to a layer of human aortic endothelial cells (HAEC) under high shear rate in vitro and in vivo (Stellos et al. 2008). Platelet-derived CXCL12 also enhances the adhesion and migration of bone marrow progenitor cells to sites of vascular injury thereby promoting repair (Massberg et al. 2006). Furthermore, CXCL12 released by activated platelets induces monocyte chemotaxis by acting on CXCR4 and monocyte adhesion under static and dynamic arterial flow conditions by acting on CXCR7 (Chatterjee et al. 2015). CCL5/regulated on activation normal T cell expressed and secreted (CCL5/RANTES) secreted by activated platelets and immobilized on the inflamed/activated endothelium of atherosclerotic arteries induces adhesion of monocytes (Mause et al. 2005; Schober et al. 2002; von Hundelshausen et al. 2001). Platelets under shear flow deposit CXCL4 and CCL5 on atherosclerotic or IL-1β-activated HAEC, enhancing the recruitment of monocytes to the endothelium (Baltus et al. 2005; Huo et al. 2003). Moreover, platelet-derived macrophage migration inhibitory factor (MIF) stimulates monocyte arrest on endothelium and chemotaxis (Wirtz et al. 2015).

Platelet-derived IL-1β induces the secretion of CCL2/monocyte chemottractant protein-1 (MCP-1) and increases the expression of intracellular adhesion molecule-1 (ICAM-1) by endothelial cells, promoting the adhesion of monocytes to the endothelium and their chemotaxis; in fact MCP-1 is a potent chemotactic factor for monocytes (Gawaz et al. 2000). Platelet-derived IL-1 induces the release of CXCL1 and CXCL8 from endothelium, which in turn induces neutrophil recruitment (Page and Pitchford 2013; Kaplanski et al. 1993; Thornton et al. 2010).

Platelet dense-granules contain serotonin, a vasoactive inflammatory mediator that can induce vascular permeability and promotes the recruitment of neutrophils into lung and peritoneum, after intraperitoneal and intratracheal LPS administration, and in aseptic skin wounds (Duerschmied et al. 2013), and the recruitment of T cells into the liver during viral hepatitis-induced hepatic injury (Lang et al. 2008). Platelet-derived ATP promotes tumor cell transendothelial migration and metastasis via stimulation of P2Y2 receptors (Schumacher et al. 2013).

Platelet release lysosomal enzymes, such as cathepsin, β-hexosoaminidase and heparinase, in vivo in humans at a localized site of vessel wall damage (Ciferri et al. 2000; Vlodavsky et al. 1992), and these may participate in cell diapedesis due to their tissue-degrading activity and by remodelling the inflammed tissues, a role already demonstrated to be involved in the migration of fibroblasts,

cancer and endothelial cells (Mohamed and Sloane 2006; Palka et al. 1997; Schraufstatter et al. 2003)

PMPs play an important role in tissue recruitment of inflammatory cells by the interaction between P-selectin expressed on their surface and P-selectin glycoprotein ligand-1 (PSGL-1) on neutrophils (Forlow et al. 2000) and simultaneously by their adhesion to the subendothelial matrix through integrin $\alpha_{IIb}\beta_3$ (Merten et al. 1999). PMPs stimulate monocyte adhesion also by inducing endothelial cells (ECs) to express ICAM-1 and by delivering chemokines, such as RANTES, to the endothelium (Barry et al. 1998; Mause et al. 2005). In addition, PMPs transport cytokines (e.g. IL-1β) that stimulate polymorphonuclear cells (PMNs) adhesion to ECs and miRNAs that may modify the phenotype of endothelial cells (Gidlof et al. 2013) and macrophages (Laffon et al. 2016). PMPs enhance the chemotaxis of invasive breast and lung cancer cells and stimulate their invasion across Matrigel by inducing MMPs production. Furthermore, PMPs act as chemotactic agent for hematopoietic stem/progenitor ($CD34^+$) cells as well as for various myeloid and lymphoid cells (Baj-Krzyworzeka et al. 2002; Janowska-Wieczorek et al. 2005, 2006).

Platelets express upon activation a number of surface proteins involved in heterotypic interactions with endothelial cells and leukocytes, mediating the rolling and adhesion of leukocytes to the endothelium and the subsequent transmigration into inflammed tissue (Gawaz et al. 2005; Weyrich and Zimmerman 2004). The formation of platelet-neutrophil and platelet-monocyte complexes, the subsequent neutrophil and monocyte adhesion to the endothelium and recruitment into the inflammed tissue is dependent on platelet P-selectin (Page and Pitchford 2013), mediated by its binding to the high affinity counter ligand PSGL-1 (Hamburger and McEver 1990; Moore et al. 1995; Kuijper et al. 1998). High-resolution videomicroscopy has revealed the existence of membrane tethers involving P-selectin/PSGL-1 bonds that regulate neutrophil rolling on platelets (Schmidtke and Diamond 2000). The importance of platelet P-selectin/PSGL-1 axis has been determined by the use of P-selectin-deficient mice, by the blockade of P-selectin or with PSGL-1 antibodies (Abdulla et al. 2012; Diacovo et al. 1996; Mayadas et al. 1993; Pitchford et al. 2005).

Platelet CD40 ligand (CD40L/CD154) binds CD40 on endothelial cells and enhances the release of IL-8 and MCP-1, the expression of E-selectin (CD62-E), Vascular Cell Adhesion Protein-1 (VCAM-1) and ICAM-1, and the release of matrix metalloproteinases (e.g., MMP-1, -2, -3, and -9). Furthermore CD40L-positive T cells activate platelets through a CD40-dependent pathway resulting in CCL5 release and T cell recruitment (Danese et al. 2004; Henn et al. 1998; Giannini et al. 2011).

Platelet Junctional Adhesion Molecule (JAM-A) can support homophilic interactions with endothelial-cell JAM-A, mediating platelet adhesion to the endothelium (Babinska et al. 2002), thus facilitating the deposition on endothelium of platelet CCL5/RANTES (Zernecke et al. 2006). Platelet JAM-C functions as a counter-receptor for the β2-integrin Mac-1 on neutrophils mediating firm adhesion of leukocytes to adherent platelets (Santoso et al. 2002).

Conclusions

Among the functions that characterize platelets as inflammatory cells, one which is little considered but is probably crucial is the ability to migrate into tissue in the direction of a chemotactic stimulus. This allows platelets to actively participate in the tissue inflammatory process by releasing stored or newly synthesized mediators acting both on other platelets and/or on other cell types. Furthermore, platelets influence and sometimes are essential for the migration of other inflammatory cells, including leukocytes and cancer cells.

This "non-classical" platelet activity is an example of the existence of a dichotomy in platelet function, i.e. the ability of platelets to display an inflammatory or a haemostatic/thrombotic response depending on the stimulus and on the environment, recently elegantly demonstrated investigating the role of different purinergic receptor subtypes on platelets (Amison et al. 2015).

Further investigation into the mechanisms regulating platelet migration, and in general the characterization of the mechanisms regulating this dichotomy of platelet function, may be crucial for the discovery of new therapeutic approaches to inflammatory diseases by the development of drugs able to interfere with the inflammatory but not with the haemostatic function of platelets.

Take Home Messages

- Platelets possess several characteristics that allow them to migrate: the expression of receptors for chemokines and for other chemotactic agents, the presence of all the signaling pathways responsible for the transduction of the extracellular chemotactic signal to the motile apparatus, a dynamic cytoskeleton and the relase of several enzymes (MMPs, cathepsins, β-hexosoaminidase, heparinase) responsible for ECM degradation.
- The ability of platelets to migrate in vitro, both randomly and in the direction of a chemotactic stimulus, such as collagen, fMLP, SDF-1α, IgE and allergens, has been confirmed using different assays.
- The penetration of platelets in inflammed tissues has been described in several animal models and in human disease conditions.

(continued)

- Platelets can induce the migration of other cell types by several mechanisms, including the shedding of PMPs, release of granular materials (chemokines, cytokines, growth factors, ATP, enzymes), and the expression of surface receptors involved in platelet heterotypic interactions with leukocytes, endothelial and cancer cells.

Platelet Secretion

Robert Flaumenhaft

Abstract

Granule secretion is a critical platelet function, essential in both physiological and pathophysiological activities of platelets. Granules constitute more than 10 % of total platelet volume and account for nearly a third of total platelet membrane. The classic platelet granule types include dense granules, α-granules, and lysosomes. Dense granules contain high concentrations of bioactive amines, cations, polyphosphates, and nucleotides. α-Granules contain hundreds of different proteins, including coagulation factors, growth factors, proteases, and transmembrane receptors. Lysosomes represent a minor granule population that contain enzymes involved in the degradation of proteins, carbohydrate, and lipids. With this diversity of contents, platelet granules participate in many functions, including hemostasis and thrombosis, inflammation, atherosclerosis, antimicrobial host defense, malignancy, angiogenesis, and wound healing. The secretion of platelet granules is tightly controlled so as to permit rapid release of contents in response to injury while preventing inadvertent release of potentially deleterious contents. This chapter will review established and recent studies describing platelet granule content and function, the mechanisms of granule secretion from platelets, and human platelet granule deficiency syndromes.

Platelet Granules

The application of electron microscopy in the 1960s enabled our current classification of platelet granules into dense granules (aka, δ-granules or dense core granules), α-granules, and lysosomes (Tranzer et al. 1966). Dense granules were readily detected on the basis of their intrinsic electron density. α-Granules were identified as an atypical granule, reminiscent of but distinct from lysosomes (Siegel and Luscher 1967). In fact, it was not until cytochemistry was coupled to electron microscopy that lysosomes and α-granules were convincingly distinguished (Bentfeld-Barker and Bainton 1982). While the existence of additional granule types and subpopulations of granules within the platelet remains an area of active investigation, dense granules, α-granules, and lysosomes remain the three universally recognized platelet granules.

- Dense granules and α-granules are lysosome-related organelles found only in platelets.
- Both dense granules and α-granules are required for normal hemostasis and thrombosis.
- Dense granules contain primarily bioactive small molecules and cations.
- α-Granules contain a matrix of tightly packed and varied proteins that participate in a broad range of physiological activities.
- Lysosomes contain enzymes for degrading proteins, carbohydrates, and lipids.

Dense Granules

Although platelet dense granules are unique to platelets, they belong to a class of granules termed lysosome-related organelles that are found in other secretory cells such as melanosomes and chromaffin cells (Raposo et al. 2007). Platelets contain an average of 3–8 dense granules (Gerrard et al. 1977; White and Gerrard 1978). These granules are approximately 150 nm in diameter and are electron dense. Dense granules are acidic, with a luminal pH of ~5.4 (Dean et al. 1984). They express a vesicular H^+-ATPase proton pump that maintains the pH gradient across granule (Fig. 1) and generates a luminal positive electrochemical gradient ($\Delta\Psi$) of 30–40 mV (Carty et al. 1981). Newer studies implicate two-pore channel 2 (TPC2) as an important regulator of dense granule luminal pH and Ca^{2+} flux from dense granules (Fig. 1) (Ambrosio et al. 2015). In addition to H^+, platelet dense granules concentrate high levels of calcium (2.2 M), magnesium, and potassium (Fukami et al. 1984; Ruiz et al. 2004), which can be free or complexed to anions.

The electron gradient across the dense granule membrane powers transporters that are responsible for the substantial concentration of cytosolic nucleotides and bioactive amines observed in the granules. Anions in platelet dense granules include adenosine nucleotides, which are concentrated at ~653 mM ADP and ~436 mM ATP (Holmsen and Weiss 1979; Fukami et al. 1984; Holmsen and Dangelmaier 1989; Lages and Weiss 1999). VNUT is a 12 transmembrane domain transporter (Van Liefferinge et al. 2013) that was first predicted to reside on platelet dense granules based on their similarity to the large dense core vesicles of chromaffin cells (Fitch-Tewfik and Flaumenhaft 2013) and subsequently found to reside on platelet dense granules (Hiasa et al. 2014). Glyoxylate, an inhibitor of VNUT, blocks ATP uptake into megakaryocyte-like cells (Hiasa et al. 2014). MRP4 is a second nucleotide transporter found on dense granule membranes. It was originally thought to function in loading adenosine nucleotides into dense granules but was more recently shown to serve an essential role in cAMP homeostasis (Decouture et al. 2015). Polyphosphate and pyrophosphates are present in dense granules in millimolar

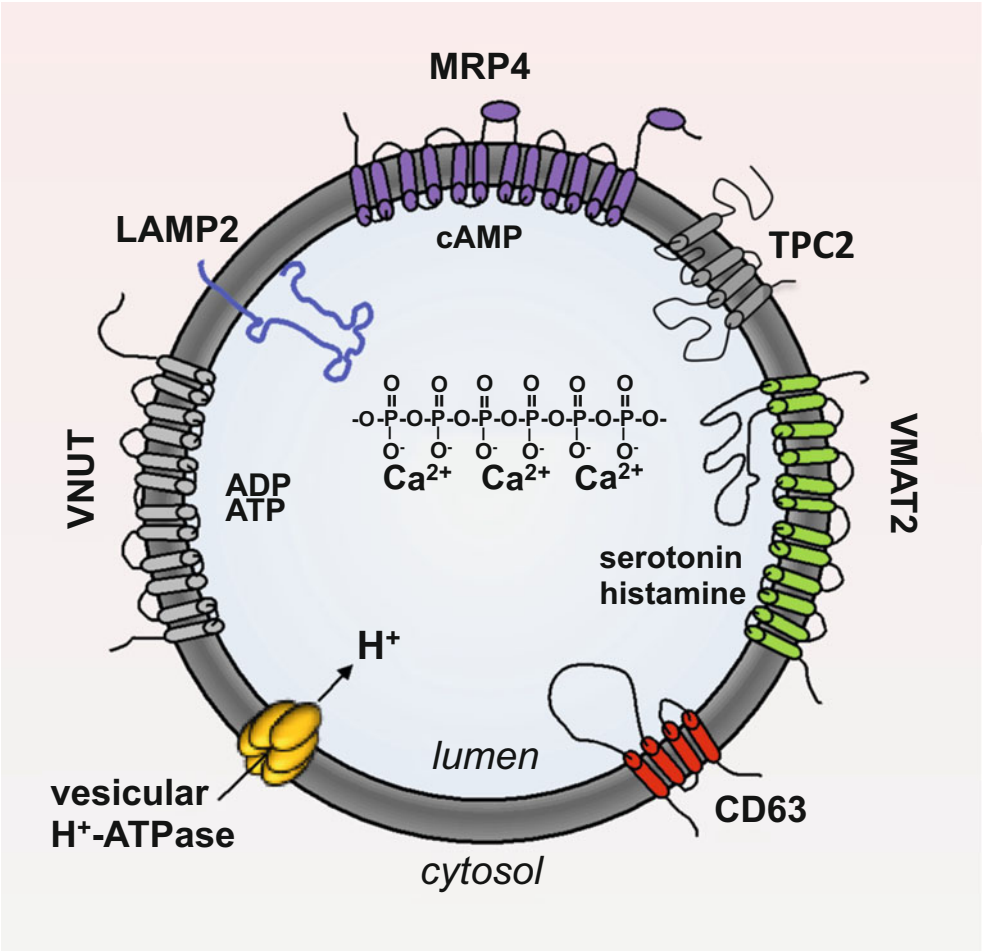

Fig. 1 Platelet dense granule. Platelet dense granules are the storage unit for the ionic species (Ca^{2+}, polyphosphate), adenosine nucleotides (ADP and ATP), and bioactive amines including serotonin and histamine. A vesicular H^+-ATPase proton pump and two-pore channel 2 (TPC2) maintains a low intraluminal pH and a transmembrane electrochemical gradient. TPC2 also functions in Ca^{2+} from dense granules. VNUT uses the electrochemical gradient to facilitate concentration of ADP and ATP in dense granules. MRP4 participates in cAMP homeostasis. VMAT2 is responsible for the transfer of serotonin from cytosol into dense granules. Membrane proteins include CD63 and LAMP-2, which is highly glycosylated and protects the membrane from the acid environment (Adapted from Fitch-Tewfik and Flaumenhaft 2013)

concentrations (in terms of Pi residues) and are typically ~60–100 phosphate units long (Muller et al. 2009; Morrissey et al. 2012), although their length can vary substantially. Mice lacking inositol hexakisphosphate kinase 1 have reduced levels of polyphosphate (Ghosh et al. 2013), implicating inositol hexakisphosphate kinase 1 in their synthesis. The mechanisms by which polyphosphophosphates are concentrated in dense granules are poorly understood. Of note, cytosol contains high concentrations of ATP and relatively little ADP and both ATP and ADP accumulate at high concentrations in dense granules. This observation has led to the theory that VNUT transports primarily ATP into dense granules and hydrolysis of ATP provides for both intraluminal ADP and phosphate substrates for polyphosphate synthesis (Hiasa et al. 2014).

Bioactive amines represent another important class of dense granules contents. Serotonin is present in platelet dense granules at a concentration of ~0.5 M (Ge et al. 2008, 2009). Vesicular monoamine transporter 2 (VMAT2) mediates uptake of serotonin into platelet dense granules (Fig. 1) (Leitner et al. 1999). During the process of serotonin concentration in dense granules, serotonin is first pumped into the cytosol from plasma by a serotonin transporter (SERT). The electrochemical proton gradient across the dense granule membrane then drives VMAT2-mediated uptake of serotonin from cytosol into platelet granules. Histamine uptake into dense granules is also mediated by VMAT-2 (Fukami et al. 1984; Tharmapathy et al. 2000). VMAT2 is targeted to dense granules by virtue of signals encoded in the C-terminal domain of the protein such as a C-terminal dileucine motif (Ambrosio et al. 2012). The C-terminus of VMAT2 also contains an acidic motif including two serines that is required for retention in granule membranes (Waites et al. 2001).

Platelet dense granules contain several other membrane proteins in addition to transporters. Both tetraspanin CD63 (granulophysin) and lysosomal-associated membrane protein-2 (LAMP-2, CD107b) are expressed on dense granule membranes (Fig. 1). CD63 is a member of the tetraspanin family that contains four membrane-spanning domains and luminal/extracellular domains that are extensively glycosylated. CD63 functions in membrane trafficking and is expressed on the platelet surface following activation where it associates with $\alpha_{IIb}\beta_3$ (Israels et al. 2001; van der Zee et al. 2006). Like other tetraspanins, platelet CD63 participates in lipid raft formation (Israels and McMillan-Ward 2007). LAMP-2 contains a single transmembrane domain and is also extensively glycosylated. LAMP-2- functions to maintain the integrity of lysosomal, and presumably dense granule, membranes during vesicle trafficking. Of note, both CD63 and LAMP-2 are also found on platelets lysosomes as well as dense granules. Adhesive receptors such as GPIb and $\alpha_{IIb}\beta_3$ have also been reported to reside on platelet dense granule membranes (Youssefian et al. 1997). However, the contribution of this pool of adhesion receptors to platelet function is unknown.

α-Granules

Platelets contain approximately 50–80 granules in a single platelet. These granules have a diameter of 200–500 nm and surface area of ~14 μm^2/platelet (Harrison and Cramer 1993; Blair and Flaumenhaft 2009. The classic α-granule was described as containing distinct regions based on TEM demonstrating a peripheral membrane, an electron dense nucleoid (containing chemokines and proteoglycans), an electron lucent zone (containing von Willebrand factor), and an intermediate zone (containing additional proteins such as fibrinogen). Yet advances in high-resolution imaging technologies have called into question these earlier findings. Electron tomography with three-dimensional reconstruction of the platelet interior (van Nispen tot Pannerden et al. 2010) demonstrates multiple forms of α-granule populations, including subtypes with multiple luminal vesicles, those with crystalline cross-striations, and forms with elongated tubular granules—previously identified as elongated dense granules (White 2010). Furthermore, superresolution fluorescence microscopy performed to evaluate granule cargos has raised the possibility that platelets contain different subpopulations of α-granules (Sehgal and Storrie 2007). These observations raise fundamental questions about the exact identity and definition of α-granules.

Like dense granules, α-granules are considered lysosome-related organelles. They share several features of dense granules including an acidic interior generated by a Ca^{2+}- or Mg^{2+}-sensitive H^+-pumping ATPase responsible for an electrochemical gradient across the α-granule membrane (Grinstein et al. 1982, 1983; Grinstein and Furuya 1983). Platelet α-granules contain high concentrations of cations (14 mM Ca^{2+} and >60 mM Mg^{2+}) (Grinstein et al. 1983). However, while dense granules are known for their high content of small molecules, α-granules are known for their abundant protein content.

The platelet α-granule proteome consists of over 300 hundred proteins including both membrane-bound proteins and soluble proteins that are secreted into the extracellular space (Table 1) (Coppinger et al. 2004; Maynard et al. 2007). The majority of α-granule proteins are synthesized in megakaryocytes and trafficked into α-granules via the regulated secretory pathway. However, proteins such as fibrinogen, IgG, and albumin are taken up by the receptor-mediated endocytosis. The high concentration of protein within α-granules raises the question of how these granules are capable of storing these proteins at such a high concentration and still maintain an osmolarity roughly equivalent to

Table 1 Contents of platelet α-granules

Type	Examples
Adhesion proteins	fibrinogen, von Willebrand factor, thrombospondin
Chemokines	CXCL1 (GRO-α), CXCL4 (PF4), CXCL5 (ENA-78), CXCL7 (PBP, β-TG, CTAP-III, NAP-2), CXCL8 (IL-8), CXCL12 (SDF-1α), CCL2 (MCP-1), CCL3 (MIP-1α), and CCL5 (RANTES)
Coagulants, anticoagulants, and fibrinolytic proteins	factor V, factor IX, factor XIII, antithrombin, protein S, tissue factor pathway inhibitor, plasminogen, plasminogen activator inhibitor 1, α_2-macroglobulin
Growth factors	vascular endothelium growth factor, platelet-derived growth factor, fibroblast growth factor, epidermal growth factor, hepatocyte growth factor, and insulin-like growth factor, transforming growth factor β
Immune mediators	complement C3 precursor, complement C4 precursor, β1H Globulin, factor D, factor H, C1 inhibitor, IgG
Integral membrane proteins	αIIbβ3, GPIbα-IX-V, GPVI, TLT-1, P-selectin
Microbicidal proteins	thymosin-β4, thrombocidins 1 and 2 (from NAP-2)

that of the cytosol. Such concentration may be achieved via aggregation and multimerization of proteins during protein sorting (King and Reed 2002). Proteins that multimerize (such as vWf and multimerin) and bind other cargo proteins may help achieve the requisite degree of aggregation within the α-granule lumen. It has recently been appreciated that α-granule cargo content is not static throughout the life of an individual and changes in α-granule cargos associated with disease states have been described (Maynard et al. 2010; Peterson et al. 2010; Burkhart et al. 2014).

α-Granule proteins participate in a broad array of physiological functions. Experimental evidence exists supporting a role of α-granule proteins in hemostasis and thrombosis, inflammation, angiogenesis, wound repair, and antimicrobial host defense. That α-granules participate in hemostasis and thrombosis was initially supported by the observation that patients with gray platelet syndrome, who lack normal α-granules, have a bleeding diathesis (Gerrard et al. 1980; Levy-Toledano et al. 1981; Swank et al. 1996; Nurden and Nurden 2007; Gunay-Aygun et al. 2010, 2011). *NBEAL2* deficient mice (Deppermann et al. 2013; Kahr et al. 2013) and VPS33B-deficient mice (Bem et al. 2015), both of whose platelets lack α-granules, were shown to have defects in hemostasis and thrombosis. α-Granules include both prothrombotic proteins, such as vWf, fibrinogen, factor V, factor IX, and factor XIII, and anticoagulant proteins, such as antithrombin, protein S, and tissue factor pathway inhibitor. They also contain components of the fibrinolytic system such as plasminogen and plasminogen activator inhibitor. Angiogenic factors in α-granules include vascular endothelial growth factor, platelet-derived growth factor, fibroblast growth factor, and transforming growth factor-β among others. α-Granules also contain antiangiogenic factors such as endostatin and platelet factor 4 (PF4). Since α-granules contain both prothrombotic and antithrombotic as well as proangiogenic and antiangiogenic proteins, the question of how cargos with opposing activities can be organized and released so as to effectively promote physiological processes has been raised. Some investigators believe that these cargos are physically separated into different α-granule subpopulations that respond to distinct platelet agonists (Sehgal and Storrie 2007; Italiano et al. 2008; Italiano and Battinelli 2009). Others postulate that cargos are spatially separated within α-granules and the kinetics of their release differs (Jonnalagadda et al. 2012). Whether these or other mechanisms account for the ability of platelets to coordinate the activities of proteins with opposing function remains to be determined.

A role for platelets in inflammation and innate immunity has become increasingly evident (Von Hundelshausen and Weber 2007; von Hundelshausen et al. 2009; Semple and Freedman 2010; Semple et al. 2011). α-Granule cargo is essential in this capacity. In addition to their role in hemostasis, platelets are immune cells and their α-granules contain many mediators of inflammation. Some of the most abundant α-granule contents are chemokines, which include CCL2 (MCP-1), CCL3 (MIP-1α), CCL5 (RANTES), CXCL1 (GRO-α), CXCL4 (PF4), CXCL5 (ENA-78), CXCL7 (PBP, β-TG, CTAP-III, NAP-2), CXCL8 (IL-8), and CXCL12 (SDF-1α) (Schenk et al. 2002; Massberg et al. 2006; Koenen et al. 2009). Many of these chemokines contribute to the development of atherosclerosis, in which platelets have been shown to serve an important role (Von Hundelshausen and Weber 2007). Platelets α-granules also contain mediators of the complement cascade such as complement C4 precursor, complement C3, C1 inhibitor, factor D, and factor H (Peerschke et al. 2008). Cargos that are directly microbicidal are also secreted from α-granules, such as thymosin-β4 and thrombocidins 1 and 2, which are derived from NAP-2 (Semple et al. 2011). PF4 is required for platelets to kill *Plasmodium falciparum* during malarial infection (McMorran et al. 2009; Love et al. 2012; Derby 2012). It is worth noting that while a few α-granule cargo proteins are specific for platelets (such as PF4), many others are found in and secreted by other cells types or circulate in plasma. The ability of platelets to act as first responders and secrete these cargos rapidly in response to injury or infection, and perhaps to concentrate these proteins at an affected

site distinguishes α-granule-derived constituents from similar proteins from alternative sources.

α-Granules contain a wide variety of transmembrane proteins that serve diverse functions. P-Selectin (CD62P) is perhaps the best-characterized protein found in the α-granule membrane. Its tissue distribution is limited to platelets and endothelial cells. P-selectin is composed of an N-teminal C-type lectin domain, an epidermal growth factor like motif, a series of complement repeats, a transmembrane domain, and a C-terminal cytoplasmic tail (Koedam et al. 1992; Furie et al. 2001). The lectin domain, EGF motif, and complement repeats reside on the luminal face of the α-granule in resting platelets. Following activation, P-selectin translocates to the extracellular surface, such that its lectin domain can interact with PSGL-1 on immune cells, recruiting neutrophils to sites of inflammation (Hrachovinova et al. 2003). Tetraspanins and integrins also reside on the platelet α-granule surface and translocate to the platelet plasma membrane surface upon platelet activation. These proteins contribute to platelet–platelet, platelet–leukocyte, and platelet–endothelial cell interactions. Most α-granule transmembrane receptors, such as $\alpha_{IIb}\beta_3$ and GPIb, are also present on the plasma membrane of the resting platelet and receptors from α-granules are thought to constitute a reserve pool. Other receptors, such as P-selectin CD109 and fibrocystin L, are sequestered in α-granules in resting platelets and their translocation to the plasma membrane serves as a sensitive indicator of platelet activation.

Lysosomes

Although platelets are replete with lysosome-related organelles (dense granules and α-granules), they contain few bona fide lysosomes. A platelet typically contains 0–3 lysosomes, which are 200–250 nm in diameter. These organelles are identified by cytochemical stains such as acid phosphatase or arylsulfatase (Bentfeld-Barker and Bainton 1982). Little is known about lysosome formation during megakaryopoiesis. However, platelet-specific knockout of PIKfyve results in excessive storage of lysosomal enzymes, implicating this phosphatidylinositol kinase in platelet lysosome formation (Min et al. 2014). Platelet lysosomes enzymes are involved in degradation of proteins, carbohydrates, and lipids (Table 2). The most abundant class is the acid hydrolases. Lysosome contents are released during platelet activation in vivo following vascular injury (Holmsen and Day 1968; Ciferri et al. 2000). Lysosomal membranes contain LAMP-1, LAMP-2, and CD63 (Bentfeld-Barker and Bainton 1982; Ciferri et al. 2000), which are highly glycosylated. These proteins decorate the luminal lysosome surface and serve to protect the lysosomal membrane. Some have suggested that enzymes released by lysosomes may serve a role in digestion and resolution of thrombi (Rendu and Brohard-Bohn 2001). However, the role of platelet lysosomes in hemostasis and thrombosis is not known.

Table 2 Contents of platelet lysosomes

Type	Examples
Carbohydrate-degrading enzymes	arabinofuranosidase, fucosidase, galactosidase, glucosidase, glucuronidase, hexosaminidase, mannosidase
Phosphate ester cleaving	acid phosphatase
Protein-degrading enzymes	carboxypeptidase, cathepsins, collagenase, elastase, proline carboxypeptidase

Mechanisms of Platelet Granule Secretion

Platelet granule secretion occurs when membranes of granules fuse with membranes of surface-connected structures, including plasma membrane and the open canalicular system (OCS). The fusion of two lipid membranes in an aqueous environment requires sufficient energy to overcome electrostatic repulsive and hydration forces between the two membranes. Platelet membrane fusion must be tightly regulated to prevent indiscriminant release of thrombogenic and inflammatory substances, growth factors, and surface expression of adhesion proteins. Regulation is achieved at several levels including control of *s*oluble *N*-ethylmaleimide-sensitive factor *a*ttachment *re*ceptors (SNAREs), proteins that provide the driving force for lipid membrane fusion, participation of the actin cytoskeleton, and changes in membrane phospholipids.

- Platelet granule release requires the fusion of granule membranes with surface-connected membranes (plasma membrane and OCS).
- SNAREs and their chaperones, cytoskeletal remodeling, and lipid modification all participate in membrane fusion required for platelet granule release.
- The dominant SNAREs that function in platelet granule secretion are VAMP-8, syntaxin-11, and SNAP-23.
- The exocytotic machinery interacts with cytoskeletal proteins: the cytoskeleton influences secretion and secretion is important for spreading.

SNAREs

SNAREs are membrane-associated proteins that are oriented to the cytosol (Fig. 2). SNAREs associated with granules are termed vesicular SNAREs (vSNAREs), while those

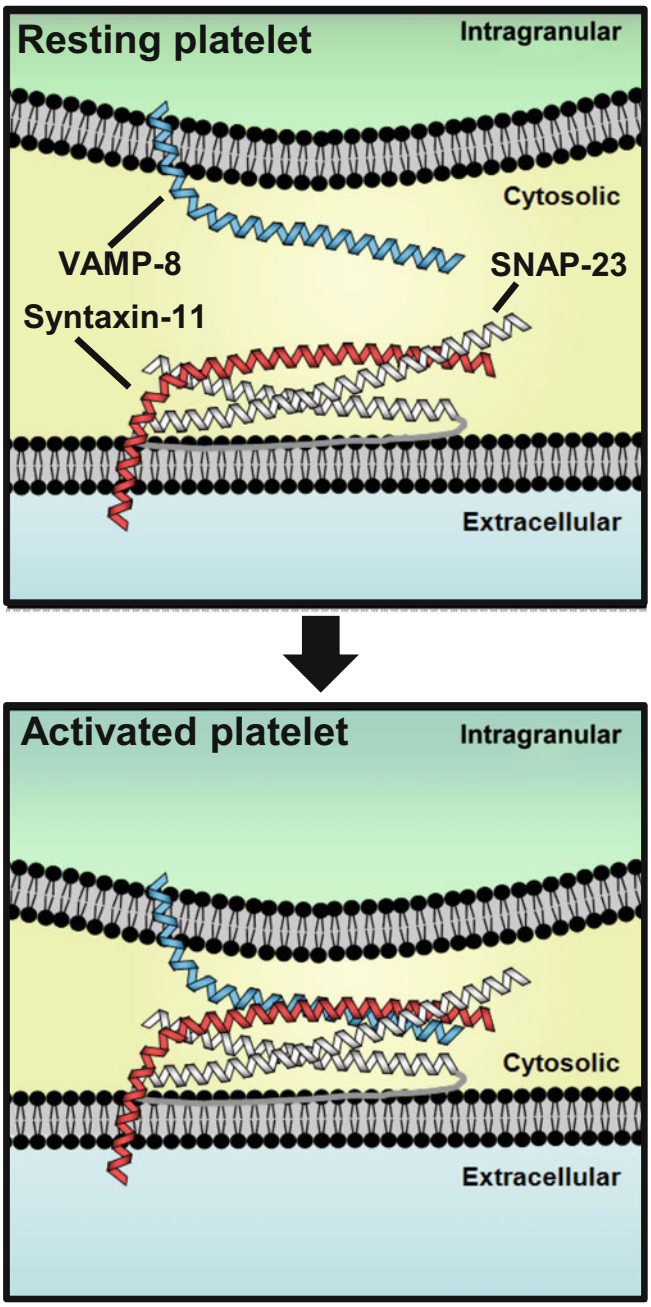

Fig. 2 Role of SNAREs in α-granule membrane fusion. (*Resting platelet*) VAMP-8 is a vSNARE found on platelet granules and is oriented with its N-terminus to the cytosol. Syntaxins-11 and SNAP-23 are tSNAREs found on plasma membranes and OCS and also oriented toward the cytosol. VAMP-8 and syntaxin-11 isoforms each contribute to one coiled-coil domain to the four-helix bundle while SNAP-23 contributes two. Only that portion of syntaxin that participates in the four-helix bundle is shown. (*Activated platelet*) vSNAREs (VAMP-8) and tSNAREs (syntaxin-11 and SNAP-23) initially associate at their N-terminal ends and interact via coiled-coil domains, bringing the opposing granule membrane and target membrane into close apposition. Binding of vSNAREs and tSNAREs generates energy required for membrane fusion (Adapted from Flaumenhaft 2013)

primarily associated with target membranes are termed tSNAREs. The characteristic feature of these proteins is the SNARE motif, a ~60 amino acid α-helix capable of interacting with other SNARE motifs to assemble into helical bundles involving coiled-coil interactions (Fig. 2). SNARE interactions occur in a parallel manner to form a four-helix bundle. Vesicle-associated membrane protein (VAMP) isoforms and syntaxin isoforms contribute one motif each and SNAP-23 contributes two motifs (Fig. 2). The binding of SNAREs brings granular and plasma membranes into close apposition. This tight association may also generate energy required for membrane fusion (Liu and Parpura 2010).

Platelets contain many SNARE isoforms. Known platelet vSNAREs include VAMP-2, -3, -4 -5, -7, and -8. Known platelet tSNAREs include syntaxins-2, -4, -7, -8, -11, and -12 and SNAP-23, -25, and -29 (Lemons et al. 1997; Flaumenhaft et al. 1999, 2007; Feng et al. 2001, 2002; Lai and Flaumenhaft 2003; Schraw et al. 2003; Ren et al. 2007; Dowal et al. 2011). However, it must be remembered that SNAREs participate in every level of membrane trafficking during megakaryopoiesis, so that only a subset of these platelet SNAREs function in granule secretion. VAMP-8- appears to be the dominant vSNARE involved in granule release (Fig. 2), since mice lacking VAMP-8 demonstrate a substantial (although not total) defect in granule release (Ren et al. 2007; Graham et al. 2009). VAMP-7 also functions in platelet granule release and may mediate coordination of granule release with cytoskeletal remodeling by virtue of an N-terminal extension that binds VPS9-ankyrin repeat protein (VARP) (Peters et al. 2012; Koseoglu et al. 2015b). VAMP-3 and perhaps VAMP-2 play subordinate roles (Schraw et al. 2003; Ren et al. 2007). Syntaxins 11 appears to be the dominant syntaxin isoform that functions in granule release (Fig. 2) based on the observation that both mice and humans that lack syntaxin 11 have a marked defect in granule release (Ye et al. 2012). A minor role for syntaxin 8 has recently been described (Golebiewska et al. 2014). The function of SNAP-23 in platelet granule release is well established (Fig. 2) (Flaumenhaft et al. 1999; Lemons et al. 2000; Polgar et al. 2003).

Posttranslational modification of SNAREs is thought to influence their activity. SNAP-23 is phosphorylated at Ser95 in an activation-dependent manner by IκB (Karim et al. 2013). Phosphorylation of SNAP-23 enhances membrane fusion in a SNARE-dependent liposome-mediated fusion system. Protein palmitoylation is a second posttranslational modification required for platelet granule release (Sim et al. 2007). VAMP-3, -4, -5, and -7; syntaxin-2, -8, -11, and -12; and SNAP-23 are all palmitoylated (Dowal et al. 2011). SNAP-23 is palmitoylated at a central membrane-binding domain, which is required for its association with membranes (Salaun et al. 2005).

SNARE Chaperones

Platelet SNAREs are regulated by a variety of binding proteins that direct their function. NSF is a Mg^{2+}-dependent hexameric ATPase that is essential for most forms of membrane trafficking, including regulated platelet granule secretion (Polgar and Reed 1999). Both inhibitory peptides and antibodies to NSF interfere with α-granule release from platelets (Polgar and Reed 1999). The *s*oluble *N*SF-*a*ttachment *p*rotein (SNAP), α-SNAP, binds and activates NSF (Clary et al. 1990). Wild-type α-SNAP augments platelet granule secretion, whereas antibodies directed at α-SNAP or a dominant-negative α-SNAP mutant (α-SNAPL294A) inhibit granule secretion (Chen et al. 2000). Syntaxin-binding proteins (STXBPs) are also important regulators of platelet granule secretion. STXBP2 (aka Munc18b) is a Sec/Munc protein that binds tightly to and regulates the activity of syntaxin-11 (Al Hawas et al. 2012). Platelets from patients with familial hemophagocytic lymphohistiocytosis type 5 (FHL5) lack STXBP2 and have defective granule secretion and a bleeding diathesis. STXBP5 (aka tomosyn) interacts with syntaxin-11/SNAP-23 heterodimers and mouse platelets lacking STXBP5 also demonstrate impaired granule release (Ye et al. 2014).

Rab proteins and their effectors are capable of docking opposing membranes and modifying SNARE function. Rab proteins represent the largest branch of the ras superfamily of GTPases and several of these, including Rabs 3b, 6c, and 8, are phosphorylated upon platelet activation (Karniguian et al. 1993). Rab GDP dissociation inhibitor (RabGDI), a general inhibitor of RabGTPases, inhibits α-granule but not dense granule release (Shirakawa et al. 2000). In addition, a dominant-negative mutant of His-tagged Rab4S22N (but not mutant His-Rab3BT36N) inhibits α-granule secretion but fails to affect dense granule release. These results suggest that Rab 4 is required for α-granule but not dense granule secretion. Rab27a localizes to lysosomal-related organelles and functions in dense granule release (Tolmachova et al. 2004, 2007). A mutation harbored by the *gunmetal* mouse in the α-subunit of the Rab geranylgeranyl complex prevents the attachment of geranylgeranyl to Rab proteins (Detter et al. 2000). Platelets from these mice demonstrate a defect in α-granule and dense granule secretion, as well as impaired granule synthesis. In nucleated cells, Rab proteins function by binding to large effector proteins that are proposed to interact with SNAREs directly or with proteins that regulate SNARE function (Zerial and McBride 2001). For example, Munc13-4 binds Rab27a in human platelets and mediates dense granule secretion (Ren et al. 2010). Patients with familial hemophagocytotic lymphohistiocytosis-3 (FHL-3) have mutated Munc13-4 and abnormal platelet granule release (Feldmann et al. 2003). In Jinx mice, which lack Munc13-4, dense granule release is essentially absent, while α-granule and lysosome release are also severely impaired (Ren et al. 2010). Synaptotagmin-like protein 4 (Slp4) interacts with Rab8 in platelets and mediates dense granule release (Hampson et al. 2012).

Cytoskeleton

The actin cytoskeleton is a dynamic structure that acts both as a barrier to prevent indiscriminant release of granule contents in resting platelets and as facilitator of membrane fusion and granule secretion in activated platelets. In resting platelets, F-actin coats purified platelet α-granules (Flaumenhaft et al. 2005). The barrier function of the actin cytoskeleton is evidenced by studies—using cytochalasins (Cox 1988), latrunculin A (Flaumenhaft et al. 2005), or the F-actin severing protein scinderin (Marcu et al. 1996)—that demonstrate increased dense granule release with inhibition of actin polymerization or with cleavage of F-actin. Inhibition of actin polymerization also augments the kinetics and degree of α-granule release (Flaumenhaft et al. 2005). These results indicate that some degree of F-actin disassembly might actually be required for normal granule secretion.

In contrast to the barrier function of the resting cytoskeleton, de novo actin polymerization during platelet activation contributes to granule release. High concentrations of inhibitors of actin polymerization block α-granule release (Woronowicz et al. 2010). In a cell-free platelet granule secretory system, inhibition of F-actin formation blocks release of α-granule contents, whereas actin polymerization stimulates α-granule release (Woronowicz et al. 2010). Actin polymerization may elicit membrane fusion by contributing to the transport or expulsion of granules or by distorting and destabilizing lipid bilayers (Eitzen et al. 2002). In addition, platelet SNAREs interact directly with actin components of the cytoskeleton. Perhaps the best example is the interaction of VAMP-7 with VARP (Fig. 3). VARP is an adaptor protein that functions in both granule exocytosis and cytoskeletal remodeling. Immunoprecipitation studies in platelets demonstrated an association of VAMP-7, VARP, and Arp2/3, an actin-binding protein that functions in actin polymerization (Koseoglu et al. 2015b). Deficiency of VAMP-7 impairs both platelet granule secretion and spreading (Koseoglu et al. 2015b). Similarly, GPS platelets, which lack α-granules, and platelets deficient in Munc13-4 also demonstrate impaired spreading (Peters et al. 2012), indicating a bidirectional link between granule exocytosis and platelet spreading. Recent studies evaluating spreading on micropatterned arrays indicate that platelet secretion responds to cues in the microenvironment to stimulate directional secretion (Sakurai et al. 2015). Directional secretion may, in turn, provide for deposition of new matrix on which platelet membranes can extend.

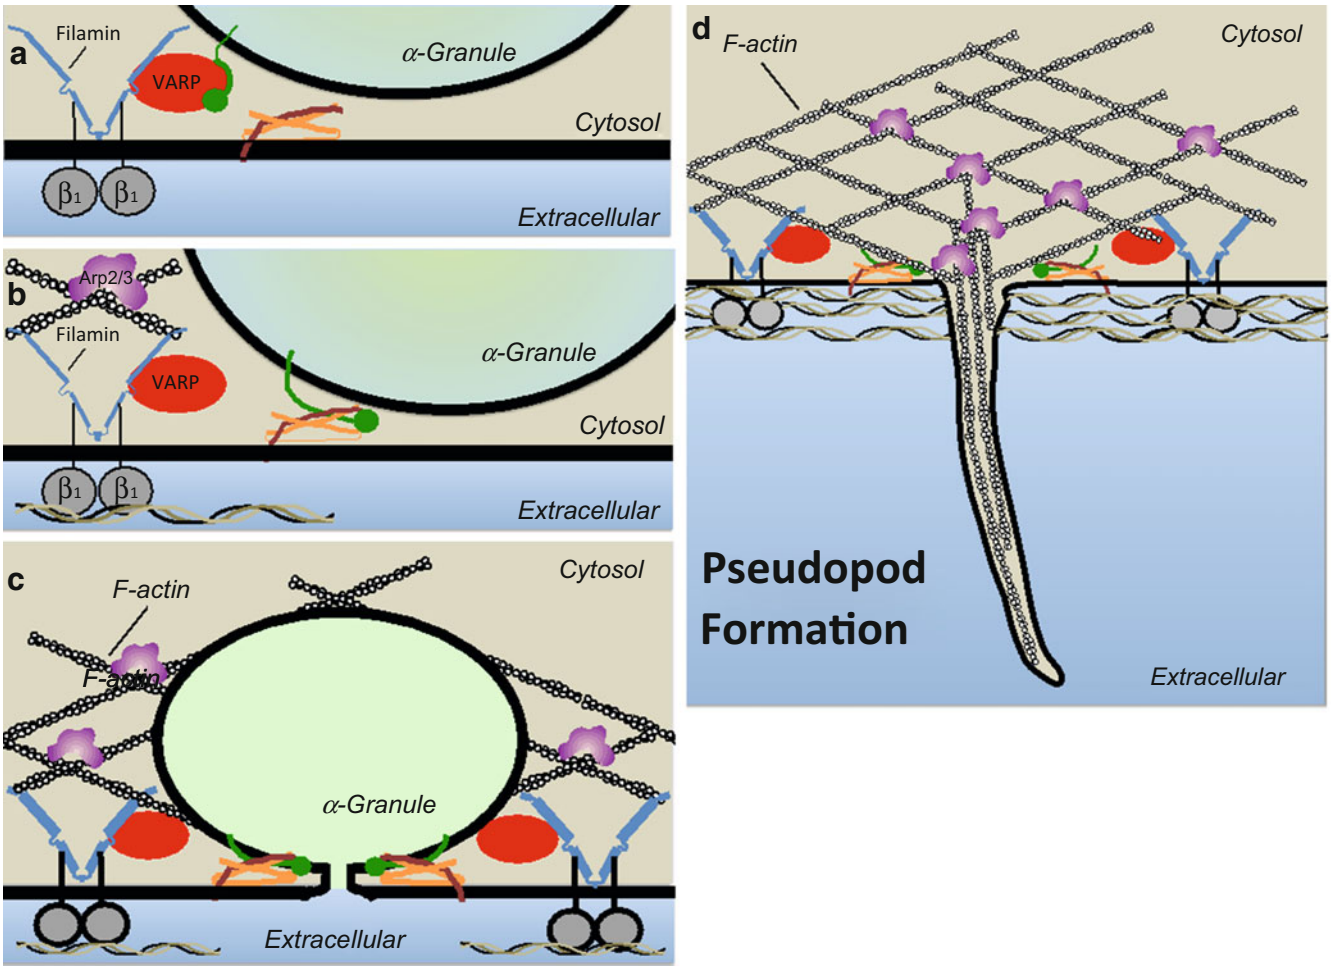

Fig. 3 A model of the molecular mechanisms linking platelet granule exocytosis and actin polymerization. (**a**) In the resting state, VAMP-7, which is associated with the granule membrane, binds to VARP, which associates with Arp2/3. This arrangement localizes the granule exocytosis machinery and the actin polymerization machinery to the same location and maintains them in an inactive state. (**b**) Mechanosensing via surface receptors (α2β1 shown here) is transmitted through actin-binding proteins (filamin A shown here) activating the platelet and releasing VAMP-7 and Arp2/3 from VARP. (**c**) VAMP-7 interacts with tSNAREs on the plasma membrane, facilitating membrane fusion, and Arp2/3 functions in actin reorganization. (**d**) Fusion of granules with the plasma membrane provides extra membrane to cover growing actin structures during spreading

Lipids

The stalk model of membrane fusion posits that release of contents from secretory cells occurs through a fusion pore (Kozlovsky and Kozlov 2002). This pore then expands, extruding granule contents and enabling the incorporation of granule membrane into plasma membrane. The fusion pore is short lived, however, and only recently have techniques such as single cell amperometry been developed with sufficient temporal resolution to provide experimental support for a fusion pore intermediate in platelets (Ge et al. 2008). Characterization of the fusion pore of platelet dense granules demonstrates a secretion time course of ~7 ms (Ge et al. 2008; Koseoglu et al. 2013). Dynamin family proteins that are capable of binding lipids and cleaving stalks of endocytotic and exocytotic vesicles have been invoked in platelet granule release.

Several phospholipid components of the platelet membrane influence its ability to fuse. Studies of fusion pore formation using single-cell amperometry demonstrate that cholesterol concentration influences fusion pore dynamics and granule release (Ge et al. 2008). The intrinsic negative curvature of cholesterol may stabilize intermediate membrane structures required for pore formation and expansion. Phosphatidylinositol 4,5-bisphosphate (PIP_2) is synthesized in platelets in an activation-dependent manner by both type I and type II PIPKs (Tolias et al. 2000; Rozenvayn and Flaumenhaft 2001, 2003). A role for PIP_2 in platelet granule secretion has been demonstrated (Rozenvayn and Flaumenhaft 2001, 2003). Although the exact role of PIP_2

in granule release is not well understood, several SNARE regulating proteins and cytoskeletal proteins contain PIP_2-binding domains and may be recruited to sites of granule exocytosis by PIP_2 (McLaughlin et al. 2002). PIP_2 also serves as a precursor for diacylglycerol and IP_3, which are essential second messengers in stimulating protein kinase C (PKC) isoforms and Ca^{2+} flux. Phosphatidic acid (PA) synthesis correlates with granule secretion and inhibition of PA synthesis inhibits secretion (Coorssen and Haslam 1993). The role of PA in potentiating membrane fusion has not been defined. However, altering membrane curvature, serving as protein attachment sites, and signaling are proposed functions for PA in membrane fusion (Jones et al. 1999; Vitale et al. 2001). Phosphatidylserine enrichment in platelet membranes resulted in decreased platelet granule secretion (Koseoglu et al. 2015a). Despite the importance of lipid composition in membrane fusion, changes in lipid composition alone are not sufficient for regulated platelet granule secretion, which requires a protein-based fusion machinery.

Inheritable Defects of Platelet Granules

Much of what is known about the function of platelet granules has been learnt from patients with platelet granule deficiencies. Platelet granule defects are categorized as δ-storage pool deficiency in which dense granules are decreased, α-storage pool deficiency in which α-granules are decreased, and αδ-storage pool deficiency in which both granule types are decreased. Defects in platelet granule secretion despite normal granule content have also been described.

- Dense granule deficiencies are the most common platelet granule deficiency syndromes and are associated with a bleeding diathesis.
- α-Granule deficiency are typically associated with macrothrombocytopenia and mild-moderate bleeding.
- Granule deficiency syndromes have provided a wealth of information regarding the granulogenesis of dense granules and α-granules.
- BLOC proteins, AP-3, and Rab proteins mediate dense granule formation.
- Neurobeachin 2, VPS16B, VPS33B, and several transcription factors mediate α-granule formation.

Dense Granule Deficiencies

The most common and well-studied platelet dense granule defect occurs with Hermansky–Pudlak Syndrome (HPS). HPS patients have variable mucocutaneous bleeding and

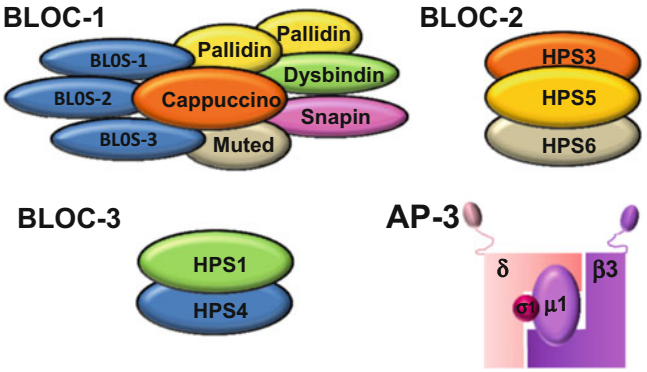

Fig. 4 Proteins that are defective in Hermansky–Pudlak syndrome. Biogenesis of Lysosome-related Organelle Complexes (BLOCs) function in the formation of dense granules. BLOC-1 contains 8 distinct proteins, with two copies of pallidin. BLOC-2 and BLOC-3 are composed of HPS protein subunits. AP-3 contains four subunits including δ, β3, μ1, and σ1. Mutations in genes encoding these proteins are responsible for HPS (Adapted from Flaumenhaft 2013)

significant postsurgical bleeding as a result of their platelet defect. In addition to the bleeding diathesis, patients suffer from oculocutaneous albinism resulting in impaired vision, inflammatory bowel disease, and progressive pulmonary fibrosis. Nine different variants of HPS have been described (Cullinane et al. 2011). Pulmonary fibrosis, a frequent cause of death in HPS, is most common in HPS-1 and HPS-4. The defect in dense granule formation results from mutations in HPS genes, which encode for components of BLOC and AP-3 complexes (Fig. 4). These complexes are required for the formation of lysosome-related organelles. Platelets from patients with HPS have a normal allotment of α-granules, suggesting that BLOC protein and AP-3 contribute to granulogenesis at a point distal to the sorting of α-granules from dense granules. However, release of α-granules and lysosomes from HPS platelets is also impaired (Meng et al. 2015). In addition, the release of protein disulfide isomerase (PDI) (Sharda et al. 2015), which is stored in T-granules derived from the dense tubular system (Thon et al. 2012), is also impaired in HPS. PDI serves an essential role in thrombus formation and impairment of its secretion contributes to defective thrombosis in HPS (Sharda et al. 2015).

Several other syndromes have been described that include dense granule deficiency. Chediak–Higashi syndrome (CHS) is an autosomal recessive disorder caused by mutations in the *LYST* gene (Barbosa et al. 1996; Perou et al. 1996). Platelets from these patients lack dense granules. CHS patients suffer from immunodeficiency, albinism, a bleeding diathesis, and neurological disorders. Many of the patients die from a lymphoproliferative syndrome. Bleeding in Chediak–Higashi syndrome patients is typically mild to moderate. Patients with Griscelli syndrome type II have a defect in Rab27a and can have bleeding along with dense granule deficiency. However, platelets also express

Rab27b, which largely compensates for the defect in Rab27a (Barral et al. 2002). Patients with thrombocytopenia with absent radii (TAR) syndrome are diagnosed on the basis of a deleted 200-kb region at chromosome band 1q21.1 and can have decreased dense granules (Klopocki et al. 2007). Wiskott–Aldrich syndrome results from a mutation in WASp, which regulates actin filament organization in complex with actin binding and nucleating proteins, and is also associated with decreased dense granules (Derry et al. 1994). Bleeding has been associated with all these dense granule deficiency syndromes.

α-Granule Deficiencies

The best known inherited disorder of α-granule formation is Gray platelet syndrome (GPS). Clinical features of GPS include progressive macrothrombocytopenia, bone marrow fibrosis, and splenomegaly. The bleeding diathesis has been defined as mild to moderate. Severe bleeding is observed almost exclusively in women with menorrhagia (Gunay-Aygun et al. 2010). Autosomal recessive GPS results from mutations in *NBEAL2* (Albers et al. 2011; Gunay-Aygun et al. 2011; Kahr et al. 2011). *NBEAL2* encodes for neurobeachin 2, a member of a family of proteins containing Beige and Chediak Higashi (BEACH) domains. These domains were originally identified in LYST, the protein that is mutated in Chediak–Higashi Syndrome. Neurobeachin 2 functions in granule trafficking. Autosomal positive GPS is caused by a mutation in growth factor independent 1B (GFI1B) resulting in a dominant negative form of this transcription factor (Monteferrario et al. 2014).

ARC syndrome is also associated with platelet α-granule deficiency. ARC syndrome is caused by mutations in a protein, VPS33B, which is involved in vesicle trafficking (Gissen et al. 2004; Lo et al. 2005). VPS33B is a membrane-associated protein that binds tightly to and regulates the function of SNAREs. In platelets, VPS33B associates with α-granules (Lo et al. 2005). Patients with this mutation possess α-granule-deficient platelets, and their platelets possess no detectable CXCL4, vWf, fibrinogen, nor P-selectin (Lo et al. 2005). Thus, loss of VPS33B affects incorporation of both endogenous and endocytosed proteins, as well as both soluble and membrane-bound proteins, into α-granules (Lo et al. 2005). The number of dense granules in VPS33B-deficient platelets is modestly increased, indicating that VPS33B function is not critical for dense granule formation. Platelets from mice with an inducible deficiency in VPS33B demonstrate a reduction in mature type II multivesicular bodies (MVB II), indicating that VPS33B functions in the maturation of α-granules as they are formed from multivesicular bodies (Bem et al. 2015).

In the Quebec platelet disorder, α-granule proteins are degraded by intragranular plasmin, which is present owing to upregulation of urokinase plasminogen activator in megakaryocytic α-granules (Veljkovic et al. 2009). The increase in megakaryocyte urokinase plasminogen activator activity is secondary to duplication of *PLAU*, the gene that encodes this protease (Paterson et al. 2010). Quebec platelet disorder is associated with a bleeding diathesis (Hayward et al. 1997).

Mutations in the transcription factor, RUNX1, result in several platelet abnormalities including CXCL4 deficiency and α-granule cargo abnormalities (Aneja et al. 2011). Mutations in GATA1 have been described in patients with thrombocytopenia and markedly reduced or absent α-granules (Balduini et al. 2004; Tubman et al. 2007).

Defects in Granule Release

Familial Hemophagocytic Lymphohistiocytosis (FHL) is a family of genetic disorders originally characterized on the basis of immunodeficiency resulting from impaired exocytosis of cytotoxic granules from natural killer cells and cytotoxic T lymphocytes (Tang 2015). Several forms of FHL are associated with a bleeding diathesis owing to impaired secretion of platelet granules. Several variants of FHL exist and the causative genetic defects have been identified. FHL-3 results from mutations in Munc13-4, which is critical for granule exocytosis in mice and men (Feldmann et al. 2003). FHL-4 results from mutations in syntaxin 11 (zur Stadt et al. 2005). FHL-5 results from mutations in Munc18b (zur Stadt et al. 2009). A severe defect in platelet dense and α-granule secretion has been reported in platelets from patients with FHL-5 (Sandrock et al. 2010).

Conclusion

Since the identification of the platelet granule types—dense granules, α-granules, and lysosomes—by electron microscopy over half a century ago, substantial progress has been made in our understanding of how platelet granules are made, what they contain, and how their contents are released upon platelet activation. Yet despite this progress, fundamental issues remain unresolved. The precise nature of α-granules, whether they constitute a single homogenous granule type or subpopulations that can be distinguished on the basis of morphology or cargo content remains controversial. New imaging technology such as superresolution microscopy, videomicroscopy, and electron tomographic analysis of platelet morphology will enhance our ability to decipher the complex nature of fusion events that include

fusion of granule membranes with plasma membrane, OCS, and other granules and may help identify granule subpopulations. While much progress has been made in identifying the SNARE isoforms and auxiliary proteins that mediate platelet membrane fusion, an understanding at the molecular level of how this machinery responds to activation signals such as elevation of intracellular Ca^{2+} and protein phosphorylation and dephosphorylation have only begun to be evaluated. Most previous studies of platelet secretory mechanisms have evaluated suspension platelets, neglecting the fact that physiological secretion occurs in adherent platelets and that the cytoskeleton has a critical influence on membrane fusion events involved in secretion. The role of mechanosensing and cytoskeletal elements in mediating granule secretion and the bidirectional interactions between exocytosis and cytoskeletal remodeling are only beginning to be understood. Understanding the molecular basis of granule secretion will enable development not only of new antiplatelet agents for use in thrombosis, but potentially for the treatment of many other diseases in which platelet granules have been invoked, such as inflammation, tumor progression, and atherosclerosis.

Take Home Messages

- Dense granules and α-granules are lysosome-related organelles found only in platelets.
- Both dense granules and α-granules are required for normal hemostasis and thrombosis.
- Dense granules contain primarily bioactive small molecules and cations.
- α-Granules contain a matrix of tightly packed and varied proteins that participate in a broad range of physiological activities.
- Lysosomes contain enzymes for degrading proteins, carbohydrates, and lipids.

A Systems Approach to the Platelet Signaling Network and the Hemostatic Response to Injury

Lawrence F. Brass, Peisong Ma, Maurizio Tomaiuolo, Scott L. Diamond, and Timothy J. Stalker

Abstract

An essential part of the hemostatic response to injury is a well-calibrated accumulation of activated platelets. Here we will consider, first, how individual signaling and regulatory pathways in platelets combine to produce a flexible signaling network that can respond appropriately to injury under conditions that range from the macro- to the microcirculation and, second, how the piling up of platelets at a site of injury reshapes the local environment in ways that help to limit continued platelet accumulation. Using a systems biology perspective, we will examine the interrelationships between the platelet signaling network, the distribution of platelet agonists, and thrombus structure. The model that this produces moves beyond the behavior of any single platelet to consider the emergent properties of the platelet mass, thereby helping to explain why a multiplicity of agonists and signaling pathways are needed to produce an optimal hemostatic response.

Why a Systems Perspective?

Systems biology can be defined in a variety of ways. In a narrow sense, it combines computational approaches and mathematical modeling to understand biology. In the broader sense that we will use here, systems biology is the study of complex interactions whose properties become apparent only when multiple cells and multiple pathways are considered. The biological system in this case is the hemostatic response to injury. The cells are platelets and the pathways are those that either promote or limit platelet activation in response to the combined effects of multiple agonists and antagonists. Earlier chapters in this volume and previous reviews (Versteeg et al. 2013; Brass et al. 2013b) have focused on the individual receptors and pathways that are central to platelet activation. Here we will take a step back from considering events in any one pathway or platelet, and instead consider how activation and regulatory pathways within platelets integrate extracellular cues, forming a flexible signaling network capable of supporting, shaping, and limiting the hemostatic response.

Viewed from this broader perspective, platelets are small cells with the ability to shift rapidly from a freely moving state in which they are normally quiescent to an adherent and activated state, acquiring in the process the ability to form a temporary barrier against further blood loss. In this perspective, vascular injuries trigger platelet accumulation by the local exposure and production of platelet agonists, some of which are stationary (collagen), while others are mobile (thrombin, ADP, TxA_2, and epinephrine). Soluble molecules are able to achieve the critical concentrations needed for platelet

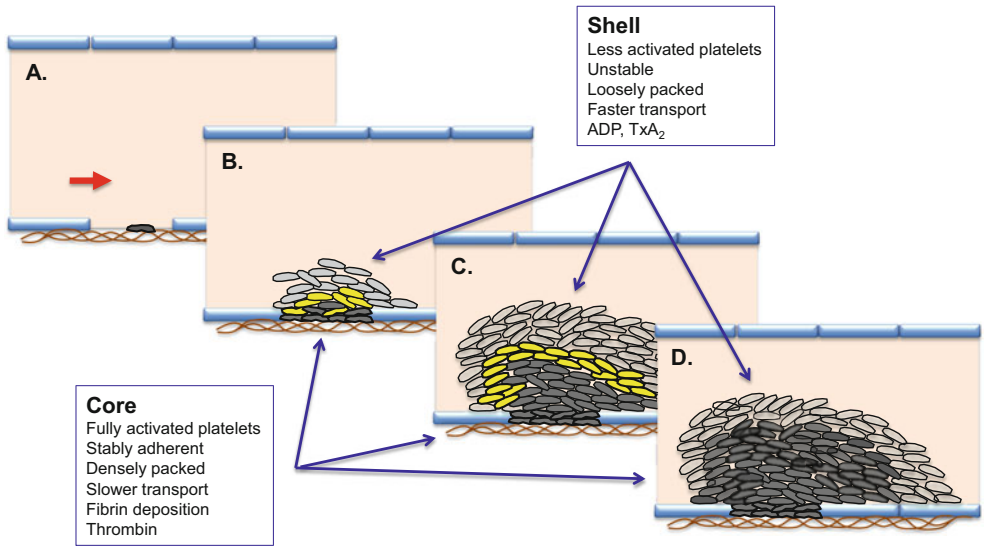

Fig. 1 Development of the heterogeneous architecture observed within hemostatic thrombi. Over time, hemostatic thrombi formed in response to penetrating injuries pass through the stages illustrated here, developing a characteristic structure in which fully activated platelets in a tightly packed core (*dark gray*) are overlaid with a more loosely packed shell (*light gray*) of incompletely activated platelets. A boundary region of higher packing density platelets that have not yet become fully activated is initially present at the boundary between the core and shell regions (*yellow*). Detectable thrombin activity and fibrin accumulation are limited to the core. In the process, individual platelets become increasingly surrounded by other activated platelets, radically altering their immediate environment

activation only if they are produced faster than they are washed away or inhibited. As will be discussed, the ability of soluble platelet agonists to accumulate is due in part to the protection provided by the growing platelet mass (Fig. 1). As a result, the platelet signaling network and thrombus structure are interdependent, possessing properties that cannot be fully understood by considering any one pathway or any one platelet at a time.

While platelet behavior has been observed for well over a century, advances in intravital imaging pioneered by the Furie laboratory (Falati et al. 2002, 2004; Celi et al. 2003) and others (oude Egbrink et al. 1988; Rosen et al. 2001; van Gestel et al. 2002; Stalker et al. 2013) have made it possible to observe the hemostatic response to penetrating injuries in real time at high resolution in mouse models. Interpretation of the results benefits from a systems perspective, which includes considering the ways that molecular transport changes in the gaps between platelets as platelets accumulate, the gaps grow tortuous, and the hemostatic mass continues to grow. The imaging studies show that platelet activation within a hemostatic thrombus is heterogeneous but not random. While some platelets change shape, activate their integrins, secrete their granule contents, and develop a procoagulant surface, others display few, if any, signs of activation. Observational studies show that this heterogeneity is ordered, producing a core of fully activated platelets closest to the site of injury that is overlaid with a shell of less activated platelets (Fig. 2) (Stalker et al. 2013).

Among the properties that distinguish the thrombus core from the shell is platelet packing density, which is greater in the core than the shell (Figs. 1 and 2) (Stalker et al. 2013). Greater packing density slows the movement of plasma-borne molecules and platelet-derived molecules passing through the gaps between platelets. Soluble molecules can include platelet agonists and coagulation factors, as well as coagulation inhibitors, inflammatory response mediators, and any other molecule found in plasma. Computational studies predict and experimental studies demonstrate that transport rates are slower in the core than in the shell and, especially in the most densely packed regions, are dominated by diffusion rather than convection due to permeation (Stalker et al. 2014; Tomaiuolo et al. 2014; Welsh et al. 2014). Regional transport differences affect the distribution of platelet agonists, producing concentration gradients in which the distribution of each agonist is determined by factors such as size, shape, half-life, and ability to bind to other molecules, including those present on the platelet surface. Greater packing density also brings platelets into closer contact with each other, enabling direct interactions between paired molecules on adjacent platelet surfaces (Brass et al. 2005).

Thus, part of the systems perspective on the hemostatic response to injury is that as platelets accumulate, the immediate environment of each platelet changes in ways that impact the growth and stability of the entire hemostatic mass. In this chapter, we will briefly consider how the platelet signaling network responds to combinations of agonists, how thrombus architecture both reflects and determines the distribution of those agonists, and how the timing of inhibitory events within each platelet helps shape as well as limit the hemostatic response.

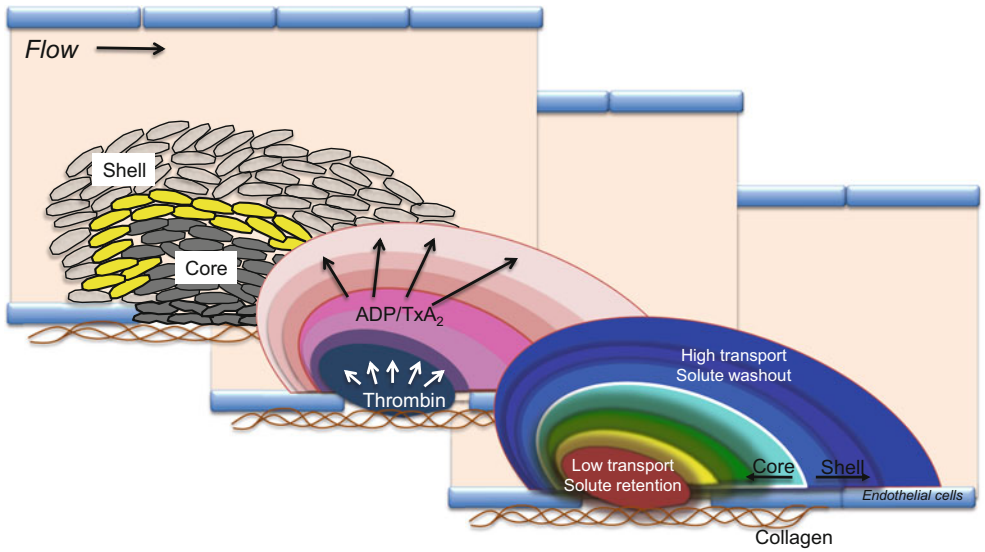

Fig. 2 The relationships between packing density, transport rates, agonist concentration gradients, and thrombus structure. As platelets within a developing thrombus become activated, they change shape, retract, and pack tightly together, driving the formation of regions with lower and higher transport rates (*right*). This leads to the retention of larger agonists, such as thrombin, within the low transport region. Smaller agonists, such as ADP and TxA_2, are able to diffuse more freely out of the low transport region (*middle*). The localization of these agonist gradients drives continued platelet activation in the low transport region leading to core formation consisting of high platelet packing density, decreased solute transport, α-granule exocytosis, and fibrin deposition (*left*). The restriction of thrombin to the core contributes to the shell consisting of loosely adherent platelets, high solute transport, reduced platelet activation, and no fibrin. Adapted from Welsh et al. (2014)

Platelet Activation Reflects Information Flow Through a Signaling Network

Figure 3 illustrates the platelet signaling network leading to integrin activation, stripped to its essentials for the purpose of this discussion and emphasizing the on/off cycling of heterotrimeric G proteins, Rap1b, and adenylate cyclase. When platelets respond to injury in vivo this network is called upon to sum the response to multiple platelet agonists and inhibitors located near each platelet, including collagen, thrombin, ADP, TxA_2, epinephrine, NO, and PGI_2, not all of which may be present at optimal or sustained concentrations.

Critical events in this network include the activation of phospholipase C (PLC), an increase in cytosolic Ca^{++}, reorganization of the platelet cytoskeleton, granule secretion, and the steps that link Ca^{++} to activation of the platelet fibrinogen receptor, $\alpha_{IIb}\beta_3$, so that platelet aggregates can form. Critical inhibitory events include an increase in cAMP and cGMP levels, driven by the local concentrations of PGI_2 and NO, and the subsequent phosphorylation of multiple platelet proteins. Most of the agonists and antagonists listed (collagen and NO are two exceptions) signal through G protein-coupled receptors on the platelet surface, producing distinctive responses by coupling to different repertoires of heterotrimeric G proteins. As an example, collagen, thrombin, and TxA_2 all cause phosphoinositide (PI-4,5-P_2) hydrolysis, IP_3 formation, and a subsequent rise in the cytosolic Ca^{++} concentration, but collagen accomplishes this by activating phospholipase Cγ via a tyrosine kinase-dependent mechanism downstream of glycoprotein VI, while thrombin and TxA_2 do so via Gq-dependent activation of phospholipase Cβ downstream of protease-activated receptors (PAR1 and PAR4 in human platelets) and TxA_2 receptors (TP) (see earlier chapters in this volume) (Stalker et al. 2012; Versteeg et al. 2013; Brass et al. 2013a, b).

Crosstalk between distinct pathways can amplify responses, as when thrombin promotes Rap1b activation via a Ca^{++} -dependent guanine nucleotide exchange factor, CalDAG-GEF (Crittenden et al. 2004), while ADP (and presumably epinephrine) promote Rap1b activation by inhibiting the turn-off of Rap1b by RASA3 in a PI-3 kinase (PI3K)-dependent manner (Stefanini et al. 2015). Rap1b is linked to integrin activation in platelets via RIAM and talin (Shattil et al. 2010). Positive autocrine and paracrine feedback loops occur when agonists activate phospholipase A_2, releasing arachidonate from membrane phospholipids to undergo cyclooxygenase-1 (COX-1)-dependent conversion to TxA_2.

At the same time, extrinsic regulators of platelet activation, including PGI_2 and NO, dampen platelet responsiveness and resist unwarranted platelet activation, while intrinsic regulators, such as RGS (Regulators of G protein Signaling) proteins, limit signaling downstream of platelet agonists once it has been initiated. RGS proteins limit the duration of G protein signaling by accelerating

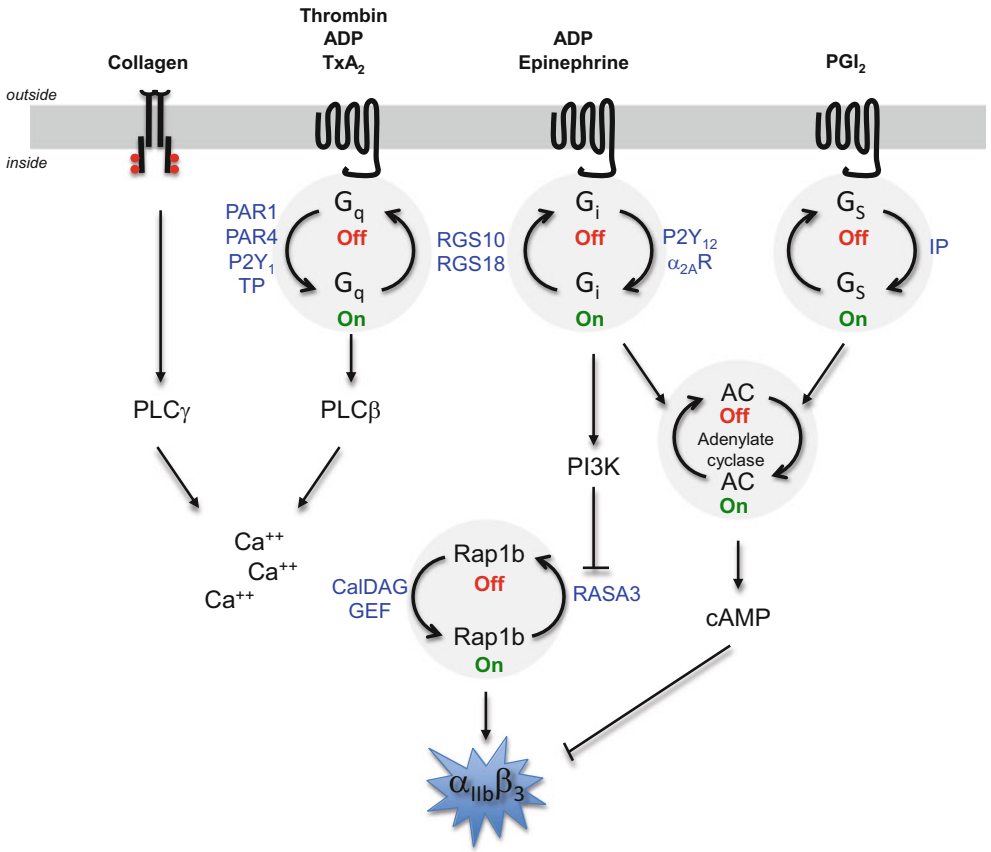

Fig. 3 The platelet signaling network leading to integrin $\alpha_{IIb}\beta_3$ activation: switching events, crosstalk, and regulatory feedback. A view of the platelet signaling network connecting platelet agonists to the platelet cohesion receptor, $\alpha_{IIb}\beta_3$, stripped to its essentials and emphasizing the role of switching events, crosstalk between pathways, and regulatory events. Platelet agonists activate either phospholipase Cγ (collagen) or phospholipase Cβ (thrombin, ADP, and TxA_2) raising IP_3 levels and triggering a rise in the cytosolic Ca^{++} concentration. Increased Ca^{++} activates the exchange factor, CalDAG-GEF, activating the monomeric G protein, Rap1b, which is linked to integrin activation by RIAM and talin (see text). Rap1b activation is also promoted by ADP via G_i, which promotes Rap1b signaling by inhibiting the Rap1b inhibitor, RASA3 (Stefanini et al. 2015). The switching events in this case center on Rap1b and the heterotrimeric G proteins, G_q and G_i. Regulatory events include the inactivation of G_q and G_i by RGS10 and RGS18, the inactivation of Rap1b by RASA3. cAMP dampens platelet responsiveness at a number of places in the platelet signaling network, including receptor desensitization, inhibition of IP_3 receptors, and an increase in free RGS18

the return of activated G proteins to the off state. Platelets express predominantly RGS10 and RGS18 (Rowley et al. 2011; Burkhart et al. 2012), which appear to be sequestered in resting platelets by the scaffold proteins, spinophilin (Ma et al. 2012) and 14-3-3γ (Gegenbauer et al. 2012) (Fig. 4). In the case of spinophilin, the release of RGS10 and RGS18 that occurs during platelet activation is agonist selective (Ma et al. 2012). Such selectivity provides a mechanism for fine tuning the consequences of platelet activation as information flow is restricted in some pathways but not others. PGI_2 and NO reduce the reactivity of resting platelets to most, if not all agonists by raising intracellular cAMP and cGMP levels, activating protein kinases A and G, and causing phosphorylation of multiple proteins in the platelet signaling network, including G protein-coupled receptors and the IP_3 receptor (Quinton and Dean 1992; Grunberg et al. 1995a, b; Smolenski 2011; Margarucci et al. 2011; Wangorsch et al. 2011; Gambaryan et al. 2010; Hayashi and Sudo 2009; Zahedi et al. 2008; Gegenbauer et al. 2012). In an example of crosstalk, cAMP dampens signaling in part by causing the dissociation of RGS proteins from spinophilin (Ma et al. 2015a, b) and 14-3-3γ (Gegenbauer et al. 2013), thereby reducing signaling downstream of platelet agonist receptors. Such events help to mold the growing thrombus by limiting the extent of platelet activation.

In a systems and network-centric view of platelet activation, instead of responding to a single agonist via a single signaling pathway, platelets accumulating at a site of injury respond to the local mix of inputs (agonists and antagonists) to which they are exposed. In vivo this mix varies over time and space, which is especially relevant when considering that the impact of multiple agonists can be synergistic and

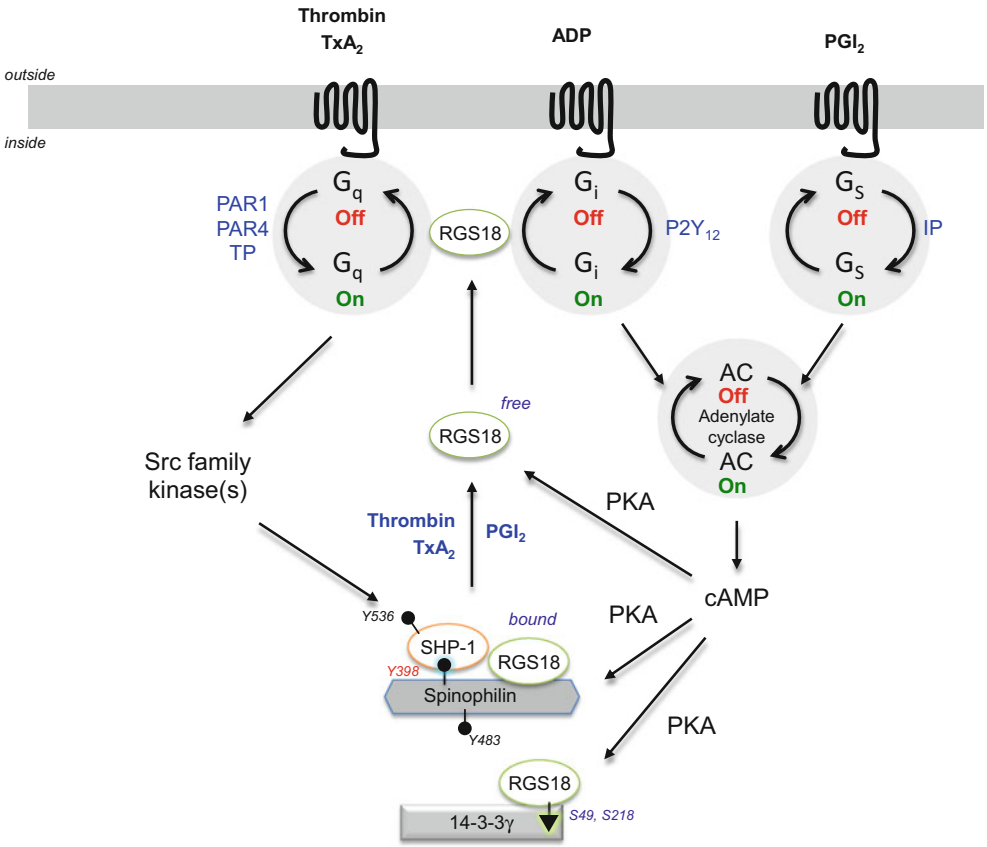

Fig. 4 RGS proteins as regulators of the platelet signaling network. In resting platelets, RGS18 is part of separate complexes built on the scaffold proteins, spinophilin, and 14-3-3γ. Addition of thrombin or TxA_2 causes dissociation of the SPL/RGS18/SHP-1 complex, freeing RGS18. Addition of PGI_2 to raise platelet cAMP levels has much the same effect, although by a different mechanism. Rising cAMP levels activate protein kinase A (PKA), which phosphorylates spinophilin and RGS18, causing dissociation of RGS18 from its binding site on 14-3-3γ as well as spinophilin. An increase in free RGS18 dampens signaling mediated by G_q and G_i in platelets. Comparable events are presumed to regulate RGS10 availability, although that has not been studied to the same extent

not simply additive (Chatterjee et al. 2010; Lee and Diamond 2015; Flamm et al. 2012). Positive and negative feedback in the form of soluble molecules plus contact-dependent interactions between adjacent platelets plays an important role in modulating platelet reactivity. Information flow within the platelet sums the effects of these inputs while nodal points in the signaling network provide links between them. As will be discussed later in this chapter, this view of platelet activation can be tied to thrombus architecture by considering, first, how gradients of different platelet agonists emanating from the point of injury differentially impact the platelet activation state and, second, how the higher packing density of platelets in the thrombus core facilitates the binding of cell surface ligands to cell surface receptors on adjacent platelets (Brass et al. 2005). These properties emerge only when considering the differences between single platelets in isolation and a multiplicity of platelets in close proximity with one another.

Studies of platelet activation performed in vitro in the clinical and research settings are commonly limited to the impact of a few agonists added one at a time in a closed, well-mixed system with concentrations that do not vary over time. Agonist concentration gradients do not form. Endpoints are often limited to platelet aggregation and secretion, supplemented in the research setting by flow cytometry using activation markers, measurements of cytosolic Ca^{++}, and accumulation on collagen and tissue factor coated surfaces in flow chambers and microfluidics devices. With the exception of the flow chambers and microfluidics devices, platelet activation in each of these settings occurs under conditions very different from those encountered in vivo. A good example of the consequences of exposure to more than one agonist comes from studies in which signaling initiated by exposure to both thrombin and collagen results in a sustained rise in the cytosolic Ca^{++} concentration, which in turn greatly promotes platelet procoagulant activity (Keuren et al. 2005).

Higher dimensional combinatorial approaches can be used to more closely mimic and predict what happens to individual platelets located within a thrombus. One approach is to expose platelets in vitro to as many as possible combinations of the agonists and inhibitors that are encountered in vivo: collagen (or a soluble GP VI agonist, such as convulxin), thrombin (or peptide agonists for PAR1 and PAR4), ADP, TxA_2 (or its stable mimetic, U46619), PGI_2 (or iloprost), and NO. Given sufficiently high throughput, each agonist and antagonist can be added at its mid-point concentration (determined from dose/response curves) as well as at concentrations that produce minimal and maximal responses. Biologically relevant readouts that have been

studied in this way include cytosolic Ca^{++} (Chatterjee et al. 2010; Lee and Diamond 2015), $\alpha_{IIb}\beta_3$ activation, and α-granule exocytosis (Jaeger and Diamond 2013). The data obtained with combinations of 1, 2, or 3 agonists and inhibitors have been used to train neural networks that correctly predict the synergistic effects of agonist combinations and the effects of combining even greater numbers of agonists. They have also been used to define differences among healthy individuals and to identify an unsuspected defect in TxA_2 signaling due to an amino acid substitution within the platelet TxA_2 receptor (Chatterjee et al. 2010; Lee and Diamond 2015; Flamm et al. 2012).

Network Regulation

The molecular mechanisms that drive platelet activation reflect an evolutionary compromise. This compromise can be thought of as establishing a threshold for platelet activation. If the threshold is too high, then platelets become useless for hemostasis. If too low, then the risk of thrombosis increases. An optimal platelet response to a penetrating injury can be defined as one in which hemostasis is achieved without unnecessary vascular occlusion. The set point is established by balancing signaling mechanisms that drive platelet activation with regulatory mechanisms that either dampen those responses or prevent their initiation in the first place. The normal environment of the platelet includes other blood cells, the soluble molecules found in plasma and, most critically, the vascular wall and the endothelial cells that line it, all of which are subject to change in the face of injury, disease, circadian rhythms, and aging. Many of these serve as extrinsic regulators of platelet activation. A healthy endothelium provides a physical barrier that limits platelet activation. It also produces inhibitors of platelet activation including NO (Furlong et al. 1987), prostacyclin (PGI_2) (Whittle and Moncada 1983; Weksler 1982; Yuhki et al. 2011), and the ecto-ADPase, CD39, which hydrolyzes plasma ADP that would otherwise sensitize platelets to activation by other agonists (Marcus et al. 1997).

In addition to these extrinsic regulators, there are intrinsic regulators that affect platelet activation. These include protein tyrosine phosphatases such as SHP-1; the cyclic nucleotides, cAMP and cGMP, which inhibit signaling events by the allosteric effects of protein serine and threonine phosphorylation; and RGS proteins and their binding partners, which limit signaling downstream of G protein-coupled receptors in platelets. Here we will focus on cAMP and RGS proteins since they provide two strong examples of network regulation and, in addition, illustrate how crosstalk between regulatory pathways can provide a context-dependent means of regulating platelet reactivity.

Regulation of G Protein-Dependent Signaling

Most platelets agonists activate platelets by binding to G protein-coupled receptors on the platelet surface. Because mechanisms exist that can limit the activation of this class of receptors, platelet activation can be tightly regulated. Receptor internalization and desensitization provide two such mechanisms. Another is provided by members of the RGS (Regulator of G protein Signaling) protein family, which limit signaling intensity and duration by accelerating the hydrolysis of GTP by activated G protein α subunits and allowing Gα to reassociate with Gβγ (Hollinger and Hepler 2002; Sjogren and Neubig 2010; Siderovski and Willard 2005). There are 37 genes encoding RGS proteins in the human genome. Transcripts for at least 8 have been detected in platelets, but protein studies suggest that human and mouse platelets express predominantly RGS10 and RGS18 (Ma et al. 2012; Rowley et al. 2011; Burkhart et al. 2012; Zeiler et al. 2014). Both proteins are relatively small, consisting primarily of a conserved RGS domain that interacts with Gα (Kimple et al. 2011). Each can serve as a GAP (GTPase activating protein) for Giα and Gqα but not Gsα (Soundararajan et al. 2008; Hunt et al. 1996; Popov et al. 1997; Nagata et al. 2001; Gagnon et al. 2002). RGS18 is primarily expressed in hematopoietic cells (Nagata et al. 2001; Park et al. 2001; Yowe et al. 2001; Gold et al. 1997; Hunt et al. 1996); RGS10 is widely expressed (Yang and Li 2007; Lee et al. 2008, 2011).

The evidence that RGS proteins are biologically relevant in platelets comes from two recent studies on RGS18 knockout mice (Delesque-Touchard et al. 2014; Alshbool et al. 2015) and on mice in which glycine 184 in the α subunit of G_{i2} has been replaced with serine (Signarvic et al. 2010). The G184S substitution prevents $G_{i2}\alpha$ from binding to RGS proteins without impairing the ability of G_{i2} to interact with either receptors or effectors (Fu et al. 2004). G_{i2} is the G protein that couples platelet $P2Y_{12}$ receptors to Akt and Rap1b and to the suppression of cAMP formation by adenylyl cyclase (Fig. 3). The knockout of the gene encoding $G_{i2}\alpha$, like the $P2Y_{12}$ receptor knockout, impairs platelet responses to ADP and produces a loss of function in vitro and in vivo (Jantzen et al. 2001; Hollopeter et al. 2001; Yang et al. 2002). The G_{i2} G184S substitution produces a gain of function in vitro and in vivo, increasing responsiveness to some platelet agonists, and enhancing thrombosis in mouse models of induced thrombosis without causing overt spontaneous thrombosis (Signarvic et al. 2010; Brass et al. 2013b). Similar effects have been reported with the RGS18 knockout (Delesque-Touchard et al. 2014; Alshbool et al. 2015). The effects observed with the RGS18 knockout suggest that RGS10 and RGS18 may not be fully redundant in platelets, but this conclusion awaits studies on platelets lacking RGS10.

If RGS proteins serve as brakes, how is the application of the brakes regulated so that platelet activation can proceed when needed? Several observations suggest that RGS10 and RGS18 are at least partially sequestered in resting platelets. Both RGS proteins have been shown to bind to the scaffold protein, spinophilin (neurabin-II or SPL) in resting platelets (Ma et al. 2012). RGS18 has additionally been shown to bind to the 14-3-3 family member, 14-3-3γ (Gegenbauer et al. 2012). The association and dissociation of the RGS proteins with each of these partners involves different mechanisms. In resting platelets, RGS10 and RGS18 form a complex with spinophilin that includes the tyrosine phosphatase, SHP-1. Within this complex, spinophilin is phosphorylated on tyrosine residues Tyr398 and Tyr483, with phosphorylated Tyr398 providing a binding site for SHP-1 (Ma et al. 2012). Platelet activation by thrombin activates SHP-1. This triggers dephosphorylation of spinophilin and the gradual decay of the SPL/RGS/SHP-1 complex that takes about 1 min to complete when measured in vitro. At least in the case of thrombin, dissociation of the complex is due to phosphorylation of SHP-1 Tyr536 by members of the Src family of tyrosine kinases, activating the phosphatase (Fig. 4). Binding to 14-3-3γ, on the other hand, is mediated by phosphorylation of RGS18 Ser49 and Ser218. Ser49 phosphorylation increases during platelet activation (Gegenbauer et al. 2012). Binding to 14-3-3γ inhibits the interaction of RGS18 with activated G proteins (Gegenbauer et al. 2013). Collectively, these observations suggest a model in which RGS10 and RGS18 provide a brake on excessive platelet activation, with the availability of the RGS proteins subject to somewhat divergent interactions with spinophilin and 14-3-3γ (Fig. 4). Studies on spinophilin knockout mice are consistent with this hypothesis (Ma et al. 2012), as are results obtained with an assay for free RGS18 in platelets (Ma et al. 2015a).

cAMP and Protein Kinase A

Rising cAMP levels inhibit platelet reactivity, rendering them resistant to activation by any of the agonists that they subsequently encounter. Thus, drugs that raise platelet cAMP levels have clinically useful antiplatelet activity (Patrono et al. 2008; Jackson and Schoenwaelder 2003) and, conversely, knocking out platelet PGI_2 receptors in mice produces a prothrombotic phenotype (Murata et al. 1997). When added to platelets in vitro, PGI_2 causes a tenfold rise in the platelet cAMP concentration, but even a relatively small increase (twofold or less) impairs platelet activation (Keularts et al. 2000). Deletion of either $G_{i2\alpha}$ or $G_{z\alpha}$ causes an increase in the basal cAMP concentration in mouse platelets (Yang et al. 2002). cAMP phosphodiesterase inhibitors such as dipyridamole act as antiplatelet agents by raising cAMP levels. Conversely, loss of PGI_2 receptor (IP) expression causes a decrease in basal cAMP levels, an enhanced response to agonists, and a predisposition to thrombosis in murine arterial injury models (Yang et al. 2002; Murata et al. 1997). Despite ample evidence that cAMP inhibits platelet activation, the mechanism by which it does this is not fully understood. cAMP-dependent protein kinase A is clearly involved, but other mechanisms may be as well. Substrates for PKA in platelets include GPCRs, IP_3 receptors, GPIbβ, vasodilator-stimulated phosphoprotein (VASP), and Rap1b (Quinton and Dean 1992; Grunberg et al. 1995a, b; Smolenski 2011; Margarucci et al. 2011; Wangorsch et al. 2011; Gambaryan et al. 2010; Hayashi and Sudo 2009; Zahedi et al. 2008; Gegenbauer et al. 2012) and, as it turns out, RGS18 (Gegenbauer et al. 2013) and spinophilin (Ma et al. 2015a).

Crosstalk Among Network Regulators

As was described earlier, current evidence shows that spinophilin and 14-3-3γ are able to sequester RGS proteins in resting platelets. Gradual dissociation of the SPL/RGS/SHP-1 complex when platelets are activated can potentially lead to an increase in free RGS10 and RGS18, but does this actually occur? Although the RGS18 and spinophilin knockout studies support this conclusion, the evidence has been indirect until recent studies showing that free RGS18 levels increase when platelets are incubated with either a thrombin receptor agonist peptide, or with PGI_2 and forskolin, both of which cause an increase in platelet cAMP levels (Ma et al. 2015a).

These results provide an example of crosstalk between inhibitory pathways within the platelet signaling network. The increase in free RGS18 levels occurs for at least two reasons. cAMP-dependent phosphorylation of RGS18 on Ser216 causes it to dissociate from 14-3-3γ (Gegenbauer et al. 2013). cAMP-dependent phosphorylation of spinophilin Ser94 causes dissociation of the SPL/RGS18/SHP-1 complex by a mechanism distinct from platelet agonists (Ma et al. 2015a).

From a systems perspective, this suggests that crosstalk between platelet activation pathways, the cAMP-dependent regulatory network, and the proteins that sequester RGS18 in resting platelets produces three states with respect to the availability of free RGS18. In resting platelets (State #1), some of the RGS18 is bound to phosphorylated spinophilin in a heterotrimeric complex that includes SHP-1. Some of the remaining RGS18 is bound to 14-3-3γ, in a complex dependent on serine phosphorylation of RGS18. When platelets are activated by thrombin or TxA_2 (State #2), SHP-1 is activated and the SPL/RGS/SHP-1 complex decays. At approximately the same time, RGS18 phosphorylation on Ser49 increases, as does the amount of RGS18 bound to 14-3-3γ (Gegenbauer et al. 2012). In a sense,

spinophilin and 14-3-3γ are working against each other in activated platelets, one releasing and one capturing RGS18, but the net result is still a net increase in free RGS18. Spinophilin can bind to G protein-coupled receptors as well as to RGS proteins, suggesting that it may guide RGS proteins into the vicinity of these receptors (Wang et al. 2004). State #3 occurs when resting platelets are exposed to PGI_2, causing cAMP synthesis to increase. In the presence of cAMP, RGS18 becomes phosphorylated on Ser216 and dissociates from 14-3-3γ (Gegenbauer et al. 2013). At the same time, spinophilin becomes phosphorylated on Ser94, displacing RGS18. The release of the RGS18 from both of its binding partners contributes to the increase in free RGS18 that we observed in PGI_2- and forskolin-stimulated platelets and would be expected to contribute to the well-described resistance of these platelets to activation by platelet agonists (Fig. 4) (Ma et al. 2015a).

Signaling and Structure

Observational studies show that the hemostatic thrombi develop a characteristic heterogeneous structure in which a core of fully activated, densely packed, and stably adherent platelets is overlaid with a shell of less activated, more loosely packed, and less stable platelets (Figs. 1 and 2). When illuminated with antifibrin antibodies or fluorescent fibrinogen, fibrin is found primarily in the thrombus core as well as in nearby tissue planes if substantial leakage of plasma occurs before hemostasis is achieved (Stalker et al. 2013). For technical reasons having to do with the ability to resolve events through vascular walls, most of these studies have been performed in the microcirculation, typically using exteriorized mesentery and cremaster muscle preparations. Conditions in the macrocirculation are considerably different and it remains to be seen whether everything that has been observed in arterioles and venules will map to arteries and veins (Welsh et al. 2015; Cooley 2015; Getz et al. 2015).

Viewed from a systems perspective, the platelets depositing first at a site of vascular injury alter the local environment in which fibrin generation and subsequent platelet activation occur (Fig. 1). Initially, this is because the first platelets to arrive are activated by collagen and thrombin, thereby helping to recruit additional platelets by releasing ADP and TxA_2. Later it is because as platelets accumulate they act as obstacles to the movement of soluble platelet agonists as well as to the escape of red cells and plasma, creating protected zones that can allow local agonist concentrations to rise. Intravital studies with a fluorescent thrombin biosensor show that detectable thrombin activity is confined to the thrombus core region, consistent with the localization of fibrin (Welsh et al. 2012). Computational studies combined with intravital studies using fluorescent albumin and dextran show that intrathrombus transport rates slow even further as platelets within the thrombus core contract, pulling each other into even greater proximity (Fig. 5) (Stalker et al. 2014; Tomaiuolo et al. 2014). Notably, this drop in transport rates precedes the appearance of P-selectin on the platelet surface, a commonly used marker of platelet activation (Welsh et al. 2014). In this section, we will consider how thrombus structural heterogeneity both reflects and alters agonist distribution and, therefore, information flow through the platelet signaling network.

The current map of the platelet signaling network derives in large part from studies in which human platelet responses to agonists were measured ex vivo, either under semistatic conditions produced in test tubes and aggregometer cuvettes or under flow conditions in collagen-coated flow chambers and microfluidic devices. Essential advances have been made by studying humans with rare inherited defects and through studies on genetically engineered mice. Numerous platelet agonists have been identified ex vivo and the most critical ones studied in vivo. The ex vivo studies have identified the key components of the platelet signaling network and defined how platelets respond to individual agonists, but they fall short when it comes to explaining why structural heterogeneity arises. The hemostatic response normally takes place in a setting in which multiple agonists are present and the ability of each to reach critical concentrations is opposed by the continued flow of blood and the presence of inhibitors. When studied ex vivo all of the platelets typically have equal access to whichever agonist is being tested. Within relatively narrow limits revealed by flow cytometry, all of the platelets become activated to a similar extent.

In vivo this is not the case. Collagen exposed by vascular injury is embedded in a connective tissue matrix, incapable of coming into direct contact with more than an initial layer of platelets. As noted earlier, the observed localization of fibrin to the core of the thrombus suggests that thrombin is not present throughout the thrombus, a hypothesis supported by studies with the thrombin biosensor (Welsh et al. 2012). Infusing hirudin to inhibit thrombin reduces the size of both core and shell (Stalker et al. 2013), as does deletion of the mouse platelet thrombin receptor, PAR4 (Vandendries et al. 2007). Very different results are obtained when the role of ADP is examined. Unlike thrombin, there are no biosensors for ADP currently available that can be used in vivo. However, studies performed with the direct-acting $P2Y_{12}$ antagonist, cangrelor, and the $G_{i2\alpha}$(+/G184S) mice show that the thrombus shell is primarily driven by ADP. Infusion of cangrelor reduces the size of the shell without affecting the size of the core, while the RGS10/RGS18-resistant $G_{i2\alpha}$(G184S) substitution increases the size of the shell (Signarvic et al. 2010; Stalker et al. 2013).

It has been known for decades that fibrin clots retract as platelets contract, pulling on fibrin that is bound to the platelet surface via $\alpha_{IIb}\beta_3$ integrin. Outside-in signaling

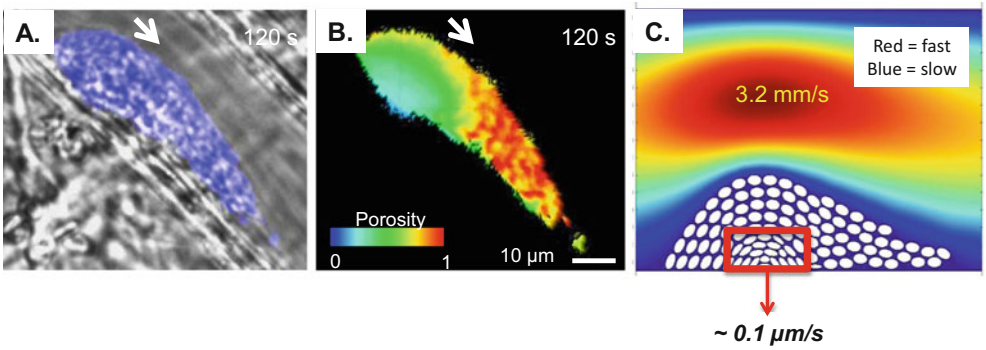

Fig. 5 Packing density and transport rates. Albumin labeled with AlexaFluor 488 was infused into the mouse prior to laser injury in the exteriorized cremaster muscle. Fluorescence was monitored within the lumen and the body of the resultant hemostatic thrombus as it developed. (**a**) A representative image of platelets (*blue*) superimposed over the bright field image captured 120 s after injury. (**b**) A pseudo-colored image of the same thrombus with colors assigned to the labeled albumin chosen to reflect the porosity based on the normalized fluorescence intensity. (**c**) Reconstruction in silico of the core/shell architecture based on experimental data. The smallest gaps between platelets were selected as 10 nm in the core and 200 nm in the shell. The inlet vessel velocity was modeled as a pressure-driven parabolic profile with maximum velocity of 2 mm/s. The computed intraluminal plasma velocity and the average intrathrombus plasma velocity in the core are shown. Platelet packing density, but not the core location, determines the average velocity between platelets (Tomaiuolo et al. 2014). Adapted from Welsh et al. (2014) and Tomaiuolo et al. (2014)

through the integrin is a primary driver for platelet contraction. Platelets bearing a double tyrosine to phenylalanine substitution (diYF) in the cytoplasmic domain of β_3 behave normally in single platelet assays but have a defect in clot retraction assays (Law et al. 1999; Stalker et al. 2014). When observed in vivo thrombi containing diYF platelets have a smaller core and accumulate less fibrin (Stalker et al. 2014). Transport studies show that soluble plasma-borne molecules move more rapidly through hemostatic thrombi formed in diYF mice than in matched controls, suggesting that the smaller core, diminished platelet activation, and reduced fibrin accumulation reflect reduced thrombin retention. Computational studies show that as the gaps between platelets grow narrower, transport becomes diffusion limited rather than convection driven (Fig. 5) (Tomaiuolo et al. 2014). Those studies are consistent with the experimental evidence showing diminished platelet activation and fibrin deposition when platelet contraction is diminished.

Is Any of This Clinically Relevant?

Aside from insights into platelet biology, there are a number of ways that applying a systems biology perspective to hemostatic thrombus formation can inform decision making by cardiologists, hematologists, and pharmaceutical companies. First, it provides a context to better understand why platelets express receptors for so many agonists, not all of which are sufficient to drive full platelet activation in vitro. There is considerable evidence that optimal platelet activation calls for simultaneous signaling through G_q, G_i, and $G_{12/13}$ family members, each of which is responsible for separate signal transduction pathways. This can be accomplished by a single potent agonist, such as thrombin, or by combinations of agonists (Jin and Kunapuli 1998). In vivo, agonists are not distributed evenly. The studies summarized in this chapter suggest that agonist concentration gradients form early in thrombus development. Critical concentrations are reached in different regions within the thrombus, which means that individual platelets within the thrombus are exposed to different combinations of agonists and these combinations can vary over time as well as space. The strengths and limitations of many commonly prescribed antiplatelet agents reflect not only their half-lives, affinities, and off-rates, but also where they work on the platelet signaling network and how well they can penetrate thrombus structure in the setting of existing disease. For example, the results with cangrelor, if generalizable to other $P2Y_{12}$ antagonists, suggest that this family of drugs limits thrombus growth and reduces the risk of recurrent thrombotic events by destabilizing the thrombus shell. This is achieved without undue bleeding risk because in many settings, the remaining thrombus core appears to be sufficient to achieve hemostasis. In contrast, a thrombin inhibitor, such as heparin, will disrupt core formation if administered before thrombus formation is initiated, but may not be able to reach thrombin in the core region of preexisting thrombi.

Second, a systems perspective on the platelet signaling network provides a different context for estimating efficacy and risk, either with new antiplatelet targets or new combinations of antiplatelet agents. Conceptually, it is safer from the hemostasis perspective to target events in the thrombus shell or, perhaps, the core-to-shell transition zone, than it is to target the core, although targeting the

core with thrombin and factor Xa inhibitors such as heparin and apixaban may be most effective in preventing thrombosis.

Third, in an era of personalized medicine, tests of on-treatment platelet function need to be better evaluated to establish their ability to work in vivo. A systems perspective the design of such tests to better reflect the complex conditions within a growing thrombus. Computational studies that recapitulate platelet accumulation and transport, may prove helpful in this regard, especially as the simulations become increasingly refined (Voronov et al. 2013; Tomaiuolo et al. 2014; Flamm et al. 2012; Wang and King 2012; Leiderman and Fogelson 2011, 2013; Kim et al. 2013; Xu et al. 2010).

Fourth, the studies described here help explain why most arterial thrombi arising from vascular disease do not initially become fully occlusive. For example, if thrombus structure in coronary arteries in the setting of atherosclerotic disease mirrors the structures described here, then the instability of the thrombus shell contributes to the failure of thrombus growth as flow rates rise in the partially obstructed arterial lumen. Finally, the perspectives described here provide new potential targets for antiplatelet agents, among them the RGS proteins, RGS10 and RGS18, and their binding partners in resting and activated platelets.

Take Home Messages

1. The platelet activation state is governed by a flexible signaling network that includes repressors as well as enhancers.
2. The enhancers promote platelet activation when vascular injury occurs. The repressors shape the hemostatic response, preventing the local accumulation of excessive numbers of platelets.
3. The elements of the signaling network that are active within each individual platelet at any given time vary not only with the time after injury, but also with the location of the platelet within the growing thrombus or hemostatic plug.
4. Location is a factor because as platelets crowd close to each other, they limit the movement of soluble agonists within the gaps between platelets, creating agonist concentration gradients. The extent of platelet activation is then determined not only by which agonists come into contact with each platelet but also by the local concentration of the agonist.

Disclosure The authors have no conflicts of interest to disclose.

Platelet-Derived Microparticles

Sylvie Cointe, Romaric Lacroix, and Françoise Dignat-George

Abstract

Numerous findings have allowed the field of microparticles (MP) to progress dramatically from the original discovery of platelet dusts characterizing the phenotypes and functions of these novel subcellular biovectors, investigating the mechanisms of their formation from parental cells, determining their effects on others cells both in physiology and disease states, and translating these notions to disease innovative diagnosis and treatment. The present chapter focuses on platelet-derived MP (PMP) characteristics, biogenesis, and biological roles. After a rapid overview of detection methods, PMP paradoxical functions in disease process and regenerative medicine are discussed, together with future prospects as diagnostic tools and therapeutic agents. PMP are naturally diffusible vectors that play a role in cell/cell communication and deliver active biomolecules. This is believed to have significant pathological implication in the development of several diseases such as cancer, thromboembolism, and atherosclerosis, among others. There is still much research required to understand the paradoxical roles played by PMP in triggering pathological events but also sustaining vessel growth and tissue regeneration. Clinical data linking PMP to pathologies should be interpreted with some caution due to the lack of standardization and technical limitations of methods for PMP exploration that have been applied so far. The recent progress in new methodologies addressing the pitfalls of current techniques in PMP isolation and detection, capable of detecting and counting PMP more accurately, to assess their variability and measure their functional activity, will contribute to a better understanding of their pathological role and also their potential promising use in regenerative medicine.

Introduction

The focus of the emerging field of microparticle (MP) research is centered upon characterizing the phenotypes and functions of these novel subcellular biovectors, investigating the mechanisms of their formation from parental cells, determining their effects on others cells both in physiology and disease states, and translating these notions to disease innovative diagnosis and treatment. In line with platelet biology, while many questions still remain unanswered, numerous findings within the past 40 years have allowed the field of MP to progress dramatically from the original discovery of platelet dust by Peter Wolf in 1967. The present chapter will focus on platelet-derived MP (PMP) characteristics, biogenesis, and biological roles. After a rapid overview of detection methods, PMP paradoxical functions in disease process and regenerative medicine will be discussed, together with future prospects as diagnostic tools and therapeutic agents.

Characteristics of Platelet-Derived MP

Platelets, like all cells, release different types of extracellular vesicles in response to cell activation and apoptosis including MP (also called microvesicles) and exosomes. While specific characteristics once vesicles are formed are lacking, these distinct entities are classically distinguished one from another based on their size, their content, the mechanisms leading to their formation, and from a practical point of view, from their mode of preparation (Table 1).

The definition of PMP started from seminal experiments conducted by Peter Wolf in 1967 (Wolf 1967) "*to provide evidence for the occurrence in normal plasma, serum and fractions derived from coagulant material of minute particulate form sedimentable by high speed centrifugation and originating from platelets but distinguishable from platelets*." Using ultracentrifugation separation, coagulation tests, and electron microscopy analyses, he observed subcellular coagulant material called "platelet *dust*." Therefore, 40 years ago, Peter Wolf revolutionized previous blood coagulation literature with his discovery of "platelet dust," which was subsequently replaced by the term of PMP.

PMP are cellular membrane fragments with a size ranging from 0.1 to 1 μm that are released in body fluids (Wolf 1967). In addition to plasma and serum, the presence of PMP has been described in vitreous fluid (Chahed et al. 2010); atherosclerotic plaques (Mallat et al. 1999; Leroyer et al. 2007); and in inflammatory fluids, such as bronchoalveolar fluid (Guervilly et al. 2011; Mutschler et al. 2002), synovial fluid (Berckmans et al. 2002), or pleural fluid (Park et al. 2013). Initially identified as an activity supporting thrombin generation in platelet poor plasma, PMP were subsequently characterized on the basis of their surface antigens. As reported for other MP subtypes, PMP externalize phosphatidylserine (PS) and thus bind annexin V in a calcium-dependent manner. They express platelet markers including glycoproteins GPIb and GPIIbIIIa, Platelet-Endothelium Cell Adhesion Molecule (PECAM-1), P-selectin, CD40 ligand (CD40L), and CXC Receptor 4 (CXCR4). However, the surface protein content may be different from that of the plasma membrane of parent cell, since the selective sorting of molecules into PMP can be regulated by the stimuli from specific agonists or microenvironments of the parent cells. When characterized by proteomic and functional studies, PMP derived from activated platelets have been separated into size classes that are heterogeneous and significantly differs in their content by membrane receptors, chemokines, and growth factors (Dean et al. 2009). Platelets carry growth factors, inflammatory mediators and cytokines, lipids, and proteases that are related to their involvement in angiogenesis, inflammation, immune response wound healing, and cell differentiation. PMP also have the ability to scavenge nitric oxide, generate reactive oxygen species, and cleave cellular surfaces proteins via metalloproteinases (Burger et al. 2013).

PMP are the most abundant MP in blood circulation, constituting approximately 70–90 % of circulating MP (Horstman and Ahn 1999; Joop et al. 2001; Berckmans et al. 2001). Studies on the half-life of MP indicate that they are rapidly cleared in the circulation (Flaumenhaft 2006; Rand et al. 2006) suggesting that PMP would need to be constantly shed from platelets from healthy individual to produce the concentration PMP circulating in the plasma of healthy individual. An alternative possibility is that PMP consist of two populations: those derived from platelets following activation and those continuously derived from megakaryocytes, the precursor cells of platelets (Cramer et al. 1997; Flaumenhaft et al. 2009; Cunningham 1995; Wang et al. 2008; Charras et al. 2006; Fackler and Grosse 2008).

In addition to MP, stimulated platelets secrete exosomes, which are smaller vesicles (40–100 nm) released as a consequence of the fusion of intraluminal membrane-bound multivesicular bodies (MVB) with the membrane, in an exocytic manner (Thery et al. 2002). In activated platelets, exosomes are formed by fusion of alpha granules and MVB with the plasma membrane. Besides differences in mechanism of formation, exosome and PMP appear morphologically, phenotypically, and functionally different (Table 1).

Table 1 Characteristics of microparticles and exosomes derived from platelets

	Exosomes	Microparticles
Size	30–100 nm	100–1000 nm
Morphology	Round	Heterogeneous
Markers	MHC, Tetraspanin (CD63, CD9, CD81, CD82, CD53), RabGTPase, Annexins, Alix, Tsg101, HSP	CD42b, CD31, CD41/CD61
		CD62P, PECAM-1, P selectin, CD63, LAMP
PS expression	–	+
Origin	Exocytose of multivesicular bodies	Vesiculation of plasma membrane
Composition	Proteins, mRNA, miRNA	Proteins, mRNA, miRNA
Method	Centrifugation > 100,000 g	Centrifugation < 100,000 g

For example, exosomes contain a very low proportion of PS if any, and have little interaction with factor X, prothrombin, or annexin V, indicating a poor or absence of effectiveness in coagulation reactions (Heijnen et al. 1999). Platelet exosome enrichment in CD63 and to a lesser extent in P-selectin suggests that they may serve specialized functions, supporting heterotypic signaling in the environment of adhering platelets and neutrophils (Heijnen et al. 1999; Denzer et al. 2000); however, none of these markers are specific of a PMP subset.

Biogenesis of PMP

MP formation results from plasma membrane budding, due to remodeling of membrane phospholipids and cleavage of cytoskeleton proteins. This process is a universal feature which occurs virtually in all cell types that are undergoing apoptosis or are being subjected to various types of stimulation or stresses. Under resting conditions, phospholipids are asymmetrically distributed in the plasma membrane, the inner leaflet containing negatively charged phospholipids such as PS and phosphatidylethanolamine. Neutral phospholipids (phosphatidylcholine and sphingomyelin) are enriched on the outer leaflet (Manno et al. 2002; Seigneuret et al. 1984; Daleke 2003). Such asymmetry is maintained by phospholipids transporters. Research over the last few years has revealed important roles for calcium-, mitochondrial-, and caspase-dependent mechanisms leading to PMP formation (Fig. 1). Indeed, in response to platelet activation, PS is exposed at the outer leaflet as a consequence of the calcium-dependent dysregulation of scramblases, floppase/ABC1, and translocase/flippase activities (Daleke 2003; Hamon et al. 2000; Zwaal and Schroit 1997). Recently, scramblase has been identified as anoctamin TMEM-16F (transmembrane protein-16F also called anoctamin 6) (Suzuki et al. 2010; Brunner et al. 2014). Membrane phospholipid remodeling also requires cytoskeleton reorganization involving calcium-activated proteases such as caspases and calpains. The exact role of transmembrane ion transport (Heemskerk et al. 2002; Bucki et al. 2006), transient transmembrane pore, and Store-Operated Calcium Entry (SOCE) in PS exposure deserves further investigations to gain insight into a potential

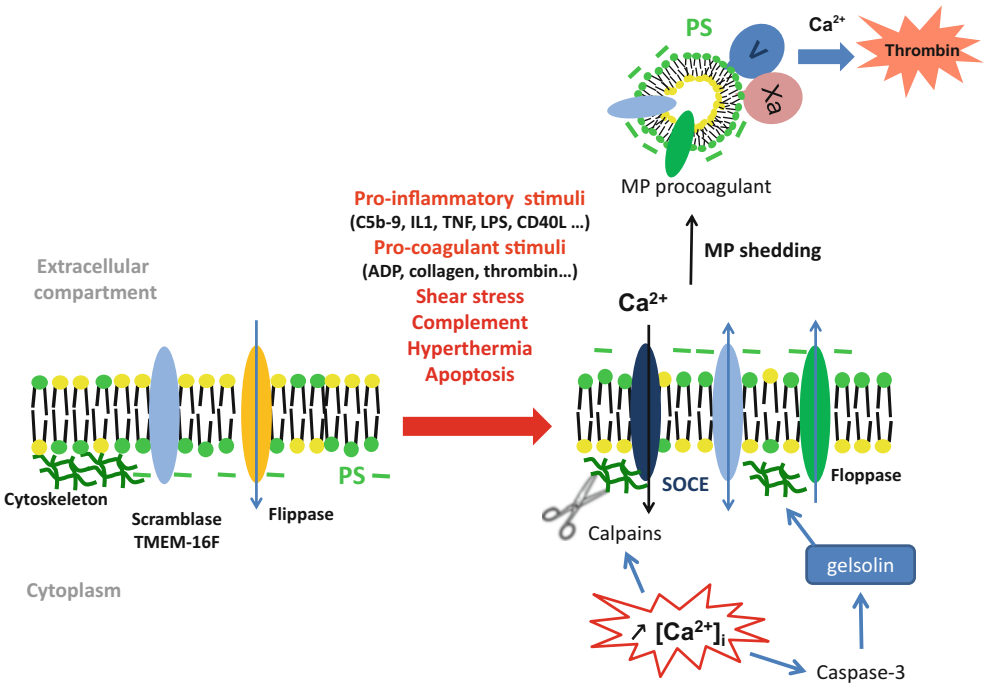

Fig. 1 Biogenesis mechanisms of PMP. At rest (*left figure*), phospholipids in the plasma membrane have an asymmetrical distribution, especially phosphatidylserine negatively charged, located in the inner leaflet. Cytoskeletal reorganization involves proteases activation by cytosolic calcium such as caspase-3 and calpains. Intracellular calcium is needed to increase the exposure of phosphatidylserine and involves different mechanisms: transmembrane pores and store-operated Ca(2+) entry (SOCE). During cell activation or apoptosis, reorganization of the cytoskeleton is dependent on the activation of rho-associated coiled-coil-containing protein kinase 1 (ROCK-I), ultimately resulting in the release of MPs into the extracellular fluid. The rearrangement of the cytoskeleton leads to budding of the membrane and release of MP that expose PS, membrane antigens, and cytoplasm components. The presence of PS on the outer leaflet of MP provides a catalytic surface able to assemble coagulation enzymatic complexes and to generate thrombin. *Ag* antigen, *PS* phosphatidylserine, *TMEM-16F* transmembrane protein-16F, *SOCE* store-operated calcium entry, *LPS* lipopolysaccharide, *TNF* tumor necrosis factor, *ADP* adenosine diphosphate, *IL1* interleukin 1, Ca^{2+} calcium, *MLC* myosine light chain

pharmacological control of PMP shedding. More recent studies indicate that mitochondrial membrane depolarization is an integral event leading to PS externalization (Lopez et al. 2008; Leytin et al. 2009). Taken together, the phospholipid transient mass imbalance between the two leaflets and the proteolysis of the cytoskeleton triggered by calcium-activated calpains induces the shedding of PMP. Compared to other cells, platelets have the highest scrambling rate known, which ensure a rapid and localized blood coagulation. It is important to emphasize that rapid phospholipid membrane remodeling and PS exposure characterize a physiological relevant procoagulant response. Accordingly, PS borne by MP provides accessible sites for the assembly of the coagulation complexes, leading to thrombin generation and clotting. In this context, shed PMP could protect from bleeding during idiopathic thrombocytopenic purpura (Jy et al. 1992). The physiological relevance of platelet membrane remodeling and PMP shedding is also well exemplified in Scott syndrome. This rare bleeding disorder is characterized by provoked hemorrhages caused by reduced floppase activity of cells, diminished externalization of PS, and reduced MP shedding (Toti et al. 1996). Several authors have described mutations in the gene encoding TMEM16F in these patients (Castoldi et al. 2011; Suzuki et al. 2010).

PMP shedding occurs after physiological activation of platelets by thrombin, adenosine diphosphate or collagen (Sims et al. 1989; Wiedmer et al. 1990; Italiano et al. 2010; Zwaal et al. 1992) or other agonists or stimulating conditions including calcium ionophore, CD40L, and oxidative stress (Morel et al. 2004; Simak and Gelderman 2006; Horstman et al. 2004). PMP shedding has also been reported following exposure of platelets to purified complement components (Sims et al. 1988). One hypothesis is that recovery of membrane potential may follow shedding of PMP carrying the C5b-9 pore membrane attack complex (MAC), on the basis that PMP from platelets exposed to MAC carried the majority of available MAC. Such hypothesis is substantiated by the observation of increased levels of PMP in Paroxysmal Nocturnal Hemoglobinuria, a pathological setting where complement-mediated platelet activation occurs (Hugel et al. 1999). It has been reported that high shear forces trigger platelet activation and PMP release. Activation of protein kinase C promotes shear-dependent PMP formation (Miyazaki et al. 1996; Holme et al. 1997). When high shear forces are applied in the microcirculation, thrombin generated in the vicinity of the hemostatic plug is crucial for PMP generation, with a correlation between platelet-activating factor release and PMP biogenesis (Iwamoto et al. 1996; Chow et al. 2000). The capacity of MP to be generated by physical reactions occurring during blood product manipulations, such as shear forces, contact surfaces, and senescence, makes PMP an integral part of transfusion medicine. Platelet activation induced by antibodies can also be accompanied by the formation of PMP. Immunoglobulins (Ig)G to heparin-platelet factor four complexes as observed in heparin-induced thrombocytopenia (HIT) generate PMP (Untch et al. 2002). This property is the basis of a PMP generation assay for HIT diagnosis (Mullier et al. 2014). Similarly, autoimmune antibodies against platelet antigens are associated with PMP generation. The role of these antibodies is supported by animal models of immune thrombocytopenia where the injection of antiplatelet antibodies in mice induced thrombocytopenia associated with increased circulating PMP (Piguet and Vesin 2002).

Vesicle shedding also occurs during senescence and apoptosis of either anucleated cells like platelets (Zwaal et al. 1992) and nucleated cells like the megakaryocytes (Flaumenhaft et al. 2009). Before cells undergo nuclear apoptotic DNA fragmentation, they show early cell membrane asymmetry and expose PS (Yang et al. 2002). Platelets contain several key regulators of apoptotic cell death including caspases, different members of the B-cell lymphoma (Bcl)-2 protein family, and mitochondrial pathways (Shcherbina and Remold-O'Donnell 1999; Zhang et al. 2007; Jobe et al. 2008). It was demonstrated that the platelet apoptotic machinery and the classical calcium-derived rapid agonist pathways, although both able to promote PS exposure, are distinct. For example, hyperthermia has been identified as a physical condition known to affect PMP biogenesis by triggering apoptotic events, including caspase 3-dependent gelsolin cleavage and PS exposure (Wang et al. 2010). The coexistence of different signaling pathways triggered either by activation or apoptotic stimuli is not restricted to platelets. It has also been reported for endothelial cells and reflects distinct mechanisms leading to the release of extracellular vesicles (Dignat-George and Boulanger 2011).

Biological Functions of PMP

PMP have crucial roles in different biological functions: hemostasis, host defense, response to injury, and immune response (Fig. 2).

The procoagulant properties of MP rely mainly on the expression of anionic phospholipids, especially PS which provide a catalytic phospholipid surface for the assembly of blood coagulation factors: FII, VII, IX, and X, as well as the assembly of the coagulation complexes, accelerating the formation of thrombin (Morel et al. 2006). Interestingly, although this phospholipid-dependent procoagulant activity appears to be a common mechanism between the different MP subsets, PMP membrane is among the most efficient to contribute to the thrombin generation and fibrin formation. PMP isolated from major thalassemia patients are more procoagulant than MP derived from erythrocyte. This

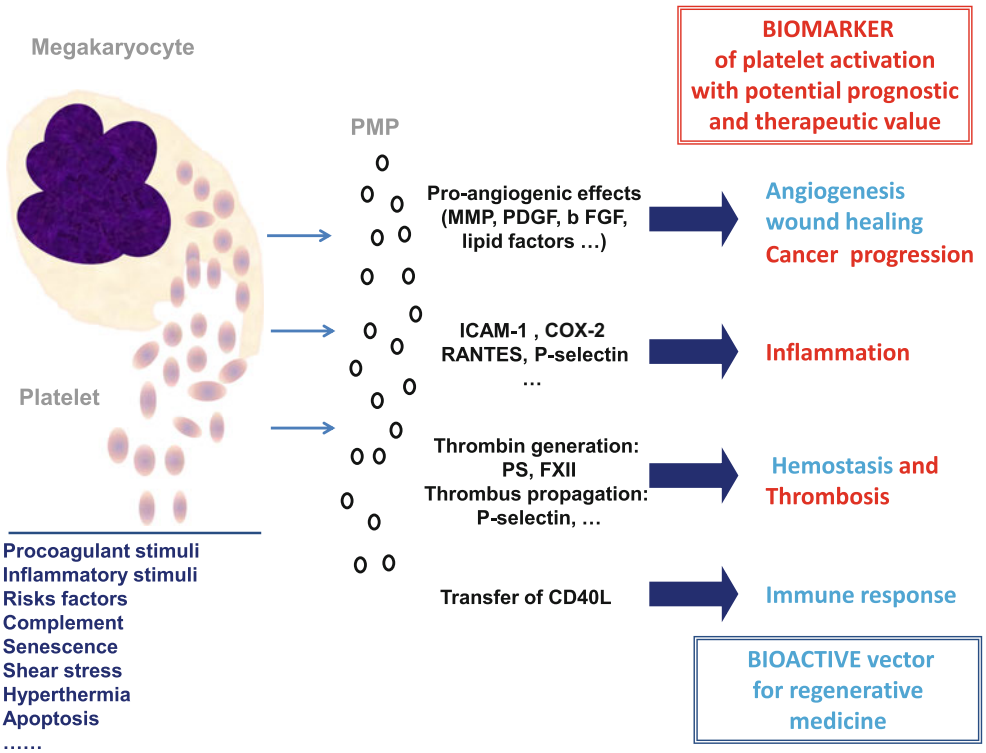

Fig. 2 Paradoxical biological functions of PMP. PMP might have deleterious effect (shown in *red*), such as promoting cancer progression or stimulating inflammation and thrombosis. Alternatively, PMP might have beneficial effect (shown in *blue*) because of angiogenesis and wound healing process and in immune response by collaborating to B-cells. *PDGF* platelet-derived growth factor, *b FGF* basic fibroblast growth factor, *ICAM-1* intercellular adhesion molecule 1, *COX-2* cyclooxygenase 2, *PS* phosphatidylserine, *VEGF* vascular endothelial growth factor, *FGF-2* fibroblast growth factor 2, *RANTES* regulated on activation, normal T expressed and secreted

activity is further amplified after splenectomy independently of the PMP numbers (Agouti et al. 2015). PMP were also suggested to express tissue factor (TF) (Schwertz et al. 2006); however, this expression is controversial and may result in part from the fusion of monocyte-derived TF^+ (positive) MP with activated platelets. Because TF-dependent procoagulant activity of PMP seems limited (Owens and Mackman 2011), it is unlikely that PMP can provide a major contribution to the pool of TF^+ MP present in healthy individuals and in patients (Lacroix et al. 2013a). However, as recently described, platelet and erythrocyte MP not only propagate coagulation by exposing PS but also initiate thrombin generation independently of TF in a factor XII-dependent manner (Van Der Meijden et al. 2012). Interestingly, PMP vectorize the plasminogen activator inhibitor (PAI)-1 and contrary to endothelium-, leukocyte-, or tumor-derived MP, they are devoid of fibrinolytic activity which may counterbalance their procoagulant activity (Lacroix et al. 2012b; Lacroix and Dignat-George 2013).

Many studies have described the involvement of circulating PMP in inflammation. In fact, PMP constitute an important source of substrate for phospholipase A2, generating lysophosphatidic acid, a potent proinflammatory mediator and platelet agonist (Barry et al. 1999). Arachidonic acid, transported by MP, is able to stimulate the expression of cyclo-oxygenase-2 on endothelial cells and monocytes and thereby the production of prostaglandins (Barry et al. 1997). The arachidonic acid transfer also induces membrane expression of ICAM-1 (intercellular adhesion molecule 1) on the endothelium which will consequently stimulate monocyte adhesion to the surface of endothelial cells (Barry et al. 1998). They may also facilitate the recruitment of many immune cells (monocytes; neutrophils; lymphocytes T, B; and Natural Killer cells), in particular, by the interaction between P-selectin on PMP and P-selectin glycoprotein ligand-1 on neutrophils (Ogura et al. 2001; Forlow et al. 2000; Baj-Krzyworzeka et al. 2002). Platelets can interact directly with the activated endothelium by increasing the monocyte recruitment after the transfer by PMP of chemokines such as RANTES (Regulated on Activation, Normal T Expressed and Secreted) (Mause et al. 2005).

Platelets play also an important role in modulating immunity (Semple and Freedman 2010). While there is support for the concept that PMP release play a role in this regulation, the underlying mechanisms by which they provide early signals to immune cells are not fully understood. Sprague et al. have shown that PMP activate adaptive immune cells in specific tissue compartments in a CD154-dependent manner that trigger antibody synthesis and alter lymphocyte activities (Sprague et al. 2008). Using an adoptive transfer model, the authors show that PMP transfer activation signals to B-cells. PMP transport and deliver CD154 (CD40L) to turn on antigen-specific immunoglobulin G production and germinal center formation. The release of PMP from sites of thrombosis in disease states may, therefore, stimulate an immune response.

Several studies have shown that PMP have the capacity to induce angiogenesis and are involved in the metastasis of cancer. Indeed, PMP promoted the proliferation, survival,

migration, and tube formation of human umbilical vein endothelial cells, suggesting that PMP may favor the formation of new blood vessels during tumor growth. This effect was mediated by the concerted action of fibroblast growth factor-2 (FGF-2), vascular endothelial growth factor (VEGF), and lipid factor such as sphingosine 1-phosphate (S1P), lysophosphatidic acid, and phosphatidate (Kim et al. 2004). PMP also induced sprouting of blood vessels both in vitro and in vivo (Brill et al. 2005). Furthermore, intramyocardial injection of PMP markedly elevated the amount of new capillaries formed in the heart muscle in the background of ischemia (Horstman et al. 2007).

PMP play also a significant role as vector in the transcellular communication as they possess various types of receptors and bioactive substances on their surface including cytokines, signal proteins, and nucleic acids, in addition to mRNA and mi-(micro)RNA (Wu et al. 2013; Freyssinet 2003). They exchange biological information with target cells such as, for example, monocytes or endothelial cells either via surface-expressed ligands or by transporting surface receptors from one cell to the other. MP also has the capacity to reprogram target cells via attaching or fusing and delivering cytoplasmic proteins and RNA to the cells. The fusion of PMP membranes to target cell membranes was demonstrated to transfer the surface protein CXCR4 to cells causing recipient cells (glioblastoma and hematopoietic cell lines or erythroblasts) susceptibility to human immunodeficiency virus infection (Rozmyslowicz et al. 2003). Arachidonic acid is a lipid mediator delivered by PMP that can be further processed into thromboxane A2 by recipient platelets or endothelial cells and contribute to their activation (Barry et al. 1997). Several works showed that PMP contain transcription factors, such as peroxisome proliferator-activated receptor (PPAR)γ (Ray et al. 2008), RuvB-like 2, Signal Transducer and Activator of Transcription (STAT)3, and STAT5A (Garcia et al. 2005) derived from platelets. Transcription factors are transported from platelets through MP and retain function within monocytes (Ray et al. 2008). Human platelets activated by thrombin release their miR-223 contents in PMP that can be internalized by Human umbilical vein endothelial cells (HUVEC). Functional Argonaute 2 (Ago2)/miR-223 complexes present in PMP were shown to regulate the expression of a reporter gene in recipient HUVEC, exerting heterotypic regulation of gene expression of endothelial cells (Laffont et al. 2013). Thus, cocultures of PMP with various cell types further allow to investigate their role in the intercellular communication.

Detection Methods and Assays for MP Determination

Platelets are easily activated in vitro; therefore, accurate characterization of PMP requires very rigorous preanalytical handling and processing of blood samples (i.e., phlebotomy, transport, plasma preparation, and storage). Controlling these steps is a prerequisite to avoid artifactual generation of PMP (Ayers et al. 2011; Lacroix et al. 2012a; Artoni et al. 2012), to allow intra- and interlaboratory standardization and data interpretation (Lacroix et al. 2013b). In the field of the International Society of Thrombosis and Haemostasis (ISTH), recommended protocol for isolation of PMPs from whole blood samples has been proposed for MP assessing in clinical samples. Important experimental factors to consider include (1) using a large needle size (21G minimum), (2) discarding the first milliliters of blood, (3) using appropriate anticoagulant (citrate) to limit artifactual vesiculation, (4) limiting agitation and horizontal transportation of tubes, (5) delaying by a 2 h maximum the first centrifugation after blood collection, and (6) carefully controlling the centrifugation process in order to remove all platelets before freezing.

Different methodologies have been adapted to characterize PMP (Table 2).

Table 2 Methods of PMP characterization (adapted from *Bartenevaetal et al. BMC Cell Biol. 2013*)

Method	Quantification	Phenotype	Sizes	Limits
Flow cytometry	+	+	Limited	Aggregates, diameter > 200 nm
DLS or NTA	+	–	+	Artifacts (cellular debris and proteins)
RPS	+	–	+	Artifacts (cellular debris and proteins, lipids)
Electron microscopy	Limited	Limited[a]	+	Artifacts during sample preparation
AFM	Limited	Limited[b]	+	Artifacts (cellular debris and proteins)
ELISA	+	+	–	Accessibility of PS or activated molecule carried by MP
Functional tests	+	+[c]	–	Accessibility of PS or activated molecule carried by MP
Mass spectrometry	–	+ (proteins extraction)	–	Sample > 10 μg

AFM atomic force microscopy, *DLS* dynamic light scattering, *ELISA* enzyme Linked ImmunoSorbent Assay, *NTA* nanoparticle tracking analysis, *RPS* resistive pulse sensing

[a]Annexin V and specific monoclonal antibodies labeled with gold beads of different diameters (up to 3 simultaneous markings)

[b]Development of surfaces coated with specific monoclonal antibodies

[c]By capture on magnetic beads

Among physical methods, flow cytometry (FCM) remains the most commonly used technique with the highest potential to determine the MP origin (van der Pol et al. 2014). Over the past few years, significant improvements in the sensitivity to detect vesicles of smaller size have confirmed this methodology as the most promising for routine enumeration of MP subsets (Robert et al. 2012; Hoen et al. 2011; Zhu et al. 2014). The possibility of simultaneously detecting two or more antigens on MPs by antibodies conjugated with different chromophores is the main advantage of the method. Generally, annexin-V, which has a high affinity for PS, is used as a general marker for MP despite the fact that not all MP expose PS. Its combination with a platelet marker such as integrin-α_{IIb} (CD41), which is the most specific, CD-61, CD42b, or P-selectin (CD-62P) allows to identify PMP. This method is also the first to benefit from standardization efforts coordinated by the ISTH standardization committee. Thus, several dedicate tools have been developed such as Megamix beads and help to improve the intra and interinstrument reproducibility (Lacroix et al. 2009, 2010; Poncelet et al. 2015). Combination of this methodology with impedance or fluorescence microscopy opens interesting perspective that needs further developments before significantly adding to the methodological toolbox of PMP assessment (Zwicker 2008; Zwicker et al. 2012; Headland et al. 2014).

To overcome the lack of sensitivity of FCM to detect MP of smaller size, alternative methodologies based on light scattering or impedance are available. Dynamic light scattering (DLS) analyzes PMP exposed to monochromatic light from a laser. PMP scatter the light and produce Brownian motion that can be analyzed to determine the size distribution (Lawrie et al. 2009). Although, determination of the PMP concentration of platelet-rich plasma and apheresis platelet concentrates by DLS was reported (Xu et al. 2011), this method is only accurate in a monodisperse system. Thus, methodologies such as Nanoparticle Tracking Analysis (NTA) allowing to measure the Brownian motion under a laser beam of individual particles have been applied (Dragovic et al. 2011). The light scattered from the particles can be visualized by microscopy, and the particle movements of each MP recorded with a camera allowing to count and measure each MP individually. NTA allowed to detect particles smaller than 100 nm but with a low resolution (van der Pol et al. 2014). The main limitation of this methodology is clearly the lack of specificity of the detected events which may be partially overcome using operation in fluorescence mode through identification of membrane markers. Optimal concentration for counting is in the range of 10^8 to 10^9 MP/ml. Thus, larger PMP are not visible because of the low volume analyzed. Alternatively, Tunable Resistive Pulse Sensing (TRPS) is a technique based on impedance to monitor individual MP of 80–1000 nm or more, as they move through tunable nanopores in elastomeric membranes (Coumans et al. 2014). Nanoparticles are measured due to a change in the electric resistance when they pass through the pores, enabling a determination of the size distribution, surface charge, concentration, and zeta potential of the nano/microparticles present in a complex and polydispersed particle samples. Although this methodology detects events smaller than FMC, it is not possible to distinguish MP from lipoproteins or protein aggregates or to determine the origin subsets of MP.

Microscopy methods have the best sensitivity to visualize PMP and determine their structure but cannot be used as a routine methodology because of the time-consuming process. Among them cryo-transmission electron microscopy which allows to image MP in their native form revealed key information about their diversity in biological fluids (Arraud et al. 2014). Origin of MP can be determined by immunogold labeling. Atomic force microscopy (AFM) allows a very sensitive detection of PMP when CD41-positive PMP are captured by anti-CD41 antibodies bound onto a flat muscovite mica surface, a nonconducting layered mineral. AFM can determine the size, antigenic properties, and numbers of defined subsets of MPs (Yuana et al. 2010).

An other group of method is composed of bulk assays providing a global information from each sample. This include immunoassays, functional assays, and hybrid assays associating capture and function testing determining the procoagulant activity, in relation to the presence of PPL or exposure to PS, TF, or other PMP surface markers. An ELISA method based on the binding of PMP by two monoclonal antibodies against glycoprotein (GP) CD42a (GPIX) and CD42b (GPIb) markers was developed in Japan (Osumi et al. 2001). This assay was used in a multicentric assessment of samples from patients with atherothrombosis and found to yield data similar to FCM (Nomura et al. 2009). Functional assays for MP are mainly based on PS- or TF-dependent procoagulant activity but only tests related to PS are related to PMP. PMP can be quantified by measuring the concentration of negatively charged PPL that induces prothrombinase activity. STA-Procoagulant-PPL* (Stago, Asnières-sur-Seine, France) is a clotting assay to detect procoagulant phospholipids (PPL) based on the time needed to generate a clot when a test sample containing PMP is added to plasma depleted of procoagulant PPL. Coagulation is triggered by the addition of activated factor X (FXa) (Gonzalez et al. 2009). MP-dependent thrombin generation tests can be performed in microplate format using the Calibrated Automated Thrombogram* system (Thrombinoscope BV, Maastricht, NL and Stago, Asnieres, F) (Hemker et al. 2002). A reagent containing TF and a minimal amount of PPL is added to the plasma sample to induce thrombin generation through TF-bearing MP. Thrombin is quantified using a

thrombin fluorogenic substrate and calcium. Finally, hybrid assays such as Zymuphen-MP* technology, commercialized by Hyphen Biomed (Andresy, F) combine solid-phase capture of MP on annexin V or antibody and determination of prothrombinase activity (Jy et al. 2004).

In addition, proteomic approaches are very useful for determining the protein composition of PMP and for elucidating their physiological functions. PMP contents have begun to be unveiled using newly developed proteomic approaches. Such exploration involves critical steps to purify PMP. Various analytical methods such as 2D electrophoresis, ultraperformance liquid chromatography, nano high-performance liquid chromatography (HPLC), matrix-assisted laser desorption ionization (MALDI) tandem mass spectrometry, spectral count analysis, etc., can be used for identification (Watts et al. 2012; Capriotti et al. 2013).

Depending on the purpose of PMP characterization (molecular composition, number, size, functional activity, etc.) and the sample nature (plasma, cell supernatant, etc.) an appropriate combination of methods should be made taking into account their current limitations.

PMP in Diseases

PMP could play a critical role in numerous physiopathology conditions: immune and inflammatory disorders, cardiovascular disorders, cancer, and infectious diseases. Boilard et al. have shown the important role played by PMP in inflammatory responses of auto-immune diseases like rheumatoid arthritis by promoting the release of inflammatory interleukines (Boilard et al. 2010) and by the presence of immune complexes on their surface (Cloutier et al. 2013). Platelets accumulate in the joints of rheumatoid arthritis patients and elevated numbers of PMP are found in their synovial fluid. PMP induce an innate immune response via the elicitation of cytokine responses (IL-1) from synovial fibroblasts and the presence of mitochondrial components inside PMP. These reports put forward that PMP might be the culprits involved in the inflammatory and thromboembolic processes in rheumatoid arthritis patients (Knijff-Dutmer et al. 2002).

Because PMP express procoagulant PS on their surface, they may be involved in the pathogenesis of arterial thrombotic and thromboembolic complications (Italiano et al. 2010; Puddu et al. 2010). Acute coronary syndrome is associated with platelet activation and the released PMP which provide a new prothrombotic interface for fibrin, blood cell, and a growing thrombus resulting in narrowing of the vessel. In fact, the PMP contain receptors ($\alpha_{IIb}\beta_3$, Ib, Ia, and IIa) for platelet–subendothelium attachment, and P-selectin for platelet–leukocyte interactions and inflammatory response (Li and Cong 2009). Several studies have evidenced that circulating MP might serve as potential prognostic markers for atherosclerotic vascular disease. PMP that express P-selectin and CD63 on their surface are a sign of platelet activation in peripheral arterial disease and myocardial infarction (van der Zee et al. 2006). PMP contribute also to cardiovascular risk in diabetes mellitus patients. Further, these patients are reported with platelet hyper-reactivity and increased platelet activation due to a multitude of factors (hypersecretion of insulin, hyperglycemia, hyperlipidemia, oxidative stress, endothelial dysfunction, and inflammatory condition). Cohen et al. reported that there was conjecture that the increased thrombin activity, PMP formation, and caspase activity together in the type 2 diabetic blood may contribute to the hypercoagulability of diabetic blood. The study highlighted the link between diabetic platelets and coagulation proteins that lead to prothrombotic condition and validates the increased risk of thromboembolic events in diabetic population (Cohen et al. 2002). PMP were also reported to promote the expression of adhesion molecules in monocytes and endothelial cells and therefore, it appears that they might even participate in the development of atherosclerosis in diabetics (Nomura et al. 2011).

High PMP levels could play a role in cancer, in particular, in tumor progression and reduced response to treatment (Helley et al. 2009). PMP are reported to promote angiogenesis during tumor growth via VEGF, FGF-2, and lipid factor (Brill et al. 2005). In gastric cancer, PMP levels are better forecasters of metastasis than IL-6, RANTES, and VEGF (Kim et al. 2003). PMP can also trigger the secretion of matrix metalloproteinase-2 in prostate cancer cells, promoting tumor invasiveness (Dashevsky et al. 2009).

Activated platelets and MP are reported to play a role in infectious diseases. In particular, in malaria infection in altering the blood–brain barrier leading to severe form of malaria called cerebral malaria (Combes et al. 2006) and in hyperthermia and dengue. In a recent study, it was reported that in the course of dengue infection activated and apoptotic platelets aggregate with monocytes and trigger specific cytokines (IL-1b, IL-8, IL-10, and monocyte chemoattractant protein-1 (MCP-1)) (Hottz et al. 2014).

Although accumulating evidence argues in favor of a key role of PMP in different pathophysiological mechanisms, their specific contribution compared to platelets is not fully established. Animal models where the vesiculation process would be blocked are critically needed to clearly identify PMP as a pharmacological target.

PMP in Regenerative Medicine

Due to their content of bioactive substances entrapped within their granules, it is well established that platelets play a major role in tissue repair, vascular remodeling, and tissue regeneration (Nurden et al. 2008). Platelet alpha

granules contain a large spectrum of growth factors orchestrating tissue regeneration, such as platelet-derived growth factor (PDGF), tumor growth factor (TGF)-beta1, VEGF, epithelial growth factor (EGF), and Brain-derived neurotrophic factor (BDNF). Platelet growth factor preparations are increasingly used in clinics for the healing of soft and hard tissues (Burnouf et al. 2013; Tzeng et al. 2013; Chen et al. 2010). However, little is known about the capacity of PMP *per se* to play a role in tissue repair. Because PMP are implicated in development, angiogenesis, wound healing and more generally, in tissue remodeling, one can hypothesize that they are acting as naturally occurring liposome-like structures, able to have beneficial role for vascular regeneration. The constant presence of PMP in the blood stream has a physiologically significant contribution to maintain the function of healthy vessels (Siljander 2011). The addition of PMP to endothelial progenitor cells enhanced their regenerative capacities in vivo by stimulating their recruitment, migration, and differentiation (Mause and Weber 2010). PMP were also reported to act by inducing the transformation of peripheral blood monocytes into endothelial progenitors, with possible implications for cardiovascular disorders (Prokopi et al. 2009). PMP also plays a role in repair of myocardial muscle as intramyocardial injections induce a marked increase in the amount of capillaries following ischemia (Italiano et al. 2010). Injection of endothelial progenitor cells preconditioned by PMP has also been reported to enhance the effect of therapeutic angiogenesis for limb ischemia, in atherosclerotic patients (Ohtsuka et al. 2013). Local application of PMP, that contain cytokines and growth factors that influence angiogenesis, may emerge as a novel therapeutic strategy for targeting angiogenesis-related conditions (Varon and Shai 2009).

The regenerative role of PMP on hard tissues is suggested by observations showing that these vesicles accelerate bone regeneration in grafting applications, as evidenced by increased mitogenic responses of trabecular bone-derived cells, thereby contributing to regeneration of mineralized tissues (Gruber et al. 2002). PMP were also reported to promote neuronal cell proliferation, survival, and differentiation, suggesting a role in treating brain injuries (Hayon et al. 2012b). Indeed, PMP were found to (1) be internalized in human brain endothelial cells in vitro and modify their function (Faille et al. 2009, 2012); (2) promote angiogenesis and reperfusion in postischemic revascularization in a rat model (Burnouf et al. 2013); (3) increase in vitro survival, proliferation, and differentiation of neural cells (Hayon et al. 2012b; Brill et al. 2005; Mack et al. 2000). The phospho-AKT (protein kinase B) and pERK (extracellular signal-regulated kinase) pathways have proposed as potential mechanisms. Interestingly, these effects were confirmed using in vivo models of cerebral ischemia, where PMP were topically applied to injured brain using a biodegradable polymer (Hayon et al. 2012a; Shan et al. 2013), nicely demonstrating the therapeutic potential of PMP in strokes and possibly in neurological diseases.

Future Directions

In this chapter, we have attempted to highlight that PMP are not merely "platelet dust" exposing procoagulant/prothrombotic molecules but are increasingly believed to act, as naturally diffusible vectors that play a role in cell/cell communication and delivery of active biomolecules. Such cell/cell communication is believed to have significant pathological implication in the development of several diseases such as cancer, thromboembolism, and atherosclerosis, among others. There is still much research required to understand the paradoxical roles played by PMP in triggering pathological events but also sustaining vessel growth and tissue regeneration. The mechanisms involved in the generation of excessive PMP and their association with various pathologies are just beginning to be unveiled. It is a known fact that platelets produce different types of MP in response to different stimuli under varying physiological and pathological conditions. These PMP vary in their composition and thereby in their effect produced on the target cells as well. Therefore, with the background of recent research activities on personalized medicines, the future of PMP would be their application as emergent biomarkers for disease management. Another side would be to generate tailor-made PMP, generated by incorporating specific effectors molecules as well as surface antigens, which target a specific set of cells or tissues. Clinical data linking PMP to pathologies should be interpreted with some caution due to the lack of standardization and technical limitations of methods for PMP exploration that have been applied so far. The recent progress in new methodologies addressing the pitfalls of current techniques in PMP isolation and detection, capable of detecting and counting PMP more accurately, to assess their variability and measure their functional activity, will contribute to a better understanding of their pathological roles and also their potential promising use in regenerative medicine.

- Much research is required to understand the paradoxical roles played by PMP in triggering

(continued)

pathological events but also sustaining vessel growth and tissue regeneration.
- Early clinical data linking PMP to pathologies should be interpreted with due to the lack of standardization and technical limitations of methods.
- The recent progress in PMP isolation and detection will contribute to a better understanding of their pathological role and their potential promising use in regenerative medicine.

Platelet Interactions with the Blood Vessel Wall

Vascular Control of Platelets

Bradley A. Maron and Joseph Loscalzo

Abstract

Appropriate hemostasis hinges on normal vascular control of platelet function to suppress thrombosis in the absence of blood vessel injury. In this regard, normal intercellular communication between vascular endothelial cells and platelets is integral to maintaining platelets in an inactivated state and inhibiting maladaptive clot (thrombus) formation. Conversely, disruption to endogenous synthesis of nitric oxide, prostaglandin I_2, and endothelial cell surface-associated ecto-ADPase/CD39 occurring due to genetic or acquired factors is an important contributor to the pathogenesis of clinically important thrombotic pathophenotypes, including myocardial infarction and stroke. By analyzing differences in vascular control of platelets according to circulatory bed, particularly with respect to the pulmonary and systemic circuits, understanding the relevance of hypoxia, inflammation, blood flow, and oxidant stress to platelet aggregation and adhesion is enhanced. It is also anticipated that clarifying the biophysical and molecular sequence of events underpinning endothelial regulation of platelet activation will require next-generation methods that utilize whole organ platforms in silico to identify novel mediators of thrombosis in vivo and prevent the attendant adverse consequences in patients.

Abbreviations

AC	Adenylyl cyclase
ADP	Adenosine diphosphate
ATP	Adenosine triphosphate
CAD	Coronary artery disease
cAMP	Cyclic adenosine monophosphate
cGMP	Cyclic guanosine monophosphate
COX	Cyclooxygenase
CTEPH	Chronic thromboembolic pulmonary hypertension
Da	Dalton
H_2O_2	Hydrogen peroxide
IL	Interleukin
IP3	Inositol triphosphate
MLC	Myosin light chain
MLCK	Myosin light chain kinase
$NO^{\cdot}$	Nitric oxide
NO_2^-	Nitrite
NO_3^-	Nitrate
NOS	Nitric oxide synthase
NOx	Nitrogen oxides
NOX	NADPH oxidase
$O_2^{-\cdot}$	Superoxide anion
$ONOO^-$	Peroxynitrite
PAH	Pulmonary arterial hypertension
PAI-1	Plasminogen activator inhibitor-1
PG	Prostaglandin
PKG	Protein kinase G

Introduction

The endothelium is a thin cell layer lining the blood vessel wall interior that performs various critical functions to maintain vascular hemostasis. While the endothelium operates as a physical barrier to prevent transvascular fluid flux (edema) and extravasation of blood to the extravascular space (hemorrhage), it also regulates vascular function by serving as a cellular source of key effectors that interact with circulating blood cells (Rondina et al. 2013). In this regard, a principal function of vascular endothelial cells is to interface with platelets to inhibit and coordinate thrombosis and hemostasis, respectively, under physiological and pathological conditions, respectively. Thus, although platelets are the central cell type involved in thrombosis and many clinically important blood dyscrasias, mammalian vascular hemostasis must be considered in the context of the platelet–endothelial cell interaction to understand the full scale of hemostasis biology.

Intercellular communication between the platelet and endothelium is driven by dynamic alterations to the protein expression profile of each cell type. This may involve changes in expression of cell-specific ligand(s) or receptor (s), such as upregulation of the integrin CD40L that interacts with $\alpha_{IIb}\beta_3$ in activated platelets to stabilize clot formation (Fuentes et al. 2013). In addition, platelet-derived paracrine factors, such as serotonin, exert control over platelet–endothelial interaction kinetics to increase vascular tone, levels of procoagulant proteins, and thrombus/fibrin synthesis (Weyrich and Zimmerman 2013). Direct transfer of RNA from platelets to endothelial cells is yet an additional mechanism leading to alterations in the programmed response to vascular stress or injury (Risitano et al. 2012; Rondina et al. 2013).

End-clinical pathophenotypes characterized by platelet overactivation, such as myocardial infarction and stroke are due, in part, to failed suppression of platelet activation by the endothelium. Broader pathogenic processes occurring concomitantly with or promoting vascular disease, such as inflammation or atherosclerosis, often trigger inhibition of mechanisms that protect the endothelium from inappropriate thrombosis. Predicting the functional consequences of maladaptive changes to bidirectional signaling between platelets and endothelial cells, however, hinges on blood vessel caliber, anatomic orientation (e.g., systemic vs. pulmonary circulation), and the presence of genetic predispositions to thrombosis.

Endothelial nitric oxide ($NO^{\cdot}$), prostaglandin I_2 (PGI_2), and endothelial cell surface-expressed ecto-ADPase/CD39 are three important bioactive systems that suppress platelet aggregation and adhesion. This chapter will review traditional and novel concepts underlying the molecular basis of platelet–endothelial interactions in the physiological and diseased state with emphasis on these three systems. We will also analyze differences in vascular control of platelet function that are observed between the systemic and pulmonary circulations, and discuss novel in silico technological platforms that aim to clarify the physical and biomechanical underpinnings of the platelet–endothelial interface.

Nitric Oxide

A 30 Da lipophilic gaseous molecule, $NO^{\cdot}$ is synthesized in mammalian tissue via activation of three nitric oxide synthase (NOS) isoforms: endothelial NOS (eNOS), inducible NOS (iNOS), and neuronal NOS (nNOS). These NOS isoforms are homodimeric enzymes containing a calmodulin-binding domain that separates an N-terminal heme-binding domain and a C-terminal reductase domain, and require five cofactors to catalyze the synthesis of $NO^{\cdot}$ from L-arginine (Porter et al. 1990; Maron and Michel 2012). Alternatively, the protonation of nitrite (NO_2^-) to HNO_2 under highly acidic conditions may also result in the spontaneous generation of $NO^{\cdot}$ through the following reactions: $2HNO_2 \rightarrow N_2O_3 + H_2O$, $N_2O_3 \rightarrow NO^{\cdot} + NO_2$ (Maron et al. 2013; Lundberg et al. 2011). Nitric oxide is critical for maintaining an antithrombotic phenotype through its inhibition of platelet activation. In particular, $NO^{\cdot}$ mediates this effect by decreasing bioavailable levels of calcium (Ca^{2+}), inhibiting the thromboxane A_2 (TXA_2) receptor and formation of eicosanoids, inhibiting fibrinogen binding to the platelet $\alpha_{IIb}\beta_3$ receptor, and downregulating cell adhesion molecules implicated in platelet-vascular wall adhesion, including P-selectin (Jin et al. 2005).

Early studies showed that platelet adhesion is decreased by 23 % in endothelial cells stimulated with bradykinin (100 nmol/L), a substance that can activate eNOS (Radomski et al. 1987), suggesting that endothelial $NO^{\cdot}$ exerts a key inhibitory effect on platelet aggregation in the absence of frank tissue injury. Indeed, activation of endothelial NOS (eNOS) is a key mechanism supporting $NO^{\cdot}$-dependent platelet inhibition in the intact endothelium. This occurs mainly in response to shear stress. The flow of blood through a blood vessel is heterogeneous, as velocity is highest at the center of the vessel and nearer the vessel wall. The difference in flow rate between two concentric trajectories within a blood vessel creates a shearing effect that perturbs the endothelial surface: the shear rate (cm/s) determines shear

stress, which is defined as force per unit area (dyne/cm^2) exerted on the vessel wall as a consequence of differences in blood flow velocity (Ruggeri and Mendolicchio 2007). Shear stress levels vary according to vessel caliber and orientation, but range between <12 dyne/cm^2 and 15–70 dyne/cm^2 in geometrically irregular and straight arteries, respectively (Chatzizisis et al. 2007; Gimbrone et al. 2000). Shear stress levels as low as 10 dyne/cm^2 are associated with increased levels of bioavailable NO$^{\cdot}$ (Go), which is generated through stimulation of eNOS mRNA transcription, posttranslational activation of eNOS (i.e., phosphorylation), and upregulation of eNOS-dependent NO$^{\cdot}$ synthesis (Boo et al. 2002). By contrast, elevated (>80 dyne/cm^2) or nonpulsatile shear stress levels are associated with platelet activation, initially through the induction of the glycoprotein Ib–V–IX interaction with von Willebrand Factor (vWF) (Shankaran et al. 2003).

A preponderance of data suggests that platelets express a constitutive NOS isoform and synthesize NO$^{\cdot}$ autonomously (Gambaryan et al. 2008). Freedman and colleagues demonstrated in gel-filtered platelets near-simultaneous increases in platelet aggregation and NO$^{\cdot}$ production, measured by nephelometric and microelectrode techniques, respectively, following stimulation with adenosine 5-′-diphosphate (ADP) (Freedman et al. 1997). More recently, others have demonstrated the functional effects of platelet-derived NO$^{\cdot}$ by measuring platelet levels of the adhesion molecule P-selectin and thrombosis burden in mice injected with collagen plus epinephrine. Findings from these observations support platelet-derived NO$^{\cdot}$ involvement in preventing thrombosis in vivo and suggest this may be an accessible treatment target. For example, repurposing of the β-adrenergic receptor antagonist d(L)-nebivolol has emerged recently as a potential antithrombotic therapy based on data indicating that its use in eNOS-deficient mice increases platelet levels of cGMP and platelet-derived NO$^{\cdot}$ metabolites (nitrite [NO_2^-] and nitrate [NO_3^-], NOx) and decreases embolism-associated mortality in an experimental model of femoral deep vein thrombosis (Momi et al. 2014). These data are consistent with findings from others demonstrating that d(L)-nebivolol stimulates β_2- and β_3-adrenergic receptor signaling, which results in eNOS phosphorylation at Ser1177, subsequent eNOS activation, and increased NO$^{\cdot}$ in platelets (Momi et al. 2014; Signorello et al. 2011). Directionally similar findings have also been reported for the HMG-CoA reductase inhibitor atorvastatin in experimental models of carotid arterial thrombosis, which is hypothesized to occur via upregulation of eNOS expression directly or by virtue of its antioxidant properties and, hence, diminished consumption of platelet-derived NO$^{\cdot}$ by superoxide anion ($O_2^{-\cdot}$) that generates the reactive oxidant peroxynitrite ($ONOO^-$) (Yokoyama et al. 2005).

Platelet-derived NO$^{\cdot}$ synthesis under basal conditions is reported to achieve 20 nM in vitro, although it is unresolved as to whether or not platelet inhibition occurs at these levels in the setting of vascular injury in vivo (Freedman et al. 1999). By contrast, unstable angina, acute myocardial infarction, stroke, atrial fibrillation, thrombotic microangiopathy, preeclampsia, and familial syndromes of atherothrombosis are examples of human diseases characterized by increased thrombosis in the setting of decreased endothelial NO$^{\cdot}$ (Freedman et al. 1996). eNOS knockout mice are characterized by abnormal vascular reactivity, systemic hypertension, and decreased NO$^{\cdot}$ release from platelets, with a shortening of bleeding time also noted. This latter finding is attributed to changes in bioavailable levels of tissue plasminogen activator (t-PA) and vWF, and, subsequently, disruption to the balance between coagulation, fibrinolysis, and platelet recruitment (Freedman et al. 1999; Iafrati et al. 2005). This perturbation has been shown in models of vascular injury to regulate platelet reactivity in vivo: thrombin-induced platelet aggregation is enhanced in mice pretreated with the NOS inhibitor N_ω-nitro-L-arginine methyl ester hydrochloride (L-NAME) (50 mg/kg) and transfused with normal platelets, suggesting that platelet-derived NO$^{\cdot}$ alone may be insufficient to control the thrombosis response fully (Tymvios et al. 2009). Studies assessing the consequence of eNOS deficiency have yielded similar findings in cerebral (Tan et al. 2015), coronary (Knudson et al. 2005), and resistance circulations (Toda and Toda 2011), again suggesting a contribution from both endothelial and platelet-derived NO$^{\cdot}$ in control of thrombosis, although differences in model type and design have been suggested to account for some inconsistent results (Ozuyaman et al. 2005).

Endothelial or platelet-derived NO$^{\cdot}$ inhibits platelet adhesion to the endothelium through several mechanisms, including attenuation of P-selectin expression (Gries et al. 1998), inhibition of ERK/p38-dependent GP IIIb/IIa activation through protein kinase G (PKG) signaling (Roberts et al. 2009), and decreased cytosolic Ca^{2+} (Fig. 1). The latter may occur via cGMP-PKG signaling that phosphorylates phospholipase C, or through cGMP-independent mechanisms by increasing sarcoplasmic/endoplasmic reticular Ca^{2+} refilling that depletes cytosolic Ca^{2+} levels (Trepakova et al. 1999). By contrast, decreased levels of bioavailable NO$^{\cdot}$ are implicated in failure to suppress these platelet regulatory mechanisms and correlate with a heightened predilection to thrombosis (Murohara et al. 1995). Likewise, strategies to boost NO$^{\cdot}$ bioactivity are associated with thrombosis prevention. For example, Wistar rats with induced myocardial infarction and heart failure that were randomized to treatment with the novel eNOS transcription enhancer AVE9488 for 10 weeks had significantly decreased platelet surface expression of P-selectin compared to

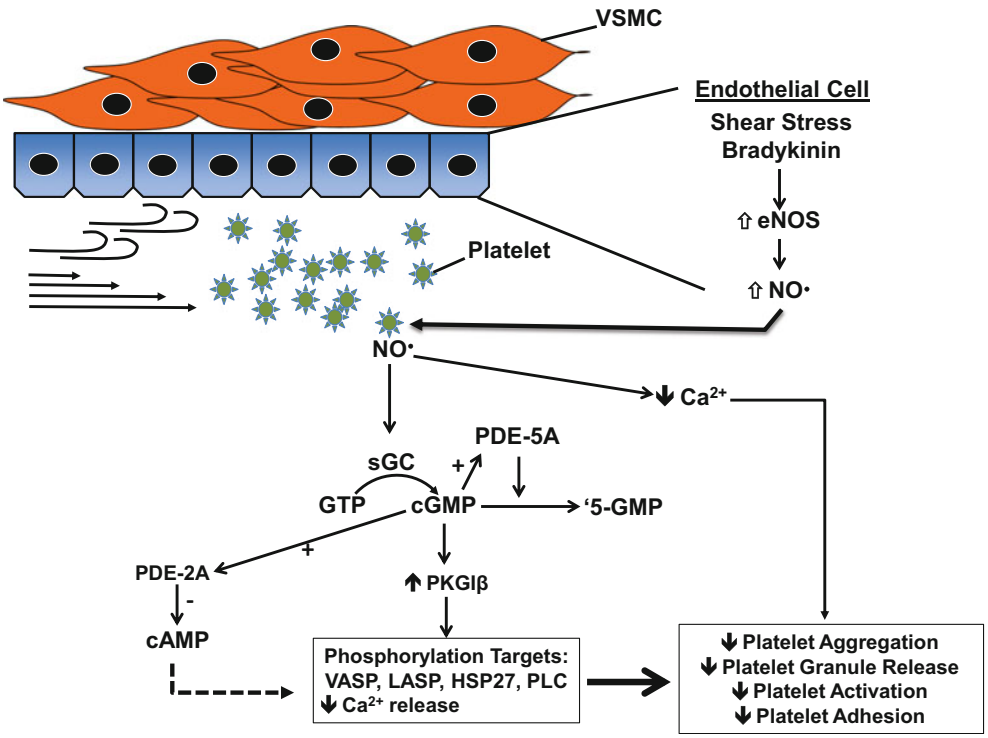

Fig. 1 The effect of nitric oxide on platelet function. Increased shear stress due to nonlaminar blood flow (*curled lines*) stimulates endothelial nitric oxide synthase (eNOS) activity in vascular endothelial cells to synthesize nitric oxide ($NO^{\cdot}$), which targets various cell types including platelets. Alternatively, eNOS-dependent synthesis of $NO^{\cdot}$ also occurs in platelets in response to increased adenosine diphosphate. In platelets, $NO^{\cdot}$ stimulates the heterodimeric enzyme soluble guanylyl cyclase (sGC), which catalyzes the conversion of guanosine triphosphate (GTP) to the second messenger cyclic guanonsine monophosphate (cGMP). Upregulation of cGMP-dependent protein kinase (GβI) in platelets promotes phosphorylation of key proteins involved in platelet inhibition, including vasodilator-stimulated phosphoprotein (VASP), Lim and SH3 protein domain (LASP), and heat shock protein 27 (HSP27). Counter-regulatory feedback mechanisms stimulated by sGC activation include phosphodiesterase type 5A (PDE-5A)-dependent hydrolysis of cGMP to 5'GMP, which is inactive, as well as PDE-2A-dependent inhibition of cyclic adenosine monophosphate (cAMP). PLC, phospholipase C; $[Ca^{2+}]_i$, intracellular calcium; VSMC, vascular smooth muscle cell; straight lined arrows represents laminar blood flow

placebo-treated rats, despite evidence of impaired NO-cGMP signaling in the pretreatment state (Schafer et al. 2009). These data complement work from others demonstrating the antiplatelet and antithrombotic effect of exogenous $NO^{\cdot}$ in biological systems in vitro and in vivo, although the benefit of pharmacological $NO^{\cdot}$ donors in reducing atherothrombotic mortality or other hard clinical end points remains less certain.

Prostacyclin

Key by-products of arachidonic metabolism relevant to platelet bioactivity include the prostanoid, thromboxane, and prostaglandins (Fig. 2). Arachidonic acid is released from the endothelial membrane following phospholipid hydrolysis by phospholipase A_2, which occurs under basal conditions, although enzymatic activity is also increased during inflammation or in the setting of atherosclerosis (Yang et al. 2006). Enzymatic activity of cyclooxygenase (COX)-1 and -2, which are constitutive and highly inducible, respectively, catalyzes the synthesis of prostaglandin by incorporating two moles of diatomic oxygen (O_2) (forming the unstable intermediary PGG_2) followed by peroxidase-mediated 2-electron reduction of PGG_2 to form PGH_2. Terminal prostanoid synthases convert PGH_2 into various prostaglandins, including thromboxane and PGI_2 that are the key species targeting platelets (Capra et al. 2014).

In 1976, Moncada and colleagues (Moncada et al. 1976) described a novel prostaglandin (PGX), which manifests antiplatelet aggregation properties and was found in high abundance in vascular endothelial cells. Later, PGX was denoted PGI_2 and was determined to be the principal prostaglandin in endothelial cells, with lesser concentrations observed in other vascular or support cells of the blood vessel. The target of PGI_2 is the prostacyclin (IP) receptor, which is a 7-transmembrane domain G-protein-coupled receptor that consists of a binding pocket that accommodates the cyclopentane ring of various PGs (Yamada et al. 2003). Murine kinetic studies using radiolabeled synthetic PGI_2

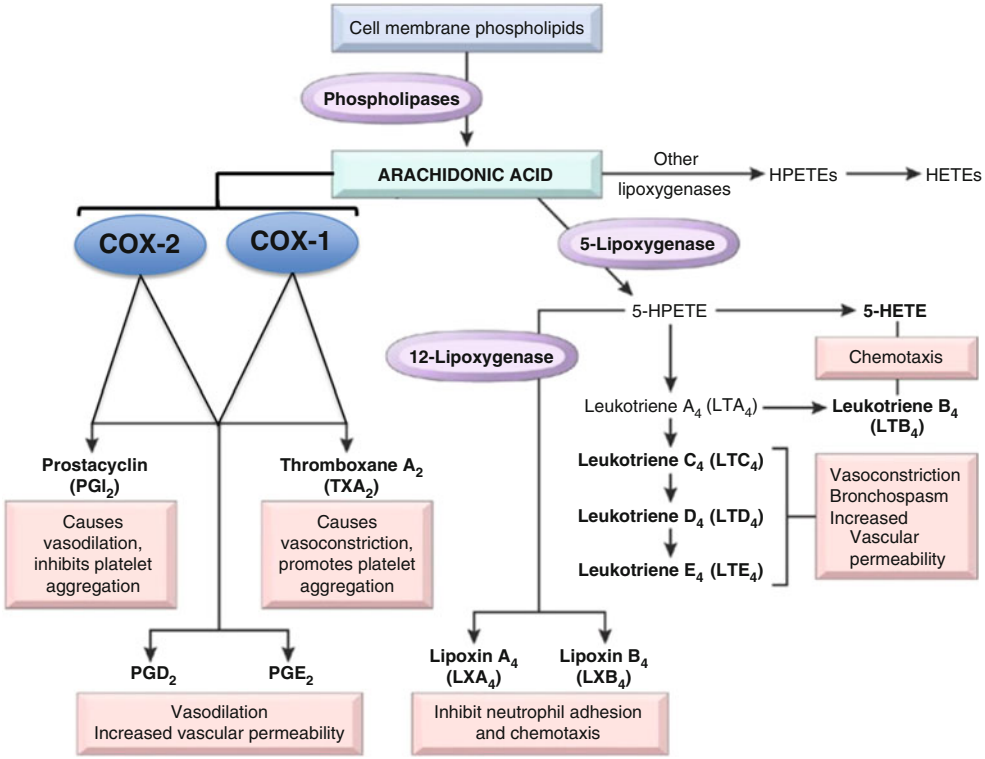

Fig. 2 Arachidonic acid metabolism. *Adapted with permission from* Robbins & Cotran's *Pathologic Basis of Disease 8th ed. Kumar V et al. (eds).* Saunders Elsevier. Philadelphia (2010)

(Iloprost) demonstrated a K_i for PGI_2-IP of 11 nM, which is akin to that for the synthetic PGI_2 cicaprost (10 nM), but substantially less than that for carbacyclin (110 nM) (Kiriyama et al. 1997). The precise structural features that influence IP binding by PGI_2 or cross-reactivity with other prostaglandins, however, remain unknown.
