

**Current Diagnosis & Treatment in Infectious Diseases 1st edition:** by Walter R. Wilson, W. Lawrence, MD Drew, Nancy K., Phd Henry, Merle A., MD Sande, David A., MD Relman, James M., MD Steckelberg, Julie Louise, MD Gerberding  
Publisher: McGraw-Hill/Appleton & Lange (June 22, 2001)

By OkDoKeY

▼ CURRENT DIAGNOSIS & TREATMENT IN INFECTIOUS DISEASES (2001)

▶ Front Matter

▶ 1 . Introduction — *Merle A. Sande, MD*

▼ Section I. Basic Principles

▶ 2 . Basic Principles of Host Defense — *Donald L. Granger, MD*

▶ 3 . Basic Principles of Microbial Virulence — *David A. Relman, MD*

▶ 4 . General Principles of Antimicrobial Therapy — *Walter R. Wilson, MD*

▶ 5 . Infection Prevention in Healthcare Settings — *Cathryn Louise Murphy, RN, PhD, CIC, Susan A Resnik, RN, Dip IC, CIC (Syd), & Julie Louise Gerberding, MD, MPH*

▶ 6 . Laboratory Diagnosis — *W. Lawrence Drew, MD, PhD, Franklin R. Cockerill, III, MD, & Nancy K. Henry, PhD, MD*

▼ Section II. Clinical Syndromes

▶ 7 . Infections of the Central Nervous System — *Zell A. McGee, MD\**

▶ 8 . Infections of the Eye & Orbit — *Marlene L. Durand, MD*

▶ 9 . Upper Respiratory Tract Infections — *Abinash Virk, MD, & Nancy K. Henry, PhD, MD*

▶ 10 . Tracheobronchitis & Lower Respiratory Tract Infections — *Abinash Virk, MD, & Walter R. Wilson, MD*

▶ 11 . Infective Endocarditis — *James M. Steckelberg, MD, & Walter R. Wilson, MD*

▶ 12 . Intra-abdominal Infections — *Jeffery Loutit, MB, ChB*

▶ 13 . Skin & Soft-Tissue Infections — *Mark P. Wilhelm, MD, FACP, & Randall S. Edson, MD, FACP*

▶ 14 . Osteomyelitis, Infectious Arthritis & Prosthetic-Joint Infection — *Douglas R. Osmon, MD & James M. Steckelberg, MD*

▶ 15 . Sexually Transmitted Diseases — *John W. Wilson, MD & Nancy K. Henry, PhD, MD*

▶ 16 . Urinary Tract Infections — *Walter R. Wilson, MD & Nancy K. Henry, PhD, MD*

▶ 17 . Sepsis Syndrome — *Andrew D. Badley, MD & James M. Steckelberg, MD*

▶ 18 . Fever of Unknown Origin — *Julie Brahmer, MD & Merle A. Sande, MD*

▶ 19 . Fever & Rash — *Peter K. Lindenauer, MD MSc, & Merle A. Sande, MD*

▶ 20 . Infectious Diarrhea — *William P. Ciesla, Jr., MD, & Richard L. Guerrant, MD*

▶ 21 . Hepatobiliary Infections — *Paul B. Eckburg, MD & Jose G. Montoya, MD*

▶ 22 . Obstetric & Gynecologic Infections — *Yenjean S. Hwang, MD & Merle A. Sande, MD*

▼ Section III. Special Patient Populations

▶ 23 . Patients With Aids — *Dani-Margot Zavasky, MD, Julie L. Gerberding, MD, MPH & Merle A. Sande, MD,*

▶ 24 . Infections in Transplant Recipients — *Robin Patel, MD*

▶ 25 . Patients With Neutropenia & Fever — *David Dockrell, MD & Linda L. Lewis,*

MD

▶ 26 . Patients with Recurrent Infections and Leukocyte Abnormalities — *Timothy R. La Pine, MD, & Harry R. Hill, MD*

▼ Section IV. Viral Infections

▶ 27 . Enteroviruses — *W. Lawrence Drew, MD, PhD*

▶ 28 . Rhinoviruses — *W. Lawrence Drew, MD, PhD*

▶ 29 . Influenza — *Lisa Danzig, MD & Keiji Fukuda, MD, MPH*

▶ 30 . Parainfluenza Virus — *Gregory Sonnen, MD, & Nancy Henry, MD, PhD*

▶ 31 . Respiratory Syncytial Virus — *Gregory Sonnen, MD, & Nancy Henry, MD,*

PhD

▶ 32 . Adenoviruses — *W. Lawrence Drew, MD, PhD*

▶ 33 . Herpesviruses — *W. Lawrence Drew, MD, PhD*

▶ 34 . Measles — *Gregory Sonnen, MD, & Nancy Henry, MD, PhD*

▶ 35 . Mumps — *Gregory Sonnen, MD & Nancy Henry, MD, PhD*

▶ 36 . Rubella — *Gregory Sonnen, MD, & Nancy Henry, MD, PhD*

▶ 37 . Rotavirus — *Gregory M. Sonnen, MD & Nancy Henry, MD, PhD*

▶ 38 . Other Gastrointestinal Viruses — *W. Lawrence Drew, MD, PhD*

▶ 39 . Hepatitis — *W. Lawrence Drew, MD, PhD*

▶ 40 . HIV & Other Retroviruses — *W. Lawrence Drew, MD, PhD*

▶ 41 . Poxviruses — *W. Lawrence Drew, MD, PhD*

▶ 42 . Parvoviruses — *W. Lawrence Drew, MD, PhD*

▶ 43 . Viral Infection of the Central Nervous System — *W. Lawrence Drew, MD,*

PhD

▶ 44 . Miscellaneous Systemic Viral Syndromes — *W. Lawrence Drew, MD, PhD*

▶ 45 . Papovaviruses — *W. Lawrence Drew, MD, PhD*

▼ Section V. Bacterial Infections

▶ 46 . Staphylococci — *Karen Bloch, MD, MPH*

▶ 47 . *Streptococcus pneumoniae* — *Jeffrey N. Martin, MD, MPH*

▶ 48 . *Streptococcus pyogenes* — *Dennis L. Stevens, PhD, MD*

▶ 49 . Enterococci — *Robin Patel, MD*

▶ 50 . Other Gram-Positive Cocci — *Robin Patel, MD*

▶ 51 . Gram-Positive Aerobic Bacilli — *Jeffrey Loutit, MB, ChB, & David Relman,*

MD

▶ 52 . *Neisseria Gonorrhoeae* & *Neisseria Meningitidis* — *D. Scott Smith, MD & David A. Relman, MD*

▶ 53 . Enteritis Caused by *Escherichia coli* & *Shigella* & *Salmonella* Species — *Gary W. Procop, MD, & Franklin Cockerill III, MD*

▶ 54 . *Pseudomonas aeruginosa* — *David Dockrell, MD, & Walter Wilson, MD*

▶ 55 . *Helicobacter pylori* — *Jay V. Solnick, MD, PhD, & Javeed Siddiqui, MD,*

MPH

▶ 56 . *Haemophilus*, *Bordetella*, & *Branhamella* Species — *Joseph W. St. Geme III, MD*

▶ 57 . *Vibrio* & *Campylobacter* — *Gary W. Procop, MD, & Frank R. Cockerill III,*

MD

▶ 58 . *Legionella* — *Michael Bell, MD*

- ▶ [59 . Important Anaerobes — Jorge Villacian, MD, & James Steckelberg, MD](#)
- ▶ [60 . Brucella, Francisella, Pasteurella, Yersinia, & HACEK — Elie F. Berbari, MD, & Walter R. Wilson, MD](#)
- ▶ [61 . Tuberculosis — Julie Brahmer, MD, & Merle A. Sande, MD](#)
- ▶ [62 . Other Mycobacteria — Julie Brahmer, MD, Yenjean Hwang, MD & Merle A. Sande, MD](#)
- ▶ [63 . Actinomycetes — Phyllis C. Tien, SM, MD & David A. Relman, MD](#)
- ▶ [64 . Treponema pallidum — Fred A. Lopez, MD & David A. Relman, MD](#)
- ▶ [65 . Borrelia & Leptospira Species — Sandra Chaparro, MD & Jose G. Montoya, MD](#)
- ▶ [66 . Mycoplasma & Ureaplasma — Jose G. Montoya, MD](#)
- ▶ [67 . Chlamydia — Jose G. Montoya, MD](#)
- ▶ [68 . Coxiella, Ehrlichia, & Rickettsia — Jeffery Loutit, MB, ChB](#)
- ▶ [69 . Bartonella — Phyllis C. Tien, SM, MD & Jeffery S. Loutit, MB ChB](#)

#### ▼ [Section VI. Fungal Infections](#)

- ▶ [70 . Histoplasma capsulatum — Zelalem Temesgen, MD](#)
- ▶ [71 . Blastomyces dermatitidis — Zelalem Temesgen, MD](#)
- ▶ [72 . Coccidioides — Caroline Milne, MD, & Merle Sande, MD](#)
- ▶ [73 . Candida species — Christopher R. Fox, MD & Merle A. Sande, MD](#)
- ▶ [74 . Cryptococcus neoformans — James J. Chamberlain, MD & Donald L. Granger, MD](#)
- ▶ [75 . Aspergillus, Pseudallescheria, & Agents of Mucormycosis — Michael R. Keating, MD](#)
- ▶ [76 . Sporothrix schenckii — Zelalem Temesgen, MD](#)
- ▶ [77 . Fusarium, Penicillium, Paracoccidioides, & Agents of Chromomycosis — Michael R. Keating, MD](#)
- ▶ [78 . Dermatophytes — D. Scott Smith, MS, MD & David A. Relman, MD](#)
- ▶ [79 . Pneumocystis carinii — James J. Chamberlain, MD & Kristen Ries, MD](#)

#### ▼ [Section VII. Parasitic Infections Part A. Protozoa](#)

- ▶ [80 . Malaria and Babesia — Gary W. Procop, MD & David H. Persing, MD, PhD](#)
- ▶ [81 . Toxoplasma gondii — Jose G. Montoya, MD](#)
- ▶ [82 . Pathogenic Amebas — Christopher R. Fox, MD & Merle A. Sande, MD](#)
- ▶ [83 . Cryptosporidium, Cyclospora, & Isospora Species & Microsporidia — Stephanie Boade Silas, MD, & DeVon Hale, MD](#)
- ▶ [84 . Giardia — Stephanie Boade Silas, MD, & DeVon Hale, MD](#)
- ▶ [85 . Leishmania & Trypanosoma — D. Scott Smith, MD & David A. Relman, MD](#)

#### [Section VII. Parasitic Infections Part B. Helminths](#)

- ▶ [86. Nematodes — James M. Steckelberg, MD & Walter R. Wilson, MD](#)
- ▶ [87 . Cestodes — Andrew D. Badley, MD, James M. Steckelberg, MD & Walter R. Wilson, MD](#)
- ▶ [88 . Trematodes — Walter R. Wilson, MD & James M. Steckelberg, MD](#)

▼ Section VIII. Miscellaneous Infections

▶ 89 . Infections in Travelers — *DeVon C. Hale, MD & Caroline Milne, MD*

▶ 90 . Zoonotic Infections — *D. Scott Smith, MD & David A. Relman, MD*

▶ 91 . Ectoparasitic Infestations & Arthropod Stings & Bites — *Walter R. Wilson, MD & James M. Steckelberg, MD*

# **CURRENT DIAGNOSIS & TREATMENT IN INFECTIOUS DISEASES (2001)**

## **Front Matter**

### **Title Page**

*a LANGE medical book*

## **CURRENT Diagnosis & Treatment in INFECTIOUS DISEASES**

### **Editors**

#### **Walter R. Wilson, MD**

Professor of Medicine  
Mayo Medical School  
Consultant  
Mayo Clinic, Rochester

#### **Merle A. Sande, MD**

Professor and Chairman  
The Clarence M. and Ruth N. Birrer  
Presidential Endowed Chair in Internal Medicine  
Department of Internal Medicine  
University of Utah, Salt Lake City

### **Associate Editors**

#### **W. Lawrence Drew, MD, PhD**

Professor, Laboratory Medicine and Medicine  
Director, Viral Diagnostic Laboratory  
Chief, Infectious Diseases  
Mt. Zion Medical Center  
University of California, San Francisco

#### **Nancy K. Henry, PhD, MD**

Associate Professor of Pediatrics  
Mayo Graduate School of Medicine  
Chair, Division of Pediatric Infectious Diseases  
Department of Pediatric and Adolescent Medicine  
Mayo Clinic, Rochester

#### **David A. Relman, MD**

Associate Professor of Medicine, Microbiology & Immunology  
Departments of Medicine, Microbiology & Immunology

Stanford University School of Medicine  
Physician, Veterans Affairs Palo Alto Health Care System

**James M. Steckelberg, MD**

Professor of Medicine  
Mayo Medical School  
Chair, Division of Infectious Diseases  
Mayo Clinic and Foundation, Rochester

**Julie Louise Gerberding, MD, MPH**

Associate Professor of Medicine  
San Francisco General Hospital  
University of California, San Francisco

**Lange Medical Books/McGraw-Hill  
Medical Publishing Division**

**New York Chicago San Francisco Lisbon London Madrid Mexico City Milan New  
Delhi San Juan Seoul Singapore Sydney Toronto**

**Notice**

**Medicine is an ever-changing science. As new research and clinical experience  
broaden our knowledge, changes in treatment and drug therapy are required. The  
authors and the publisher of this work have checked with sources believed to be  
reliable in their efforts to provide information that is complete and generally in  
accord with the standards accepted at the time of publication. However, in view of**

the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

This book was set in Times Roman by Pine Tree Composition.  
The editors were Shelley Reinhardt, Isabel Nogueira, and Peter J. Boyle.  
The production supervisor was Richard Ruzycka.  
The art manager was Charissa Baker.  
The illustrators were Laura Pardi Duprey and Teshin Associates.  
The index was prepared by Katherine Pitcoff.

R.R. Donnelley and Sons, Inc. was printer and binder.

This book is printed on acid-free paper.

## Contents

Authors...xv

Preface...xx

1. Introduction...1

*Merle A. Sande, MD*

### I. BASIC PRINCIPLES

2. Basic Principles of Host Defense...3

*Donald L. Granger, MD*

Innate Host Defenses 4

    Defense Mechanisms at the Physiologic Level 4

    Innate Defense Mechanisms at the Cellular Level 5

    Defense Mechanisms at the Level of Protein Molecules 10

Adaptive Immune Responses 11

    Humoral Immunity 11

    Cell-Mediated Immunity 15

3. Basic Principles of Microbial Virulence...20

*David A. Relman, MD*

Microorganisms as Pathogens 20  
Regulation of Virulence 22  
Adherence & Colonization 22  
Toxins 24  
Entry Into & Life within Host Cells 24  
Manipulation or Avoidance of the Host Immune Response 25  
Transmission & Life Outside the Mammalian Host 26

#### **4. General Principles of Antimicrobial Therapy...28**

*Walter R. Wilson, MD*

Etiologic Agent & Susceptibility Testing 28  
Dosage & Route of Administration 29  
Underlying Host Factors 30  
Monitoring the Response to Antimicrobial Therapy 32

#### **5. Infection Prevention in Healthcare Settings...33**

*Cathryn Louise Murphy, RN, PhD, CIC, Susan A Resnik, RN, Dip IC, CIC (Syd), & Julie Louise Gerberding, MD, MPH*

Role of the Infection Control Practitioner 33  
Role of the Healthcare Epidemiologist 34  
The Infection Control Committee 34  
Infection Control Policies & Procedures 34  
    Infection Monitoring & Prevention 35  
Patient Isolation 35  
Preventing Antimicrobial-Agent-Resistant Infections 36  
Hand Hygiene 36  
Asepsis 38  
Occupational Health Issues 39  
Infectious Conditions of Concern 39  
    Blood-Borne Pathogens 39  
    Tuberculosis 40  
    Vaccine-Preventable Diseases 40  
    New & Emerging Agents 41

#### **6. Laboratory Diagnosis...43**

*W. Lawrence Drew, MD, PhD, Franklin R. Cockerill, III, MD, & Nancy K. Henry, PhD, MD*

Diagnosis of Bacterial, Fungal, & Parasitic Infections 43  
    Rapid, Direct Test Methods & Culture-Based Methods 51  
    Serologic Test Methods 55  
Diagnosis of Viral Infections 57  
    Detection of Viral Antigens 61  
    Molecular Test Methods 55  
    Susceptibility Testing of Bacterial & Fungal Isolates to Antimicrobial Agents 55  
Cytology 57  
Culture-Based Methods 57  
Serologic Test Methods 61  
Molecular Test Methods 63

## **II. Clinical Syndromes**

### **7. Infections of the Central Nervous System...65**

*Zell A. McGee, MD*

Acute Bacterial Meningitis 65

Aseptic Meningitis Syndrome 73

Infectious Disorders With Dementia as a Dominant Feature 76

Infections Presenting as Stroke Syndromes 77

Infections Presenting as Spinal Cord Syndromes 77

Infectious Disorders with Focal Disturbances as a Dominant Feature 78

Infectious Disorders Involving Cranial Nerves 82

Infectious Disorders with Dysphagia & Dysarthria as Dominant Features 82

### **8. Infections of the Eye & Orbit...85**

*Marlene L. Durand, MD*

Eyelid Infections 85

Hordeolum 85

Chalazion 85

Blepharitis 85

Preseptal Cellulitis 85

The Tear Film 86

Lacrimal System Infections 86

Dacryocystitis 87

Canaliculitis 87

Dacryoadenitis 87

Orbital Infections 87

Orbital Cellulitis 89

Orbital Abscess 89

Subperiosteal Abscess 89

Cavernous Sinus Thrombosis 89

Conjunctivitis 89

Hyperacute Conjunctivitis 90

Acute Conjunctivitis 90

Chronic Conjunctivitis 91

Keratitis (Corneal Ulcer) 92

Bacterial Keratitis 92

Interstitial Keratitis 93

Viral Keratitis 93

Parasitic Keratitis 93

Fungal Keratitis 93

Endophthalmitis 94

Postcataract Endophthalmitis 94

Bleb-Related Endophthalmitis 94

Post-Traumatic Endophthalmitis 94

Endogenous Endophthalmitis 94

Uveitis & Retinitis 96

Anterior Uveitis 96

Posterior Uveitis 96

Toxoplasma 96

*Candida* Species 96  
Syphilis 96  
Tuberculosis 96  
Cytomegalovirus 96

### **9. Upper Respiratory Tract Infections...98**

*Abinash Virk, MD & Nancy K. Henry, PhD, MD*

The Common Cold 98  
Pharyngitis 100  
Acute Laryngitis 103  
Acute Laryngotracheobronchitis (Croup) 104  
Acute Epiglottitis 106  
Otitis Media 108  
Otitis Externa 112  
Acute & Chronic Sinusitis 113

### **10. Tracheobronchitis & Lower Respiratory Tract Infections...118**

*Abinash Virk, MD & Walter R. Wilson, MD*

Acute Bronchitis 118  
Chronic Bronchitis & Acute Exacerbations 121  
Bronchiolitis 125  
Pneumonia 128  
Parapneumonic Effusion & Pleural Empyema 144  
Lung Abscess 148

### **11. Infective Endocarditis...155**

*James M. Steckelberg, MD & Walter R. Wilson, MD*

### **12. Intra-Abdominal Infections...164**

*Jeffery S. Loutit, MB, ChB*

Abdominal Pain 164  
Clinical Syndromes 165  
    Appendicitis 175  
    Caecitis (Typhlitis) 175  
    Peritonitis 165  
    Intraperitoneal Abscess 171  
    Acute Cholecystitis 175  
    Cholangitis 176

### **13. Skin & Soft-Tissue Infections...177**

*Mark P. Wilhelm, MD, FACP & Randall S. Edson, MD, FACP*

The Pyodermas 177  
    Impetigo 177  
    Erysipelas 179  
    Ecthyma 179  
    Cellulitis 181  
    Cutaneous Abscesses 182  
    Furuncles & Carbuncles 182  
    Folliculitis 183

Necrotizing Soft-Tissue Infections 183  
Clostridial Myonecrosis (Gas Gangrene) 184  
Necrotizing Fasciitis 185  
Progressive Bacterial Synergistic Gangrene 186  
Anaerobic Cellulitis 186  
Infections Associated with Human or Animal Bites 187  
Diabetic Foot Infections 187

#### **14. Osteomyelitis, Infectious Arthritis & Prosthetic-Joint Infection...191**

*Douglas R. Osmon, MD & James M. Steckelberg, MD*

Osteomyelitis 191  
Infectious Arthritis 197  
Prosthetic-Joint Infection 199

#### **15. Sexually Transmitted Diseases...203**

*John W. Wilson, MD & Nancy K. Henry, MD, PhD*

Urethritis 203  
Cervicitis 207  
Vulvovaginitis 208  
Genital Ulcer Disease 212  
Other Sexually Transmitted Diseases 215  
Skin & Mucous Membrane Diseases 215  
Pelvic Inflammatory Disease 215  
Epididymitis 215  
Proctitis 215

#### **16. Urinary Tract Infections...220**

*Walter R. Wilson, MD & Nancy K. Henry, PhD, MD*

Community-Acquired Urinary Tract Infections 220  
Nosocomially Acquired Urinary Tract Infections 227

#### **17. Sepsis Syndrome...231**

*Andrew D. Badley, MD & James M. Steckelberg, MD*

#### **18. Fever of Unknown Origin...240**

*Julie Brahmer, MD & Merle A. Sande, MD*

#### **19. Fever & Rash...247**

*Peter K. Lindenauer, MD MSc & Merle A. Sande, MD*

Patient History 247  
Season & Geographic Setting 249  
Special Populations 249

#### **20. Infectious Diarrhea...255**

*William P. Ciesla, Jr., MD & Richard L. Guerrant, MD*

#### **21. Hepatobiliary Infections...269**

*Paul B. Eckburg, MD & Jose G. Montoya, MD*

Infections of the Liver 271

Acute Viral Hepatitis 271  
Chronic Viral Hepatitis 273  
Granulomatous Hepatitis 275  
Hepatic Abscess 276  
Liver Infections in Patients with HIV 279  
Infections of the Biliary Tract 280  
Acute Calculous Cholecystitis 280  
Acute Acalculous Cholecystitis 281  
Acute Cholangitis 282  
Recurrent Pyogenic Cholangitis 284  
Sclerosing Cholangitis 284  
AIDS-Related Cholangitis 285

## **22. Obstetric & Gynecologic Infections...287**

*Yenjean S. Hwang, MD & Merle A. Sande, MD*

Gynecologic Infections 287  
Vulvovaginitis 287  
Cervicitis 289  
Pelvic Inflammatory Disease 292  
Infections after Gynecologic Surgery 295  
Intrapartum & Postpartum Infections 296  
Chorioamnionitis 296  
Postpartum Endometritis 297  
Puerperal Ovarian Vein Thrombophlebitis (POVT) 299  
Episiotomy Infections 301  
Septic Abortion 302  
BR>Infections of Special Concern During Pregnancy 303  
Group B Streptococcus (GBS) 303  
Teratogenic Infections & Other Infections of Concern in Pregnancy 305  
Syphilis in Pregnancy 305  
Toxoplasmosis in Pregnancy 307  
Cytomegalovirus in Pregnancy 308  
Rubella in Pregnancy 309  
Varicella Infection During Pregnancy 310  
Herpes Simplex Virus Infections in Pregnancy 310  
Human Papillomavirus in Pregnancy 311  
Measles, Mumps, & Parvovirus Infection in Pregnancy 311

## **III. SPECIAL PATIENT POPULATIONS**

### **23. Patients With AIDS...315**

*Dani-Margot Zavasky, MD, Julie L. Gerberding, MD, MPH & Merle A. Sande, MD*

Predictors Of Disease Progression 316

Clinical Syndromes 317

### **24. Infections in Transplant Recipients...328**

*Robin Patel, MD*

Bacterial Infections 331

Common Bacterial Infections 331

*Legionella* Species 333

*Nocardia* Species 333  
*Salmonella* Species 333  
*Listeria Monocytogenes* 333  
Viral Infections 336  
  Cytomegalovirus 336  
  Herpes Simplex Virus 339  
  Varicella Zoster Virus 339  
  Epstein Barr Virus 340  
  Other Viruses 341  
Fungal Infections 341  
  *Pneumocystis Carinii* 341  
  *Candida* Species 342  
  *Cryptococcus Neoformans* 342  
  Mycelial Fungi 342  
Mycobacterial Infections 343  
  Mycobacterium Tuberculosis 343  
  Nontuberculous Mycobacteria 344  
Parasitic Infections 344  
  *Trypanosoma Cruzi* 344  
  *Toxoplasma Gondii* 344  
  *Strongyloides Stercoralis* 344

## **25. Patients with Neutropenia & Fever...347**

*David Dockrell, MD & Linda L. Lewis, MD*

## **26. Patients with Recurrent Infections & Leukocyte Abnormalities...356**

*Timothy R. La Pine, MD & Harry R. Hill, MD*

T-Lymphocyte Defects 356  
  Severe Combined Immunodeficiency 359  
  Purine-Nucleoside Phosphorylase Deficiency 360  
  DiGeorge Syndrome 360  
  Wiskott-Aldrich Syndrome 360  
  Ataxia-Telangiectasia 361  
B-Lymphocyte Defects 361  
  Bruton's Agammaglobulinemia 362  
  X-Linked Hypogammaglobulinemia with Normal to Increased IgM Concentrations 362  
  Selective IgA Deficiency 363  
  Common Variable Immunodeficiency 363  
Defects in the Phagocytic System & Its Related Immunodeficiency Syndromes 363  
  Leukocyte Adhesion Deficiency 364  
  Job's Syndrome 365  
  Chronic Granulomatous Disease 365  
  Chediak-Higashi Syndrome 366  
The Complement System & Its Related Defects 367  
  Deficiency of C1 Complex & C4 368  
  Deficiency of C2 368  
  Deficiency of C3 368  
  Deficiency of C5-C9 368  
  Properdin Deficiency 368

## **IV. VIRAL INFECTIONS**

### **27. Enteroviruses...371**

*W. Lawrence Drew, MD, PhD*

Clinical Syndromes 373

Poliovirus Infection 373

Coxsackievirus & Echovirus Infections 373

### **28. Rhinoviruses...377**

*W. Lawrence Drew, MD, PhD*

Rhinovirus Infection 377

### **29. Influenza...380**

*Lisa Danzig, MD & Keiji Fukuda, MD, MPH*

Influenza Infection 381

### **30. Parainfluenza Virus...388**

*Gregory Sonnen, MD & Nancy Henry, MD, PhD*

Clinical Syndromes 388

Acute Laryngotracheobronchitis (Croup) 388

Bronchiolitis 389

Pneumonia 390

### **31. Respiratory Syncytial Virus...392**

*Gregory Sonnen, MD & Nancy Henry, MD, PhD*

Clinical Syndromes 392

Bronchiolitis 392

Pneumonia 393

### **32. Adenoviruses...396**

*W. Lawrence Drew, MD, PhD*

Clinical Syndromes 397

Acute Respiratory Disease 397 BR> Conjunctivitis 397

Acute Gastroenteritis 397

Acute Hemorrhagic Cystitis 398

Systemic Infection in Immunocompromised Patients 398

### **33. Herpesviruses...400**

*W. Lawrence Drew, MD, PhD*

Herpes Simplex Virus 400

Varicella-Zoster Virus 404

Cytomegalovirus 406

Epstein-Barr Virus 408

Human Herpesvirus Type 6 410

Other Herpesviruses 411

### **34. Measles...413**

*Gregory Sonnen, MD & Nancy Henry, MD, PhD*

Clinical Syndromes 413  
  Typical Measles 413  
  Modified Measles 415  
  Atypical Measles 416

#### **48. Streptococcus Pyogenes...502**

*Dennis L. Stevens, MD, PhD*

- Clinical Syndromes 504
  - Pharyngitis & the Asymptomatic Carrier 504
  - Scarlet Fever 504
  - Streptococcal Pyoderma (Impetigo Contagiosa) 505
  - Erysipelas 505
  - Cellulitis 505
  - Lymphangitis 506
  - Necrotizing Fasciitis 506
  - Myositis 506
  - Pneumonia 507
  - Streptococcal Toxic Shock Syndrome 507

#### **49. Enterococci...511**

*Robin Patel, MD*

- Clinical Syndromes 513
  - Urinary Tract Infection 513
  - Bacteremia & Endocarditis 513
  - Intra-Abdominal & Pelvic Infection 513
  - Wound & Soft Tissue Infection 513
  - Meningitis 513
  - Neonatal Sepsis 513

#### **50. Other Gram-Positive Cocci...518**

*Robin Patel, MD*

- Viridans Group Streptococci, Including *Abiotrophia Defectiva* & *Abiotrophia Adjacens* 518
  - Clinical Syndromes 519
- Group B Streptococcus (*S Agalactiae*) 520
  - Clinical Syndromes 521
- Streptococcus Dysgalactiae* Subspecies: *Equisilimis* & *Streptococcus Zooepidemicus* 523
  - Clinical Syndromes 524
- Streptococcus Bovis* 525
  - Clinical Syndromes 525
- Other Gram-Positive Cocci 526
  - Streptococcus Iniae* 526
  - Leuconostoc* Species 526
  - Pediococcus* Species 527
  - Stomatococcus Mucilaginosus* 527
  - Aerococcus* Species 527
  - Gemella* Species 527
  - Alloiococcus Otitis* 527
  - Micrococcus* Species 527
  - Lactococcus* Species 527
  - Globicatella* Species 527

*Helcococcus Kunzii* 527

**51. Gram-Positive Aerobic Bacilli...528**

Jeffrey S. Loutit, MD & David A. Relman, MD

*Listeria Monocytogenes* 528

Anthrax 530

Other *Bacillus* Species 532

Diphtheria 533

*Corynebacterium Jeikeium* 536

Other *Corynebacterium* Species 536

*Erysipelothrix Rhusiopathiae* 536

**52. Neisseria Gonorrhoeae & Neisseria Meningitidis...538**

D. Scott Smith, MD & David A. Relman, MD

*Neisseria Gonorrhoeae* 538

*Neisseria Meningitidis* 541

**53. Enteritis Caused by Escherichia coli & Shigella & Salmonella Species...548**

Gary W. Procop, MD & Franklin Cockerill III, MD

*Escherichia coli* 548

Clinical Syndromes 553

*Shigella* Species 556

*Salmonella* Species 559

Enteric Fever 561

*Salmonella* Enteritis 562

**54. Pseudomonas Aeruginosa...567**

David Dockrell, MD & Walter R. Wilson, MD

Pulmonary Infections 568

Infections in Patients with Cystic Fibrosis 570

Bacteremia 570

Skin & Soft Tissue Infections 571

Urinary Tract Infection 572

Ear, Nose & Throat Infections 572

Orthopedic Infections 572

Endocarditis 573

Ophthalmologic Infection 574

Clinical Syndromes 587

*Bordetella* Species 596

Clinical Syndromes 597

*Branhamella Catarrhalis* 600

Clinical Syndromes 600

**57. *Vibrio* & *Campylobacter*...603**

*Gary W. Procop, MD & Frank R. Cockerill III, MD*

*Vibrio* Infections 6030

*Vibrio Cholera* Infections 603

Clinical Syndromes 604

Other *Vibrio* Infections 605

Clinical Syndromes 607

Noncholera Gastroenteritis 607

Extraintestinal Disease 608

*Campylobacter* Infections 609

*Campylobacter* Enteritis 611

Extraintestinal *Campylobacteriosis* 612

**58. *Legionella*...614**

*Michael Bell, MD*

Clinical Syndromes 615

**59. Important Anaerobes...620**

*Jorge Villacian, MD & James Steckelberg, MD*

Clinical Syndromes 621

Head & Neck 621

Central Nervous System 623

Respiratory Tract 623

Intra-Abdominal 624

Female Genital Tract 624

Skin, Soft Tissue, & Bone Infections 625

Bacteremia 625

Osteomyelitis 625

Toxin-Mediated Infections 625

**60. *Brucella*, *Francisella*, *Pasteurella*, *Yersinia*, and HACEK...630**

*Elie F. Berbari, MD & Walter R. Wilson, MD*

Brucellosis 630

Tularemia 632

Plague 635

*Yersiniosis* 637

*Pasteurella* 639

HACEK Infection 641

**61. Tuberculosis...644**

*Julie Brahmer, MD & Merle A. Sande, MD*  
Clinical Syndromes 645  
Pulmonary Tuberculosis 645  
Extrapulmonary Tuberculosis 646  
Tuberculosis in Patients with HIV Infection 646

**62. Other Mycobacteria...653**

*Julie Brahmer, MD, Yenjean Hwang, MD & Merle A. Sande, MD*  
Clinical Syndromes 653  
*Mycobacterium Avium* Complex (Disseminated & Pulmonary Disease) 653  
*Mycobacterium Leprae* (Leprosy) 655  
*Mycobacterium Kansaii* (Chronic Pulmonary Infection) 656  
*Mycobacterium Scrofulaceum* (Lymphadenitis) 657  
*Mycobacterium Bovis* (Tuberculosis in Animals) 657  
*Mycobacterium Marinum* (Classic Fish Tank Granuloma) 657

**63. Actinomycetes...662**

*Phyllis C. Tien, SM MD, & David A. Relman, MD*  
Nocardia 662  
*Actinomyces* 665  
Other Actinomycetes 667

**64. Treponema Pallidum...669**

*Fred A. Lopez, MD & David A. Relman, MD*  
Primary Syphilis 670  
Secondary Syphilis 672  
Latent Syphilis 673  
Late Syphilis 673  
Congenital Syphilis 674

**65. Borrelia & Leptospira Species...680**

*Sandra Chaparro, MD & Jose G. Montoya, MD*  
*Borrelia* Species 680  
Relapsing Fever 680  
Lyme Disease 682  
*Leptospira* Species 686

**66. Mycoplasma & Ureaplasma...690**

*Jose G. Montoya, MD*  
*M Pneumoniae* Infection & Disease 690  
Infections Caused by *U Urealyticum* & Other Mycoplasmas 693

**67. Chlamydia...694**

*Jose G. Montoya, MD*  
*C Trachomatis* Infections 695  
*C Psittaci* Infections 699  
*C Pneumoniae* Infections 700

**68. Coxiella, Ehrlichia, & Rickettsia...703**

*Jeffery S. Loutit, MD*

*Coxiella Burnetii* Infection (Q Fever) 703

*Ehrlichia* Infection (Ehrlichiosis) 705

*Rickettsial* Infections 708

Rocky Mountain Spotted Fever 708

Rickettsialpox 710

Other Spotted Fevers 711

Endemic (Murine) Typhus 711

Epidemic (Louse-Borne) Typhus 711

Scrub Typhus 711

### **69. *Bartonella*...713**

*Phyllis C. Tien, MD & Jeffery S. Loutit, MB ChB*

Clinical Syndromes 713

Bacillary Angiomatosis 715

Cat Scratch Disease 716

*B Bacilliformis*-Associated Disease 716

Fever & Bacteremia/Trench Fever/Endocarditis 716

## **VI. FUNGAL INFECTIONS**

### **70. *Histoplasma Capsulatum*...721**

*Zelalem Temesgen, MD*

Clinical Syndromes 721

Pulmonary Infections 721

Disseminated Histoplasmosis 722

Histoplasmosis in AIDS 723

### **71. *Blastomyces Dermatitidis*...726**

*Zelalem Temesgen, MD*

Clinical Syndromes 726

Pulmonary Infection 726

Extrapulmonary Infection 727

Blastomycosis & AIDS 728

Blastomycosis in Other Immunocompromised Hosts 728

### **72. *Coccidioides*...731**

*Caroline Milne, MD & Merle A. Sande, MD*

### **73. *Candida* Species...734**

*Christopher R. Fox, MD & Merle A. Sande, MD*

Clinical Syndromes 735

*Candida* Dermatitis 735

Oral Candidiasis 735

Esophageal Candidiasis 738

*Candida* Vulvovaginitis 738

Candiduria, *Candida* Cystitis & Urinary Tract Candidiasis 740

Candidemia & Disseminated Candidiasis 740

*Candida* Endocarditis 742

GI Candidiasis (Nonesophageal) 742

Other *Candida* Syndromes 743

**74. *Cryptococcus neoformans*...745**

*James J. Chamberlain, MD & Donald L. Granger, MD*

**75. *Aspergillus*, *Pseudallescheria*, & Agents of Mucormycosis...751**

*Michael R. Keating, MD*

*Aspergillus* Infection 751

Clinical Syndromes 752

*Pseudallescheria Boydii* Infection 759

Mucormycosis 760

Clinical Syndromes 761

**76. *Sporothrix Schenckii* ...764**

*Zelalem Temesgen, MD*

Clinical Syndromes 764

Cutaneous Sporotrichosis 764

Extracutaneous Sporotrichosis 764

Disseminated Sporotrichosis 765

**77. *Fusarium*, *Penicillium*, *Paracoccidioides*, & Agents of Chromomycosis...768**

*Michael R. Keating, MD*

*Fusarium* Infection 768

*Penicillium* Infections 770

Paracoccidioidomycosis 772

Chromomycosis 774

**78. Dermatophytes...777**

*D. Scott Smith, MS, MD & David A. Relman, MD*

**79. *Pneumocystis Carinii* ...785**

*James J. Chamberlain, MD & Kristen Ries, MD*

Clinical Syndromes 786

*P Carinii* Pneumonia 786

Extrapulmonary *P Carinii* Infections 786

**VII. PARASITIC INFECTIONS**

**A. PROTOZOA**

**80. Malaria & Babesia...793**

*Gary W. Procop, MD & David H. Persing, MD, PhD*

*Plasmodium* Species 793

Nonfalciparum Malaria (*P Vivax*, *P Ovale*, *P Malariae*) 798

*P Falciparum* Malaria 797

*Babesia* Species 803

**81. *Toxoplasma Gondii*...807**

*Jose G. Montoya, MD*

## **82. Pathogenic Amebas...817**

*Christopher R. Fox, MD & Merle A. Sande, MD*  
*Entamoeba Histolytica & Entamoeba Dispar* 817  
Clinical Syndromes 817  
  Intestinal Disease 818  
  Amebic Liver Abscess 819  
Pathogenic Free-Living Amebas 822  
  *Acanthamoeba* Infection 822  
  *Naegleria Fowleri* Infection 822

## **83. Cryptosporidium, Cyclospora, & Isospora Species & Microsporidia...824**

*Stephanie Boade Silas, MD & DeVon C. Hale, MD*  
*Cryptosporidium* 824  
  Clinical Syndromes 825  
*Cyclospora* 828  
*Isospora* 830  
Microsporidia 831  
  Clinical Syndromes in Non-HIV Infected Patients 832  
  Clinical Syndromes in HIV-Infected Patients 833

*Patients With AIDS*

**Preface**

*Current Diagnosis & Treatment in Infectious Diseases* is a "one-stop" source of essential, clinically oriented information on infectious diseases for students, house officers, practitioners, and other health care providers in both hospital and ambulatory settings. *CDTID* covers all infectious disease topics of concern to primary care physicians, infectious disease specialists, and other specialists who provide preventative, diagnostic, or therapeutic care for patients with infectious diseases. It stresses the practical features of clinical diagnosis and patient management.

**OUTSTANDING FEATURES**

- Incorporates current advances up to time of publication
- Practical information on clinical presentation, physical findings, laboratory diagnosis, treatment, and prevention of the vast array of infectious diseases that infect humans
- Concise, readable format facilitates efficient use in any practice setting
- Emphasis on diagnosis, treatment, and prevention
- Current recommendations for drug dosages for adults and children
- Up-to-date coverage of HIV infection and highly active antiretroviral therapy (HAART)
- More than 300 boxes summarize key diagnostic and treatment information
- Coverage of antibiotic use and misuse
- Discussion of significant new and reemerging infectious diseases
- Overviews of basic principles of host defense, microbial virulence, hospital infection

control, and lab tests

- Useful evaluation, testing, and decision-making tools and criteria

### **INTENDED AUDIENCE**

House officers and medical students will find concise, clinically oriented descriptions of diagnosis and treatment of use daily in the care of patients and for preparation for rounds and clinical conferences.

Internists, family physicians, pediatricians, and other specialists who provide generalist care, as well as infectious disease specialists, will appreciate *CDTID* as a quick reference and review text.

Physicians in other specialties, surgeons, and dentists may use the book as a basic reference on infectious diseases.

Nurses, nurse practitioners, physicians' assistants, and other health care workers will welcome *CDTID* as a useful reference for all aspects of care of patients with infectious diseases.

### **ACKNOWLEDGMENTS**

We wish to thank our contributing authors for their time and hard work involved in preparing this text. We wish to thank the editors of McGraw-Hill and their staff for their valuable assistance and support. We welcome comments and recommendations for future editions in writing or via electronic mail. The editors' and authors' institutional addresses are given in the preceding listing of Authors.

## 1 . Introduction — *Merle A. Sande, MD*

As a leading cause of death worldwide, infectious diseases have hardly been conquered or controlled. In fact, one might consider the 1990s as an era of reawakening, when new and reemerging infectious diseases were recognized as a major worldwide health problem. The continued explosion of cases of infections caused by the human immunodeficiency virus has now produced negative population growth and major disruption in the societies of many African countries, where more than 35% of young adults are infected and more than 25% of children are orphans. By the end of the millennium, the virus had infected more than 50 million people; it now ranks with childhood diarrheal diseases, pneumonia, malaria, and tuberculosis as a leading cause of death. While highly active antiretroviral therapy (HAART) has been astonishingly effective in treating the disease, the necessary drugs are available to only a small percentage of infected populations, and transmission of the virus continues unabated in many regions of the world.

The ability of modern technology to control infectious diseases has been found lacking. Antibiotics, which were developed within the last 60 years, resulted in the cure of many previously lethal infections, rightfully earning the name "wonder drugs." However, only several years into the "antibiotic age," pathogenic staphylococci were found to have the ability to produce enzymes (penicillinases) that destroyed penicillin, thus rendering the drug useless against these strains. The future quickly became clear to microbiologists and infectious disease clinicians studying bacterial genetics; the methods used to impede the organism's ambition to multiply and grow will eventually be defeated by the power of natural selection through the rapid emergence of resistant mutations. The more antibiotic pressure that has been applied, the more rapidly these subpopulations of drug-resistant pathogenic organisms have emerged. Public health-minded clinicians and scientists have issued warnings that overuse and misuse of these "wonder drugs" will eventually render them useless. These warnings have gone largely unheeded.

As we enter the next century, the possibility is quite real that these organisms have won and that we will return, in a sense, to the preantibiotic era. It will remain for our children or grandchildren to try to answer the question: Why did this generation of health providers not take better care of the future? It will be incomprehensible to them that we allowed antibiotics to be used in animal feed, to be used to treat colds and bronchitis due to viruses, and to be given to inpatients and outpatients without careful diagnostic evaluation. Will future generations eventually blame societal need to be "cost-effective" and the emergence of so-called managed care? Will they blame the pharmaceutical industry, whose need to make a profit led to misleading advertising, often directed at patients themselves? Will they blame physicians who did not learn microbiology and never bothered to consider the public health implications of their prescribing practices? Or will they blame our governmental agencies (the FDA, CDC, EPA, or NIH), whose job was to protect the public's health and make available scientific information that would dictate public policy but who did not do this? Will they blame patients themselves, who, because of misperceptions of the value and effectiveness of antibiotics, insisted on having their physicians prescribe them? Whatever future generations conclude about us, the facts are obvious: we continue to misuse and abuse antibiotics, one of the most

important advances in human history, with little attempt to change.

The impact of antibiotic resistance is especially felt in hospitals, where infections caused by resistant organisms are increasing dramatically and have the potential to destroy gains enjoyed in other medical disciplines, such as organ transplantation, prosthetic devices, artificial organs, indwelling pacemakers, and neonatal and adult intensive care. Future medical advances will be determined to a large extent by the ability to prevent and successfully treat the nosocomial infections caused by antibiotic-resistant pathogens. The great irony is that the same areas of medicine where these latest dramatic advances are happening are also those where the most dramatic changes in microbes have taken place. Physicians involved in caring for transplant recipients, cancer patients, and patients requiring intensive care are entirely free to prescribe any and all antibiotics they want *without* consulting infectious disease specialists. There seems to be a puritanical obsession at work in medicine whereby narcotics, which relieve a patient's pain, are considered controlled substances that require a prescribing physician to fill out duplicate and triplicate forms, whereas any physician is free to prescribe any antibiotic, whether indicated or not.

Another great human accomplishment during the last century was the worldwide elimination of smallpox through vaccination. It was an example of warring nations actually cooperating for the common good. In the early 1970s, the majority of the world stopped vaccinating against smallpox. Only two vials of the virus were thought to be preserved and the two "superpowers" had agreed to destroy those vials in 1999, to rid the world forever of this deadly virus. It therefore came as a horrible shock, in 1998, to find out from Russian scientists that they had "weaponized" the smallpox virus and readied it for use against the West, along with anthrax spores, *Yersinia pestis*, and other organisms. The human potential for destructive acts seems limitless.

Other infectious diseases have also slipped back into our society. Our attempts to control mosquitoes were initially successful, and federally funded programs reduced the *Aedes aegypti* and *Anopheles* species to the point where the arthropod-borne encephalitis viruses almost disappeared.

Malaria, once the scourge of the southern United States and Central America, was nearly eliminated. However, while these mosquitoes became resistant to DDT, apathy dominated the governments' response, and funding was cut. The mosquitoes have returned en masse, as have dengue, yellow fever, diseases induced by the various encephalitis viruses, and malaria. Finally, cholera, which had disappeared from the Western Hemisphere for decades, reappeared in Peru in the early 1990s and spread throughout Central and South America, wherever poor sanitation and poverty dominate the domestic scene. Within several years, over a million cases and thousands of deaths were reported, another reminder of the fragile control we have on infectious diseases.

When the public health infrastructure of our cities is allowed to deteriorate, microbial pathogens are ready and willing to take advantage of our citizens. In New York City in the late 1980s, funding for the tuberculosis program, among many others, was reduced and case follow-up was discontinued; the follow-up rate for patients discharged from hospitals with a diagnosis of active tuberculosis was approximately 10%. Partly because of poor patient compliance with therapy, multiple-drug-resistant tuberculosis emerged

and began to spread to other parts of the country. Many people, especially AIDS patients, died before the epidemic was finally controlled, when directly observed therapy was widely embraced and implemented. Similarly, when immunization slackened in Eastern Europe after the fall of communism, diphtheria reappeared, and more than 50,000 cases per year were reported in the early 1990s.

Our record of dealing with infectious diseases has been a checkered one, with some fantastic successes followed by dramatic mistakes and failures. It now seems clear that the virtual sea of microorganisms with which we must share this planet must be treated with care and understanding. We must learn to live in harmony with our normal flora and protect it from factors that breed resistance. We need to understand better the public health implications of unwise interventions such as mass use of antibiotics for the purpose of stimulating animal growth, or prophylaxis to prevent otitis media, or routine antibiotic treatment of respiratory tract infections caused by viruses.

One might be justified in greeting these challenges with an air of optimism. The requisite tools and insight necessary to predict, blunt, or suppress microbial virulence are at hand. The molecular language spoken between microbe and host cell is increasingly well described. So far, we know that the host-pathogen relationship is a two-way, intricate affair with features of codependence.

This textbook of infectious diseases is aimed at the student, house officer, or other trainee and at the practicing healthcare provider, with the hope of teaching these principles while providing a source of information that will help in the recognition, diagnosis, treatment, and prevention of these many emerging and reemerging infections. The book's format is one we hope allows easy access to the pertinent information that will facilitate the decision-making process and become a useful reference as we fight these current and future battles.

## Section I. Basic Principles

### 2 . Basic Principles of Host Defense — *Donald L. Granger, MD*

#### INTRODUCTION

Higher animals have evolved many host defense mechanisms that ensure the relatively long-term survival of individuals despite their coexistence with countless microorganisms. Healthy people are at equilibrium with the microbial world; their internal soma, rich in nutrients, remains free of replicating microorganisms. Disease can be viewed as progression away from this equilibrium, in which microorganisms invade the body from the environment and replicate, causing inflammation and destruction of the tissues, as well as depletion of the host's nutrients. Unchecked, the rapid expansion of the microbial population leads to the death of the host.

A similar but distinct scenario is that the internal environment contains a variety of viruses, bacteria, fungi, protozoa, and microscopic metazoa, which are acquired throughout life. Again, these organisms achieve equilibrium with the mammalian host. Under these conditions they do not replicate, nor do they produce toxins. Instead, they exist in a dormant or latent state, which is infection without disease. Disease is a progression away from the equilibrium. When the balance is disturbed, microbial replication begins; host nutrients are then consumed by the proliferating population of microorganisms. This process leads to disease and ultimately death unless microbial replication is blocked.

To maintain equilibrium with the microbial world—that is, to maintain a state of health—host-protective mechanisms must fulfill distinct functions. In a broad sense, the functions come in two forms.

The first form includes the antimicrobial defense mechanisms that have evolved throughout the vertebrate species. Specifically, this first form is composed of a variety of mechanisms to prevent invasion of sterile tissues from contiguous body sites that are teeming with microbial flora. These mechanisms involve the actions of specialized cells—phagocytes and lymphocytes. For example, the upper respiratory tract is colonized with large numbers of bacteria, yet further down into the respiratory tract, below the vocal cords and into the lungs, few or no bacteria are found. Those bacteria that do gain access to the lung are rapidly destroyed. In another example, microbes may gain entrance to sterile body sites when an open injury introduces bacteria into the skin, subcutaneous tissue, muscle, or bone. This is countered by mechanisms in which the injured tissue is walled off to prevent spread and is invaded by phagocytic cells that envelop and kill bacteria. This is bactericidal activity. Yet another example involves specialized microorganisms that have evolved into successful parasites and that gain ready access to sterile sites in the host. They may be highly resistant to host-killing mechanisms. Under these conditions, equilibrium between parasite and host is reached by establishing microbiostasis in the tissues. In this way, living microbes may remain dormant or latent within host tissues for years, or even decades. This scenario implies

microbiostatic host-defense mechanisms. For example, the human tubercle bacillus (*Mycobacterium tuberculosis*) is inhaled into the lung. In the immunocompetent host, immunity is acquired, microbial replication ceases, and the mycobacteria become dormant, especially (but not exclusively) in the lung apices.

A second way to thwart infectious disease is through a set of uniquely human prevention schemes that have resulted from brain development and intelligence. Our understanding of infectious disease transmission has led to effective prevention methods, such as the addition of chlorine to the water supply and modern sewage treatment. Knowledge of immunology has led to vaccine strategies that have achieved results such as the elimination of smallpox from the human population. Understanding microbial physiology and metabolism led to the discovery of antibiotics for treating heretofore lethal infections.

This chapter deals exclusively with the first category of anti-infection mechanisms. These mechanisms can be subdivided into two broad categories: (1) innate or natural host defenses and (2) adaptive immune responses. There are distinct mechanisms characteristic of each of these two, but there is overlap as well. Some innate responses use mechanisms that, when analyzed at the cellular and molecular levels, were previously thought to reside exclusively as part of the adaptive immune response. Conversely, acquired immunity may lead to microbicidal mechanisms, which are not immunologically (antigen) specific and probably exist as an evolutionary blend of the innate and adaptive host defenses.

## **INNATE HOST DEFENSES**

### **DEFENSE MECHANISMS AT THE PHYSIOLOGIC LEVEL**

#### **Introduction**

Numerous physiologic factors influence susceptibility to infection. Prime examples of these factors are discussed in the sections that follow.

#### **Normal Microbial Flora**

Body surfaces in continuity with the environment typically support a complex but characteristic set of numerous microbial species ([Table 2-1](#)). This group of microorganisms is called the normal flora and includes microorganisms that inhabit the integument, upper respiratory tract, gastrointestinal tract, and urogenital tract. More than 200 different bacterial species occupy the human colon as normal flora. The normal flora fill these body sites to the exclusion of other species. Thus, the presence of the normal flora provides a protective function. A relatively virulent species such as the fungus *Candida albicans* cannot occupy the vagina unless the normal flora are eliminated, for example, by use of broad-spectrum antibacterial agents used to treat urinary tract infections. Sometimes virulent microorganisms colonize a body site and coexist along with the normal flora. For example, *Streptococcus pneumoniae* is often found in the oropharynx of healthy individuals. Colonization is a critical requirement for the pathogenesis of bacterial pneumonia caused by this pathogen. At some point microaspiration events introduce *S pneumoniae* into the lower respiratory tract. Then

virulence mechanisms prevent the killing of these microorganisms by innate host defense mechanisms. This leads to microbial replication in a nutrient-rich environment that is devoid of competing microbial species, and bacterial pneumonia results.

What determines which species predominate as the normal flora at a particular site? Although this is a complex process, the phenomenon of attachment to host cells is an important requisite. Particular microbial species express structures on their surface that bind to receptors on host epithelial cells. For example, strains of viridans streptococci adhere (by special attachments) to pharyngeal epithelial cells and are able to flourish and exist as the predominant species in the oropharynx.

### **Anatomic & Physiologic Factors**

The normal human anatomy provides numerous examples of anatomic barriers that prevent microbial replication and invasion. This is best illustrated when a breach in these barriers occurs and infection follows. The skin is a highly efficient barrier that prevents bacteria and fungi from entering into the subcutaneous tissue. In burn victims this barrier is lost. Without aggressive countermeasures, individuals with extensive burns succumb to overwhelming bacteremia because enormous numbers of bacteria invade the damaged tissue and thereby gain access to the circulatory system.

Physiologic mechanisms provide similar functions that prevent microbial invasion. Secretions contain antimicrobial molecules. For example, lysozyme in tears dissolves the cell walls of particular gram-positive bacteria. Salivary secretions contain bactericidal proteins. Smooth muscle peristaltic movements prevent the overgrowth of bacteria in the small intestine by creating a continuous flow, which has a cleansing effect; hydrochloric acid in the stomach kills numerous bacterial cells that enter upon swallowing. The respiratory tract contains a mucociliary carpet that is under constant motion outward, which helps remove inhaled bacteria from the respiratory epithelium.

Similar to a breach in an anatomical barrier, when physiologic processes malfunction, disease is usually the result. For example, autoimmune diseases that destroy the salivary glands lead to severe problems with dental caries and gingivitis, which are caused by overgrowth of oral bacteria. Periodontal disease and loss of permanent teeth follow. This is in part because the saliva normally contains antibacterial and antifungal compounds.

### **Host Nutritional Status**

The nutritional status of the host ranks as a critical factor for both innate and acquired resistance to infection. Protein-calorie malnutrition in children is associated with severe measles (rubeola virus). Historical observations point to reactivation of dormant tubercle bacilli during acute food shortage in populations with a high prevalence of this pathogen. Pyogenic bacterial infections and periodontal disease are additional examples. The original description of *Pneumocystis carinii* as a human pathogen was based on observations of pulmonary disease in starving European infants during and after World War II. Experimental research shows that starvation impairs phagocytes and cell-mediated immunity (CMI) before its effects on antibody production are observed.

## Hormonal Influences

Glucocorticoids exert profound effects on host resistance to infection. In severe bacteremia, physiologic cortisol secretion improves chances of survival. Yet it is well known that pharmacologic dosages of glucocorticoids depress the inflammatory response and increase susceptibility to primary infection as well as reactivation of latent infection. Pregnancy, as it progresses into the third trimester, results in immunosuppression, primarily of CMI. This leads to increased susceptibility to certain infections such as the food-borne infection listeriosis.

## Aging

Aging affects many aspects of innate defenses. Consequently, pneumonia, urinary tract infections, cholecystitis, diverticulitis, and bacteremia caused by pyogenic bacteria are increased. The aged are more likely to reactivate latent organisms such as Herpes zoster virus and *Mycobacterium tuberculosis*, which suggests decreased CMI. Aged individuals have reduced ability to mount immunoglobulin (Ig) synthesis against polysaccharide antigens.

## The Acute-Phase Response

The acute-phase response is a phylogenetically primitive, pleiotropic collection of responses designed by evolution to inhibit microbial replication and enhance acquired immune responses. The acute-phase response is triggered by invasion of microorganisms. Its complex, multiorgan involvement is fundamental for the inflammatory response characterized by swelling, pain, redness, heat, and loss of function. With the evolution of specific adaptive immune responses in vertebrates, the acute-phase response was preserved and is used as an activator of T and B lymphocytes.

Signal molecules that emanate from bacteria and other microorganisms (eg, endotoxin, muramyl dipeptide from the peptidoglycan of cell walls, glucans, mannans, and microbial toxins) bind to receptors on mononuclear phagocytes (MNPs) and endothelial cells [the reticuloendothelial system (RES)]. Secretion of a major proinflammatory cytokine, interleukin-1 (IL-1), and possibly others induces a pleiotropic response that involves a variety of different organs and functions ([Table 2-2](#)). The acute-phase response also leads to induction of specific immune responses, namely antibody synthesis by B cells and CMI, which are controlled by T cells. In a practical sense, measurements of the acute-phase response in blood samples are used in diagnosis of infections and other inflammatory diseases. Phenomena affected by IL-1, namely fever, increased erythrocyte sedimentation rate, high white blood cell count, and muscle wasting are important clues to the presence of infection, autoimmune inflammatory diseases, and neoplastic diseases that involve lymphoreticular cells.

## INNATE DEFENSE MECHANISMS AT THE CELLULAR LEVEL

### Introduction

Ever-present cells and molecules (constitutive mechanisms) form an on-the-spot

defensive line against microbial invasion. Compromise of this innate multifaceted system results in predictable serious infections, usually with invading species of the microflora. Thus, the importance of constitutive nonspecific defense mechanisms is revealed. Phagocytes and natural killer (NK) cells are discussed as examples of innate cellular defenses.

## Phagocytes

Two types of cells can be considered "professional phagocytes" or cells that consume microbes. These are the polymorphonuclear leukocytes (called neutrophils, or granulocytes) and the MNPs (monocytes and macrophages). These cells emanate from bone marrow precursors and enter the circulation to perform their antimicrobial functions. Lack of either of these cell lineages is incompatible with life.

Neutrophils live for 1-4 days after entering the circulation. Continued neutrophil production is essential for survival. Neutrophils are an important regulator of homeostasis between the body, which harbors sterile enclaves, and the microbial world. Neutrophils deal with pyogenic bacteria and fungi. Neutrophils possess tightly regulated microbicidal systems that are activated within seconds after encountering microorganisms. In healthy individuals, neutrophils are constantly at work destroying small numbers of microbes that enter the body by various routes. Severe neutropenia (< 500 cells/uL of blood) leads to overwhelming bacteremia from enteric bacilli. Neutrophils are constitutively bactericidal to a high degree for gram-positive and gram-negative cocci and enteric bacilli. To maintain this constitutive defense, neutrophils have special functional properties, to be discussed below. A defect in any one of these important functions invariably leads to a life-threatening infection. However, neutrophils have less or little activity against facultative or obligate intracellular pathogens such as mycobacteria, dimorphic fungi, and protozoans. The human immune system has evolved other mechanisms for dealing with these pathogens.

MNPs leave the bone marrow as blood monocytes. They mature into macrophages in the periphery. Stationed throughout all organs of the body, they compose the RES. The RES of the sinusoids of the liver and spleen provides an important clearance mechanism to remove a variety of microbes from the circulation. Thus, the spleen serves as a highly efficient, specialized RES site for removal of virulent bacteria. These bacteria avoid clearance in other RES sites, such as the lung or liver, because they possess virulence factors that have extraordinary antiphagocytic properties, such as particular serotypes of exopolysaccharide capsules. Individuals with no spleen may succumb to high-grade infection caused by bacteria that possess antiphagocytic capsules. The alveolar spaces of the lung are inhabited by macrophages, which form a first-line defense of the lung. These cells phagocytize and kill inhaled viruses, bacteria, and fungi. Macrophages and macrophage-like cells (eg, dendritic cells) contribute to the adaptive immune response. Macrophages, which function in concert with T lymphocytes, are responsible for CMI defense against intracellular pathogens. Macrophages process and present antigen to lymphocytes and receive "activating" signals during the immune response. These signals enable the macrophages to control the replication of intracellular microorganisms; they are also capable of killing these microorganisms (see below). Some of the functions listed in [Table 2-3](#) for neutrophils are also relevant for MNPs.

To kill bacteria and fungi, phagocytes must make physical contact with them. This involves a coordinated sequence of regulated events: (1) production, (2) release into the circulation, (3) attraction to a site of infection, (4) adherence onto and translocation through (diapedesis) adjacent capillary walls, (5) chemotaxis, (6) attachment to and phagocytosis of the microbe, (7) activation of killing mechanisms, and (8) digestion of dead microorganisms (see [Table 2-3](#)). These events are depicted in [Figure 2-1](#). Genetic or acquired conditions that interfere with one or more of these steps are associated with increased propensity to develop pyogenic infections caused by microorganisms which are usually constituents of the normal flora.

**A. Phagocyte Production (Stage 1).** Phagocytes are produced in the bone marrow (see [Figure 2-1A](#)). Neutrophils are produced in bone marrow from precursor stem cells under the mitotic and differentiation influence of several low-molecular-weight proteins called colony-stimulating factors (CSF). CSF for granulocytes (neutrophils) (granulocyte CSF), monocytes/macrophages (macrophage CSF), phagocytes (granulocyte-macrophage CSF), and multiple cell types (IL-3) are secreted by endothelial cells, fibroblasts, and cells of the immune system. A large number of granulocytes are produced each day ( $\sim 10^{11}$  cells). Granulocytes are short-lived cells; once they enter the tissues their half-life is only 6-8 h. There may be as many as  $10^{10}$ - $10^{11}$  granulocytes/ml of abscess fluid. Thus, the turnover of these cells is high, and, when production is inhibited, by anticancer drugs, for example, neutropenia may become severe and lead to invasive bacterial and fungal infections.

**B. Phagocyte Release (Stage 2).** Phagocytes are released into the circulation (see [Figure 2-1B](#)). IL-1, a cytokine product from macrophages, signals release of neutrophils from the marrow. The circulating neutrophil population increases the peripheral white blood cell count, a hallmark of acute infection. Neutrophils that normally adhere to the vascular endothelium form the marginated pool. Certain chronic stimuli (eg, drugs, hypoxia, stress, and exercise) cause demargination with increased white blood cell counts.

**C. Chemokinesis (Stage 3).** Phagocytes are guided to sites of infection by chemical signals called chemokines. Sentinel tissue macrophages and migrating immune cells, in response to invading microbes, secrete proteins called chemokines. Numerous distinct molecules have been identified—some are the ligands for specific receptors on different leukocytes, and some control the types of leukocytes that infiltrate inflammatory foci. The chemokines exert their effect by facilitating adherence of particular cell types to endothelium adjacent to an inflammatory site.

**D. Margination, Spreading, and Diapedesis (Stage 4).** For phagocytes to enter foci of infection, they must adhere to adjacent capillaries and migrate out of the bloodstream into the tissues. This is a multistep, tightly regulated process. The initial adherence step is mediated by surface molecules called selectins that bind neutrophil (L-selectin) to the endothelial cell (E-selectin) as well as to platelets (P-selectin). At this stage leukocytes roll along the endothelium in the direction of blood flow ([Figure 2-1C](#)). Tight adherence with leukocyte flattening is mediated by receptors ( $\beta$ -integrins) that bind to intercellular adhesion molecules called ICAMs that are expressed on endothelial cells. This

interaction is controlled by regulation of these surface molecules through inflammatory mediators that diffuse from an infected site. Cytokines and arachidonic acid metabolites up-regulate  $\beta$ -integrin (on neutrophils) and ICAM-1 (on endothelial cells) expression. Specialized adhesion molecules localized at endothelial cell junctions (platelet/endothelial cell adhesion molecules) guide neutrophil motility between endothelial cells into infected tissue by a process called diapedesis ([Figure 2-1D](#)).

**E. Chemotaxis (Stage 5).** Phagocytes seek pathogens by attraction to gradients of microbial products and signals generated by the host inflammatory response. Motility of neutrophils increases in response to environmental signals called chemotaxins, which include cytokines [IL-6, IL-8, granulocyte macrophage CSF, tumor necrosis factor  $\alpha$  (TNF $\alpha$ ), interferon- $\gamma$  (IFN- $\gamma$ )], leukotrienes, and chemical products from microorganisms themselves (eg, microbial oligopeptides such as formylmethionine-leucine-phenylalanine). When no concentration gradient is present, increased motility is random [chemokinesis ([Figure 2-1E](#))]; however, in the presence of even weak gradients, neutrophil motility becomes directed toward an increased concentration of stimulus [chemotaxis ([Figure 2-1F](#))]. The interaction between chemotaxins, their high-affinity receptors on the neutrophil surface, and cytoplasmic cytoskeletal events, which propel the cell forward, are not entirely worked out. However, it is important that phagocyte motility depends on a substrate upon which the phagocytes crawl. These cells cannot swim. Thus it becomes clear that whenever bacteria gain access to nutrient-rich fluid-filled spaces (eg, cerebrospinal, pleural, peritoneal, pericardial, or synovial fluid), phagocyte defenses are put at considerable disadvantage. Neutrophils must make physical contact with the bacteria they kill. In a fluid-filled space (eg, massive ascites), this contact depends on random collisions between bacterial and phagocytic cells. Indeed, in the preantibiotic era, pyogenic infections of fluid-filled spaces were frequently fatal. Because bacteremia is often a precursor to meningitis, pericarditis, peritonitis, or septic arthritis, one major function of the RES is to clear bacteria from the bloodstream, which thereby prevents seeding of fluid-filled spaces. Bacteria that most often cause these infections are notoriously difficult to clear from the bloodstream because they possess antiphagocytic factors, most often capsules (*S pneumoniae*, *Streptococcus pyogenes*, *Neisseria meningitidis*, and *Haemophilus influenzae*).

**F. Phagocytosis (Stage 6).** Phagocytosis is required to kill invading microorganisms. Phagocytosis is a two-step process: (1) attachment of the particle to the phagocyte occurs and (2) the phagocyte extends lamellipodia circumferentially around the particle to enclose it within a phagocytic vacuole called the phagosome ([Figure 2-1G](#)). As noted above, opsonic proteins (Igs and complement proteins) coat microorganisms and, by engaging their receptors on the surface of phagocytes, they mediate attachment. These receptor-ligand interactions also induce intracellular events, which activate the engulfment process. Engulfment itself is a highly energy-dependent process and is powered by an ATP-dependent cytoskeletal polymerization-depolymerization of actin microfilaments. Nonopsonic phagocytosis may occur for some microorganisms. Molecules on the surfaces of both target and phagocyte interact with oligosaccharide moieties, which mediate attachment and activate the engulfment "motor" of the phagocyte.

Another aspect of phagocytosis involves interaction between the phagocyte and the

surrounding tissue substrate (ie, the surface on which the phagocyte is crawling). This involves specialized serum molecules (extracellular matrix proteins) such as fibronectin, laminin, and vitronectin. These proteins do not interact with microorganisms directly. However, facilitation of interaction between phagocyte and substrate by these molecules leads to substantial enhancement of phagocytosis.

**G. Microbicidal Activity (Stage 7).** There are numerous phagocyte microbicidal mechanisms ([Figure 2-1H](#)). As microorganisms are internalized within phagosomes, microbicidal functions are initiated. Two general categories of killing mechanisms are recognized. These are the oxygen-dependent and -independent mechanisms. Oxygen-dependent killing is by the oxidative burst, sometimes called the respiratory burst. There are multiple oxygen-independent mechanisms that are mediated by microbicidal proteins that are delivered into the phagosome by degranulation. Degranulation occurs when specific cytoplasmic granules in the neutrophil fuse with the phagocytic vacuole and discharge their contents on particles sequestered therein. A phagosome that has undergone this process is called a phagolysosome. The phagolysosomal membrane contains a proton pump that acidifies the compartment. The low pH (~ pH 4.5) is an ideal environment for many enzymes, acid proteases, defensins, cationic proteins, and other proteins (bactericidal permeability-increasing protein, azuricidin, indolicin, and bactenectins) that kill and digest (stage 8; see [Figure 2-1H](#)) bacteria.

The oxidative burst is based on a unique enzyme system, which in the resting cell is inactive. This enzyme is the NADPH/oxygen oxidoreductase of neutrophils and MNPs. The NADPH oxidase is activated upon stimulation induced by phagocytosis of a microorganism. Oxygen is reduced to superoxide with NADPH serving as the electron donor. There is abrupt, large-scale oxygen consumption by the enzymatic reaction—the respiratory or oxidative burst. Of the numerous biochemical events that ensue, the most important is the generation of several microbicidal products. All are formed ultimately from superoxide itself, the proximal enzymatic product. Hydrogen peroxide, singlet oxygen, and hydroxyl radical—all highly efficient microbicidal agents—are generated from superoxide. Hydrogen peroxide and chloride form hypochlorite and, ultimately, chloramines, through catalysis by myeloperoxidase. Thus the neutrophil relies on an arsenal of chemical weaponry to kill microorganisms. In the test tube, several million neutrophils undergoing the respiratory burst kill 10 million *Escherichia coli* within minutes; the same process occurs in the body, but only if neutrophils can phagocytose their targets and if substrates for the respiratory burst are available. It is evident that these highly reactive and toxic oxygen reduction products may destroy host cells along with invading microbes. Consequently, systems have evolved in mammals for protection of the surrounding host tissues at sites of inflammation. Catalase, superoxide dismutase, and glutathione peroxidase/glutathione reductase are detoxifying enzymes whose mechanisms scavenge oxygen intermediates. Other small organic molecules function as nonenzymatic scavengers. Neutrophil oxidative metabolism is extremely important for the maintenance of homeostasis in humans. Rare mutations that ablate NADPH oxidase activity lead to serious, frequent and invariably fatal pyogenic infections in children. Recent advancements have led to strategies that can augment other defenses and thereby prevent serious infections in these children.

Oxygen-independent microbicidal mechanisms compose a heterogeneous group. The

most important are the microbicidal peptides and proteins that are released after bacteria are ingested during phagolysosomal fusion. An extensively studied example is the defensin family of molecules. By assembling into hydrophobic structures, which form pores through which bacterial components are lost, defensins lead to perturbation of bacterial membranes. This culminates in death of the bacterial cell.

## Natural Killer Cells

NK cells are non-B, non-T lymphocytes that circulate in blood and function in constitutive host defense by identifying and destroying cells infected with viruses. Equipped with specialized proteins and enzymes packaged within intracellular granules, NK cells lyse virus-infected host cells and thereby interfere with viral replication. NK cells can bind yeast cells and destroy them. NK cells are an important source of cytokines, chemical messenger molecules that regulate the immune response. In rapidly developing infections, NK cell-derived IFN- $\gamma$  (one of the most important cytokines) activates macrophages to a microbicidal state.

## DEFENSE MECHANISMS AT THE LEVEL OF PROTEIN MOLECULES

The complement proteins, designated collectively as C', constitute a complex system of plasma zymogens that operate as part of innate host-defenses (the alternate pathway) and with antibodies, in adaptive immunity (the classical pathway). Although composed of different proteins, the complement system bears a striking analogy to the blood clotting system.

Complement proteins are produced primarily in the liver by hepatocytes. MNPs also synthesize and secrete all of the complement proteins, but the bulk of production depends on the liver.

The initial step of the alternative pathway is always active, but it occurs at a very low level. When bound to a microbial surface product, such as the lipopolysaccharide polymer from the cell wall of gram-negative bacteria, limited proteolysis proceeds stepwise until C3 is cleaved to C3b and C3a. C3b is a short-lived protein. It forms a covalent thioester bond near its formation site, namely on the surface of a bacterial cell. MNPs and polymorphonuclear phagocytes express a family of distinct C3 receptors. Ligand-receptor binding anchors the bacterial cell to the phagocyte. This attachment event initiates phagocytosis. In animal models, depletion of C' proteins with cobra venom factor renders the host highly susceptible to infection with encapsulated bacteria such as *S pneumoniae*. Thus, the main function of the complement system is to generate opsonins, primarily C3b, molecules that increase the efficiency of phagocytosis.

Further in the complement cascade, C5 is cleaved into large C5b and small C5a proteolytic fragments. C5a diffuses from the site of inflammation, which sets up a concentration gradient that directs phagocyte emigration by chemotaxis.

Still later in the cascade a complex forms composed of C7, C8, and C9—the membrane attack complex (MAC). The MAC inserts itself into the outer lipid bilayers of gram-negative bacteria-forming pores visible by electron microscopy; this drastic

perturbation leads to bacteriolysis. Bacteriolysis effected by the MAC is thus a mechanism for killing bacteria by fluid phase components—a phagocyte is not directly involved. However, bacteriolysis has limitations. First, gram-negative bacteria spawn mutants that are resistant to the lysing capability of the MAC. Second, gram-positive bacteria, mycobacteria, and fungi are naturally resistant to the MAC. Although protozoa may be killed by the MAC, CMI is the main defense mechanism against these pathogens.

The complement system performs three important host-defense functions: (1) it generates C3b, a major opsonic component that promotes phagocytosis; (2) it generates C5a, a chemotaxin that directs phagocyte motility toward an inflammatory stimulus; and (3) it kills some gram-negative bacteria through the MAC.

Humans with complement deficiencies, although uncommon, have been identified. These individuals exhibit characteristic susceptibilities to infection, such as disseminated infection with *Neisseria meningitidis* and *N gonorrhoeae*.

## **ADAPTIVE IMMUNE RESPONSES**

### **INTRODUCTION**

There are two general categories of adaptive immune responses. The first comprises the synthesis of specific Ig proteins (antibodies) by specialized lymphocytes called plasma cells. This is called humoral immunity. The second type of response, CMI, involves direct or indirect attack on microorganisms mediated by lymphocytes and other accessory cells (eg, macrophages). Both humoral immunity and CMI are characterized by two important features. First, the responses are directed toward specific biochemical moieties on microorganisms, called antigens. Second, the responses impart a "memory" in the host. This means that subsequent exposures to specific antigens are met with a much enhanced immune response.

### **HUMORAL IMMUNITY**

#### **Production of Antibodies**

Antibodies are complex glycoproteins called Igs, which bind specifically to moieties called antigens. After an antigen is bound by an antibody, a variety of cellular and molecular mechanisms come into play. These mechanisms, which function to protect the host from microbial invaders, are discussed in the sections that follow. In conjunction with the complement system, antibodies are the main effector molecules of humoral immunity. Antibodies are used to inhibit or destroy foreign cells. In the circulation and on mucosal surfaces, antibodies help define acquired resistance to particular pathogens. The mechanistic bases for antibody-mediated resistance are varied and complex. It is necessary for the antibody alone to bind the antigen. Even this is not sufficient in all cases because additional mechanisms may be required to kill microorganisms (eg, participation by a phagocyte). Examples of antibody effector mechanisms include the following: (1) complement activation that leads to bacteriolysis; (2) opsonophagocytic function, in which antibodies attach microorganisms to phagocytes, which then kill the microorganisms; (3) antibody-dependent cellular

cytotoxicity (ADCC), an antibody bridge between an effector cell (eg, lymphocyte or monocyte) and target cell (eg, virus-infected somatic cell) that activates a killing mechanism, whereby the target cell is destroyed; and (4) neutralization, whereby the antibody binds to a microbial toxin or virus, which renders it unable to bind to its receptor through steric hindrance.

Two critical functions are encoded in the structure of the antibody molecule. The N-terminal end (variable or V region) of the molecule defines the antigen recognition site. There are many possible different amino acid sequences that lead to different antigen-binding specificities. The carboxy-terminal portion determines one of nine classes and subclasses of Ig isotypes. Each isotype carries a distinct functional attribute suited for various biologic tasks, such as complement fixation, opsonization, or distribution into certain body sites and surfaces. B lymphocytes produce antibodies that express surface-bound Igs of a single specificity. When these antigen receptors are engaged by specific ligands, B cells proliferate and differentiate into plasma cells. These cells then begin to secrete Ig molecules that are specific for the target antigen.

### **Immunoglobulin Structure**

All Igs share the same basic molecular structure. This structure consists of two identical peptide heterodimers linked by disulfide bridges. Each heterodimer consists of a heavy chain ( $C_H$ ) and a light chain ( $C_L$ ) ([Figure 2-2](#)).

The antigen-binding site is in the Fab portion. Three hypervariable regions containing 10-12 amino acids with markedly variable sequences occupy the  $V_K$  and  $V_H$  domains. The quaternary structure of the  $C_L$  and  $C_H$  in this region determines antigen specificity. Because each Ig molecule has two heavy and two light chains, antibodies are bivalent for antigen binding. The portion of the antigen recognized is called the epitope. The complementary Fab-binding site is called the paratope.

A constant region of the  $C_H$  is the product of distinct genes. This region defines the "class" of Igs. A hinge region determines flexibility of the molecule related to biological function. The Fc portion is critical for biological function, such as complement activation, the ability to bind to phagocyte receptors, and the ability to cross anatomic barriers such as placental membranes.

### **Immunoglobulins in Humans**

Five Ig classes defined by their  $C_H$  type are present in humans ([Table 2-4](#)). There are four IgG and two IgA subclasses. There are two classes of  $C_L$ s (? and ?). Each B lymphocyte produces only one class of  $C_L$ .

**A. Immunoglobulin M.** During the primary immune response, IgM antibodies are the first to be produced. The pentameric structure endows IgM with 10 antigen-binding sites. This assists in complement activation and aggregation of antigen and microbes. Antigen affinity for IgM is usually less than for IgG. Measurement of IgM antibody specificity and concentration is useful in diagnosis because its presence correlates with primary, active infection.

**B. Immunoglobulin D.** IgD is expressed on the surface of B cells and functions as antigen receptor. Membrane anchoring is a function of the extended hinge region of IgD molecules.

**C. Immunoglobulin G.** IgG is the most abundant Ig, making up ~ 75% of the total. It crosses the placenta and hence provides protection to the newborn during the first 6 months of life. It is present in the lower respiratory tract and in exudative secretions. There are four subclasses (IgG<sub>1</sub>, IgG<sub>2</sub>, IgG<sub>3</sub>, and IgG<sub>4</sub>), which are determined by the constant regions of their heavy chains. Each bears distinct biologic activities. IgG<sub>1</sub> and IgG<sub>3</sub> fix complement well. IgG<sub>3</sub>, but not IgG<sub>2</sub> and IgG<sub>4</sub>, binds and activates leukocyte Fc receptors. IgG<sub>2</sub> is produced against the polysaccharide determinants of bacterial capsules. IgG<sub>4</sub> may compete with IgE for antigen and thereby alter immediate-type hypersensitivity reactions.

**D. Immunoglobulin A.** There are two subclasses of IgA—IgA<sub>1</sub> and IgA<sub>2</sub>. IgA is produced in gut lymphoid tissue and is dimeric. It is transported from submucosa to the gut lumen. This is mediated by a special secretory component, expressed as an integral membrane protein on the basolateral surface of gastrointestinal epithelial cells. This secretory component is a receptor for dimeric IgA and initiates endocytosis, transcytoplasmic transport, and release of IgA dimers into the intestinal lumen. This process occurs at other mucosal sites in the respiratory and urogenital tracts, as well as in nasal secretions, tears, saliva, and colostrum. IgA interferes with attachment of microorganisms to mucosal surfaces. It neutralizes ingested toxins, and it may promote phagocytosis by leukocytes emigrating into mucosal epithelium.

**E. Immunoglobulin E.** Although only trace amounts are present in the circulation, IgE predominates on the surface of mast cells and basophils through noncovalent high-affinity receptor binding of its Fc portion. Immediate-type hypersensitivity or reaginic responses occur when antigen binds to cell surface IgE. Degranulation with release of histamine, eicosanoids, and peptide mediators of inflammation from mast cells may lead to urticaria, laryngeal and intestinal wall edema, and anaphylactic shock. The evolution of reaginic responses was driven by the necessity for a host-defense mechanism against invasion of tissues, especially epithelial surfaces, by helminths and ectoparasites. Monocytes, eosinophils, and platelets may cooperate with IgE in ADCC reactions against certain trematodes.

## **B Cells**

Generation of an effective humoral immune response is vested in progenitor cells located in the bone marrow, which undergo differentiation to become mature B cells in the spleen and lymph nodes. Activation of mature B cells into antibody-producing plasma cells is a complex, highly regulated process. Regulation occurs through the expression of B-cell surface receptor molecules, which alter cell function upon binding ligand. Important B-cell receptors and their functions are shown in [Table 2-5](#).

Antigen binding to its specific receptor on B cells leads to the formation of the B-cell receptor complex. When formed, the complex lowers the threshold for B-cell activation.

Intracellular signal transduction through protein phosphorylation by Src kinases activates membrane phospholipase C $\gamma$ 2. Inositol triphosphate and diacylglycerol are formed. Intracellular calcium is mobilized and protein kinase C is activated. Transcription of cellular genes is induced by regulating cell division, differentiation, and Ig synthesis. However, these events are usually not sufficient for high-level antibody production. T cells, which recognize processed antigen-derived peptide in association with complementary major histocompatibility complex (MHC) class-II determinants, physically aggregate with B cells and promote B-cell activation. This is called T-cell helper function. This is the main pathway for antibody production against protein antigens.

Certain polymeric antigens, especially bacterial polysaccharides bearing repetitive monosaccharide units, can activate B cells without T cells. This type of T-cell-independent antibody response may relate to cross-linking B-cell receptor complexes (and hence more efficient signal transduction) by long strands to linear polysaccharide antigen molecules. T-cell-independent antibody responses tend to produce low-affinity IgM and IgG<sub>2</sub> isotypes in relatively low levels. Furthermore, memory B-cell formation is inefficient. Thus, bacterial polysaccharide vaccines may not be particularly immunogenic. By coupling a bacterial polysaccharide to a protein component (eg, tetanus toxoid) a T-cell-dependent B-cell response is induced, and memory cells become more abundant. Recently, lymphocytes not ordinarily classified as T or B cells, which bear the CD1 surface marker, were shown to help process polysaccharide antigens covalently attached to lipid moieties. This pathway of antigen presentation, which is not restricted by MHC, could prove useful for future development of polysaccharide vaccines.

## Antibody Diversity

Antibody diversity is explained by rearrangements of DNA sequences within unique regions of Ig genes. Antibodies produced during a primary antibody response after an encounter with a new antigen are IgM in isotype. They appear 5-10 days after exposure to antigen, and their antigen affinity is relatively low. On reexposure to antigen, secondary antibody responses result in rapid production (1-3 days) of higher-affinity, higher-titer IgG, IgA, or IgE isotypes. Memory B cells formed during a primary response mediate the more efficient secondary response with the help of T cells. Switching of isotypes from IgM to IgG, for example, is controlled by T cells and the cytokines they secrete to communicate with B cells. Isotype switching and affinity maturation and epitope diversity of Igs are the result of four distinct molecular processes:

1. Multiple segments within the hypervariable region of the DNA encoding light and heavy chains ( $V_L$  and  $V_H$ ; [Figure 2-2](#)) undergo recombination.
2. The segments are rejoined inexactly.
3. The quaternary association between  $V_H$  and  $V_L$  protein products leads to unique antigen-binding sites. These events lead to an enormous repertoire of B cells bearing different antigen receptor specificities. These specificities are directed against those portions of antigen molecules called epitopes.

4. A nonrecombinatorial mechanism involving somatic point mutations in the  $V_H$  and  $V_L$  regions leads to idiotype diversity. This mechanism is believed to account for maturation, when repeated administration of antigen results in antibody production with incrementally increased affinity for the eliciting epitope.

### Immunoglobulin Fc Receptors

Antibodies function in host defense in conjunction with other proteins (eg, complement components) and cells (eg, phagocytes). Antigen bound to the Fab portions is connected to functional components by the Ig Fc portion. Thus, the specificity of Fc ligands interacting with Fc receptors on other immune cells determines the character of immune responses mediated by antibodies. Families of Fc receptors and their functional activities are shown in [Table 2-6](#).

### Function of Antibody-Mediated Host Defense

Through specific binding of antigen and Fc portion receptor-ligand interaction, antibodies facilitate destruction of microbes and neutralize toxins. They may act at a distance from their cell of origin, and their soluble properties allow for dispersion throughout the body in the circulation and lymph. The utility of Igs in host defense is multifactorial. However, the overriding feature is their functional capability for attaching microorganisms to phagocytes and lymphocytes bearing microbicidal mechanisms. The following sections summarize antibody-directed immune mechanisms.

**A. Activation of Complement Proteins.** The  $C_{H2}$  (IgG) and  $C_{H3}$  (IgM) domains (see [Figure 2-2](#)) of antibody Fc regions activate complement by binding to microbes and then interacting with multiple sites on C1q, the first component of the complement cascade (classical complement pathway). Activation of complement on microbial surfaces leads to bacteriolysis in some instances or, more commonly, to phagocytosis. Gram-negative bacteria are susceptible to bacteriolysis as are some protozoans. But gram-positive bacteria, fungi, and viruses cannot be lysed. Furthermore, gram-negative bacilli resistant to complement-mediated lysis (serum resistance) can be selected for during natural infection. Opsonophagocytic antibodies important for the resolution of infection have been identified during infection with *S pyogenes*, *S pneumoniae*, *H influenzae*, *N meningitidis*, and *Staphylococcus aureus*.

**B. Promotion of Phagocytosis.** The three classes of IgG Fc receptors mediate phagocytosis of IgG-coated particles. IgG<sub>2</sub> and IgG<sub>3</sub> subclasses are generally required. Mucosal phagocytes, namely macrophages and neutrophils, bearing IgA Fc receptors facilitate engulfment of microorganisms. Fc receptors alone are usually sufficient for phagocytosis of most bacteria and fungi; however, removal of encapsulated bacteria may require Fc and C3 receptors functioning in concert. In experimental *S pneumoniae* bacteremia caused by highly virulent strains, clearance of bacteria from the circulation failed when animals were depleted of complement proteins, even when anticapsular IgG antibody was present.

**C. Antibody-Dependent Cellular Cytotoxicity.** ADCC is a mechanism by which

leukocytes destroy somatic cells infected with microorganisms. Antibody-coated microorganisms or parasitized host cells can be killed when Fc receptors on leukocytes are engaged. This reaction occurs without phagocytosis, but depends on contact between effector and target cells. Nonphagocytic immune cells (eg, NK cells) lyse antibody-coated virus-infected host cells through IgG RIII receptors. In this reaction, NK cells exocytose cytotoxic protein molecules called perforins onto target cells. Perforins assemble in the target cell membrane-forming pores similar to the MAC of complement. Rapid lysis ensues. Macrophages and neutrophils participate in ADCC reactions. IgE-coated metazoans such as parasitic helminths are destroyed by eosinophils bearing Fc receptor II molecules. Eosinophils exocytose a cytotoxic molecule, called major basic protein, onto the parasite surface on engagement and cross-linking of these Fc receptors.

**D. Neutralization of Microbial Toxins.** Microbial toxin neutralization is a striking example of protection mediated by antibodies. Lethal toxins produced by *Clostridium* spp. (eg, botulinum toxin and tetanus toxin) and by *Corynebacterium diphtheriae* (diphtheria toxin) are efficiently detoxified by specific IgG. Antibodies bind to toxin molecules and, through steric hindrance, block their receptor-mediated uptake by susceptible cells. The antitoxin effect of antibodies is the basis for some of the most successful immunization practices in medicine.

Endotoxins are the lipopolysaccharide polymers that form part of the structure of the outer membrane of gram-negative bacteria. Their biologic effects are myriad, but they include the induction of lethal collapse of the circulatory system. Much effort has been made to produce protective antibodies against endotoxins for administration to patients in shock. Despite broad reactivity and monoclonal antibody technology, this strategy has not yet led to significant advances for the treatment of endotoxemia.

**E. Neutralization of Viruses.** IgM, IgG, and IgA antibodies bind to specific epitopes on virions and block virus access to host cells. The effective prevention of polio, smallpox, hepatitis A and B, and rabies by immunization is based on this principle. Other viruses, most notably herpes viruses and human immunodeficiency virus (HIV)-1, spread from cell to cell and hence evade neutralizing antibody. One exception may be the intracellular neutralization of viruses within mucosal epithelial cells as polymeric IgA is transported through these cells.

**F. Blockage of Microbial Adhesion.** Pathogenic microorganisms entering the body via mucosal surfaces first attach to epithelial cells by receptor-ligand binding. Specific IgA directed at these determinants may block adherence and hence abort microbial invasion.

**G. Agglutination of Microorganisms into Large Aggregates.** Polyvalent IgM, IgG, and IgA can cross-link microbes forming large aggregates. In the respiratory tract, the mucociliary clearance mechanism may then facilitate removal of these aggregates before invasion can occur.

## CELL-MEDIATED IMMUNITY

### Introduction

CMI refers to an immune response against organisms (usually facultative or obligate intracellular microorganisms) in which antibody has a subordinate or no role. CMI was first demonstrated experimentally as an immune response that occurred in passively immunized animals transfused with cells (lymphocytes) but not with specific Igs. Such strict division between cell-mediated and humoral immune responses is oversimplified because specific Igs and antigen-antibody complexes interact to both enhance and inhibit CMI reactions.

CMI involves signal transmission between cells participating in the response. Intercellular signaling is accomplished in two ways: (1) by cell-cell interaction involving surface molecules on the interacting cells and (2) via chemical messenger molecules called cytokines. These mechanisms operate both in innate immune responses and in antigen-specific CMI. Intercellular signaling mechanisms are then used to activate cytotoxic effector cells for microbistatic and microbicidal functions. Cell signaling and activation are discussed individually in the next section.

## Cell-Cell Interactions

**A. Major Histocompatibility Complex Molecules.** MHC molecules compose a group of polymorphic integral membrane proteins encoded by segments of clustered genetic loci. These molecules participate in binding antigenic peptides for T-cell recognition. Two structurally distinct types of MHC molecules exist. MHC class I molecules are involved in classic immune responses to virus-infected cells, foreign tissue grafts, and tumors. There are ~ 70 different alleles composing three separate subclasses of MHC class I genes. MHC class I molecules express peptides synthesized within the host cell (eg, a protein encoded by a viral gene) and transported from endoplasmic reticulum via the Golgi apparatus to the cell surface.  $\beta_2$ -Microglobulin and calnexin are required to stabilize MHC class I complexes. MHC class I antigens are presented as nonapeptides, and class I can be presented by all nucleated cells.

MHC class II molecules express antigens only on "professional" antigen-presenting cells (APCs), such as MNP (macrophages) and related cells, dendritic cells throughout the body and Langerhans cells in the skin, and some B lymphocytes. MHC class II antigens are presented as 12- to 24-amino-acid peptides that are endocytosed from the environment and are expressed on the cell surface, having made their way through the endosomal/liposomal pathway.

**B.T Lymphocytes.** T cells interact directly with APCs. This cell-cell interaction drives specific immune responses by inducing clonal expansion of antigen-specific T cells. This expansion in turn results in secretion of signaling molecules, called cytokines. Cytokines direct the activities of additional immune response cells. Thus, the response to a specific antigen is vastly amplified. T cells bear receptors that bind to peptide antigen-MHC molecule complexes on antigen-presenting cells. Antigen-presenting cells bearing MHC class I antigens bind to T cells expressing the  $CD8^+$  T-cell receptor surface marker. MHC class II antigens bind to  $CD4^+$  T cells. This means that class I and II antigens stimulate separate populations of T cells. This separation directs the immune response toward different mechanisms adapted to deal with different antigenic

challenges. CD4<sup>+</sup> T cells function as cytokine secretors, and they help B cells produce Igs. CD8<sup>+</sup> T cells become efficient cytotoxic cells, capable of lysing cells infected with viruses. Both CD4<sup>+</sup> and CD8<sup>+</sup> T cells bear the CD3 cell surface marker. The CD3 molecule transduces an up-regulating intracellular signal on binding to MHC class I or II antigens with CD8 or CD4 receptors, respectively. Mice with null mutations of the CD4 gene lack T-cell helper function; mice with null mutations of the CD8 gene lack cytotoxic T-cell function.

T-cell activation is maximized by coaggregation of the T-cell receptor with CD4 or CD8 bound to an MHC molecule-antigen complex on the APC. Other costimulatory molecules participate in T-cell activation, such as the CD28 T-cell marker bound to the B7/BB1 family of molecules on APCs. Upon aggregation and binding of these molecules between T cells and APCs, a complex cascade of intracellular events ensues. These events lead to T-cell differentiation and T-cell replication with clonal expansion. The latter is mediated by the T-cell growth factor, IL-2, which is secreted upon T-cell activation. The immunosuppressant antibiotic cyclosporin A inhibits IL-2 secretion by T cells by blocking the intracellular calcium-dependent functions in the complex cascade during T-cell activation.

Microbial superantigens activate T cells. Particular microbial toxins (ie, staphylococcal enterotoxin, toxic shock syndrome toxin, and streptococcal pyrogenic exotoxin A) are presented as MHC class II antigens, but they bind nonspecifically to the T-cell receptor. Up to 10% of T cells may be activated. This leads to widespread cytokine secretion and the systemic toxicity of a generalized cell-mediated immune response. Particular MHC class II genotypes and the T-cell receptor  $\beta$ -chain genotypes are more prone to these reactions.

Memory T cells help mediate secondary cell-mediated immune responses. These T cells bear the CD29 surface marker. Memory T cells show enhanced secretion of particular cytokines, and they mediate rapidly developing cytotoxicity responses.

Lymphocyte adhesion molecules mediate trafficking and homing of T cells to particular body sites. Some T cells home to mucosal sites where they are strategically stationed to participate with APCs upon entry of foreign antigens into the tissues.

## **Cytokines**

Cytokines function as chemical messengers, sending signals from one immune cell to another. Cytokines are glycoprotein molecules secreted by lymphocytes. These molecules were originally called lymphokines. As their identities and cells of origin were defined, the term lymphokine was replaced by cytokine to include signal molecules elaborated during CMI whose cells of origin included other cell types (eg, macrophages, endothelial cells, and fibroblasts). As cytokines became characterized molecularly through cloning, sequencing, and expression techniques, they were assigned numbers and designated as interleukins ([Table 2-7](#)). However, some cytokines retained their original names, based primarily on their immunologic activities (eg, IFNs, TNFs, and CSFs). During CMI, cytokines act locally, infiltrating tissue sites of inflammatory cells. However, they may exert systemic effects when released into the circulation. This occurs during widespread infection and certain toxemias (eg, in response to

superantigens as noted above).

Cytokines act to amplify or attenuate the immune response coordinately. Their action is not antigen specific, but their secretion is often driven by antigen-specific reactions. Certain microbial products (eg, lipopolysaccharide of gram-negative bacilli) directly stimulate cytokine secretion (eg, TNF and IL-1). Cytokines regulate clonal expansion for both T and B lymphocytes. They mediate recruitment of immune cells to sites of inflammation. They activate effector cells (eg, macrophages) to microbicidal states. Some cytokines deactivate cells to prevent local tissue damage after the destruction of invading microbes. Cytokines interact with specific receptors on the cells they signal. The receptors act as transducers and relay signals into the cells, leading to additional secretions, replication, cell cycle arrest, and activation for microbicidal activities.

Cytokines secreted by MNP are called monokines. Monokines help initiate CMI as macrophages phagocytose microbes and present their antigens to T cells. Two important cytokines come almost exclusively from T cells (hence they are lymphokines)—IL-2 and IFN- $\gamma$ . IL-2 leads to many effects including replication of T cells activated by specific antigen. IFN- $\gamma$  is the main lymphokine for activation of effector cells (macrophages) to destroy or inhibit pathogens. T cells respond with lymphokine secretion only if the T-cell receptor is engaged with specific antigen presented in context with MHC class I or class II molecules. An exception is the stimulation by superantigens. This is in contrast to monokine secretion, which occurs in response to a wide variety of stimuli. NK cells are also a source of IFN- $\gamma$  during primary infection, before T-cell activation.

CD4<sup>+</sup> T cells change the profile of cytokines they secrete, and this directs the cell-mediated immune response toward activities suited best for defense against particular pathogenic agents. In the mouse during infection with intracellular pathogens, CD4<sup>+</sup> T cells secrete IL-2 and IFN- $\gamma$ . This leads to macrophage activation and arrest of microbial intracellular replication by unknown mechanisms (T<sub>H</sub>1 response). The monokine, IL-12, directs CD4<sup>+</sup> T cells into a T<sub>H</sub>1 phenotype. During systemic helminth infections CD4<sup>+</sup> T cells secrete IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13. This profile leads to expansion of B-cell clones for production of Igs, including IgE (so-called T<sub>H</sub>2 response). IgE participates in release of products from basophils, mast cells, and eosinophils that mediate cytotoxicity for multicellular animals that invade tissue usually via the intestinal tract. IL-10 directs CD4<sup>+</sup> T cells into a T<sub>H</sub>2 phenotype.

Transforming growth factor- $\beta$ , IL-4, and IL-10 down-regulate CMI to intracellular pathogens. Mice lacking a functional transforming growth factor- $\beta$  gene die after birth with massive infiltration of lymphocytes and macrophages in their vital organs.

Other roles for cytokines include (1) control of hematopoiesis, (2) T-cell maturation and proliferation, (3) B-cell differentiation, and (4) T-cell suppressor function. Cytokines also regulate innate immune responses such as fever (IL-1) and the acute-phase response (IL-6, IL-1, and TNF). Cytokines released systemically cause shock (TNF) during septicemia.

## Activation of Effector Cells

Effector cells of the cell-mediated immune response are microbiostatic and microbicidal for intracellular pathogens. These cells are cytotoxic T-cells, NK cells, and macrophages. Effector cells mediate and cytokines modulate antimicrobial activity during cell-mediated immune responses. Effector cells participating in CMI along with the functions they perform are listed in [Table 2-8](#).

**A. Cytotoxic T Cells.** Cytotoxic T lymphocytes (CTLs) kill somatic cells that are infected with microbial pathogens. These T cells express CD8 and mediate antigen-specific, class I MHC-restricted cytolytic activity. Recall that class I recognition occurs for antigens synthesized within the host cell. This occurs during the replication cycle of viruses. CTLs are ideally suited for destroying virus-infected cells. Release of immature, unassembled virus components upon host-cell lysis blocks efficient viral replication. CTLs may lyse cells infected with bacteria. This thwarts the strategy of some facultative intracellular pathogens, whose survival in the host may depend on evasion of the immune system by sequestration within an intracellular niche. Differentiation of CTLs to the cytotoxic state is regulated by cytokines. Of those involved, IL-2 is most important. The biochemical mechanisms of cytolysis involve a  $\text{Ca}^{2+}$ -dependent assembly of a protein present in CTL granules, called perforin. The protein is assembled into a cylinderlike structure that is inserted into the plasma membrane of the antigen-bearing target cell. Serine proteases within CTL granules, called granzymes, enter the target cell through perforin pores. The enzymes then become catalytically active and participate in target cell destruction.

**B. Natural Killer Cells.** NK cells participate in CMI by acting as effector cells and cytokine-secreting cells. NK cells are  $\text{CD158}^+$  lymphocytes that lack the T-cell receptor. They lyse certain neoplastic cells and virus-infected cells by a recognition mechanism that does not involve antigen-MHC restriction. These cells are active against virus-infected host cells, in particular the human herpes viruses. NK cells also function as an important source of IFN- $\gamma$  early during bacterial infections before CD4 cell activation. Their large granules contain granzymes and perforin monomers, such as CTLs.

**C. Mononuclear Phagocytes.** MNPs include circulating monocytes and tissue macrophages. They play two key roles in the cell-mediated immune response, as APCs and as cytotoxic effector cells. Their latter role is discussed here. Activated MNPs are recruited from a pool of precursor cells in the bone marrow. These phagocytes are released into the circulation and adhere to capillaries adjacent to infected tissue by a process involving intracellular adhesion molecules. Chemokines specific for MNPs participate to attract these cells. MNPs migrate between capillary endothelial cells and crawl toward microorganisms by chemotaxis. Chemotactic molecules from the host and infecting microbes act as stimuli, setting up a concentration gradient sensed by MNPs.

In the inflammatory milieu, MNPs are exposed to activating cytokines, primarily IFN- $\gamma$  and TNF. Macrophages phagocytize microorganisms via a variety of receptor interactions involving IgG, IgA, and complement components, as well as via lipopolysaccharide and carbohydrate ligands present on bacteria, protozoa, fungi, and virus outer envelopes. Lysosomal granules within MNPs fuse with phagocytic vacuoles

forming phagolysosomes. Granule components, including proteases, lysozyme, and microbicidal proteins, are released as the phagolysosome is acidified.

Activated MNPs inhibit and kill phagocytized microorganisms by a variety of mechanisms involving reactive-oxygen and reactive-nitrogen (from nitric oxide) intermediates, microbicidal proteins, liposomal proteases, and as-yet-unknown biochemical mechanisms. Activated MNPs play an important host defense role in combating a wide variety of bacteria, protozoans, fungi, and metazoans that have adapted virulence mechanisms for intracellular survival. Activated MNPs are critical for granuloma formation. They become epithelioid cells occupying the centers of granulomas. Granulomas are the histopathologic hallmark of the cell-mediated immune response against intracellular pathogens such as tubercle bacilli. T<sub>H</sub>1 response cytokines are required for granuloma formation. Activated MNPs may also mediate destruction of these same pathogens through a contact-dependent mechanism not requiring phagocytosis. Activated MNPs may also participate in cell-mediated immune responses through more efficient antigen presentation to T cells as well as through the production of cytokines that enhance T-cell-dependent killing mechanisms. [Table 2-9](#) lists some examples of activated MNP-dependent host defenses against microbial pathogens.

**Figure 2-1.** The life of a neutrophil (~ 4 days). (A) Neutrophils are produced in the bone marrow from progenitor cells called myeloblasts. Here a group (4) of myeloblasts, which are heavily laden with granules, are seen amidst some red cell precursors (stage 1). (B) Mature and less mature (band forms) neutrophils seen in the bloodstream. The white blood cell count is elevated in response to a bacterial infection (stage 2). (C) Having been attracted to this focus of infection through the action of chemokines (stage 3), neutrophils are adherent (marginated) to the endothelium of a small blood vessel adjacent to an inflamed appendix (stage 4). (D) Diapedesis of a neutrophil as the cell leaves the circulation by crawling between endothelial cells from upper left to lower right (stage 4). (E) Random neutrophil mobility. These are neutrophils (bright dot at end of tracks) crawling on soft agar. As they crawl they leave tracks in the agar that can be visualized by the phase contrast microscope (stage 5, undirected motility). (F) Chemotaxis of neutrophils in vitro. A concentration gradient of a chemotactic stimulus is established by injecting the stimulus from a port on the right. The neutrophils sense the gradient, assume a polarized shape, and begin crawling along the substrate (a plastic petri dish) toward the greater concentration (stage 5, directed motility). (G) This neutrophil is phagocytizing a rod-shaped bacterium (stage 6). The cell is polarized and is extending its lamellipodia around the bacillus from its ruffled leading aspect. Photo taken 40 s after attachment of bacterium to phagocyte. (H) Neutrophils showing fungicidal activity (stage 7). The phagocytic vacuole labeled "A" contains two *C albicans* cells. The top yeast of the pair is disintegrating and fails to take up the stain (stage 8). The neutrophils are undergoing a "respiratory burst" used to kill the yeast cells (stage 7).

#### **INTRODUCTION**

Among the vast diversity of microscopic life on this planet, only a small subset is believed to be capable of infecting the human body and causing disease. For example, only 7 of the 38-40 extant bacterial divisions on the earth contain members that are recognized pathogens in humans. The features that distinguish this subset of microbes (bacteria, fungi, parasites, and viruses) from all others have been revealed in increasing detail over the past few decades through the development of methods in microbial genetic manipulation, host cell imaging, structural biology, and, more recently, genomics. The findings indicate adaptation and coevolution of host and pathogen. Common themes are apparent among the strategies and mechanisms used by some microbes in their behavior as pathogens; these themes are the focus of this chapter. From an evolutionary perspective, pathogenicity appears to have "arisen" on multiple occasions, among diverse putative microbial ancestors. The commonality of themes and strategies that we witness today in extant pathogens probably reflects convergent evolutionary processes, operating in part over long periods of time, as host and pathogen adapt and counteradapt. Pathogenic capabilities are also acquired over much shorter time periods through mechanisms of horizontal genetic exchange. A comparison of a pathogen and closely related nonpathogen often identifies only small discrete differences between the two, sometimes in the form of a single contiguous chromosomal segment, a plasmid, or a gene.

The intimate dynamic between human host and microbe is easily disrupted by changes in either participant, especially when strong selective pressures are brought to bear on the microbe, whose capabilities for adaptation are enormous. This is the concept behind the "emergence" of newly recognized infectious diseases, an issue that has received a great deal of attention over the past decade. Emergence occurs either when a microbe gains new relevant genetic traits (discussed in the next section) or when the host or environment provides new opportunities and niches that enhance microbial access to or survival within a host. Some of these opportunities can be appreciated from an understanding of normal host defenses to infection (see [Chapter 2](#)), as in the loss of humoral or cellular immunity (eg, from cytotoxic chemotherapy or malnutrition), or normal anatomic barriers (eg, from trauma). Others arise from human behavior at the individual (eg, sexual) or societal (eg, from war or migration) level. A better understanding of this dynamic might lead to more enlightened therapeutic and preventive strategies against infectious disease.

#### **MICROORGANISMS AS PATHOGENS**

The last few decades of experimental investigation in microbial pathogenesis have taught us that virulence is a polygenic attribute of certain microorganisms that chose to persist or multiply within privileged anatomic niches of a host. A pathogen is a microbe that causes damage to a host as part of its (the pathogen's) strategy for multiplication within the host or for transmission to or from a host. Some microbes routinely cause disease (damage) within a given host and are called primary pathogens; other microbes

cause disease only when normal host defenses are impaired, and these are called opportunistic pathogens. The difference between these two types of pathogens is related to the particular skills of the first group in either finding a privileged anatomic niche within the host as a site for multiplication or competing with the normal endogenous microflora for a crowded niche (eg, mucosal surface or skin). Virulence is a measure of the frequency with which a microbe causes disease in a specific host, the severity of the resulting disease, the efficiency with which the organism is transmitted to or from a host, or a combination of these factors.

The mechanisms and strategies adopted by pathogens that result in disease are often encoded by genes that are clustered together in a pathogen's genome. The examination of genome structure in many bacterial pathogens reveals so-called pathogenicity islands, 10- to 200-kilobase segments of DNA with as many as tens to hundreds of genes that often have a significantly different guanine-plus-cytosine nucleotide composition from the rest of the genome. This difference in island nucleotide composition is believed to reflect its origin in a distantly related microorganism. Pathogenicity islands are usually flanked by direct repeats of DNA or transfer RNA genes, suggesting that they may have been transduced into the bacterium and into specific sites of the bacterial genome by a bacteriophage. Remnant plasmid mobilization genes suggest that in some cases the island may have existed as an extrachromosomal element at some time in the distant past (tens to hundreds of millions of years ago). Most islands contain genes that encode specialized secretion systems, adhesins, or toxins that are necessary for disease causation. It is not uncommon for bacterial pathogens to contain multiple islands; for example, *Salmonella* serovar Typhimurium has one island, SPI1, whose gene products are required for bacterial entry into host cells, and another island, SPI2, whose products mediate survival and replication inside a phagosomal vacuole within host cells.

Given this evidence for large-scale genetic exchange and the presence of clusters of specialized genes within pathogens, it should not be surprising to find frequent horizontal transmission of virulence-associated genes among contemporaneous microbes, on a shorter time scale. This form of horizontal transmission is mediated by bacteriophages, plasmids, and transposable elements such as transposons. The number of plasmid- and phage-associated virulence genes is substantial; a partial list is provided in [Table 3-1](#). The clinical significance of these transmission events should not be underestimated. Outbreaks of diphtheria may result from corynephage infection of nontoxigenic *Corynebacterium diphtheriae* strains within hosts and the conversion of these strains to toxin producers after phage delivery of the diphtheria toxin gene (see [Chapter 51](#)). The same type of event appears to be responsible for the dissemination of Shiga-like toxin genes among otherwise harmless *Escherichia coli* serotypes and the subsequent creation of enterohemorrhagic strains. Furthermore, recent data indicate that fluoroquinolone exposure may boost Shiga-like toxin production by these phage-infected strains through phage regulatory pathways and, therefore, may be detrimental to the host.

All microbial pathogens follow the same steps in causing disease. After entry into a susceptible host, they find a specialized niche for attachment and subsequent colonization. To multiply and successfully colonize, they must confront and counter host defenses. Toxins and other secreted products often play a role in this effort, as well as

in the effort to find an appropriate anatomic niche in this and other hosts. Transmissibility and transmission are a trait and process less well understood, except in those circumstances that involve a mechanical or biological vector. Pathogens, like other microbes, constantly sense their changing environment and regulate their behavior accordingly. The regulation of virulence-associated traits is complex and well integrated into systems used to regulate other microbial characteristics. Despite the universal nature of these steps, each pathogen displays a unique set of mechanisms, products, and responses that defines its pathogenic signature. Two members of the poxvirus family, smallpox virus and molluscum contagiosum virus, cause radically distinct clinical syndromes (skin lesions with and without a fulminant systemic inflammatory response, respectively). Although they share 103 genes, molluscum contagiosum virus and smallpox virus possess 59 and 83 genes, respectively, that the other does not contain; these virus-specific genes are predicted to encode proteins that subvert host innate immune defenses in a contrasting manner.

## REGULATION OF VIRULENCE

Precisely timed and measured responses characterize the expression of microbial virulence attributes. Timing and measurement are critical to a successful pathogenic strategy, owing to the highly changing environments faced by microbial pathogens and the energy costs associated with expression of virulence, as well as the complex set of host defenses designed to recognize and neutralize pathogens. For these reasons, pathogens recognize multiple environmental cues, use diverse regulatory mechanisms and systems, and integrate these cues and systems in a well-tuned network. A regulon is a group of physically unlinked genes that respond in a coordinated fashion to a given stimulus. Common features of microbial virulence-associated regulatory schemes are apparent.

Some of the most important environmental signals recognized by pathogens are extracellular iron concentration, temperature, osmolarity, oxygen and CO<sub>2</sub> partial pressures, specific signaling factors secreted by themselves, and contact with a host cell surface. Extracellular iron concentration, for example, tells pathogens when they have arrived within an animal host, since the latter expends great efforts to sequester and keep this critical element from microorganisms at mucosal surfaces. Pathogens and other microbes use a wide variety of sensing systems to read these signals and transduce the information into an appropriate response. Iron is recognized in some bacteria by intracellular iron-binding proteins that regulate the expression of iron acquisition proteins and receptors (eg, transferrin-binding proteins), as well as a number of bacterial toxins (eg, diphtheria and Shiga toxins) at the level of transcription. Other sensing systems that transcriptionally regulate virulence genes include the AraC class of transcriptional activators (eg, *V cholerae* ToxT), alternative RNA polymerase sigma factors, histonelike proteins, quorum-sensing systems whereby bacterial population density and growth phase are recognized in a species-specific manner, and the two-component sensor-response regulator family.

The two-component family is one of the most well-studied bacterial virulence-associated regulatory systems. Each of these systems comprises a sensor protein that spans the cytoplasmic membrane and a cytoplasmic response regulator protein with which it interacts, usually by means of high-energy phosphate transfer. Phosphorylation induces

activation of the response regulator, thereby allowing it to bind DNA promoter sequences and control gene expression. It is not surprising that the genomes of pathogens whose lifestyles require adaptation to multiple diverse environments contain a large number of such systems (eg, *E coli*, > 40), whereas those pathogens that face a restricted number of environments contain few (eg, *Helicobacter pylori*, only 5). With closer examination, variations on this theme become apparent. *Vibrio* spp., for example, express a protein in the cytoplasmic membrane, ToxR, that acts as both sensor (of osmolarity) and response regulator (of porin expression) ([Figure 3-1](#)). This protein is expressed by most marine vibrios. For *Vibrio cholerae*, the expansion of its preferred environments to include the human intestinal tract has brought with it the means to acquire cholera toxin genes (via a bacteriophage) and to acquire an intestinal attachment organelle that also serves as the toxin phage receptor (also via a phage), and this expansion placed both of these virulence attributes under the control of ToxR.

Regulation of virulence genes also takes place at the level of genome structure. Amplification of gene copy number enables up-regulation of gene product expression. Gene rearrangements are responsible for antigenic variation in such diverse pathogens as *Neisseria gonorrhoeae* (see [Chapter 52](#)), *Borrelia recurrentis* (see [Chapter 65](#)), and *Trypanosoma brucei* (see [Chapter 85](#)). Changes in DNA or RNA conformation can also effect modulation of gene expression.

## ADHERENCE & COLONIZATION

Attachment to host substrates is an early and critical step for most pathogens. Those organisms that remain outside a host cell often rely on redundant and complementary attachment systems to ensure continued colonization of the host. In some cases, the expression of an attachment factor (ie, adhesin) alone confers on a microbe the ability to cause disease. In many other cases, adhesins and their cognate host receptors determine host species specificity for the pathogen, as well as tissue or organ tropism, and cell specificity. For many of the reasons described above, adhesin expression is regulated. The dominant adhesin for *Bordetella pertussis* is the 220-kDa protein filamentous hemagglutinin. Because filamentous hemagglutinin is the most abundant secreted protein for this organism, consuming a considerable proportion of the cell's resources for expression, it is important for *B pertussis* to make this protein only when it is needed. Thus, it is placed under the control of a two-component system.

Microbial adherence is critical for microbe-microbe interactions and the formation of biofilms. Bacteria such as *Staphylococcus* spp. secrete a polysaccharide slime substance that enables them to colonize foreign material and exclude antimicrobial agents. Surfaces of foreign and natural acellular material in the human body provide a substrate for microbial community development. On the tooth surface, for example, a diverse but well-ordered community of bacteria form a biofilm that begins on a layer of host proline-rich proteins and relies on many different binding interactions between bacterial receptors and ligands. The streptococci and *Actinomyces* spp. are among the "early colonizers," whose presence is necessary before "late colonizers" such as *Porphyromonas gingivalis* and treponemes can attach.

Complex multimeric structures are critical for the attachment of many microbial pathogens. The hairlike bacterial appendage known as a pilus (or fimbria) is a

well-characterized example. Pili are composed of structural subunits arranged in a helical fashion, extending out from the bacterial surface. They are flexible and are often capped by adhesin proteins that provide diverse binding specificities. Pili mediate lectinlike interactions with host cells and are also recognized by protein receptors. Regulated expression and assembly of pili are highly orchestrated and involve clusters of cotranscribed genes organized as an operon. Because pilin proteins are often antigenic, their expression and structure are variable. A class of protozoa shares a different sort of attachment organelle, known as the apical complex. This polar structure found on *Toxoplasma* spp., *Cryptosporidium* spp., and other "apicomplexans" controls host cell attachment through an active mechanism and secretes factors necessary for entry of the protozoan into host cells in some cases.

Pathogens often co-opt host attachment proteins and host receptors for their own adherence-related purposes. A wide variety of pathogens coat themselves with host extracellular matrix proteins such as fibronectin in order to bind to extracellular matrix receptors such as integrins. In this way, extracellular matrix proteins act as a molecular bridge between microbe and host cell. Rhinoviruses bind to intercellular adhesion molecule-1, a critical host cell attachment receptor, and HIV binds to CD4 and chemokine receptors on lymphocytes and macrophages, which are critical for antigen recognition and chemotactic responses, respectively.

The particular selection of ligand-receptor combinations by any given microbe dictates the subsequent course of events. These events include induction of up-regulated binding affinity, microbial internalization, and host cell intoxication. In a dramatic example, enteropathogenic *E coli* (and other bacterial pathogens) inject their own receptor into a host cell, using a specialized ("type" III) secretion system, where the receptor subsequently becomes activated by phosphorylation, localized to the host cell membrane and then promotes formation of an unusual host cell cytoskeletal rearrangement, culminating in formation of a "pedestal" on which the bacterium forms an intimate attachment.

## **TOXINS**

Host cell intoxication is one of the oldest-known mechanisms associated with microbial virulence. Toxins block host cellular defenses, elicit or create microbial nutrients, break down anatomic barriers, and facilitate microbial transmission. In some extreme cases, virulence can be entirely ascribed to the action of a secreted toxin; examples include diphtheria and tetanus. In these cases, antitoxin immunity is sufficient for protection against disease. But most infectious diseases and pathogenic strategies are not that simple. Microbial toxins exist in many forms and with many different activities. Some are intrinsic to the microbial cell wall, such as the lipopolysaccharide (or endotoxin) of gram-negative bacteria, while other toxins are secreted (exotoxins), either nonspecifically from the cell or through specialized secretion systems, such as the type III and type IV systems, directly into a host cell. Exotoxins of the first type usually facilitate their own entry into a host cell by means of a binding subunit that may take advantage of host cell internalization pathways. In a manner and for reasons similar to those described for adhesins, toxin expression is often tightly regulated.

Microbial toxins can be classified on the basis of shared mechanisms of action. The

nature of the host cell receptor or molecular target, the mechanism of activation, or the intracellular trafficking of a microbial toxin may determine its specificity of effect. One of the most well-known families of microbial exotoxins is the group of bacterial ADP-ribosylating toxins, which includes diphtheria toxin, cholera toxin, pertussis toxin, *E. coli* heat-labile enterotoxin, and *Pseudomonas* exotoxin A. Each catalyzes the transfer and covalent binding of ADP-ribose from NAD to a target protein. The different targets explain the diverse biological outcomes of these toxins. Sometimes, the explanation for difference in effect lies elsewhere. Tetanus and botulinum toxins are zinc metalloproteases that enter motor neurons at the neuromuscular junction. They cleave the same group of proteins within neurotransmitter-containing vesicles. But the clearly distinct neurological results of this action, flaccid and spastic paralysis, can be explained by differential intracellular trafficking of these two toxins: botulinum toxin remains in the terminal neuron at the neuromuscular junction where excitatory neurotransmitters are normally released, while tetanus toxin is transported in a retrograde fashion across the interneuron synapse where inhibitory neurotransmitters are normally released. Other families of microbial toxins include pore-forming hemolysins, secreted adenylate cyclase toxins, RNA glycosidases, and superantigens.

## **ENTRY INTO & LIFE WITHIN HOST CELLS**

For viruses and more specialized bacterial and eukaryotic pathogens, entry into a host cell is an essential feature of their survival or replication strategy within the host. Intracellular entry can be either a passive or active process on the part of either participant. Although most microbes that routinely enter host cells find the intracellular compartment a favored site for replication, this is not always the case; some may be simply passing through on their way to deeper portions of a tissue or the bloodstream (eg, *Neisseria meningitidis* and the Whipple's disease bacillus *Tropheryma whippelii*) or may remain inside a cell in a nonreplicating state. Only those agents that replicate inside a host cell or exist primarily within host cells rather than outside them are properly defined as intracellular pathogens. The inside of a host cell offers a number of significant features for a microbe. First, there may be essential nutrients, macromolecular synthetic machinery, and sources of energy. Organisms that can replicate only when inside a host cell (eg, viruses or *Coxiella burnetii*) are obligate intracellular pathogens, while those that can replicate both inside and outside (eg, *Salmonella* serovar Typhimurium) are facultative intracellular pathogens. Second, the intracellular compartment offers protection from a variety of extracellular microbicidal factors. Third, it may provide a ready means for dissemination. Pathogens (eg, *Salmonella* spp. or HIV) that persist or grow within leukocytes may be carried to distant sites within the host by these cells. For *Legionella* spp., the internal compartment of a free-living amoeba provides a protected niche in external freshwater environments. Encystment of the amoebae allows persistence of the symbionts under environmental conditions that are unfavorable for growth.

Intracellular pathogens take advantage of many naturally occurring internalization pathways in professional phagocytic cells, as well as creating their own opportunities and pathways in nonprofessional phagocytes. Leukocyte integrin receptors mediate host cell-cell contact, communication, and development; they also mediate internalization or attachment of complement-coated microbes, as well as those that express their own integrin ligand (eg, *B. pertussis* filamentous hemagglutinin). Entry

through this route does not necessarily trigger an oxidative burst; ie, microorganisms can survive this process. Fc receptors on phagocytes offer another route for entry, but they target the subsequent phagocytic compartment for fusion with lysosomes. Most intracellular pathogens seek to avoid this event. For example, the highly successful intracellular pathogen *Toxoplasma gondii*, if forced to bind to Fc receptors, will die within a host cell.

Entry into nonprofessional phagocytes is usually either induced by the pathogen or forced by the pathogen through an active process. These entry processes require actin polymerization in most cases. Induced entry involves manipulation of the host cell actin cytoskeleton, through a zipperlike mechanism. Host cell receptors that are coupled to the host cell cytoskeleton, such as dystroglycan, E-cadherin, and integrins, provide internalization pathways of this sort for microbes (*Mycobacterium leprae* and arenaviruses, *Listeria monocytogenes*, and *Yersinia* spp., respectively), even though the usual role for these receptors may involve cell adhesion. On the other hand, induced entry is sometimes a more dramatic event, when microbes elicit membrane ruffling to become internalized. *Shigella* and *Salmonella* spp. both secrete proteins into nonprofessional host cells that cause this type of event (a trigger mechanism) through interactions between these effector proteins (eg, *Salmonella* SopE) and host low-molecular-weight GTP-binding proteins of the Rho family. Active, forced entry is described for the apicomplexan parasites, which rely on their own actin-based contractile skeleton and attachment proteins localized near the apical complex to pull the host membrane around them.

Intracellular pathogens choose different sorts of anatomic compartments for themselves, once inside (Table 3-2). To a large degree they create or modify these compartments by selecting entry receptors and then by secreting a variety of factors. All pathogens are encompassed by a vacuolar membrane immediately upon entry. Some remain within this vacuole and allow it to mature through the endocytic pathway and fuse with lysosomes. *Coxiella burnetii* requires the acidic environment of a phagolysosome for completion of its lifecycle. Others block phagosomal development and modify intravacuolar conditions to suit their needs. *Legionella pneumophila*, for example, recruits mitochondria and other organelles so that they surround the vacuole. Finally, some pathogens destroy the vacuolar membrane quickly and escape into the host cell cytoplasm. *L. monocytogenes* illustrates this last strategy. Listeriolysin-O lyses the vacuole membrane and is required for bacterial virulence. Once in the cytoplasm, *L. monocytogenes* induces actin polymerization at one bacterial pole and is thereby pushed through the cytoplasm at the end of a comet tail-like structure (see Chapter 51). The bacterium moves from the inside of one cell to the inside of an adjacent cell through protrusions of host cell membrane and subsequent engulfment by the next cell. *Shigella* and *Rickettsia* spp. and vaccinia virus also induce the same kind of actin-based movement within host cell cytoplasm.

## MANIPULATION OR AVOIDANCE OF THE HOST IMMUNE RESPONSE

Coevolution and adaptation of host with pathogen are well illustrated by the extensive efforts of pathogens to evade, subvert, or co-opt the wide array of host immune defenses. These efforts include the establishment of latency, antigenic variation (described above), inhibition of antigen processing or presentation, inhibition of

phagocytosis or oxidative burst, inhibition or stimulation of cytokine responses, anticomplement strategies, induction or inhibition of apoptosis, and inhibition of lymphocyte homing ([Table 3-3](#)). Viruses provide many examples, although they are by no means the exclusive operators of these mechanisms. Apoptosis (programmed cell death) is a common host cell antiviral defense mechanism. Some viruses, such as papillomaviruses and adenoviruses, prevent host cell apoptosis by expressing proteins that bind to the host cell cycle control proteins p53 and Rb. It makes sense that papillomavirus would want to promote the growth of its host cell, the squamous cell of the skin, since this cell is terminally differentiated and poorly able to replicate. Epstein-Barr virus and other herpesviruses express homologs of Bcl-2, a human antiapoptotic protein, whereas molluscum contagiosum virus and herpesviruses produce proteins with death effector domains that interfere with Fas- and tumor necrosis factor receptor-1-associated apoptotic signaling pathways. In contrast, a number of bacterial pathogens induce apoptosis as a means of eliminating host defense cells (eg, activated macrophages).

Disruption or co-optation of cytokine-mediated host responses is also a common pathogen counter-defensive strategy. Kaposi's sarcoma herpesvirus (human herpesvirus 8) encodes homologs of the human chemoattractant cytokines macrophage inflammatory protein-1 $\alpha$  and RANTES that are biologically active. They are angiogenic and also compete with other ligands for their cognate chemokine receptors. Kaposi's sarcoma herpesvirus produces a version of interleukin-6 that signals through the same proinflammatory pathways as does the human homolog. Finally, Kaposi's sarcoma herpesvirus expresses a G-protein-coupled receptor that is homologous to the human interleukin-8 receptor. It stimulates constitutive host cell proliferation. Poxviruses encode a soluble form of the human interleukin-1 receptor. Deliberate disruption of the viral gene in animal models of poxvirus infection causes more fulminant disease. It is believed that this soluble receptor down-regulates the effects of host interleukin-1, which is elicited by the virus and which would otherwise kill the host before the virus has had adequate time for replication.

## **TRANSMISSION & LIFE OUTSIDE THE MAMMALIAN HOST**

Transmission of pathogens is essential to their ultimate survival. Some rely on arthropod (biological) or mechanical vectors; this is especially true of pathogens that reside in nonhuman animal reservoirs (zoonotic agents; see [Chapter 90](#)). Adaptation to and recognition of vector niches are increasingly well understood for these microbes. The agent of Lyme disease, *Borrelia burgdorferi*, for example, expresses certain outer surface proteins only when it is in the tick and expresses others only when it is in a human. Other pathogens rely on human disease symptoms such as cough and diarrhea for transmission. Any pathogen that spends significant time in an external inanimate environment must find a strategy for surviving harsh conditions. Sporulation or encystation is one strategy. Another is incorporation within the integument or internal structures of another life form; for example, *V. cholerae* attaches to algae and copepods during the periods that it spends in brackish estuarine aquatic environments. The bridging of the environmental sciences with medical microbiology will be an important step in further elucidating this poorly understood phase in the life of microbial pathogens.

## 4 . General Principles of Antimicrobial Therapy — *Walter R. Wilson, MD*

### INTRODUCTION

Anti-infective agents such as inorganic salts, myrrh, and acidic solutions have been used topically for centuries. For several hundred years, European and Arabic physicians noted that the administration of heavy metals such as arsenic, mercury, or bismuth was effective against syphilis and other infections. The modern era of antimicrobial chemotherapy began in the 1930s with the introduction of sulfonamides and gathered momentum in the 1940s with the discovery of penicillin and streptomycin. Currently, antimicrobial agents are among the most widely used classes of drugs. Worldwide expenditures for antimicrobial agents exceed \$20 billion annually, and antimicrobial agents represent 20-40% of drugs administered to hospitalized patients. Although the choice of a single agent or a combination of agents should be individualized for each patient, certain general principles of therapy should guide the selection of specific drugs. The following factors are important in determining appropriate antimicrobial therapy for patients with bacterial or fungal infections. The drugs of choice for the treatment of infections are discussed in the chapters on specific infections. Antimicrobial therapies for mycobacterial, fungal, parasitic, and viral infections are discussed in their respective chapters.

### ETIOLOGIC AGENT & SUSCEPTIBILITY TESTING

The identification and antimicrobial susceptibility of an etiological agent(s) are the most important factors in determining the choice of antimicrobial therapy. When a microorganism is identified and its susceptibilities are known, specific antimicrobial therapy may be administered. In general, the agent selected should be bactericidal, have a narrow spectrum, be well tolerated, and be cost effective. However, in many instances, empiric therapy must be instituted before such information is known. For empiric therapy, the choice of a single drug or a combination of drugs should be based on the suspected site of infection and knowledge of which microorganisms are likely to cause infection in a specific site. For example, the bacteria that most likely cause community-acquired pneumonia are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Branhamella catarrhalis*, *Mycoplasma pneumoniae*, or *Chlamydia* spp.; acute pyelonephritis is usually caused by *Escherichia coli* or other *Enterobacteriaceae*, a soft-tissue infection is usually caused by *Streptococcus pyogenes* or *Staphylococcus aureus*; and otitis media is usually caused by *S pneumoniae*, *H influenzae*, or *B catarrhalis*.

Most infections may be treated with a single antimicrobial agent. However, in either specific or empiric therapy, it may be necessary to administer a combination of drugs. Synergistic combinations of drugs may be necessary to treat certain infections such as some central nervous system infections or prosthetic valve endocarditis or to treat serious infections caused by enterococci. In other infections, synergistic combinations may be advantageous for the therapy of infections caused by a resistant microorganism or for infections involving a site where antimicrobial penetration is reduced, such as

endocarditis, osteomyelitis, or meningitis ([Table 4-1](#)). Combination therapy may be necessary for the treatment of polymicrobial infections such as intra-abdominal or pelvic infections. In febrile neutropenic patients or other immunocompromised hosts, combination therapy for empiric or specific treatment may be preferable to single-drug therapy.

Appropriate cultures should be obtained before starting antimicrobial therapy. An exception to this rule is a patient with acute bacterial meningitis. In these patients, blood cultures should be obtained and antimicrobial agents administered, and spinal fluid cultures may be obtained as soon as possible after onset of therapy (see [Chapter 7](#)).

A Gram stain of an appropriate specimen is the most useful and cost-effective method for rapid diagnosis. Immunologic methods for antigen detection, polymerase chain reaction, and DNA probes are described in [Chapter 6](#). Antimicrobial susceptibility tests should be performed using disk diffusion, agar dilution, E-testing, or other standard methodology on most bacterial pathogens, and antimicrobial therapy adjusted as necessary according to the results.

## **DOSAGE & ROUTE OF ADMINISTRATION**

Once the decision is made to initiate antimicrobial therapy, the next choice is between oral and parenteral administration, with the later either intravenous or intramuscular. The oral administration is appropriate for mild to moderately severe infections in patients with a normally functioning gastrointestinal tract. Some antimicrobial agents, such as vancomycin, quinupristin-dalfopristin, and aminoglycosides, are not absorbed after oral administration. They must be administered parenterally. Others, like fluoroquinolones and trimethoprim-sulfamethoxazole, have excellent bioavailability after oral administration and may be administered orally even in patients with serious infections.

The mechanism of bacterial killing by antimicrobial agents affects decisions regarding the amount of drug administered, the frequency, and the route of administration ([Table 4-2](#)). There are two major mechanisms of bactericidal activity by antimicrobial agents ([Table 4-3](#)). The first is characterized by saturation of the rate of killing by concentrations of antibiotic at or near the minimum inhibitory concentration (MIC) of the microorganism. Accordingly, increasing the concentration of drug in serum does not result in an increased rate or magnitude of bacterial killing. With these drugs, the duration of time of drug concentration in serum or tissue that exceeds the MIC is the major determinant of bacterial killing. This time-dependent killing is observed with beta-lactams, vancomycin, macrolides, and clindamycin. This phenomenon should be considered when selecting optimal dosing of these antimicrobial agents. Failure to do so may result in administration of unnecessarily high or frequent dosages. With this mechanism of killing, the dosage of an antimicrobial agent should be adjusted so that the concentration in serum exceeds the MIC for 40-50% of the dosing interval. However, in bacterial meningitis, infective endocarditis, or other infections in sites with diminished antibiotic penetration, the administration of higher dosages of antimicrobial agents, often at more frequent intervals, may be necessary to ensure an adequate concentration of drug at the site of infection.

The second major mechanism of bactericidal activity is characterized by

concentration-dependent killing. The higher the concentration of drug in serum or tissue, the greater the rate and magnitude of killing. This mechanism of killing occurs with aminoglycosides and fluoroquinolones. Additionally, these two drugs and others that inhibit bacterial protein synthesis, such as macrolides, rifampin, and tetracyclines, induce a prolonged post-antibiotic effect on gram-negative bacilli. In contrast, beta-lactams produce minimal or no postantibiotic effect. The phenomenon of concentration-dependent killing supports the concept of single daily dosing for this class of drugs, such as with aminoglycosides and some fluoroquinolones.

Other factors that influence the dosing of antimicrobial agents include the patient's age, renal and hepatic function, and immune status (see next section). Some antimicrobial agents require dosing adjustments in patients with abnormal renal function, and others do not ([Table 4-4](#)).

## **UNDERLYING HOST FACTORS**

### **Introduction**

The underlying conditions of the host, such as history of drug allergy or intolerance, age, renal and hepatic function, and immunosuppression, are major factors which influence the selection of therapy, dosing, efficacy, and safety of antimicrobial agents.

### **Drug Allergy, Adverse Events, & Drug Interactions**

The first factor to be considered in the choice of therapy is a history of adverse drug reactions or allergy ([Table 4-5](#)). Failure to do so may result in serious or fatal consequences. Additionally, one should review carefully other medications administered concomitantly. Numerous drug interactions with antimicrobial agents have been reported. These may result in decreased absorption of orally administered antimicrobial agents or may result in or potentiate serious drug toxicity resulting from the concomitant drug, the antimicrobial agent, or both. The potential drug interactions are so numerous and newly described interactions are reported so frequently that it is difficult, if not impossible, for the practicing physician to be aware of all of these interactions. Computer software programs are available to identify potential drug interactions. It is important for the patient and the care team, which includes the physician, nursing staff, and pharmacist, to provide accurate and complete information regarding a history of drug allergy, intolerance, or concomitant medications before antimicrobial agents are prescribed.

### **Age**

Patient age, especially at the extremes of lifespan, is a major factor that influences appropriate antimicrobial therapy. Elderly patients may have a normal serum creatinine, but creatinine clearance decreases with age. Antimicrobial agents that are renally excreted may require reduction in dosages in elderly patients, including those with a normal serum creatinine. Failure to recognize this factor may result in accumulation of toxic concentrations of antimicrobial agents in serum that may produce serious consequences, including central nervous system manifestations such as seizures or coma, nephrotoxicity, hepatotoxicity, or ototoxicity. Similarly, renal function is diminished

in neonates. Dosages of antimicrobial agents that are excreted by the kidneys should be altered.

Hepatic function is underdeveloped in neonates. Chloramphenicol is metabolized in the liver. High serum concentrations of unconjugated chloramphenicol may occur in neonates, resulting in severe toxicity, such as shock and cardiovascular collapse (gray-baby syndrome). Chloramphenicol should not be administered to neonates. Sulfonamides compete with bilirubin for binding sites on serum albumin and, when administered to neonates, increase the concentrations of unbound bilirubin in serum, which may result in kernicterus. Consequently, sulfa drugs should not be administered to neonates.

Tetracyclines readily pass the placental barrier and bind to bone and teeth of neonates and children; therefore, the use of tetracyclines should be avoided in this age group. Fluoroquinolones cause arthropathy and cartilage damage in puppies and have not yet been approved for use in children. Fluoroquinolone use should be avoided, if possible, in children who are <15 years of age.

### **Other Underlying Conditions**

Patients with peripheral vascular disease or shock may not adequately absorb drugs administered intramuscularly. Sulfonamides, nitrofurantoin, or chloramphenicol may cause hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency. Sulfonamides may cause hemolysis in patients with hemoglobinopathies, such as hemoglobin Zurich or hemoglobin H.

Antimicrobial agents must be chosen carefully for administration to pregnant or nursing mothers. Virtually all antimicrobial agents cross the placental barrier to some degree. Macrolides and beta-lactam drugs with the possible exception of ticarcillin, which may cause teratogenic effects in rodents, may be administered safely to pregnant females. Tetracycline use should be avoided in pregnant women as mentioned above. In addition, the administration of tetracycline intravenously has been associated with acute fatty necrosis of the liver in pregnant women. Streptomycin may cause vestibular or ototoxic damage to the fetus.

Most antimicrobial agents administered to women may be detected in the breast milk of nursing mothers, although their concentrations in breast milk are usually low. Sulfonamide and fluoroquinolone use should be avoided, if possible, in nursing mothers. Tetracyclines may be administered to nursing mothers. Tetracyclines are excreted in breast milk, but tetracycline forms an insoluble chelate with calcium in breast milk, which is not absorbed by the nursing child.

The underlying renal and hepatic function must be considered in the choice of antimicrobial agent. The effect of impaired renal function in elderly patients is described above. Tetracyclines (except doxycycline and possibly minocycline) should not be administered to patients with impaired renal function, because the elevated concentrations in serum that result may produce worsening of uremia because of their anti-anabolic effect. Additionally, the elevated serum concentration of tetracycline may result in hepatotoxicity. Antimicrobial agents which are metabolized or excreted primarily

by the liver include rifampin, macrolides, clindamycin, metronidazole, some beta-lactams (eg, ceftriaxone and cefoperazone), nitrofurantoin, and some fluoroquinolones (eg, trovafloxacin). The dosages of these drugs do not require adjustment in patients with renal dysfunction but should be reduced in patients with hepatic failure, and some (eg, trovafloxacin and tetracycline) should be avoided or used with extreme caution.

The immunocompromised condition of the patient is a major factor that influences the selection of antimicrobial agents. Combinations of agents may be preferable, at least as initial therapy (see [Chapters 23, 24, and 25](#) on AIDS, febrile neutropenic patients, and organ transplant recipients, respectively).

## MONITORING THE RESPONSE TO ANTIMICROBIAL THERAPY

The most important factor in determining the response of patients to antimicrobial therapy is the clinical assessment. Measurement of concentrations in serum may help guide subsequent dosage adjustment in patients who are receiving vancomycin or an aminoglycoside or other agents in the presence of impairment of renal or hepatic functions. The major value in measuring concentrations in serum is to avoid toxicity from excessively high concentrations. After the onset of antimicrobial therapy, repeating cultures such as from blood, urine, or spinal fluid may be useful in selected patients. The determination of serum bactericidal titers is of minimal if any value in assessing the efficacy of therapy, and this test should not be performed routinely.

## **5 . Infection Prevention in Healthcare Settings — Cathryn Louise Murphy, RN, PhD, CIC, Susan A Resnik, RN, Dip IC, CIC (Syd), & Julie Louise Gerberding, MD, MPH**

### **INTRODUCTION**

In 1958, the American Hospital Association first recommended that United States hospitals have formal programs to monitor and prevent infections. Early hospital infection control programs dealt primarily with the management and control of staphylococcal outbreaks in nurseries and among surgical patients, and these efforts emphasized teaching the principles of asepsis to clinical staff, monitoring cases of infection, and providing advice on the reprocessing of used equipment and instruments. Since that time, hospital epidemiology has grown in breadth and scope and is recognized as an important component of healthcare quality promotion. In recent years, changes in the healthcare delivery system and increased utilization of non-hospital-based healthcare services have created conditions conducive to the acquisition and spread of infections in long-term care facilities, outpatient clinics, dialysis centers, and the home care environment. Hence, the domain of infection control programs has expanded beyond the hospital to include these settings. The primary goals of a modern infection control program now include the following:

- preventing acquisition and spread of pathogens in healthcare settings, especially among high-risk populations;
- preventing emergence and spread of antimicrobial-agent-resistant pathogens;
- monitoring, analyzing, reporting, and responding to endemic healthcare-associated infections;
- recognizing and controlling outbreaks of infections and related adverse events;
- evaluating and modifying specific clinical procedures and equipment to promote patient safety;
- protecting healthcare workers through immunization programs, recommendations for use of protective apparel, and patient placement and isolation systems;
- preventing transmission of blood-borne pathogens among patients and their healthcare providers.

Principal stakeholders who have been responsible for developing clinical guidelines and supporting the development of programs to achieve these goals include the Centers for Disease Control and Prevention (CDC), the Association for Professionals in Infection Control and Epidemiology, and the Society for Healthcare Epidemiology of America.

This chapter provides healthcare providers with basic information that will enable them

to prevent additional transmission of infectious agents in the healthcare setting and to respond appropriately in the event of inadvertent exposure to infectious agents prevalent in the health care environment.

## **ROLE OF THE INFECTION CONTROL PRACTITIONER**

In the United States, early studies demonstrated that an effective infection control program with at least one trained infection control practitioner per 250 occupied hospital beds led to lower infection rates than programs with a lower ratio of expert infection control staff to patients. Most infection control practitioners are nurses, although in some settings physicians, epidemiologists, microbiologists, medical technologists, or specific administrators may coordinate the infection control program. Ideally, the infection control practitioner has experience and knowledge in adult education techniques, epidemiology, patient isolation strategies, and basic patient care. In addition, knowledge of antimicrobial agents, infectious diseases, microbiology, and basic principles of asepsis, sterilization, and disinfection is essential. The infection control practitioner often consults with other staff members on these issues and regularly assesses patient outcomes to evaluate the effectiveness of infection control recommendations. Additionally, the practitioner intervenes when data or direct observation suggests that variation from recommended practice is jeopardizing patient safety, recovery, or well being.

The specific functions performed by the infection control practitioner vary according to the type and size of the facility as well as the acuity of the patient population. However, regardless of these factors, the practitioner usually is responsible for implementing and evaluating effective prevention and control activities. Additionally, the infection control practitioner ensures that staffers are aware of relevant regulatory and legislative mandates and are equipped to comply with them.

The principal goals for infection control and prevention programs in extended-care and nonhospital settings are identical to those for acute-care settings. These goals are to protect patients, healthcare workers, and visitors and to do so in a manner that is timely, evidence based, and cost effective. Surveillance, development of local policies, intervention to prevent infections, and provision of education and training to the staff provide mechanisms for these goals to be met.

## **ROLE OF THE HEALTHCARE EPIDEMIOLOGIST**

Ideally, the infection control practitioner works in collaboration with a healthcare epidemiologist. Typically, the epidemiologist is a physician trained in infectious diseases, internal medicine, or pediatrics who has special skills or experience in utilizing the basic tools of epidemiologic investigation. This individual usually is employed by the facility or serves as a paid consultant to the facility's infection control service.

The epidemiologist complements the infection control practitioner by providing additional clinical insight into specific problems. In addition, the epidemiologist is often better able to persuade administration and fellow clinicians to support and comply with the recommendations and directives of the infection control program. In some facilities, including nonhospital settings, the size of facility, available resources, or both may dictate the level of involvement of consultants—outside experts in infectious diseases,

infection control, and epidemiology—in coordination of the infection control program.

## **THE INFECTION CONTROL COMMITTEE**

In hospitals, the infection control practitioner and the epidemiologist usually interact with a hospital-based infection control committee (ICC). The ICC includes members with specific areas of expertise and interest, including hospital administration, infectious diseases, surgery, microbiology, pharmacy, occupational health, reprocessing, and other related fields. A primary function of the ICC is to develop and implement infection control policies and procedures. The multidisciplinary nature of the ICC ensures that the specific interests and needs of individual clinical and administrative units within the hospital are represented and addressed in infection control decisions and recommendations. Increasingly, nonhospital facilities also rely on multidisciplinary committees to oversee the infection control program.

## **INFECTION CONTROL POLICIES & PROCEDURES**

### **INTRODUCTION**

ICCs routinely develop local policy positions that address specific clinical issues. These policy positions are often available in a locally focused infection control manual, a useful document that usually includes relevant state or federal standards and regulations. The following sections summarize basic infection control recommendations for common clinical issues. Clinicians should seek additional detail from the infection control manual within their respective facilities. Assisting other staff to comply with appropriate accreditation and regulatory requirements is a key role of the infection control program staff.

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) stipulates that the goal of hospital infection control is to identify and reduce the risk of infection acquisition and transmission among patients and healthcare providers. Hospitals participating in the JCAHO accreditation process must demonstrate their efforts to achieve this goal. These efforts involve compliance with six specific infection control standards. The standards address staffing and management systems, monitoring and reporting of infections, intervention in outbreaks, and other preventive actions. The JCAHO also accredits infection control components of ambulatory and long-term-care facilities as well as pathology and clinical laboratory services.

The Health Care Financing Administration (HCFA) is a federal agency that, in addition to providing healthcare insurance, surveys and certifies nonhospital healthcare facilities. Facilities surveyed by HCFA are expected to comply with predetermined infection control standards. Similarly, the National Committee for Quality Assurance administers an accreditation program and combines the results with data from a set of standardized performance measures to provide information to healthcare purchasers and consumers on comparative performance of managed-healthcare plans. Finally, several state and federal agencies promulgate regulatory directives that have direct implications for infection control programs. Generally, the infection control team ensures that staffers understand and comply with such requirements.

## **INFECTION MONITORING & PREVENTION**

One of the most important activities of the infection control team is to monitor healthcare-associated infections and related events within the facility. Routine monitoring potentially provides valuable data that can be used to establish the endemic infection or event rate, identify the need for targeted prevention interventions, and assess the effectiveness of specific interventions. The quality and usefulness of data are improved if the system uses methods that are standardized and based on sound epidemiological principles. If a facility intends to compare its data with those collected by others, it is critical that the data be collected in a standard manner and that adjustment be made for relevant intrinsic (eg, severity of illness) and extrinsic (eg, use of central venous catheters) risk factors in the patient population.

The CDC's National Nosocomial Infections Surveillance (NNIS) system is a comprehensive system for standardized monitoring of healthcare-associated infections. By 2000, more than 300 hospitals were contributing data to the NNIS system about surgical-site infections, central venous catheter infections, ventilator-associated pneumonia, and other serious infections among intensive care patients. These data are used to develop risk-adjusted benchmarks that are widely disseminated and that serve as a reference for comparing and monitoring infection rates in comparable hospitals.

The NNIS system recently identified significant reductions of reported infection rates over the past decade. The reasons for these improvements are not entirely known, but activities characterizing hospitals that have reported improvements are presented in [Figure 5-1](#). This model, which is based on the continuous-quality-improvement paradigm, involves initial measurement of infection rates, using standardized case definitions. The second stage involves comparison of data with an aggregate data set such as the benchmarks periodically published by CDC. In the next stage, the comparative data are interpreted locally to identify needed targeted interventions. Multidisciplinary teams of local experts and stakeholders are assembled to help develop and implement these interventions. Finally, follow-up progress is measured and disseminated to local stakeholders to motivate and document ongoing improvements. By default, completion of this final stage actually initiates the first stage of the next continuous-quality-improvement cycle.

Similar strategies have been successful in improving use of antimicrobial agents and limiting resistance to them in some intensive care units. A national system for standardized monitoring of occupational exposures and infections among healthcare personnel (CDC's National Surveillance System for Healthcare Workers) is in the early stages of development. As interest in patient safety and reporting of adverse events increases, it is likely that similar systems for monitoring and motivating improvements will be adopted in other healthcare settings to address infectious diseases and other patient safety issues.

## **PATIENT ISOLATION**

CDC currently advocates a two-tiered approach for infection control and isolation systems. The first tier includes "standard precautions." Standard precautions are precautions recommended for the delivery of care to all patients regardless of their

diagnosis or presumed infection status. Standard precautions apply to the following:

- blood;
- all body substances, secretions, and excretions except sweat, regardless of whether they exhibit visible blood;
- nonintact skin;
- mucous membranes.

Standard precautions are designed to limit healthcare exposure to blood or other body substances and include elements such as routine hand hygiene and use of appropriate protective apparel, eg, masks, eye protection, and gloves when needed to prevent direct contact.

The second tier in the infection control and isolation system recommended by CDC encompasses "transmission-based precautions," which are specifically designed for the management of patients known or suspected to be infected with pathogens whose transmission can be limited by the adoption of additional precautions beyond those included as standard precautions. The three defined types of transmission-based precautions are the following:

- airborne-organism precautions, for organisms transmitted by airborne or aerosol routes (eg, agents of tuberculosis or varicella);
- droplet precautions, for organisms transmitted in droplets from airway secretions (eg, *Neisseria meningitidis*);
- contact precautions, for organisms transmitted from person to person via hands, fomites, or environmental sources (eg, vancomycin-resistant enterococci).

The essential components of each individual type of precaution are summarized in [Table 5-1](#).

## **PREVENTING ANTIMICROBIAL-AGENT-RESISTANT INFECTIONS**

The expanding use of broad-spectrum agents in more severely ill patients (eg, critically ill patients in intensive care) and those housed in settings with a high potential for person-to-person transmission (eg, long-term-care facilities) has resulted in emergence and spread of multidrug-resistant pathogens. By 2000, at least 70% of hospital-acquired pathogens were resistant to one or more antimicrobial agents commonly used for treatment. These resistant pathogens adversely affect the outcome of care for many patients and add to the expense of treatment.

Antimicrobial-agent-resistant pathogens emerge and spread through several convergent mechanisms. First, pathogens develop or acquire the genetic traits responsible for resistance. Then they are introduced into healthcare settings via patients, visitors, or healthcare personnel or via contaminated materials. Antimicrobial therapy selects for

strains that express the resistance mechanism, which in turn increases their capacity to spread to other patients or personnel.

Previous studies have demonstrated a relationship between the emergence of resistant organisms and inappropriate or extended use of antimicrobial agents, noncompliance with hand hygiene and other infection control precautions, and indiscriminate use in food animals of products containing antimicrobial agents.

Clinicians can act to prevent the emergence and spread of multidrug-resistant infections in all healthcare settings. Professional societies, healthcare organizations, healthcare purchasers, and federal agencies have mounted efforts to promote judicious antimicrobial use. CDC has developed a series of 12-step programs to prevent infections in various patient settings. These programs emphasize four key strategies: infection prevention (eg, through immunization and decreased use of invasive devices in other procedures); effective pathogen-directed antimicrobial treatment to eradicate infection when present; judicious antimicrobial use; and prevention of person-to-person spread (eg, through effective hand hygiene and patient isolation practices) ([Table 5-2](#)). Effective strategies for improving antimicrobial-agent prescription practices are outlined in [Table 5-3](#). Of these, providing individual clinicians or groups with feedback on prescription practices and real-time decision support via computerized pharmaceutical-ordering systems holds the most promise for effecting meaningful improvements.

## HAND HYGIENE

Hand hygiene is a critical component of programs to prevent transmission of healthcare-associated infections. When hands or other skin surfaces are contaminated with blood or other body substances, they should be cleaned as soon as practicable. The requirements for hand hygiene apply regardless of whether gloves are worn.

There are three key methods for healthcare personnel to maintain hand hygiene: hand washing, hand antisepsis, and surgical scrubbing. The appropriate method depends on the degree of soiling of the hands, the available equipment and supplies, the nature of the intended work that will be undertaken immediately following hand hygiene, and the susceptibility of the patient with whom the healthcare provider will be in contact.

Hand washing typically involves the use of running water and plain soap to remove soil and transient skin flora. Hand antisepsis is preferred when contact with pathogens is highly likely and when patients are highly susceptible to infection. Removal or destruction of transient flora occurs when personnel perform hand antisepsis using an antimicrobial soap or hand rub. Some commonly used agents for hand antisepsis include products that contain alcohols (eg, *n*-propanol, isopropanol, and ethanol in appropriate concentrations), chlorhexidine gluconate, iodine or iodophors, *para*-chloro-*meta*-xylenol, and triclosan. The optimal duration of either hand washing or hand antisepsis is not clearly defined, but most experts suggest that hand washing for 15-30 s is sufficient. Manufacturers' instructions should be followed for determining the duration of hand contact with antiseptics.

The most aggressive form of hand hygiene is the surgical scrub. The surgical scrub is

undertaken to remove or destroy transient flora and to reduce the resident flora so that surgical wounds will not be contaminated even if gloves are torn. If an antimicrobial soap or detergent is used, personnel should use a brush and an action that involves friction for a minimum of 2 min. Care must be taken to include nail beds, wrists, and all surfaces of the hand.

Clinician compliance with hand hygiene recommendations is universally poor. Accordingly, hand hygiene should be encouraged whenever there is any doubt about the need to do so. Hand-washing facilities should be easily accessible and supplied with clean, running water and either soap or an antiseptic hand-washing agent. When clean, running water is inaccessible, waterless antiseptic agents such as alcohol-based hand rubs or foam products may provide acceptable alternatives.

## **ASEPSIS**

Asepsis refers to the absence of microorganisms that are capable of causing disease. Healthcare workers routinely use the following methods to provide healthcare aseptically:

- cutaneous antisepsis—skin antisepsis designed to inactivate as much of the skin flora as possible;
- cleaning—the removal of soil and organic matter through a physical or mechanical action involving the use of water and a cleaning agent;
- decontamination—a nonspecific term for removal of pathogenic microorganisms from objects or equipment;
- disinfection—the elimination of pathogenic microorganisms, excluding spores, from inanimate objects and environmental surfaces through thermal or chemical means;
- sterilization—the complete destruction of all pathogenic microorganisms including spores through chemical or physical means.

Clinicians should first use an antiseptic solution to prepare a patient's skin for insertion of invasive devices or for other invasive procedures that breach the skin. The goals are to prevent translocation of flora into the wound and egress of flora from adjacent tissue into the wound. When a maximum and immediate antiseptic effect of relatively short duration is required, alcohols are preferred. When a more prolonged duration of antiseptic activity is relevant (eg, during intravenous-catheter insertion), a product containing 2% aqueous chlorhexidine may be superior to plain alcohols or povidone-iodine. For preoperative surgical cutaneous disinfection, an alcohol-based preparation of iodine or povidone-iodine solution is preferred.

The intended use of an item or piece of equipment and manufacturer's instructions dictate its appropriate method of reprocessing, ie, whether cleaning, disinfection, or sterilization is in order. Intact skin provides an effective barrier to most microorganisms; thus, items touching only intact skin require only routine cleaning unless contaminated by blood or other body fluids. Instruments or equipment coming into contact with

mucous membranes or nonsterile tissue (other than intact skin) must, before use, be cleaned and then disinfected with a suitable disinfectant. Those instruments or pieces of equipment used to enter or capable of entering tissue that would be sterile under normal circumstances or to enter the vascular system of a patient must be thoroughly cleaned and then sterilized before use.

Proper cleaning to remove organic debris is essential before any disinfection or sterilization procedure. Relevant manufacturer's instructions for equipment, instruments, disinfectants, sterilants, sterilizers, and processors should be followed during reprocessing. Sterilized items should be handled and stored in a manner that ensures the integrity of packing material and prevents contamination of contents from any source. If an item is suspected of being nonsterile or its sterility cannot be guaranteed, the item should not be used.

## **OCCUPATIONAL HEALTH ISSUES**

A core component of any healthcare infection control program is a system that ensures that clinical and nonclinical healthcare personnel can perform their work in an environment where the risk of acquiring or transmitting infection is as low as possible. Provision of education, training, personal protective gear, safety equipment, appropriate patient placement, and protection through immunization or vaccination are strategies routinely used to minimize the risk of transmission of infectious disease from or to healthcare personnel. In 1998, CDC developed a new guideline for infection prevention in healthcare personnel (see Bolyard 1998). This guideline outlines the requirements for an effective occupational health program in healthcare settings and provides specific recommendations for prevention and management of occupational infectious diseases.

## **INFECTIOUS CONDITIONS OF CONCERN**

### **BLOOD-BORNE PATHOGENS**

Blood-borne pathogens are an important concern in healthcare settings. Most attention has been focused on hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV, but any infectious pathogen in the blood can probably be transmitted under some circumstances. HBV is the most highly transmissible of these agents, but vaccination programs have dramatically reduced the proportion of healthcare personnel at risk. For HIV, the best estimate of the average risk associated with punctures by a needle or similar "sharp" contaminated with blood from an HIV-infected patient is still approximately 0.32%. Risk is highest when the exposure involves blood from a patient with preterminal AIDS, the injury is deep, or it is inflicted by a visibly blood-contaminated device that has been used in an artery or vein. Fewer data are available to determine the HCV transmission risk, but current data suggest that approximately 1.9% of HCV-contaminated-needle injuries result in infection.

CDC's standard precautions (above) include measures to prevent exposure to blood and other body fluids, which will in turn prevent transmission of blood-borne occupational infections. The single most important prevention strategy is to eliminate or at least prevent, to the extent technologically possible, injuries caused by needles and other sharps. Reducing the number of needle punctures and injections used for patient

treatment is an important and sometimes overlooked component of this effort. Proper training and supervision are also important. Facilities that use trained phlebotomists or other skilled staff to obtain blood samples and insert catheters are often rewarded with fewer injuries and exposures. Technologic improvements in the design of needles and related devices also contribute to safety efforts, provided that their implementation is accompanied by comprehensive training in their safe use and disposal.

Management of an occupational exposure to blood or another body fluid should include the following:

- immediate first aid—cleaning the wound or nonintact skin with soap and water and rinsing exposed mucous membranes with clean water or sterile eye irrigant if available;
- reporting the incident to the relevant supervisor or manager;
- medically assessing the type of exposure and whether indicated postexposure care was provided, including prophylaxis for HBV, HIV, and tetanus;
- documenting the exposure circumstances and characteristics in a confidential medical record;
- collecting a blood specimen from the exposed person to document hepatitis B immune status (if not known) and baseline HIV and HCV serostatus;
- evaluating the status of the source patient's blood-borne infection (eg, by testing for HbsAg, HCV antibody, or HIV antibody with appropriate consent) if exposure circumstances suggest a risk of transmission of blood-borne pathogens;
- follow-up testing for implicated viruses for at least 6 months to identify new infections, if the source patient was infected with that virus and the exposure posed a risk for transmission.

Detailed guidelines for postexposure care, including HBV, HCV, and HIV prophylaxis, have been prepared by CDC and are periodically updated. These documents can be found on the World Wide Web at <http://www.cdc.gov/ncidod/hip/Guide/guide.htm>.

## **TUBERCULOSIS**

Tuberculosis infection can be acquired and transmitted in healthcare settings. Patients, healthcare personnel, and even visitors have been sources of spread to others. Outbreaks of drug-resistant infection in New York City in the early 1990s, with high attack rates observed among exposed healthcare and prison personnel, illustrate the tremendous morbidity this infection can still cause. Employee health programs in settings where exposure to tuberculosis can reasonably be expected are now charged with the responsibility for conducting surveillance (skin testing) and postexposure follow-up. Current CDC guidelines for preventing tuberculosis transmission in healthcare facilities can be found at [http://www.cdc.gov/ncidod/hip/Guide/tb\\_excerpt.htm](http://www.cdc.gov/ncidod/hip/Guide/tb_excerpt.htm).

Tuberculosis prevention in healthcare settings relies first and foremost on prompt

recognition and isolation of suspected cases. Precautions against airborne infectious agents include appropriate air containment, filtration, and exchange to prevent tuberculosis transmission. Appropriate respiratory protection may provide an additional measure of safety, but it cannot substitute for proper ventilation. Patients suspected of having tuberculosis should be placed in a room that meets the precautionary specifications for such airborne pathogens, including monitored negative air pressure in relation to the surrounding area, 6-12 air changes per hour, and appropriate discharge of air outdoors or monitored high-efficiency filtration of room air before the air is circulated to other areas in the hospital.

If these steps are not feasible in the short run, then patients should at least be advised to don a surgical mask to reduce dissemination of droplets that may desiccate to form infectious aerosols. Healthcare personnel and others sharing air with patients who are known or suspected to have active tuberculosis should use a properly fitted respirator (eg, the N95 respirator—a half-mask filtering face piece respirator rated at least 95% efficient by the National Institute for Occupational Safety and Health [see National Institute for Occupational Safety and Health 1987]). High-risk procedures, eg, bronchoscopy and other cough-inducing procedures, should be performed in isolation rooms with suitable ventilation, by personnel using appropriate respiratory protection.

CDC recommends periodic tuberculin skin tests (TST) for healthcare workers who have the potential for exposure to *Mycobacterium tuberculosis*. Results are used in the clinical management of healthcare workers and in the assessment of the adequacy of infection control measures in healthcare facilities. CDC recommends that the periodicity of routine TSTs be based on an assessment of the risk of transmission of *M tuberculosis* in that particular setting. This includes a profile of TB in the community, the number of infectious TB patients admitted to the area or ward, or the estimated number of infectious TB patients to whom healthcare workers in an occupational group may be exposed, and the results of analysis of healthcare workers' TST conversions, where applicable, and possible person-to-person transmission of *M tuberculosis*. Epidemiologic investigations to evaluate the possibility of nosocomial transmission should be conducted when TST conversions are noted. Finally, TST programs should be evaluated periodically to ensure that healthcare workers who should be included are being tested at the appropriate intervals.

## **VACCINE-PREVENTABLE DISEASES**

The CDC's Advisory Committee on Immunization Practices (ACIP) strongly recommends that healthcare personnel with direct patient contact be immunized against HBV, influenza, measles, mumps, and rubella. Depending on the nature of their work, susceptibility, and risk, individual staff may benefit from immunization against hepatitis A virus, meningococcal disease, pertussis, typhoid, and smallpox. Specific recommendations regarding preimmunization screening, dose schedule, indications, precautions, contraindications, and other considerations are contained in the relevant CDC guideline, which is based on the recommendations of the U.S. Public Health Service's Advisory Committee on Immunization Practices that is available at <http://www.cdc.gov/eppo/mmwr/preview/mmwrhtml/00050577.htm>.

Personnel performing work that involves contact with blood or other body fluids

containing blood are at greatest risk of acquiring occupational HBV infection. This group should routinely be vaccinated against HBV. Persons vaccinated due to occupational risk do not require prevaccination serologic screening although serologic testing should be undertaken 1-2 months postvaccination to establish and record the serologic response.

Influenza is also gaining appreciation as an important occupational infection. Healthcare personnel are at risk for acquiring and transmitting this pathogen across the entire spectrum of care delivery sites. Despite widespread recognition that immunization of healthcare personnel saves time lost from work, money, and probably lives, most healthcare personnel still do not receive the yearly vaccination. With the growing concern about another global influenza pandemic, emergence of new influenza strains, and advent of new antiviral treatments, influenza detection and prevention are growing components of infection prevention in healthcare settings.

The U.S. Public Health Service's Advisory Committee on Immunization Practices recommends that all healthcare personnel should be immune to varicella. Accordingly, it is prudent to ensure that all healthcare workers are screened for varicella immunity within 2 weeks of commencing duties. Healthcare personnel are considered immune if they have either a positive history of varicella-zoster virus (VZV) infection or proof of varicella immunization. Cases of nosocomial transmission of VZV have been reported, and patients, visitors, and staff have been implicated as sources of infection. Healthcare worker exposure to VZV is considered to have occurred when a susceptible healthcare worker not wearing respiratory protection enters a confined space occupied by a person with active varicella or zoster. A person is also infectious in the 48 h before the appearance of varicella, and contact during this time may also lead to infection in susceptible persons. Airborne precautions should be used in the care of patients with varicella or zoster. Following exposure, healthcare personnel should be assessed and a decision made regarding administration of varicella-zoster immune globulin (VZIG). Exposed susceptible healthcare workers should cease work for 8-21 days. Healthcare personnel with varicella are considered fit for duty when they are well enough to return and only when all lesions have dried and crusted, which is most often after 5 days.

## **NEW & EMERGING AGENTS**

Infectious diseases continue to emerge, threatening the health and well being of both patients and healthcare providers. Legionnaires' disease, Lyme disease, AIDS, and the development of drug-resistant strains of tuberculosis, certain pneumonias, and *Staphylococcus aureus* demonstrate the seriousness of emergent infectious diseases. Vigilant compliance with recommended infection control measures and judicious prescribing and dispensing of antimicrobial agents offer two opportunities for healthcare workers to limit the emergence of further infectious disease. Timely identification and reporting of cases of notifiable disease assists in the accurate estimation of the magnitude of the infectious disease problem and in the development of additional preventative and treatment measures.

**Table 5-1.** Summary of the essential elements of recommended isolation precautions.<sup>1</sup>

<b>Element</b>	<b>Standard Precautions</b>	<b>Airborne Precautions</b>
Hand washing	Before and after patient contact, regardless of glove use.	As for standard precautions
Gloves	To prevent contact with blood and body fluids, mucous membranes, and contaminated equipment.	As for standard precautions
Masks, eye protection, face shield	To protect against potential splashes/sprays of blood/body fluids.	If susceptible persons must enter room of a patient with measles or varicella, respiratory protection must be worn; respiratory protection must be worn if patient has infectious pulmonary tuberculosis.
Gown	To prevent soiling of clothing; gown material dependent on expected activity and risk of contamination.	As for standard precautions
Patient care equipment, & patient transport	Protective apparel should be worn when handling contaminated equipment; reprocessing should be appropriate for the intended use of the item.	Patient transport should be minimized; droplet nuclei dispersion can be limited by patient wearing surgical mask during movement.
Control of the environment	Cleanliness of the environment should include all surfaces and patient care equipment.	As for standard precautions
Linen and transmission of pathogens in the environment.	Gloves should be worn and careful handling should be used to limit contact with soiled	As for standard precautions
Occupational health, blood-borne pathogens of occupational exposure.	Sharps and needles should be handled, used, and disposed in a manner that limits the risk	As for standard precautions
Patient placement cohort with similar patient.	Private room may be required if soiling of the environment or poor personal hygiene is likely.	Door must be closed; optimally requires negative-pressure room with 6-12 changes an hour, external discharge of air, or HEPA filtration before recirculation; if no private room is available,

- TABLES

- Table 5-1. Summary of the essential elements of recommended isolation precautions.

---

**Table 5-2.** Twelve steps to prevent antimicrobial resistance in hospitalized adults.

**Prevent infection**

1. Vaccinate.

Get influenza vaccine.

Give influenza/*S pneumoniae* vaccine to at-risk patients before discharge.

2. Get the catheters out.

Use catheters/invasive devices only when essential.

Use proper insertion/catheter care protocols.

Remove catheters/invasive devices when no longer essential.

**Diagnose and treat infection**

3. Target the pathogen.

Diagnose infection.

Diagnose the pathogen.

Diagnose antimicrobial susceptibility.

4. Access the experts.

Optimize regimen, dose, route, and duration.

Monitor response.

Adjust treatment when needed.

**Use antimicrobials wisely**

5. Practice antimicrobial control.

Support your local antimicrobial control programs.

6. Use local data.

Customize antibiograms by:

Infection site

Healthcare setting/unit

Patient population

Duration of hospitalization

7. Know when to "say no to vanco." (vancomycin)

Know the MRSA epidemiology in your hospital.

Fever and an IV are not routine indications for vancomycin treatment.

MRSA may be sensitive to other antimicrobial agents.

8. Don't treat contaminants.

Use proper antisepsis for blood cultures.

Don't routinely culture catheter tips.

Don't routinely culture through lines.

9. Don't treat colonization.

Treat pneumonia, not the endotracheal tube.

Treat urinary tract infection, not the Foley catheter.

Treat bacteremia, not the catheter tip.

Treat the bone infection, not the skin flora.

10. Quit when you are ahead.

Stop antimicrobials . . .

When infection is not diagnosed

When infection is unlikely

When cultures are negative

**Prevent transmission.**

11. Isolate the pathogen.

Use standard infection control precautions.

Contain infectious body fluids by using . . .

Airborne/droplet/contact precautions

Cohorting

When in doubt, use common sense.

12. Break the chain of contagion.

Keep your hands clean.

Contain your contagion.

Keep your hands clean.

Stay home when you are sick.

Set an example!

MRSA, methicillin-resistant *Staphylococcus aureus*; IV, intravenous line.

## 6 . Laboratory Diagnosis — W. Lawrence Drew, MD, PhD, Franklin R. Cockerill, III, MD, & Nancy K. Henry, PhD, MD

### INTRODUCTION

Throughout the world, bacteria and viruses are among the most commonly encountered microbial pathogens in humans. Dimorphic fungi (ie, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Coccidioides immitis*, *Sporothrix schenckii*, and *Paracoccidioidomyces brasiliensis*) and most parasites are generally limited to certain geographic areas. Immunocompromised patients are susceptible to common bacterial, viral, and parasitic pathogens that cause disease in normal hosts and to unusual bacterial, viral, fungal, and parasitic pathogens that infrequently cause disease in normal hosts. These latter organisms are opportunists and, owing to humoral or cell-mediated immune dysfunction within the host, may produce life-threatening disease.

Other organisms may cause disease in patients as the result of anatomical-barrier disruption. Endotracheal intubation may permit colonization of the oropharynx with nosocomial pathogens. These include gram-negative bacteria, especially members of the family *Enterobacteriaceae* (eg, *Escherichia coli*, *Klebsiella* spp., *Enterobacter* spp., *Proteus* spp., and *Serratia* spp), *Pseudomonas* spp., *Stenotrophomonas maltophilia*, or *Burkholderia cepacia*; or gram-positive bacteria, especially methicillin-resistant staphylococci (methicillin-resistant *Staphylococcus aureus* and methicillin-resistant coagulase-negative staphylococci) and vancomycin-resistant *Enterococcus* spp. (VRE) and yeasts. Any of these nosocomial pathogens may colonize the upper respiratory tract and spread to the lower respiratory tract, secondary to endotracheal intubation. VRE may also colonize the lower gastrointestinal tract and be spread from one patient to another by fecal contamination. Mucositis, as the result of total body irradiation and/or chemotherapy, may be associated with septicemia caused by oral flora, especially *Streptococcus* spp. of the viridans group and *Candida* spp. Intravascular catheters may become infected with cutaneous flora or nosocomial pathogens. These organisms include *Staphylococcus* spp., *Streptococcus* spp., and *Corynebacterium* spp., including *Corynebacterium jeikeium*, the same nosocomial gram-positive and gram-negative bacteria described previously, and yeasts. All of these organisms may be introduced into the bloodstream directly if intravenous fluids or medications are injected through an infected catheter port. Alternatively, these organisms may first colonize a proximal port and over time ascend to the catheter tip.

Neutropenia secondary to chemotherapeutic agents is frequently associated with bacteremia. Enteric gram-negative bacteria, notably members of the family *Enterobacteriaceae*, *Pseudomonas* spp., and the gram-positive organisms *Staphylococcus* spp. or *Enterococcus* spp., account for the majority of these bacteremias. Disseminated fungal infections caused by *Candida* spp. or *Aspergillus* spp. may also occur.

Because of the wide variety of microorganisms (bacteria, fungi, viruses, and parasites) that can cause infections in immunocompromised patients, in some instances, test-ordering protocols may be useful to assure that appropriate specimen processing

and analyses are performed. This is especially important for specimens that are obtained by using relatively invasive procedures. For example, a standard battery of microbiology tests should be considered for all specimens obtained by bronchoalveolar lavage or transbronchoscopic, transthorascopic, or open-lung biopsies from immunocompromised patients. For all patients (normal or immunocompromised), the development of disease management strategies for commonly encountered infections may result in more consistent and appropriate use of laboratory tests.

## **Diagnosis of Bacterial, Fungal, & Parasitic Infections — *Franklin R. Cockerill, III, MD, & Nancy K. Henry, PhD, MD***

### **INTRODUCTION**

[Tables 6-1](#), [6-2](#), and [6-3](#) summarize currently available recommended test methods for the detection of bacterial, fungal, and parasitic pathogens from human specimens. Methods for detection of viral pathogens are discussed later in this chapter. For completeness, the tables include pathogens common to both normal and immunocompromised hosts. Selected specimen collection procedures are shown in [Table 6-4](#). However, this important step in the diagnostic-testing process cannot be overstated. An adequate amount of specimen (using sterile techniques when appropriate) should be placed in the appropriate transport device, and the specimen should be transported to the laboratory under appropriate environmental conditions and within a reasonable period. Because a large number of transport devices are available, consultation with the laboratory personnel is important, especially when unusual bacteria are considered. Comprehensive reviews of the specifics of specimen collection, transport, and storage are described elsewhere. As a general point, specimens requiring strictly anaerobic conditions for viability must be sent in appropriate anaerobic transport devices. Depending on the volume, most other specimens can be sent in either a swab transport device (the swab is immersed in nutrient broth) or a sterile container. Some studies have demonstrated the utility of blood culture bottles for transporting as well as culturing sterile body fluids, especially peritoneal fluid.

### **RAPID, DIRECT TEST METHODS & CULTURE-BASED METHODS**

#### **Introduction**

Direct, rapid diagnostic-test methods if available should be used in addition to conventional culturing techniques for diagnosing bacterial or fungal infections in critically ill patients. Most parasitic infections can be diagnosed by direct staining methods, and these tests should be performed emergently, especially if life-threatening infections like malaria are suspected. Rapid diagnostic tests are provided in [Table 6-1](#), and culture-based diagnostic tests, which require longer time periods to complete, are presented in [Table 6-2](#).

#### **Blood**

Both direct and culture-based techniques may be useful for identifying common and uncommon bacterial, fungal, and parasitic pathogens in blood. Some of the specialized testing methods shown in [Tables 6-1](#) and [6-2](#) are generally available only at reference

laboratories. If the clinician feels strongly that one of these tests is useful, an aliquot of the specimen should be sent to a reference laboratory. Direct test methods for the detection of bacterial or fungal pathogens in blood are limited in the number of different bacteria that they can detect and are less sensitive than culture methods.

Bacterial-antigen tests for commonly encountered encapsulated organisms (*Haemophilus influenzae* type b, *Neisseria meningitidis*, or *Streptococcus pneumoniae*) are easy to perform and available in most laboratories. A latex agglutination procedure can be used to detect the yeast *Cryptococcus neoformans*.

Blood cultures should be obtained from all patients in whom sepsis is considered. The standard blood culture set for adults consists of 20-30 ml of blood equally distributed between two or among three culture receptacles. Blood volume for pediatric patients is less and is dependent on patient weight. When 20 ml of blood is drawn, the standard practice is to culture 10 ml in an aerobic atmosphere and 10 ml in an anaerobic atmosphere. If 30 ml of blood is drawn, the same practice is followed except that the additional 10 ml is cultured under aerobic conditions. In patients with suspected endocarditis or endovascular infections, conditions in which bacteremia is continuous, two or three separate blood cultures collected at various intervals over a 24-h period are sufficient. For other types of bacteremia, 99% will be detected by three separate blood cultures collected at various intervals over a 24-h period. Most conventional broth-based blood culture systems also have the ability to detect candidemias. Specialized broth or procedures (see lysis centrifugation below) may be required to detect fastidious bacteria and dimorphic fungi, especially *Histoplasma capsulatum*.

Recently some authorities have questioned whether anaerobic blood cultures should be performed routinely in all patients, especially those in whom anaerobic bacteremia is unlikely. However, it has recently been demonstrated that anaerobic blood cultures may recover some facultatively anaerobic bacteria (eg, *Enterococcus* spp. and viridans streptococci) more efficiently than aerobic blood cultures. The lysis centrifugation method is a specialized blood culture method which is useful for recovering common as well as many unusual bacterial pathogens and fungi. In this system, blood is inoculated into a test tube containing saponin, a chemical that lyses erythrocytes and leukocytes, thereby releasing intracellular bacteria. The tube is centrifuged, and the sediment is inoculated onto solid agar plates or into broth. *Mycobacterium* spp., especially *Mycobacterium avium-intracellulare*, occasionally produce bacteremias in severely immunocompromised patients. The inoculation of the sediment from a lysis centrifugation blood culture tube onto specialized mycobacteria agar or into BACTEC 13A broth bottles is useful for recovering mycobacteria. Controversy exists as to whether blood cultures can be obtained from intravascular lines. Several investigators have shown that such a practice results in the isolation of more contaminating microorganisms than if blood is obtained from peripheral veins. Whenever possible, blood for culturing should be obtained from peripheral veins; however, this recommendation must be considered in the context of the clinical situation of the patients. For example, phlebotomy via peripheral veins may be risky in severely thrombocytopenic bone marrow transplant patients.

Parasitemias caused by malarial or filarial organisms are diagnosed with thick and thin blood smears. Thick smears permit screening for malaria parasites, and speciation is possible by careful evaluation of thin smears. When parasitemias are suspected, the

laboratory director should be notified so that proper processing and careful evaluation of blood specimens are undertaken. In some cases, referral of specimens to reference laboratories may be beneficial.

### **Other Sterile Body Fluids or Tissues**

Direct antigen testing for *H influenzae* type b, *N meningitidis*, *S pneumoniae*, group B streptococci, *E coli*, and *C neoformans* can be performed on cerebrospinal fluid (CSF) or urine. Direct antigen testing for *Legionella pneumophila* and *H capsulatum* can be performed on urine. For staining and culturing methods, CSF or joint, peritoneal, or pleural fluids should be concentrated by filtering or centrifugation. In contrast, Gram stains of urine should be performed on unconcentrated specimens. The presence of =2 bacteria per oil immersion field ( $\times 1000$ ) in a Gram-stained smear of a drop of unconcentrated urine should represent  $\sim 10^5$  colony forming units of bacteria/ml of urine. Other rapid screening tests for bacteruria are commercially available. These tests, which detect either bacteria or leukocytes by direct or indirect methods, are generally no more accurate than the Gram stain method and may be more costly.

Cultures of bone marrow specimens may be particularly valuable for diagnosing *Salmonella typhi* (the agent of typhoid fever), *Brucella* spp., disseminated mycobacteria infections (*M avium-intracellulare*) or *H capsulatum* and can be processed by using the lysis centrifugation method. Granulomas surrounding small vessels in a bone marrow biopsy (ring granulomas) are associated with *Coxiella burnetti* (agent of Q fever) infection. Bone marrow specimens may be positive by staining methods in patients with disseminated infection caused by a variety of organisms, including *H capsulatum*, *M avium-intracellulare*, *Trypanosoma* spp. or *Leishmania* spp.

### **Respiratory Tract Specimens**

All spontaneously produced sputa that are submitted for general bacteria culture should be screened for the presence of squamous epithelial cells. It has been demonstrated that expectorated sputum samples having  $> 25$  squamous epithelial cells per low-power microscopic field are unacceptable for bacterial culture, because these samples likely are contaminated by oropharyngeal secretions. Common community-acquired respiratory bacterial pathogens include *S pneumoniae*, *Streptococcus pyogenes* (Lancefield group A  $\beta$ -hemolytic streptococci), *Klebsiella pneumoniae*, *S aureus*, *Legionella* spp., *Chlamydia pneumoniae*, and *Mycoplasma pneumoniae*. Gram-negative bacilli, especially *Enterobacteriaceae* and *Pseudomonas* spp., and VRE and staphylococci may cause nosocomial respiratory infection. *Pseudomonas aeruginosa* and *B cepacia* are frequently associated with pulmonary infection in patients with cystic fibrosis. All of the above bacteria, with the exception of *C pneumoniae* and *M pneumoniae*, are easily diagnosed by culture-based methods. Indirect serologic methods are the best methods for diagnosing the latter two pathogens.

Although *Legionella* spp., *Mycobacteria* spp., and *Nocardia* spp. can cause pulmonary disease in normal hosts, they may be a more frequent cause of pulmonary disease in immunocompromised hosts. *Legionella* spp. can be diagnosed by direct examination of pulmonary secretions or alveolar tissue, with a fluorescent antibody technique. Alternatively, acute infection with the most frequently encountered *Legionella* spp., *L*

*pneumophila*, can be diagnosed by screening for antigen in the urine. *Legionella* antigenuria can persist for months after acute infection, a factor that may limit the usefulness of this direct test for diagnosing subsequent *L pneumophila* infections. Microorganisms that stain poorly by the Gram stain method and that appear to branch or are beaded in appearance should be suspect for *Nocardia* spp. These organisms frequently stain acid-fast by a modified acid-fast staining method. This method uses less intense decolorizing agents than those used for conventional acid-fast staining of mycobacteria. *Nocardia* spp. grow more slowly than other bacteria, but can be recovered on standard bacteriologic media. *Nocardia* spp. also grow well on media used for isolating fungi and mycobacteria and on media used to isolate *Legionella* spp. (buffered charcoal yeast extract). A recently described opportunist gram-positive bacillus, *Rhodococcus equi*, also may cause pulmonary infection in immunocompromised patients and, like *Nocardia* spp., may branch and stain acid-fast by a modified acid-fast staining method.

The dimorphic fungal pathogens (yeast and hyphal forms) *H capsulatum*, *Blastomyces dermatitidis*, *Coccidioides immitis* and *Paracoccidioides brasiliensis* and the monomorphic fungus (yeast form only) *C neoformans* may cause pulmonary or disseminated disease in both normal and immunocompromised hosts. The dimorphic fungal pathogen *Sporothrix schenckii* rarely produces respiratory disease and more frequently presents as cutaneous disease in normal hosts. Monomorphic fungi (hyphal form only) such as *Aspergillus* spp. generally cause respiratory or disseminated infection in immunocompromised hosts. *Pneumocystis carinii* has recently been reclassified as a fungus. It is an opportunistic fungal pathogen that causes disease only in immunocompromised hosts, especially patients coinfecting with human immunodeficiency virus (HIV). All fungal pathogens, with the exception of *P carinii*, can be cultured from pulmonary secretions. Diagnosis of *P carinii* requires direct examination of pulmonary secretions or tissue. Some fungal infections can also be diagnosed by indirect serologic methods; additionally, *H capsulatum* antigen and *C neoformans* antigen can be detected in urine and in the serum in disseminated disease.

In certain areas of the world where helminths (*Ascaris lumbricoides*, *Strongyloides stercoralis*, *Paragonimus westermani*, and *Echinococcus granulosus*) are endemic, pulmonary infection with these parasites may occur. Disseminated infection with *S stercoralis*, including respiratory infection, may occur in immunocompromised hosts. *Toxoplasma gondii* may cause pulmonary disease in immunocompromised hosts. Direct examination of wet preps of pulmonary secretions may be useful to identify helminths; direct examination of tissue, culture, and indirect serologic methods are useful for diagnosing *T gondii*.

## **Feces**

Enteric infections caused by *Salmonella* spp., *Shigella* spp., *Yersinia enterocolitica*, pathogenic *E coli*, and *Campylobacter* spp. are increasing in frequency in the United States. These infections are diagnosed by culture of feces, although direct detection of antigens by enzyme-linked immunoassays are sometimes useful for *Salmonella* spp. and *E coli* O157:H7. At present, Whipple's disease caused by the bacterium *Tropheryma whippelii* can be definitively diagnosed by evaluating small-bowel tissue for the presence of nucleic acid that is unique to this organism. Traditionally, periodic acid

Schiff staining has been used to demonstrate the organism in tissue (see subsequent discussion).

Occasionally, in severely immunocompromised patients, acid-fast staining and culture may be useful for diagnosing enteric infection caused by *Mycobacterium tuberculosis* or *M. avium-intracellulare*. However, cultures for mycobacteria should be performed only on stools with positive acid-fast stains. If mycobacteria are recovered from feces, disseminated disease is frequently present.

Enteric parasitic infections are diagnosed by direct examination of fresh or preserved stools; however, direct immunoassays may be useful for some parasitic organisms (*Giardia lamblia* and *Cryptosporidium parvum*). Extraintestinal parasitic infections may require other methods, including culture for diagnosis. Not shown in [Table 6-2](#) are culture methods for *Trypanosoma* spp., *Leishmania* spp., *T. gondii*, and *Entamoeba histolytica*. These specialized tests are available only at a few reference laboratories in North America. Culture methods for *Acanthamoeba* spp. and *Naegleria* spp. are included in [Table 6-1](#). These methods are easy to perform and especially useful for diagnosing these parasitic infections in patients with corneal infections, which can occur with contact lens use.

Considerable attention has focused recently on newly discovered parasites that are opportunists in immunocompromised patients. These include species of four genera of coccidia (*Isospora*, *Sarcocystis*, *Cryptosporidium*, and *Cyclospora*) and species of five genera of microsporidia (*Enterocytozoon*, *Septata*, *Nosema*, *Encephalitozoon*, and *Pleistophora*). Infections caused by the coccidia or microsporidia have been reported in immunosuppressed patients, notably those patients coinfecting with human immunodeficiency virus. Intestinal disease has been demonstrated to occur with all coccidia genera, *Enterocytozoon* spp., and *Septata* spp. Extraintestinal disease has been reported with *Sarcocystis* spp., *Cryptosporidium* spp., *Septata* spp., *Encephalitozoon* spp., *Nosema* spp., and *Pleistophora* spp. As previously mentioned, *T. gondii* and the helminth *S. stercoralis* can cause severe disseminated disease in immunocompromised hosts.

## **Intravascular Catheters**

Patients who have indwelling central intravascular catheters for prolonged periods are susceptible to infection. If other sources for infection are ruled out, then infection related to the intravascular catheter must be considered. Diagnosing intravascular-catheter-associated infection can be challenging for the clinician, considering that a definitive diagnosis cannot be achieved unless the catheter is removed and a culture of the tip yields potentially pathogenic bacterium in sufficient quantity (ie, >15 colony forming units of bacteria). If there is evidence for a catheter tunnel infection (subcutaneous infection around the catheter), swabs of the affected area or pus if present should be stained and cultured for bacteria, mycobacteria, and fungi. Occasionally, the fungus *Malassezia furfur* can infect intravascular catheters and the blood in patients receiving intralipid infusions. Special culture techniques are required to isolate this organism (see [Table 6-2](#)).

## **Surveillance Cultures**

In certain instances, surveillance cultures for bacteria and fungi may be useful. Patients who are immunocompromised, receiving broad-spectrum antimicrobial agents, or both may be surveyed for drug resistant bacteria or fungi. As part of infection control programs, institutionalized patients may be surveyed for VRE or methicillin-resistant *S aureus* carriage. In both of these examples, cultures of the upper airway, feces, or both may be useful to screen for carriage of these potential pathogens.

## SEROLOGIC TEST METHODS

Indirect serologic methods may be useful for diagnosing infections caused by certain bacteria, fungi, and parasites and in some cases may be the only means by which a diagnosis is achieved. To diagnose infections by *Rickettsia* spp., for which alternative diagnostic test methods are limited (attempts at culturing these organisms should be avoided owing to their high infectivity), these tests may be the only means by which a diagnosis is established. [Table 6-3](#) shows the serologic test methods currently available at most reference laboratories. Of note, these methods detect immunoglobulin G (IgG) antibody, IgM antibody, or both to specific bacteria pathogens and for the most part require that the infection has existed in a patient for a finite period so that detectable levels of antibody exist. For IgG analyses, a fourfold increase between baseline and convalescent antibody titers may be required to confirm infection. Because the demonstration of a fourfold rise in antibodies may require > 4 weeks, the diagnostic utility of IgG analyses may be limited, especially in the acute disease phase. However, in some situations, baseline IgG antibody levels may exceed a critical threshold, which is considered diagnostic for infection. Except for the last example, indirect serological methods cannot be considered as rapid diagnostic tests and therefore may be of limited utility. These tests may also be of limited value in patients who lack a humoral response, especially bone marrow transplant recipients.

## MOLECULAR TEST METHODS

Molecular test methods, including nucleic acid-probing and -sequencing techniques, allow for the detection of pathogens directly from human specimens. Molecular test methods and nucleic acid amplification techniques, which are frequently available at most reference laboratories are shown in [Table 6-5](#). These methods are potentially useful for fastidious or slowly growing organisms like *Legionella* spp., *Bartonella* spp., *Mycobacterium* spp., *Borrelia burgdorferi*, and dimorphic fungi. The bacterial agent of Whipple's disease, *T whippelii*, has never been recovered on culture and presently can be diagnosed only by nucleic acid testing methods. Quantities of parasites in blood or tissue might be sufficiently low (eg, *T gondii* or *Babesia microti*) that direct examination does not provide a diagnosis. In these cases, molecular diagnostic tests may also be useful. It must be emphasized that some studies, particularly those that have evaluated molecular identification methods for group A streptococci and mycobacteria, have demonstrated that these methods, including those that use nucleic acid amplification techniques, are less sensitive than culture. Therefore, if the results for molecular test methods such as these are negative, other diagnostic test methods including culture techniques should be considered.

## SUSCEPTIBILITY TESTING OF BACTERIAL & FUNGAL ISOLATES TO

## **ANTIMICROBIAL AGENTS**

The National Committee for Clinical Laboratory Standards (NCCLS) provides published guidelines for conventional susceptibility test methods for commonly encountered bacterial organisms that grow aerobically or anaerobically and for yeasts. For bacteria that are not easily cultured (eg, *Bartonella* spp., *Ehrlichia* spp., or *T whippelii*), antimicrobial susceptibility testing is currently not possible. Tentative NCCLS guidelines exist for mycobacteria. No standards exist for parasites. Antimicrobial susceptibility methods include disk diffusion, broth dilution, and agar dilution. For disk diffusion, the inhibition of growth of an organism on solid media is assessed around a paper disk from which an antimicrobial agent diffuses. The greater the zone of inhibition of bacterial growth, the more effective the antimicrobial agent. In the broth dilution procedure, the effect of a known concentration of antimicrobial agent dispersed along with the organism in liquid media is assessed. No growth of the organism (the broth remains clear) indicates that the organism is inhibited at the concentration of antimicrobial agent tested. For agar dilution, a known amount of antimicrobial agent is dispersed in solid medium, and its effect on growth of organisms that are spot inoculated onto the surface of the medium is assessed. No visible growth of the organism means that it is inhibited by the specific concentration of antimicrobial agent that is present in the solid medium.

Interpretation of the results for each of these methods may differ with the antimicrobial agent and organism tested, and guidelines for such are provided by the NCCLS. These interpretations are provided as the following categories: resistant, susceptible, or intermediately susceptible. If an organism is identified as resistant to a particular antimicrobial agent, that agent should not be used in the clinical setting.

## **Diagnosis of Viral Infections — *W. Lawrence Drew, MD, PhD***

### **INTRODUCTION**

It is becoming increasingly important for the practitioner to perform viral diagnostic studies because prognostic, epidemiologic, and therapeutic considerations may be greatly influenced by knowledge of the specific virus causing a given illness. Even if no therapy is available, the establishment of a definite diagnosis of viral infection is often beneficial in (1) epidemiologic monitoring, (2) educating physicians and patients, (3) defining the disease process, and (4) evaluating therapeutic implications, both positive and negative. Moreover, identification of a virus as the cause of a patient's illness may be cost effective, because expensive diagnostic procedures and antibiotic therapy may be avoided or discontinued.

The virology laboratory can confirm the suspected diagnosis by cytologic examination of clinical specimens; attempting to isolate the virus; detecting the presence of viral antigens, or nucleic acids or evaluating the patient's immune response to the virus (serology).

### **CYTOLOGY**

The simplest technique for viral diagnosis is cytologic examination of specimens for the presence of characteristic viral inclusions, but this approach is insensitive and

applicable to only a few viruses, especially herpes viruses. These intracellular structures may represent aggregates of virus within an infected cell or may be abnormal accumulations of cellular material resulting from the virus-induced metabolic disruption. Papanicolaou (Pap) smears may show these inclusions in single cells or in large syncytia (aggregates of cells containing more than one nucleus), as in a patient with herpes simplex infection of the cervix. Cytology can be used to detect infections with herpes simplex virus, varicella-zoster virus, cytomegalovirus, human papillomavirus, and adenoviruses. Rabies infection may also be detected by finding Negri bodies (rabies virus inclusions) in brain tissue.

## **CULTURE-BASED METHODS**

### **Introduction**

The historical "gold standard" of viral diagnosis is recovery of the agent in tissue culture, embryonated eggs, or experimental animals. Embryonated eggs are still used for the growth of virus for some vaccines but have been replaced by cell cultures for routine virus isolation in clinical laboratories. Likewise, the use of experimental animals rarely occurs in most clinical laboratories. Just as multiple media are used in bacteriology, several different types of tissue culture cells (eg, monkey kidney, human fetal lung, human amnion, or human cancer cells) are inoculated with each viral specimen.

Most clinically significant viruses can be recovered in at least one of these cell cultures, but several clinically important viruses are not isolated in these cells. For example, specimens submitted for the identification of viruses such as human immunodeficiency virus, coxsackie A virus, and rubella virus require, respectively, cocultivation with normal human peripheral blood mononuclear cells, inoculation of suckling mice, and the use of specialized cell cultures, which are not generally available. Therefore infections caused by these and several other viruses are most frequently diagnosed serologically or by detection of virus-specific antigens or nucleic acids.

Detection of the growth of a virus is by observation of changes in the cell culture monolayer [cytopathic effect (CPE)]. Characteristic CPEs include changes in cell morphology, cell lysis, vacuolation, syncytia formation, and presence of inclusion bodies. Inclusion bodies are histologic changes in cells caused by the presence of viral components or changes in cell structures. With experience a technologist can distinguish CPE characteristics of the major virus groups. The observation of which cell culture exhibits CPEs and the rapidity of viral growth can be used for the presumptive identification of many clinically important viruses. This approach for identifying viruses is similar to bacterial identification based on growth and morphology of colonies on selective, differential media. Some viruses do not readily cause CPEs in cell lines typically used in clinical virology laboratories. However, some of these can be detected by other techniques, such as (1) erythrocyte hemadsorption onto cells infected with paramyxoviruses or mumps virus or (2) interference with the replication of other viruses (eg, picornaviruses cannot replicate in cells previously infected with rubella virus; this is known as heterologous interference).

In contrast with the intrinsic delay of antibody studies, the results of viral culture can be surprisingly rapid. Almost 50% of all viral isolates can be reported within 3 to 4 days of

culture, with herpes simplex virus and influenza A virus usually detected within 1 to 3 days ([Table 6-6](#)).

The selection of the appropriate specimen for viral culture is complicated because several different viruses may cause the same clinical disease ([Table 6-7](#)). For example, several types of specimens should be submitted from patients with viral meningitis to enhance the recovery of the possible etiologic agents: CSF (enteroviruses, mumps virus, and herpes simplex virus), throat swabs and washings (enteroviruses), and stool or rectal swabs (enteroviruses). Also, serum should be collected as an acute-phase specimen in case subsequent serologic tests are indicated (eg, acute and convalescent sera for mumps virus or arbovirus infections). Many considerations, however, allow the physician to select the most appropriate specimens ([Table 6-8](#)). For example, during the summer, when enteroviral meningitis is prevalent, CSF, throat, and stool specimens should be submitted. On the other hand, the development of encephalitis in children after being bitten by mosquitos in wooded areas endemic for California encephalitis virus suggests that a serum specimen for antibody testing would be preferred. Central nervous system disease after parotitis would suggest collection of CSF and urine for the isolation of mumps virus. The specimens that should be collected for other viruses are summarized in [Table 6-7](#).

### **Timing of Specimen Collection**

Proper timing of specimen collection is essential for adequate recovery of viruses. Specimens should be collected early in the acute phase of infection. Studies with respiratory viruses indicate that the mean duration of viral shedding may be only 3-7 days. Also, herpes simplex virus and varicella-zoster virus may not be recovered from lesions beyond 5 days after onset. Isolation of an enterovirus from the CSF may be possible for only 2-3 days after onset of the central nervous system manifestations.

### **Transport to Laboratory**

The shorter the interval between collection of a specimen and its delivery to the laboratory, the greater is the potential for isolating an agent. When feasible, all specimens other than blood, feces, urine, and tissue, which need special processing, should be inoculated directly onto cell cultures at the patient's bedside ([Table 6-9](#)). These should then be transported to the laboratory promptly.

For specimens that cannot be inoculated onto cell cultures immediately, several types of transport media have been used. It is generally believed that protein (serum, albumin, or gelatin) incorporated into a transport medium enhances survival of viruses.

Improper storage of specimens before processing can also adversely affect viral recovery. Significant losses in infective titer occur with enveloped viruses (eg, herpes simplex virus, varicella-zoster virus, or influenza virus) after specimens have been frozen and then thawed. This is not observed with nonenveloped viruses (eg, adenoviruses or enteroviruses). Therefore, when it is impossible to process a specimen immediately, it should be refrigerated *but not frozen* and packed in shaved ice for delivery to the laboratory if delays in transit are anticipated. Storage of specimens for the recovery of viruses at 4°C is far superior to storage at ambient temperature.

## Interpretation of Culture Results

In general the detection of any virus in host tissues, CSF, blood, or vesicular fluid can be considered highly significant. Recovery of viruses other than cytomegalovirus in urine may be diagnostic of significant infection. For example, both mumps virus and adenovirus type 11 (associated with acute hemorrhagic cystitis) may be recovered in urine and indicate acute infection. However, the presence of cytomegalovirus in urine is difficult to interpret because this may reflect asymptomatic virus replication long after infection or indicate a significant active infection in the patient. In the newborn, viremia (isolation of virus in urine) in the first 3 weeks of life establishes a diagnosis of congenital cytomegalovirus infection, whereas the onset of viral excretion after 3-4 weeks of life reflects intrapartum or postpartum infection. Diagnosis of acquired cytomegalovirus in older patients usually requires a combination of findings, including positive cultures, illness compatible with cytomegalovirus disease, reasonable exclusion of other potential etiologic agents, and support by specific serologic or histologic data.

The significance of viruses isolated in upper respiratory tract, vaginal, or fecal specimens varies greatly. At one extreme, isolates such as measles, mumps, influenza, parainfluenza, and respiratory syncytial virus are significant because asymptomatic carriage and prolonged shedding of these viruses are unusual. Conversely, other viruses can be shed continually or intermittently without symptoms for periods ranging from several weeks (enteroviruses in feces) to many months or years (herpes simplex virus or cytomegalovirus in the oropharynx and genital tract; adenoviruses in the oropharynx and intestinal tract). Herpes simplex virus, cytomegalovirus, varicella zoster virus, and Epstein-Barr virus may remain latent for long periods and then become reactivated in response to a variety of stressful stimuli, including other infectious agents. In this setting their detection may not be significant, may merely represent a secondary problem complicating the primary infection (eg, herpes simplex virus "cold sores" in patients with bacterial sepsis), or may be associated with significant disease, especially in the immunocompromised patient.

Based on the epidemiology of adenovirus infections and observed serologic responses, the simultaneous isolation of these viruses from throat and feces is significantly associated with febrile respiratory disease. Isolation of viruses from the throat alone is less frequently associated with disease, and isolates from feces alone are probably nondiagnostic in a patient with respiratory disease.

Enteroviruses are generally found in infants and children, particularly during the late summer and early autumn. A knowledge of the relative frequency of virus shedding among various age groups in a particular locale is extremely helpful in assessing the significance of results of throat or stool cultures. For example, the peak prevalence of enteroviruses in the stools of toddlers during the late summer may range from 5% in temperate zones to > 20% in subtropical climates. Even in temperate areas, rates may approach 30% in infants during periods of enterovirus activity. Shedding of enterovirus in the throat usually occurs for 1-2 weeks, whereas fecal shedding may last 4-16 weeks. Thus, in a clinically compatible illness, isolation of an enterovirus from the throat supports a stronger temporal relationship to the disease than does an isolate from only the feces.

Herpes simplex virus is unusual in a fecal culture. In such cases it usually represents either severe disseminated infection or local infection of the perianal areas. Detection of herpes simplex virus in the upper respiratory tract may mean nothing other than nonspecific reactivation of virus caused by fever unless typical vesicles or ulcers are also present. Because of the fever-related phenomenon, isolation of herpes simplex virus in the throat or mucocutaneous lesions of patients with encephalitis cannot be interpreted as causing the central nervous system disease. Currently the definitive way to establish a diagnosis of herpes simplex encephalitis is by direct demonstration of the virus in a brain biopsy or by polymerase chain reaction (PCR) on CSF. In neonates, however, isolation of the virus from any site should raise the possibility of severe infection.

Isolation of adenoviruses, herpes simplex virus, varicella-zoster virus, and some enteroviruses from the cornea and conjunctiva in patients with inflammatory disease at these sites usually establishes the etiology of the infection.

## **DETECTION OF VIRAL ANTIGENS**

Antibodies can be used as sensitive tools to detect, identify, and quantitate the presence of viral antigen in clinical specimens or cell culture. Monoclonal or polyclonal antibodies prepared in animals may be used. Viral antigens on the cell surface, within the cell, or released from infected cells can be detected by IF, EIA, RIA, and latex agglutination (LA). IF detects and locates cell-associated antigens, whereas RIA or different variations of enzyme-linked immunosorbent assay (ELISA) are used to detect and quantitate soluble antigens. LA is a rapid, easy assay for antigen; viruses or viral antigens in a sample cause the clumping of latex particles coated with specific antibody.

Virus-infected tissue or cell cultures can be detected by IF or EIA. By attaching a fluorescent signal to an antiviral antibody, and reacting it with the sample, viral antigen can be detected; this is called direct IF. A modification of this technique is the use of unlabeled antiviral antibodies and then a second antibody with a fluorescent label that will bind to IgM or IgG antibodies. EIA uses a second antibody conjugated to an enzyme, such as horseradish peroxidase or alkaline phosphatase, which releases a chromophore to mark the presence of antigen.

Direct IF assay is especially useful for (1) respiratory viruses (eg, respiratory syncytial virus or influenza A), (2) varicella-zoster virus and herpes simplex virus antigen in lung and visceral biopsies, and (3) cytomegalovirus in leukocytes from blood or CSF.

Soluble antigen can be quantitated by ELISA, RIA, and LA. The basis for these procedures is the separation and quantitation of antibody-bound and free antigen. Many of the ELISA and RIA techniques use an antibody immobilized to a solid support to capture soluble antigen and a labeled antibody to detect captured antigen.

Influenza, parainfluenza, and togaviruses produce a glycoprotein that binds erythrocytes. This property allows detection of free virus produced in cell culture by agglutination of erythrocytes, a process termed hemagglutination. The infected cells also adsorb erythrocytes to the surface by a process referred to as hemadsorption.

Detection and assay of characteristic enzymes can identify and quantitate specific viruses. For example, reverse transcriptase in cell culture is used as an indicator of infection by retroviruses.

## **SEROLOGIC TEST METHODS**

### **Introduction**

Serology can be used to determine whether an infection is primary or a reinfection and if acute or chronic. The first antibodies to be produced by the immune system are directed against antigens on the virion or infected cell surfaces and are best detected by, eg, IF. Later in the infection, when cells have been lysed by the infecting virus or the cellular immune response, antibodies are directed against the cytoplasmic viral proteins and enzymes and can be detected by, eg, complement fixation. Seroconversion is characterized by a change from negative to positive antibody between serum taken during the acute phase of disease and that taken = 2-3 weeks later; it is the best serologic marker of recent infection. A fourfold or greater rise in antibody titer in paired sera may also be significant but fluctuations in antibody titer do occur naturally. Detection of virus-specific IgM is theoretically associated with recent infection, but technical difficulty in measuring specific IgM responses may lead to false-positive and false-negative results.

For many viruses, culture or antigen detection is the best diagnostic test. However, certain viruses (eg, HIV, hepatitis A and B viruses, rubella virus, Epstein-Barr virus, measles virus, coronaviruses, and togaviruses) are difficult to isolate in cell culture, and infections are diagnosed most easily by serologic techniques. When a virologic workup is planned for a patient, it is generally useful to obtain = 2-3 ml of serum during the acute phase of disease and store it at -20°C. This may become valuable, particularly if virus detection subsequently fails or if the significance of an isolate is uncertain. In these instances a convalescent-phase serum specimen may be requested 2-3 weeks later, and both the acute and convalescent sera may then be tested against appropriate viral antigens. In general, if a virus is isolated, the antibody titers need not be measured to confirm infection; for example, if a patient has aseptic meningitis and an enterovirus is recovered from the throat, that agent is probably responsible for the illness. Similarly, if influenza virus is recovered from the throat of a patient who has clinical influenza, no serologic confirmation of the etiology is necessary.

Complement fixation is a standard but technically difficult serologic test. The serum is first reacted with the suspected viral antigen and complement, and the residual complement is assayed by lysis of indicator antibody-coated erythrocytes. If the complement is used in the first reaction and is therefore not available for the second reaction, it indicates the presence of antibody to the suspected virus. Antibodies measured by this system generally develop slightly later in the course of an illness than those measured by other techniques. This delayed response is useful for documenting seroconversion when the initial serum specimen is collected late in the clinical course. Members of some virus groups (eg, enteroviruses) do not possess group-specific antigen and must be tested individually.

The neutralization test is essentially a protection test. When a virus is incubated with homologous type-specific antibody, the virus is rendered incapable of producing infection in an indicator cell culture system. A neutralization antibody response is virus type specific, with titers rising rapidly and persisting for long periods.

The hemagglutination inhibition test can be performed with a variety of viruses that can selectively agglutinate erythrocytes of various animal species (eg, chicken, guinea pig, or human). The hemagglutination capacity of a virus is inhibited by specific immune or convalescent sera. Hemagglutination-inhibiting antibody develops rapidly after the onset of symptoms, plateaus, declines slowly, and may last indefinitely at low levels. This test is useful for both the detection of acute viral infection and the determination of immunity.

For the indirect fluorescent antibody test, virus-infected cells are placed in prepared wells on microscope slides and then fixed in cold acetone and dried. Patient serum is applied and, after incubation, anti-human globulin conjugated with fluorescein is added. If fluorescence is observed, it indicates the presence of specific antiviral antibody.

### **Interpretation of Serologic Results**

Virus-specific IgM antibody usually rises during the first 2-3 weeks of infection and persists for several weeks to months. Thus an elevated titer of specific IgM antibody suggests a recent primary infection, which may be further supported by demonstrating a fall in IgM antibody in subsequent sera. Detection of specific IgM has been used with success in the diagnosis of infections caused by cytomegalovirus and rubella virus and is currently the procedure of choice to establish a recent or acute infection from hepatitis A or B.

Several limitations of interpretation must be remembered. It is now recognized that IgM-specific antibody responses are not always restricted to primary infections. Reactivation or reinfection may result in IgM responses, particularly in herpes virus infection. In addition, patients may continue to produce IgM-specific antibody to rubella virus or cytomegalovirus for many months after a primary infection. Heterotypic IgM responses may also occur. For example, antibody responses to cytomegalovirus may develop in Epstein-Barr virus infections and vice versa. Other pitfalls include falsely low or negative IgM titers caused by competition from high-titer IgG antibody for antigen-binding sites and false-positive reactions resulting from rheumatoid factor. Both types of errors appear to occur most frequently in solid-phase assays with IF.

The serologic diagnosis of most viral infections is based on demonstration of a seroconversion or a rise (fourfold or greater) of IgG antibody. However, significant antibody titer rises may result from cross-reactions to related antigens; for example, an antibody rise to parainfluenza virus may actually result from infection with mumps virus. Furthermore, seroconversions may not be seen with some patient populations (eg, infants and immunocompromised patients) or when the initial serum is collected late in the course of disease.

A serum specimen can also be used for screening an infant's blood for certain antibodies of the IgG class. Antibodies to *Toxoplasma* spp., rubella virus, cytomegalovirus, and herpes simplex virus (known as the "TORCH" screen) may be

measured to determine possible congenital infection with these agents. However, the value of these tests must be understood. They are useful in excluding a possible infection but not in proving an etiology. For example, if rubella antibody is absent, an infant almost certainly does not have congenital rubella infection. To diagnose active rubella infection in such a baby, viral cultures are required. Screening of blood supplies for cytomegalovirus antibody is used to eliminate transmission of antibody-positive blood to seronegative babies and other immunocompromised patients.

## **Serologic Panels**

Selection of several antigens for testing with paired sera in cases in which a virus is suspected can usually be made based on clinical syndrome, the known local epidemiology of particular viruses, and the patient's age. This has led to the concept of serologic batteries or panels. Some examples of possible panels are included in [Table 6-10](#).

Antigens from mumps, western equine encephalitis, eastern equine encephalitis, St. Louis encephalitis, and California encephalitis viruses—and perhaps lymphocytic choriomeningitis virus, Epstein-Barr virus, and HIV—may be included in a panel of tests for central nervous system diseases. Although herpes simplex antigen is sometimes included in such a panel, a rise in antibody titer is not sufficient to diagnose herpes encephalitis. Many viral central nervous system illnesses, especially aseptic meningitis, are caused by the enteroviruses; however, the many serotypes and the cumbersome serologic methods necessary for their diagnosis usually make it impractical to include them in a panel. When one or two enteroviruses have been shown to be epidemic in an area in one summer, one can pick up some additional cases by performing neutralization tests on paired sera by using only those specific enteroviruses that are endemic in the community.

The viral antigen panel for testing respiratory syndromes might include influenza A and B; respiratory syncytial virus; parainfluenza types 1, 2, and 3; and adenoviruses.

To test for viral causes of exanthems, the panel would include measles and rubella. If the disease is vesicular, herpes simplex virus and varicella-zoster virus should be included, although the herpes viruses are best diagnosed by culture or antigen detection.

Antigens from group B coxsackie virus types 1-5 and perhaps influenza A and B viruses could make up the panel for myocarditis and pericarditis. Although numerous viruses have been implicated in inflammatory diseases of the heart and its covering membranes, the group B coxsackieviruses are believed to account for almost one half of the cases. Unfortunately, much of the clinical illness is expressed late in the infection, at the time when standard methods of virus detection are likely to fail and it is too late to demonstrate seroconversion or significant antibody titer rises.

## **MOLECULAR TEST METHODS**

In recent years a variety of assays have been developed to detect viral nucleic acid—either DNA or RNA. The best known of these is PCR, an amplification technique

that allows the detection and selective replication of a targeted portion of the genome. The technique uses special DNA polymerases that initiate replication in either the 3' or 5' direction. The specificity is provided by primers that recognize a pair of unique sites on the genome so that the DNA between them can be replicated by repetitive cycling of the test conditions. Because each newly synthesized fragment can serve as the template for its own replication, the amount of DNA doubles with each cycle. The amplification power of PCR offers a solution for the sensitivity problems inherent in the direct application of probes. Although the nucleic acid segment amplified by PCR can be seen directly on a gel, the greatest sensitivity and specificity are achieved when probe hybridization is carried out after PCR. A probe is a fragment of DNA that has been cloned or otherwise recovered from a genomic or plasmid source. In some cases the probe is synthesized as a single chain of nucleotides (oligonucleotide probe) from known sequence data. The probes are labeled with a radioisotope or other marker and used in hybridization reactions either to detect the homologous sequences in unknown specimens or in gel electrophoresis.

The diagnostic use of DNA probes is to detect or identify microorganisms by hybridization of the probe to homologous sequences in DNA extracted from the entire organism. A number of probes have been developed that will quickly and reliably identify organisms that have already been isolated in culture. The application of probes for detection of infectious agents directly in clinical specimens such as blood, urine and sputum is more difficult.

Recently, the branched DNA (bDNA) a rapid assay for direct quantification of viral nucleic acid has been developed for hepatitis B, hepatitis C, and HIV infections. Because the bDNA assay measures viral nucleic acids at physiological levels by boosting the reporter signal, rather than by amplifying target sequences, it is not subject to the errors inherent in the amplification steps of PCR-based methods. Inherently quantitative and amenable to routine use in a clinical setting, the bDNA assay may be useful in the management of patients with chronic viral diseases. Recent studies have illustrated the potential clinical utility of the bDNA assay in determining the prognosis and in therapeutic monitoring of infection. Additional nucleic acid tests include hybrid capture and nucleic acid sequence-based amplification.

TABLES

Table 6-3. Serologic methods currently available for detecting antibodies to bacterial, fungal, or parasitic pathogens

---

**Table 6-4.** Selected specimen considerations for bacterial, fungal, and parasitic agents.

<b>Specimen Source</b>	<b>Considerations</b>
Throat, nasopharyngeal, nasal secretions	Nasopharyngeal aspirates are superior to swabs for culturing <i>Bordetella pertussis</i> ; swabs are adequate for the detection of <i>S pyogenes</i> ; nasal swabs are recommended for detecting carriers of methicillin-resistant <i>Staphylococcus aureus</i> .
Respiratory secretions	Sputa may be induced with nebulized saline in patients who cannot spontaneously produce sputa; spontaneously produced specimens should be screened by microscopy for suitability for bacterial culture.
Eye	Secretions are obtained by swab from the palpebral conjunctiva; NOTE eye scrapings should be obtained by an ophthalmologist or other trained person and plated directly at bedside if possible.
Blood	For adults, 20-30 ml of blood are collected per phlebotomy (ie, one set blood cultures), and 10 ml are placed in each blood culture receptacle; least one 10-ml aliquot should be cultured anaerobically; three blood culture sets collected over a 24-h period are adequate for diagnosing ~99% of bacteremias; peripheral blood smears and malaria thick and thin smears should be performed at the bedside.
Sterile body fluids other than blood and urine	Disinfect site if collection obtained percutaneously by aspiration; sterile fluids (pleural, peritoneal, pericardial, and joint) are best transported to the laboratory in an anaerobic transport system; some studies have demonstrated the utility of blood culture media for recovery of organisms from these sources.
Abscess	Tissue or fluid is superior to a swab specimen; swabs are especially inadequate for anaerobic bacterial culture; use an anaerobic transport system for sending specimen to the laboratory.
Tissue	A Stomacher may be useful to homogenize the samples for culture.
Urine	A spontaneously voided midstream urine sample is collected after proper cleansing of the genitalia; catheterized specimens or suprapubic specimens may be preferred in some instances where midstream collection is not possible or is impractical.
Rectal swabs and stool specimens	Rectal swabs may be used to survey patients for vancomycin-resistant enterococci; spontaneously passed stool samples are preferred for bacterial cultures; spontaneously passed or purged stool samples may be used for ova and parasite (O&P) examinations; a series of three specimens collected on separate days is recommended for O&P examination; collection kits with stool preservatives are required for O&P evaluation if there is significant delay between the time the stool is passed and the time it is evaluated in the laboratory; however, freshly passed specimens are mandatory for the recovery of motile trophozoites; pinworm exams may be performed with an adhesive (scotch tape or a paddle kit) that is applied to the perianal area.

    - Section I. Basic Principles
      - 6 . Laboratory Diagnosis — *W. Lawrence Drew, MD, PhD, Franklin R. Cockerill, III, MD, & Nancy K. Henry, PhD, MD*
- TABLES
- Table 6-7. Appropriate specimens for viral isolation.
-

**Table 6-8.** Specimen collection considerations for viral agents.

<b>Specimen Source</b>	<b>Considerations<sup>1</sup></b>
Throat, nasopharyngeal swab and aspirate	Nasopharyngeal aspirates are superior to swabs; throat swabs are probably adequate for enteroviruses, adenoviruses, and HSV; nasopharyngeal specimens are preferred for respiratory syncytial virus and most other respiratory viruses; nasal specimens are best choice for rhinoviruses.
Rectal swabs and stool specimens	In suspected enteroviral disease (aseptic meningitis, myopericarditis, hand-foot-and-mouth disease), positive cultures from rectal cultures support but do not prove that enteroviruses are cause of disease; stool specimens are more productive than rectal swabs; fecal specimens from patients with viral gastroenteritis show nonculturable agents such as rotaviruses or adenoviruses.
Urine	Used for CMV, mumps, and adenoviruses; in mumps-related central nervous system disease, virus can be isolated from urine even when specimens from other sites are negative.
Dermal lesions	Fluid and cells from vesicles are superior to specimens from ulcers or crusts for both cultures and antigen stains.
Cerebrospinal fluid (and other sterile fluids)	Can be inoculated directly into tissue culture.
Eye	Secretions are obtained by swab from the palpebral conjunctiva; NOTE: eye scrapings should be obtained by an ophthalmologist or other trained person.
Blood serum for HBgAg	Leukocytes are collected by centrifugation to obtain buffy coat layer or by Ficoll- Hypaque separation; anticoagulated blood or a clot can be used for isolation of arboviruses; Plasma for HIV, HCV, HBV by PCR bDNA.
Tissue	Lung intestine, liver is used for CMV, influenza virus, and adenoviruses; brain is used for HSV.

<sup>1</sup>HSV, Herpes simplex virus; CMV, cytomegalovirus.

**Table 6-9.** Summary of procedures for obtaining and transporting specimens for viral studies.

<b>Specimen</b>	<b>Procedures</b>
General	Obtain specimens as early in the patients <sup>1</sup> illness as possible; inoculate tissue cultures at patient's bedside if possible.
Throat	Use swabs in transport medium.
Nasopharynx	Obtain a nasopharyngeal swab in transport medium or a nasal wash specimen with a bulb syringe and buffered saline.
Stool	Obtain as for bacteriologic culture; if a specimen cannot be passed a rectal swab of feces may be obtained.
Cerebrospinal fluid	Obtain 1 ml as for bacteriologic culture.
Urine	Obtain as for bacteriologic culture.
Skin or mucosal scraping	Obtain with swab in transport medium.
Biopsy material	Use sterile technique and submit in a sterile container (urine culture container).
Blood for culture	Submit =3 ml of heparinized blood.
Blood for serologic studies	Submit at least 5 ml of clotted whole blood (red-top vacutainer tube); in certain viral syndromes (lower respiratory) an acute-phase specimen should be submitted; if a virus is not isolated, a convalescent specimen should be obtained =7 days after the acute specimen; certain viral illnesses (rubella, rubeola, hepatitis, arbovirus, and encephalitis) are diagnosed most readily by serologic studies.
Transportation	Transport specimens as rapidly as possible, using a messenger service; specimens should be stored and transported at refrigerated temperature (4°C); do not freeze.

## Section II. Clinical Syndromes

### 7 . Infections of the Central Nervous System — Zell A. McGee, MD\*

#### INTRODUCTION

\*The author is grateful to J. Richard Baringer, MD, Professor of Neurology, University of Utah School of Medicine, for his careful review of this chapter, his constructive suggestions, and the several sections he wrote on subjects that represent special areas of his expertise.

The signs and symptoms of infections of the central nervous system (CNS) are not specific to each type of infection (eg, brain abscess or meningitis), but certain clusters of signs and symptoms can limit the range of CNS infectious diseases that must be considered. The following elements of a patient's history, signs, and symptoms may indicate or accompany meningeal or parenchymal CNS infections, especially if one or more occur in the same patient: fever; headache; nausea and vomiting; confusion, obtundation, or uncharacteristic behavior; stiff neck; or focal neurologic dysfunction.

When these signs and symptoms follow those of infection of the upper or lower respiratory tract, the cluster suggests the transition of the respiratory tract infection to bacteremia or viremia and then its progression to meningitis or another type of CNS infection.

#### ACUTE BACTERIAL MENINGITIS

##### General Considerations

More than most other infectious diseases, acute bacterial meningitis threatens the life, personality, and functional ability of a patient. The disease may be obvious or quite subtle in its initial presentation. Empiric therapy usually relies on a one-step (or monosynaptic) thought process (disease ? antimicrobial agent) that is not optimal for managing most infectious diseases. Optimal recognition and management of acute bacterial meningitis use a progressive, three-step (or polysynaptic) thought process that is also effective for managing most other infectious diseases ([Table 7-1](#)).

##### 1. DISEASE (DIAGNOSIS)

The key findings in meningitis are the presence of fever, headache, stiff neck, nausea and vomiting, and, often, variable states of confusion. Note that neck stiffness, although usually present, is often overlooked. Although a stiff neck is *not* required to make the diagnosis of meningitis, its presence demands immediate pursuit of the diagnosis of meningitis.

Perhaps the most helpful indication that the diagnosis of meningitis should be considered seriously enough to warrant the performance of a spinal tap (if a thorough

examination yields no signs of an intracranial mass or increased intracranial pressure) is the transition of a sore throat or other upper respiratory tract irritation to nausea and vomiting. Whereas most patients who actually have meningitis have fever and headache, the pattern of evolution of meningitis, especially meningococcal meningitis, is from sore throat to tachypnea (perhaps a sign of early meningococemia with disseminated intravascular coagulation) and then to nausea and vomiting as the meningococemia seeds the cerebrospinal fluid (CSF) space and establishes meningitis with cerebral edema.

The constellation of headache, fever, nausea, vomiting, or a combination of these symptoms should immediately prompt the consideration of meningitis, especially in the context of previous disease or irritation of the upper respiratory tract (eg, sinusitis, otitis media, or pharyngitis). Often patients with meningitis will complain of ocular pain or an increase in headache when turning their eyes from side to side. Although this sign is not specific for meningitis, its presence should prompt suspicion of the disease.

Although the accuracy of the clinical examination in the diagnosis of meningitis is limited by the paucity of prospective data, Attia et al (1999) have evaluated the clinical findings in meningitis and cite the 97% sensitivity and 60% specificity of the jolt test of Uchiyama and Tsukagoshi (1991) in diagnosing meningitis. The jolt test, accentuation of headache by rapid movement of the head from side to side, appears to have potential usefulness, but more widespread systematic evaluation is needed before incorporation of the test into routine practice can be recommended.

In a febrile patient with a history of previous upper respiratory tract irritation, vomiting should elicit concern about meningitis rather than being considered a sign of gastroenteritis or "the flu."

Note that almost all patients with bacterial meningitis give a history of upper respiratory tract irritation that can be interpreted as pharyngitis. However, health care personnel should consider the context of such complaints, and, if there is fever  $> 101^{\circ}\text{F}$ , nausea or vomiting, headache, confusion, or any signs of neurologic irritation, meningitis should be strongly suspected. The author has seen patients who suffered permanent neurologic damage because their meningitis was not recognized and health care personnel, using an algorithm for pharyngitis, gave oral antimicrobial therapy, which is inappropriate for meningitis.

Although patients often do not complain spontaneously of neck stiffness, they frequently will admit to the symptom if questioned. Detecting neck stiffness is best done by cupping the patient's occiput in the examiner's hands, gently turning the head from side to side, which usually causes little discomfort, and then gently flexing the neck while observing the patient's face for signs of pain and feeling for sudden resistance as the neck is flexed. Modest degrees of meningeal irritation are usually evident with this procedure. Whereas the traditional Kernig and Brudzinski signs may be present in acute meningitis, in the author's experience they are present much less often than is neck stiffness and are less sensitive in the detection of minor degrees of meningeal irritation than is testing for neck stiffness as described above.

Once the diagnosis of meningitis has been seriously considered and care has been

taken to assure that there are no signs of an intracranial mass (eg, no papilledema or focal neurologic abnormalities), a lumbar puncture should be performed.

## 2. PREDICTION OF THE MOST LIKELY CAUSATIVE ORGANISM

### Introduction

Acute meningitis is most often caused by bacteria that have capsules (eg, *Neisseria meningitidis*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*). These organisms are passed from person to person by droplet spread or mucosa-to-mucosa spread during close contact. Although some yeasts (eg, *Cryptococcus neoformans*) cause acute meningitis in patients with ostensibly normal immunity, they cause meningitis more often in patients whose cell-mediated immunity is compromised (eg, by lymphoma, AIDS, steroids, or other forms of iatrogenic immunosuppression), and yeast infections must be sought in such patients.

Empiric therapy entailing the choice of broad-spectrum antibiotics instead of organism-specific therapy is suboptimal for acute meningitis, because such therapy is at danger of being less active and less effective than therapy specifically targeted for the most likely organism. Therefore, optimal therapy entails predicting the most likely organism to be causing the meningitis and then administering the therapy that is optimal for that organism. Usually one can correctly deduce the most likely organism to be causing the meningitis by considering four kinds of information regarding the patient: (1) personal risk factors, (2) community risk factors, (3) physical examination, and (4) laboratory and imaging studies (see [Tables 7-1](#), [7-2](#), [7-3](#), and [7-4](#)).

### Personal Risk Factors

The bacterial pathogen most likely to cause meningitis varies with the site of acquisition and the age of the patient ([Table 7-2](#)). Patients who are asplenic or alcoholic or who have preexisting ear or paranasal sinus infections are at greater risk of having infections with *S pneumoniae*.

Among patients who have conditions that allow access of stool to CSF, for instance, a pilonidal sinus or *Strongyloides stercoralis* infestation, *Escherichia coli* is often the most likely organism to be causing their meningitis.

In some cases, the most likely organism may be predicted by the nature of prior antimicrobial therapy. Certain broad-spectrum, oral antimicrobial agents such as ciprofloxacin or cefixime may predispose a patient to bacterial meningitis, apparently by eradicating normal nasopharyngeal flora and allowing overgrowth of meningitis-causing bacteria, especially *S pneumoniae*, which is less susceptible to these antibiotics than are normal flora. A substantial number of patients have developed fatal pneumococcal sepsis and meningitis while being treated with such antibiotics (Lee et al, 1991; Ottolini et al, 1991). Ironically, most of the antibiotics were prescribed for upper respiratory tract infections, bronchitis, and otitis media, which may not benefit from antimicrobial therapy (Gonzales et al, 1997; Nyquist et al, 1998).

The microorganism causing the antecedent respiratory tract or other type of infection is

the likely cause of meningitis in many patients. Patients with enteroviral meningitis have sometimes had recent contact with children or others with diarrhea. A recent episode of genital herpes should prompt consideration of a herpetic etiology of the meningitis.

### **Community Risk Factors**

Cases of meningococcal disease may occur in epidemics or clusters, and state or local health departments may be helpful in predicting the most likely organism from such epidemiologic data.

Similarly, clusters of meningitis caused by *Listeria monocytogenes* have occurred in conjunction with the ingestion of raw and cooked meat, poultry, and, especially, unpasteurized dairy products such as cheese that have entered the commercial food supply contaminated with *L monocytogenes*.

### **Physical Examination**

Several physical signs, considered in light of the patient's age, can be extremely helpful in correctly predicting the infecting organism ([Table 7-3](#)). If there are no physical signs suggesting the most likely organism, the organism can be predicted on the basis of the locale of acquisition of the meningitis and the patient's age as described above (see [Table 7-2](#)).

### **Laboratory/Imaging Studies**

The laboratory findings in the CSF can also be helpful in either predicting or determining with certainty the most likely organism or type of organism to be causing the meningitis ([Table 7-4](#)).

Chest x-rays showing pneumonia in conjunction with meningitis suggest that the cause of the pneumonia may be the same as that of the meningitis; this association has been observed with *N meningitidis* and *S pneumoniae* infections. If the pneumonia in conjunction with meningitis is cavitory, organisms that cause cavitory pneumonia such as *Staphylococcus aureus* or *Pseudomonas aeruginosa* should be suspected.

## **3. DESIGN OF OPTIMAL THERAPY FOR THE PARTICULAR PATIENT**

### **Introduction**

It is important to initiate therapy as promptly as possible. In general, it is preferable to begin therapy after CSF and blood cultures have been obtained, but before the results of the laboratory examinations are available. Therefore, the hypothesis about the most likely organism should be used to initiate therapy, then the hypothesis should be tested by examining the CSF with nonspecific tests such as the leukocyte count and differential and CSF protein and glucose concentrations, all of which can be helpful in indicating groups of causative agents (see [Table 7-4](#)). A more sensitive and specific identification of the most likely organism often can then be obtained by performing a Gram stain on CSF subjected to cytopspin slide centrifugation and culture and, if the Gram stain is negative, also testing the CSF for evidence of cryptococcal antigen and tuberculous

infection, using polymerase chain reaction (PCR) or culture. Microscopic detection of the organism causing meningitis is more effective if the CSF is first subjected to cytospin slide centrifugation, which substantially increases the sensitivity of the Gram-staining endeavor (Shanholtzer et al, 1982). Rapid bacterial antigen tests were once used to attempt identification of the causative microorganism if prior antimicrobial therapy made it undetectable. However, bacterial antigen tests were found to be of "no detectable clinical benefit" in diagnostic and therapeutic decision-making (Perkins et al, 1995), and many laboratories no longer perform these tests.

If pneumococcal meningitis is likely (see [Table 7-2](#)), a premium should be put on culturing the organism from blood or CSF so that knowledge of its penicillin susceptibility can help facilitate design of an optimal treatment regimen. If specific tests such as PCR analysis of the CSF point to an organism different from the one originally hypothesized, the therapy can be changed to another specific therapy (such a change will seldom be necessary).

Whereas the foregoing considerations represent the optimal approach to acute bacterial meningitis, one must remember that tuberculous, cryptococcal, and occasionally coccidioidal meningitis also may have an acute onset and may produce clinical findings indistinguishable from those in acute bacterial meningitis.

## **Differential Diagnosis**

Note that vomiting, although a common symptom of gastrointestinal disease, occurs frequently in meningitis. Meningitis is likely to be much more threatening to the life and function of the individual than is gastrointestinal disease, so one should not assume that vomiting in the febrile patient represents gastroenteritis.

A patient with meningococcal sepsis may have a normal or low total peripheral leukocyte count, but there is often an increased proportion of "bands" or immature polymorphonuclear leukocytes in the peripheral blood. In patients who have such laboratory findings in conjunction with other signs or symptoms of sepsis, strongly consider initiating parenteral therapy for sepsis, using antimicrobial agents appropriate for the most likely causative microorganism.

Syphilitic meningitis develops more often during the secondary or tertiary stages of the disease, generally at a slower pace than meningitis caused by other microorganisms, and presents with seizures in ~ 18% of patients with this disease. Thus, in patients with signs and symptoms suggestive of meningitis, especially seizures, syphilitic meningitis should be considered as part of the differential diagnosis, and appropriate serologic tests for syphilis should be performed on the serum and CSF.

## **Cautions Prior to Lumbar Puncture**

It is very important to establish whether the patient with signs and symptoms of acute meningitis has papilledema, which is rare in acute meningitis without complications such as a mass lesion. A thorough examination should also be performed to detect any lateralizing findings (eg, hemiparesis or homonymous field defect) or localizing findings (eg, aphasia), which might suggest the presence of some other process such as a brain

abscess, subdural empyema, or cerebral infarction with mass effect. The presence of papilledema, localizing signs, or lateralizing signs mandates an imaging study before the performance of a lumbar puncture. A lumbar puncture performed in the presence of a mass lesion, particularly one that displaces intracranial structures, can result in a herniation syndrome and possibly death. However, antimicrobial therapy for the meningitis should be initiated before the patient is sent for the imaging study, as noted below.

In many emergency rooms, it is common practice to obtain a computed tomography (CT) scan for patients who have signs and symptoms suggestive of meningitis, before a diagnostic lumbar puncture is performed or antimicrobial therapy is instituted. Most authorities agree that any delay involved in obtaining such imaging studies could result in a significant hazard to the patient with meningitis if antibiotic treatment has not already been instituted. Bacteria multiply rapidly in the sheltered environment of the subarachnoid space, and the delays that are commonly encountered in obtaining imaging studies create a significant additional hazard to the patient. Therefore, if imaging studies are indicated (see previous paragraph), the patient should be stabilized, and optimal parenteral antibiotic therapy should be begun before such imaging studies are obtained. However, Baker et al (1994), after a systematic study of the efficacy of routine head CT scans prior to lumbar puncture in the emergency department concluded, "Routine use of CT scans in the absence of localizing signs prior to lumbar puncture in the emergency department is not indicated."

In some instances it may be necessary to perform a lumbar puncture without CT or magnetic resonance imaging (MRI) to establish the diagnosis of meningitis in order to permit initiation of prompt, optimal, specific antibiotic treatment. For instance, if a patient with signs of meningitis (but with no suggestion of papilledema or lateralizing or focal neurological deficits) is cared for in a setting where imaging studies are not available, eg, a rural office or clinic, it may be necessary to perform a lumbar puncture to establish the diagnosis of meningitis and institute optimal parenteral therapy. In such a situation, if the patient is to be transferred to a tertiary facility, the parenteral antimicrobial therapy should be continued and part of the CSF, as well as blood cultures obtained before therapy, should be transported with the patient. In addition, in the midst of a community-wide epidemic of meningococcal meningitis or when the patient has signs of meningococcal sepsis (eg, petechiae or purpura fulminans) with meningitis, it is probably safe to do a lumbar puncture without antecedent CT or MRI imaging if there are no signs of an intracranial mass.

Once treatment of meningitis has commenced and the patient has been stabilized, it is the practice of some experts to image the brain at some time during the course of therapy because of the frequency of associated pathologic processes. These associated processes include paranasal or mastoid sinusitis, subdural empyemas or effusions, basilar skull fractures, intracerebral abscesses or infarctions, and hydrocephalus, many of which may require neurosurgical intervention. Other experts reserve CT or MRI scans for patients with signs of a mass lesion, patients who remain febrile for > 5 days after initiation of optimal antimicrobial therapy, patients who have altered consciousness, or patients who were initially infected with bacteria such as *S pneumoniae* that are especially likely to cause sinusitis or loculated pus that requires drainage.

Optimally, for the diagnosis and therapy of most patients with known or suspected meningitis, the steps in [Table 7-5](#) should be taken, but, if the presence of even questionable findings of papilledema, lateralizing signs, or localizing signs raises concerns over a possible mass lesion, or, if there is worsening headache or a diminishing level of consciousness, imaging studies should be considered as follows:

**A. Immediately Available CT Scan.** If a CT scan can immediately be performed, obtain a CT scan and proceed to a lumbar puncture if no mass lesion is present, and follow the remainder of the steps in [Table 7-5](#).

**B. CT Not Readily Available.** If a CT scan is not readily available or a significant delay is anticipated, most experts recommend that blood cultures be obtained immediately and antibiotic treatment optimal for the most likely organism (see [Tables 7-2](#) and [7-3](#)) be instituted before the CT or other imaging study and before a lumbar puncture (see Treatment section below). The prior institution of antibiotic therapy will only minimally decrease the diagnostic sensitivity of CSF cultures and may still allow detection and identification of the causative microorganism by stains or PCR. The initial emergency therapy can be changed if findings of stains, cultures, or PCR on the CSF so indicate. A change in therapy will seldom be necessary. Especially in pneumococcal meningitis, with increasing resistance of pneumococci to beta-lactam antibiotics, it is helpful to culture the organism rather than simply detecting it with stains or PCR, because the viable organisms are necessary for determining the penicillin susceptibility of the infecting pneumococcus, which is information that may be important in designing an optimal antipneumococcal antimicrobial regimen.

Patients with known or suspected meningitis should not be sent out on oral antibiotics, but should be admitted to the hospital and treated with parenteral antimicrobial agents that are optimal for the most likely organism.

## Treatment

To put the imperative for speed in initiating therapy into more concrete terms, some experts have suggested a goal of allowing no more than 30 min from the time of clinical diagnosis to starting an IV infusion of the best antibiotic for the most likely organism to be causing the meningitis. A suggested use of the 30 min appears in [Table 7-5](#) and assumes that the above-mentioned precautions and procedures regarding signs of a mass lesion will be observed.

Intravenous antimicrobial agents are the optimal types of therapy for acute bacterial meningitis. Specific, optimal antimicrobial agents for the therapy of acute meningitis that is known or suspected to be caused by particular organisms are reviewed in [Table 7-6](#). The antimicrobial agent chosen should meet a number of criteria, which are listed under "Best Antimicrobial" in [Table 7-1](#). As noted, the antimicrobial agent chosen should avoid the patient's special vulnerabilities. For example, if possible, the patient should not be given an antibiotic to which he or she is allergic; patients with myasthenia gravis, which causes intrinsic neuromuscular blockade, should not be given aminoglycosides, which may induce further neuromuscular blockade; and, if possible, patients with hemolytic anemias such as sickle cell disease should not be given chloramphenicol, which

diminishes erythrocyte production.

## Complications

It may be difficult to separate the complications of the bacteremia and septicemia that are associated with the meningitis from the complications of the meningitis per se. The complications of the septicemia include coagulation disorders such as disseminated intravascular coagulation (manifested in meningococemia as a petechial rash and "purpura fulminans" or in some cases as hemorrhagic adrenal necrosis—"Waterhouse-Friderichsen syndrome"), myocarditis with congestive heart failure, shock, and prolonged fever. The more frequent complications of the meningitis per se result from the inflammatory reaction, including tumor necrosis factor-alpha (TNF- $\alpha$ ) induction, which may cause damage to cranial nerves with resulting ophthalmoplegias, deafness, and blindness. Seizures or hydrocephalus may occur as early or late complications. In meningitis caused by *H influenzae* in children, some of these complications appear to occur less frequently if dexamethasone is administered in conjunction with antimicrobial agents to diminish the production of TNF- $\alpha$  (see [Table 7-6](#)). No comparable information is available for meningitis in adults or for meningitis caused by other bacteria.

## Prognosis

Although the mortality rate for bacterial meningitis varies with the specific etiologic agent and the clinical circumstances, especially the age of the host, with early diagnosis and prompt, targeted (not broad-spectrum) antimicrobial therapy, the mortality rates for meningococcal and *H influenzae* meningitis are generally < 10% and 5%, respectively. Pneumococcal meningitis has a worse prognosis, with mortality rates of ~ 20%; in addition, neurologic complications, such as hydrocephalus, subdural empyema, seizures, and cranial nerve palsies, occur more frequently in meningitis caused by *S pneumoniae*.

## Prevention & Control

A first line of defense against meningitis is the induction of anticapsular antibodies by means of vaccines or natural exposure. Timely administration of *H influenzae* type b (Hib) conjugate vaccine has dramatically reduced the frequency of *H influenzae* meningitis in the United States; however, in some states, less than half of the eligible children have been immunized.

By reducing pneumococcal bacteremia, a pneumococcal vaccine theoretically should decrease the frequency of pneumococcal meningitis, and the limited immunogenicity of some of the pneumococcal serotype polysaccharides in children < 2 years old has recently been circumvented by conjugating the polysaccharides to a diphtheria protein. The resulting, currently available, 7-valent pneumococcal vaccine has been shown to prevent pneumococcal carriage and invasive pneumococcal infections, including meningitis, in children < 2 years old.

A 23-valent pneumococcal vaccine is recommended for all patients aged  $\geq$  65 and for nursing home residents, as well as for immunocompromised and other high-risk

patients. Anatomic or functional asplenia is an absolute indication for the vaccine, and the vaccine should be given, if possible, at least 2 weeks before splenectomy. The vaccine is also recommended 2 weeks before beginning any immunosuppressive treatment.

The conjugate pneumococcal vaccine is indicated for the active immunization of infants and toddlers against invasive disease caused by pneumococci of the capsular types represented in the vaccine. The routine schedule is vaccination at 2, 4, 6, and 12-15 months of age. This vaccine is not for use in adults.

A quadrivalent meningococcal vaccine (including groups A, C, Y, and W135) is available. If there is an epidemic or cluster of cases in a closed population, such as that of a college campus or group home, or for individuals traveling to countries where meningococcal disease is epidemic, the use of the meningococcal vaccine should be considered. The quadrivalent vaccine is recommended for use in epidemics of meningococcal disease caused by strains of any group whose capsular type is represented in the vaccine. Help in determining the need for a vaccine administration program and in planning such a program should be sought from the appropriate state health department or from the Centers for Disease Control [telephone (404) 639-2215].

### **Protection of Contacts in Cases of Meningitis**

**A. Meningococcal Meningitis.** Individuals who have had prolonged close contact with a meningococcal meningitis patient, especially those who have had mucosa-to-mucosa contact with such a patient, are at risk of becoming newly colonized with meningococci either from the patient or from the same source as the patient. It is newly colonized individuals, lacking serum anti-meningococcal antibodies, that are at greatest risk of developing meningococemia or meningitis. The purpose of chemoprophylaxis is to eradicate the newly acquired meningococci and their progeny before they cross the nasopharyngeal epithelium and enter the bloodstream.

The physician managing a patient with meningococcal meningitis should notify local public health authorities about the case and work out a strategy for announcing promptly and proactively who does need and who does not need chemoprophylaxis.

Meningococcal vaccine should not be used instead of rifampin chemoprophylaxis for individuals at risk, because the response to meningococcal vaccine is not rapid enough to meet the immediate need of protecting the contacts of patients with meningococcal meningitis. Such at-risk individuals should be given chemoprophylaxis with rifampin.

Chemoprophylaxis should be given to close contacts of the patient (eg, family members, girlfriends or boyfriends, or others who may have had direct contact with the index patient's oral secretions). Chemoprophylaxis is not recommended for casual contacts, such as individuals with no history of direct exposure to the index patient's oral secretions (eg, school- or workmates). Those medical personnel who have had mucosa-to-mucosa contact with victims of meningococcal disease (eg, through mouth-to-mouth resuscitation, intubation, or suctioning before antibiotic therapy is begun) appear to be at risk and should receive chemoprophylaxis. Other medical personnel appear to be at minimal risk, but most experts would offer them

chemoprophylaxis if they were exposed to a case.

The chemoprophylaxis regimens for protecting individuals exposed to a case of invasive disease caused by *N meningitidis* or Hib are the same as those used to eradicate the carrier state of the index patient prior to discharge from the hospital (see boldfaced text under the respective organisms in [Table 7-6](#)). The rifampin powder in the proper dosage can be made into a liquid formulation or incorporated into other vehicles such as applesauce for young children.

**B. *H influenzae* Meningitis.** The recommendation for chemoprophylaxis for contacts of cases of Hib meningitis is as follows: "In those households with at least one contact younger than 48 months whose immunization status against Hib is incomplete, rifampin prophylaxis is recommended for all household contacts, irrespective of age" (*1997 Red Book*, p. 223). See [Table 7-6](#) for the recommended rifampin prophylaxis for protection of individuals exposed to a case of invasive Hib disease.

Because penicillins and some cephalosporins—antimicrobial agents often used to treat meningococcal or *H influenzae* meningitis—do not penetrate human cells well, meningococci and *H influenzae* organisms may remain safely inside cells of the nasopharyngeal mucosa of a patient cured of meningitis and emerge later to cause meningitis in the patient's siblings. Therefore, depending on the type of therapy of a patient with meningitis, the patient may need to be given chemoprophylaxis-like antimicrobial therapy to eradicate his or her carrier state before discharge. Such predischarge therapy is recommended for patients with either meningococcal or *H influenzae* meningitis and, for children older than 1 month, should consist of rifampin given essentially as indicated for chemoprophylaxis of contacts and detailed in [Table 7-6](#). Some experts do not give such therapy if the cephalosporin used for treatment of the meningitis was cefotaxime or ceftriaxone, either of which appears to eradicate nasopharyngeal foci.

## ASEPTIC MENINGITIS SYNDROME

### Essentials of Diagnosis

- Signs and symptoms suggestive of the aseptic meningitis syndrome include fever, headache, nausea, and vomiting.
- CSF pleocytosis is present.
- Gram's stains as well as routine bacterial and fungal cultures are negative.

Some patients who present with the signs and symptoms of meningitis have CSF pleocytosis, but they also have negative Gram stains and routine bacterial cultures of the CSF, and they have no other evidence (such as positive blood cultures) to indicate the etiology of the meningeal inflammation. In considering the management of such patients, it is helpful to designate them as having the aseptic meningitis syndrome rather than "viral meningitis" because some of these patients have proven to have infectious processes that require antimicrobial therapy ([Table 7-7](#)), which is not indicated for most cases of viral meningitis.

Diagnosis and management of the aseptic meningitis syndrome and optimal care of the patient is made more difficult if a patient with the aseptic meningitis syndrome is casually diagnosed as having viral meningitis, with a resulting cessation of attempts to make an etiologic diagnosis or to determine the cause of the meningeal inflammation.

## General Considerations

Although viral infection is the most frequent cause of aseptic meningitis syndrome, there are many antimicrobial-requiring causes of the syndrome (see [Table 7-7](#)).

Arthropod-borne viruses (arboviruses) cause disease more often in late summer and early fall; enterovirus disease follows a similar seasonal pattern, with echoviruses and coxsackieviruses predominating. Mumps virus meningitis occurs more often in late winter and early spring. Meningitis due to herpes simplex virus may occur at any time, often in association with a first episode of genital herpes infection.

## Clinical Findings

In general, patients with aseptic meningitis syndrome are alert and complain of severe headache, primarily when they turn their eyes to one side or the other or flex their necks. They often seek a dark, quiet room. They rarely become confused or obtunded; so, if confusion or obtundation is evident, bacterial meningitis becomes much more likely. Nevertheless, patients in the early stages of bacterial meningitis can look exactly like those with the aseptic meningitis syndrome.

To determine the cause of the aseptic meningitis syndrome in a particular patient, it is helpful to consider three characteristics of the patient's illness: (1) the pace of development of the illness, (2) the presence or absence of focal or lateralizing neurologic findings, and (3) the presence or absence of confusion.

**1. The Pace of Development of the Illness**—Depending on the underlying disease and the specific causative microorganism, the development of signs and symptoms of meningeal inflammation may be relatively slow (taking weeks to months) or rather rapid (taking hours to days). Tuberculous and fungal meningitis, as well as syphilitic meningitis and meningeal inflammation caused by bacterial endocarditis, generally develop at a slower pace, whereas pyogenic bacterial meningitis and viral meningitis develop more rapidly (over hours to days). Tuberculous meningitis and fungal meningitis are most expeditiously diagnosed if consultation with a microbiology laboratory is sought, so that optimal media and genetic probing techniques can be used to test the CSF. Similarly, the most incisive serologic tests for syphilis should be used in consultation with an immunology laboratory if syphilis appears to be a likely etiologic agent. Syphilitic meningitis develops more often during the secondary or tertiary stages of the disease and presents with seizures in ~ 18% of patients. Thus, in patients with signs and symptoms suggestive of meningitis, especially seizures, syphilitic meningitis should be considered as part of the differential diagnosis, and appropriate serologic tests for syphilis should be performed on the serum and CSF.

**2. The Presence or Absence of Focal or Lateralizing Neurologic and Other Findings**—Whereas acute bacterial meningitis may cause cranial nerve abnormalities

such as deafness or ophthalmoplegias, viral meningitis seldom causes such neurologic dysfunction. Similarly, brain abscesses, even if they have not ruptured into the subarachnoid space, may cause CSF pleocytosis in the absence of detectable bacteria in the CSF. Brain abscesses are more likely than bacterial or viral meningitis to cause focal neurological findings such as hemiparesis or aphasia. Spinal epidural abscesses, which may cause fever, CSF pleocytosis, and focal neurologic deficits, are usually accompanied by pain and percussion tenderness over the spine. With both brain abscesses and spinal epidural abscesses, CT scans with enhancement or MRI scans may be required to determine the cause of the culture-negative meningeal inflammation.

**3. The Presence or Absence of Confusion**—In general, patients with aseptic meningitis syndrome as a result of viral meningitis are alert; therefore, if confusion or obtundation is evident, a bacterial etiology or some other nonviral etiology of the meningeal inflammation is more likely.

**A. Signs and Symptoms.** Signs and symptoms suggestive of the aseptic meningitis syndrome depend on its underlying etiology, but often include fever, headache, nausea, vomiting, and neck stiffness.

**B. Laboratory Findings.** CSF pleocytosis is present. Gram stain and routine cultures are negative. The CSF glucose, protein, leukocyte count, and differential can be helpful in determining the cause of the syndrome (see [Table 7-4](#)).

**C. Imaging.** A number of the antimicrobial-requiring causes of aseptic meningitis syndrome require imaging studies to identify the lesion for diagnosis, optimal antimicrobial therapy, and, if indicated, surgical drainage. Whereas the CSF in true viral aseptic meningitis has a lymphocytic pleocytosis, abscesslike processes, including contiguous sinusitis, often have predominantly polymorphonuclear leukocyte pleocytosis of the CSF. Thus, the presence of the aseptic meningitis syndrome plus clinical signs suggesting the presence of a mass lesion, especially if there is polymorphonuclear pleocytosis of the CSF, should prompt imaging studies of the areas likely to be involved. A CT scan may suffice if acute intracranial hemorrhage is a possibility or if the patient cannot remain motionless in an MRI scanner; otherwise, MRI scans are the preferred imaging modality. Brain abscesses may not be visualized on CT scans unless contrast enhancement is used ([Figure 7-1](#)). Thus, contrast enhancement should be used with CT scans that are performed because a brain abscess is in the differential diagnosis. If a brain abscess is a possibility, a CT scan should not be considered to be completed unless it was done with contrast enhancement.

## Differential Diagnosis

There are a substantial number of causes of aseptic meningitis syndrome, which can be life-threatening if not treated appropriately, sometimes with antimicrobial agents (see [Table 7-7](#)). The antimicrobial-requiring causes of aseptic meningitis syndrome should be excluded before embarking on an extensive workup of the non-antimicrobial-requiring causes ([Table 7-8](#)).

Some antibiotics and other pharmaceutical products can induce aseptic meningitis syndrome ([Table 7-9](#)). Whereas infectious causes of the meningitis should be excluded

first, the drugs that cause meningitis are usually not critical, and substitutions of drugs that do not cause meningitis can easily be made. In a patient with meningitis who is having seizures, treatment with phenytoin usually suffices when intravenous administration is necessary; carbamazepine may be used when oral administration is possible, keeping in mind that it rarely may produce an aseptic meningitis syndrome.

To avoid inducing drug-related meningitis, avoid antimicrobial treatment of respiratory tract infections (eg, sinusitis and pneumonia) with oral antibiotics that do not have optimal activity against pneumococci and other streptococci. A substantial number of patients have acquired fatal pneumococcal sepsis and meningitis while taking such antibiotics. For instance, life-threatening pneumococcal and other streptococcal infections, including meningitis, have complicated therapy with the following oral antimicrobial agents: ciprofloxacin (Lee et al, 1991; Richter, 1990) and cefixime (Ottolini et al, 1991).

## **Complications**

The complications of aseptic meningitis syndrome depend on its etiology. If caused by a pharmaceutical product such as ibuprofen, cessation of the inciting drug usually results in disappearance of the meningitis without complications. On the other hand, aseptic meningitis syndrome resulting from a brain abscess may be fatal if the brain abscess is not identified and treated properly, so that it is allowed to rupture into the CSF space.

## **Treatment**

As with bacterial meningitis, the antimicrobial therapy should be specifically targeted toward the most likely organism to cause the aseptic meningitis syndrome. For instance, the most likely organism to cause an epidural abscess is *S aureus*, whereas multiple brain abscesses associated with endocarditis are likely to be caused by the same organism that is infecting the heart valves.

In some patients, the best therapy for aseptic meningitis syndrome may be stopping a drug that is causing the meningitis. For instance, in a patient with AIDS who develops aseptic meningitis syndrome while receiving sulfa-trimethoprim prophylaxis against *Pneumocystis carinii* infections, it would be reasonable, after excluding infectious causes of the aseptic meningitis syndrome, to change the prophylaxis from sulfa-trimethoprim, which can cause an aseptic meningitis syndrome (see [Table 7-9](#)), to pentamidine for *Pneumocystis* prophylaxis. Antiviral therapy is not indicated for most cases of viral meningitis.

## **Prognosis**

The prognosis of aseptic meningitis syndrome is the same as that of its underlying cause. For instance, neoplastic meningitis as the cause of aseptic meningitis syndrome has a dire prognosis, whereas drug-induced aseptic meningitis syndrome and virus-caused aseptic meningitis syndrome have an excellent prognosis.

## **Prevention & Control**

Aseptic meningitis syndrome has such diverse causes that there is no single means of prevention and control. For instance, syphilis-related aseptic meningitis syndrome might be prevented by the use of condoms, and Lyme disease-related aseptic meningitis syndrome might be prevented by using an insect repellent that protects against the *Ixodes* tick vector.

## **INFECTIOUS DISORDERS WITH DEMENTIA AS A DOMINANT FEATURE**

### **Essentials of Diagnosis**

- If caused by infection, the progression of dementia is over weeks to months rather than years.
- Frontal lobe abscesses may produce dementia without lateralizing or localizing signs.
- Creutzfeldt-Jakob disease should be considered in middle-aged patients with dementia that progresses over a few weeks.

Most dementing processes with infectious causes progress subacutely, that is, over weeks to months rather than over a course of years. A more slowly progressive course may be seen occasionally with communicating hydrocephalus, as a result of prior meningeal infection and interference with reabsorption of CSF. The dementia of tertiary syphilis may also progress over a very long time course.

### **Frontal Lobe Infections**

Infections localized to the frontal lobes of the brain can present as dementias with few other manifestations. For example, a brain abscess in the frontal lobes may fail to produce lateralizing or localizing signs that would be obvious if the abscess were located elsewhere in the brain. Progressive multifocal leukoencephalopathy (PML) (see [Chapter 45](#)), even though a disease predominantly affecting the white matter can be present in the frontal lobes and produce dementia prior to the appearance of focal deficits. Although previously encountered as a rare complication of lymphoma or Hodgkin's disease, PML is now most often seen as a complication of AIDS. Dementia in AIDS is commonly seen in the late stages of the process, where it appears to be a direct result of the viral infection. The dementia is characterized by slowness of thought, apathy, and inability to perform consecutive tasks. Loss of motor functions with ataxia and spasticity are seen as the disease progresses. Dementia becomes increasingly frequent as AIDS progresses, with 50-75% of patients affected in the terminal course of the disease.

### **Creutzfeldt-Jakob Disease**

In middle-aged patients with dementia progressing over a few weeks, one must consider the possibility of Creutzfeldt-Jakob disease, which appears to be a prion disease (Ferrer et al, 2000). The dementia in these patients often presents abruptly and worsens perceptibly every few days to weekly, evolving into a state of mutism within 2-5 months. Myoclonic jerking of limb and trunk muscles often accompanies the process,

and the patients often startle easily. The electroencephalogram is always abnormal and sometimes may show a characteristic periodic burst-suppression pattern. The CSF is usually normal. An unusual protein has recently been described in the CSF of Creutzfeldt-Jakob patients, but its presence is not sufficiently specific to serve as a diagnostic test. Recently a few cases of Creutzfeldt-Jakob disease have been described in which MRI has demonstrated increased signal in the anterior striatum.

Although Creutzfeldt-Jakob disease, as it is seen sporadically, is not due to an infection, it is thought to result from a mutation in the prion protein gene with production of abnormal isoforms of normal prion proteins; these abnormal prion proteins, if transmitted into another human host, are infectious and, after prolonged incubation, cause the same disease in the recipient. Examples have been the occurrence of the disease in recipients of corneal transplants, dura mater grafts, and human-derived pituitary growth hormone after incubation periods of many months to many years. A variant form of the disease has recently appeared in Great Britain in young individuals, perhaps related to ingestion of beef from animals afflicted by "mad cow disease," another disorder related to infectious prions.

## **INFECTIONS PRESENTING AS STROKE SYNDROMES**

### **Essentials of Diagnosis**

- History: known or recently acquired valvular heart disease *plus* prior infectious processes (eg, staphylococcal sepsis), genitourinary or dental procedures, or intravenous drug use; presence of indwelling intravenous catheters; immunocompromised host predisposed to fungal infections.
- Antecedent signs of infection: fever and chills, heart murmurs.
- Signs of systemic embolism: ocular (Roth spots and other hemorrhages); skin or mucosal (petechiae, Osler's nodes); renal (hematuria); splenic (abdominal pain).
- Laboratory studies: imaging of brain, CSF analysis, cardiac echo studies, blood cultures.

Infections as a cause of stroke are uncommon but must be considered in young individuals, in patients with valvular or congenital cardiac disease, or in immunocompromised hosts. Stroke in young individuals is less often due to atherosclerosis or hypertension and more often related to thrombosis or endocarditis complicating congenital or acquired valvular heart disease as a result of intravenous drug use, right-to-left cardiac shunts, or combinations of the above.

### **Bacterial Endocarditis**

Bacterial endocarditis must always be considered in at-risk individuals, particularly if there is intravenous drug use or if the patients have recently undergone oral or genitourinary surgery or have a prosthetic cardiac valve (see [Chapter 11](#)). Embolic infarctions of brain in these individuals, although dominantly in the middle cerebral distribution, can occur in any vascular distribution and are often multiple, frequently in

the distal territories of the cerebral vessels, and most frequently encountered when the causative organism is *S aureus*. The formation of mycotic aneurysms at the site of embolism is not uncommon, and may occur late in the course of the condition. Rupture of the mycotic aneurysm with subarachnoid hemorrhage is uncommon, but, when it occurs, is frequently fatal. The management of these problems, if caused by infective endocarditis, requires prolonged intravenous optimal antibiotic therapy and often repair or replacement of damaged cardiac valves.

Clues to the presence of subacute bacterial endocarditis include known previous congenital or rheumatic heart disease or rheumatic fever and the development of anorexia, backaches, myalgia, or signs of emboli in the spleen, kidney, eyes, or skin. The foregoing signs may all be easily overlooked if attention is devoted exclusively to the neurological phenomena. Repeated blood cultures may be required to identify the causative organism; identification and determination of the organism's susceptibility to antibiotics is of critical importance in determining the nature and duration of treatment with intravenous antibiotics.

## **Fungal Infections**

Immunocompromised hosts, particularly if neutropenic or diabetic, are susceptible to fungal diseases and, of these, *Candida*, *Aspergillus*, and *Mucor* species have a predilection for invading the walls of cerebral blood vessels, resulting in stroke syndromes. The source for *Aspergillus* infection of cerebral vessels is often in the respiratory tract (see [Chapter 75](#)). *Candida* infection with involvement of cerebral vessels is seen in association with prolonged use of intravenous lines and in intravenous drug users (see [Chapter 73](#)). *Mucor* infections are characteristically seen in diabetic patients with frequent episodes of acidosis (see [Chapter 75](#)). Branches of the internal carotid artery, cranial nerves III through VI, and orbital tissues are often involved.

## **Other Meningeal Infections**

Stroke syndromes may be seen in a variety of meningeal infections as a result of the involvement in the inflammatory exudate of penetrating vessels at the base of the brain. Often such vascular involvement is seen relatively late in the course of a meningeal infection and is related perhaps to the duration and intensity of the inflammatory process. It is also seen in acute bacterial meningitides caused by pneumococci (see [Chapter 47](#)) or *H influenzae* (see [Chapter 56](#)), in subacute meningitides caused by tuberculosis or fungal infections, and in low-grade chronic meningeal infections such as those caused by syphilis (see [Chapter 64](#)). It is rarely observed in viral meningitides but can be seen in the aftermath of herpes zoster (see [Chapter 33](#)) when it affects the trigeminal nerves, presumably resulting from a zoster infection of adjacent cranial vessels.

# **INFECTIONS PRESENTING AS SPINAL CORD SYNDROMES**

## **Essentials of Diagnosis**

- Antecedent fever or peripheral bacterial infection.

- Development of back pain and tenderness, often with radicular pain.
- Development of paraparesis with involvement of the bladder.

Infections, along with tumors, can cause acutely or subacutely developing spinal cord deficits, frequently in the form of a paraparesis with lower-extremity weakness, paralysis of bladder function, and sensory deficits below a segmental spinal level.

## **Epidural Abscess**

Epidural abscess is the most urgent infectious process causing a cord deficit. This infection usually originates in lung, skin, or elsewhere and spreads hematogenously to the epidural space, where the abscess typically causes radicular back pain, percussion tenderness over the spine, and a rapidly evolving loss of motor and sensory functions. Whereas *S aureus* is the most frequent causative organism (see [Chapter 46](#)), aerobic and anaerobic streptococci, gram-negative bacilli, and a wide spectrum of other bacterial and fungal organisms have been shown to cause epidural abscesses. Thus, a premium should be put on obtaining pus from the abscess for culture and determination of the antimicrobial susceptibility of the causative organism. Until that information is available, initial therapy should be an intravenous penicillinase-resistant synthetic penicillin such as oxacillin or nafcillin in conjunction with rifampin. However, if there is a likelihood of a methicillin-resistant *S aureus* (MRSA) strain in the patient (eg, recent hospitalization in a unit with prevalent MRSA), vancomycin should be included in initial therapy and discontinued if the *S aureus* proves susceptible to oxacillin or nafcillin, which should then be the drugs of choice, in conjunction with rifampin.

Epidural abscess must always be considered in patients with back pain and rapidly evolving signs of cord compression. The presence of an obvious primary infection, with recent bacteremia (eg, recent incision and drainage of an abscess and/or fever) may be helpful in pointing to the diagnosis (and to the most likely organism), but these antecedent signs may be absent. Intravenous drug abuse is an increasingly frequent cause of epidural abscess.

The most frequent process mimicking an epidural abscess is cord compression from metastatic tumor. The diagnosis of these conditions is most easily made or excluded by a sagittal-screening MRI scan, which shows (for epidural abscess) a diffuse or multiloculated collection of pyogenic material compressing the cord over several segments, most often in the mid thoracic region; as the next most likely location, in the lumbar spine; and also, but least likely, the cervical spine. Rapid surgical intervention is necessary in most cases and certainly in all cases in which the neurological deficit is progressing.

## **Genital Herpes**

Genital infection with herpes simplex virus (usually type 2) occasionally causes meningitis resulting in paraparesis, a dysfunction at the sensory level or a dysfunction in the bowel, the bladder, or both (see [Chapter 33](#)). A similar picture may occasionally be observed with segmental varicella-zoster infection. Whether these syndromes are

caused by direct viral invasion of the spinal cord or an autoimmune-mediated myelopathy is unknown. A variety of viral illnesses such as mumps or chicken pox or vaccination procedures can cause a transverse myelitis, presumably by an immunologic reaction to CNS tissue triggered by the foreign antigen. The inciting agent in the majority of cases of acute transverse myelitis remains unknown. A chronic progressive myelopathy with ataxia, lightning-like pains, and later spastic weakness formerly was seen in tabes dorsalis but is rarely seen now. In contrast, HIV infection commonly causes a vacuolar myelopathy initially affecting the posterior columns; it presents with slowly progressive ataxia and culminates in a spastic paraparesis (see [Chapter 23](#)).

## **INFECTIOUS DISORDERS WITH FOCAL DISTURBANCES AS A DOMINANT FEATURE**

### **Essentials of Diagnosis**

- History: fever, headache, chills, sweats, malaise; focal neurological deficits—acute or subacute; infections in paranasal sinuses, mastoid, or elsewhere; intravenous drug use.
- Signs: Fever, leukocytosis; heart murmur; focal neurological deficits.
- Laboratory studies: MRI imaging; lumbar puncture, if not contraindicated by papilledema or presence of a mass lesion on MRI scanning; blood cultures, where appropriate.

The presence of fever, headache, focal neurological deficits, alterations of mental status, seizures, or some combination of these features suggests both focal disturbance of brain parenchyma and meningeal irritation. The range of conditions that can produce these disorders is large. Among the noninfectious causes, one must consider cerebrovascular disorders and primary or metastatic cancer as leading possibilities. In approaching such problems, it is important to try to determine the precise tempo of progression of the problem (ie, did the symptoms appear and become maximal in seconds to minutes, over a few hours, or over days?). Apoplectic onset or a seizure suggests an embolic process, whereas the development of a deficit over minutes to hours is more consistent with thrombosis or hemorrhage. Slower developing deficits suggest the growth of a mass lesion or sequential vascular insults which become additive.

### **Bacterial Endocarditis**

The neurological complications of bacterial endocarditis are multiple, but the most frequent are those due to multiple emboli with infarction of the brain. Although larger emboli can cause obvious strokelike syndromes (most often in middle cerebral artery distribution), multiple smaller emboli may produce complex confusion states admixed with lesser degrees of focal disturbance. Brain abscesses, although infrequent in endocarditis, are usually associated with *S aureus* endocarditis and, if present in endocarditis, are usually small. They usually resolve with antimicrobial therapy alone. The formation of mycotic aneurysms at the site of embolism is not uncommon and may occur late in the course of the condition. As noted above, rupture of such aneurysms may be fatal.

One must be alert to the possibility of bacterial endocarditis in any patient with known congenital or acquired alteration of the heart valves, particularly if there has been recent oral or urogenital surgery or intravenous drug use. The traditional signs and symptoms of subacute bacterial endocarditis include asthenia, arthralgias, myalgia, anorexia, heart murmurs, splenomegaly, Roth spots, clubbing, fever, and sweats. Most such cases were caused, in the preantibiotic days, by oral streptococci, which have intrinsically low virulence, infecting heart valves damaged by rheumatic fever and causing small vegetations. However, such cases are now less prevalent and, with increasing intravenous drug use, *S aureus*, which can infect normal heart valves, is an increasingly prevalent cause of endocarditis. *S aureus* causes "acute" endocarditis with large vegetations, which embolize to cause metastatic abscesses, Osler's nodes, and, a much more toxic appearance than is typical of subacute endocarditis. The metastatic abscesses in staphylococcal endocarditis often occur in the brain and other parts of the CNS, so that the first presentation of endocarditis is often (20-40%) with stroke or another neurologic problem. The signs of endocarditis may all be easily overlooked, and the cause of the neurologic dysfunction missed if attention is devoted exclusively to the neurological phenomena. Thus, fever in the patient with neurologic findings should prompt a search for signs and symptoms of endocarditis, outlined above. The diagnostic criteria have recently been codified by Durack et al (1994). Once endocarditis is suspected, the most sensitive and specific diagnostic study is the transesophageal echocardiogram (ECHO). Repeated blood cultures may be required to identify the causative organism, but identification of the infecting microorganism and quantitative determination of its susceptibility to antibiotics are of critical importance in determining the nature and duration of treatment with intravenous antibiotics.

### **Herpes Simplex Virus-Induced Encephalitis**

Encephalitides caused by viral infection of the brain frequently result in acutely or subacutely developing syndromes that combine headache, fever, alterations of mental status, seizures, and focal deficits. The most frequent cause of sporadic viral encephalitis is herpes simplex virus (HSV). The process in neonates is most frequently due to HSV type 2 (HSV2) resulting from maternal genital infection that was present at the time of birth. In children or adults, the encephalitic process is almost always caused by type 1 HSV (HSV1). Whether the brain infection results from exogenously acquired virus or from virus resident in cranial sensory ganglia or in the brain has not been determined.

In children or adults, the process usually takes place over a few hours to days. Initially the patient may exhibit behavioral changes or loss of memory or occasionally may complain of unusual olfactory or gustatory sensations. If present, these are valuable hints that herpes encephalitis should be considered. These symptoms may be followed by the development of headache, fever, focal deficits (hemiparesis or aphasia), and progressive disturbance of consciousness. Signs of meningeal irritation (stiff neck or vomiting) are often lacking. The diagnosis is most easily established by an MRI scan combined with typical CSF changes. The MRI scan is more sensitive than a CT scan for detecting HSV1 encephalitis; CT scans often appear normal during the first several days of the illness (when therapy is likely to have the greatest impact). Abnormalities on an MRI scan typically consist of contrast-enhancing lesions (bright on T-2-weighted

images) in the medial temporal lobe and inferior frontal lobe, often extending medially and upwards into the putamen. Occasionally a seemingly separate area of disease is present in the cingulate gyrus.

The lesions are often associated with cerebral edema, and they are often bilateral, though rarely symmetrical. In our experience the lesions of HSV may be mimicked by cerebrovascular lesions in the temporal lobe or by the lesions associated with mitochondrial encephalopathies. The CSF is abnormal with a lymphocytic pleocytosis and moderately elevated protein concentration. The presence or absence of erythrocytes in the CSF is not of diagnostic help. Use of the HSV1 PCR to detect the presence of HSV genomes in CSF is generally very sensitive and highly specific, and this method has generally supplanted brain biopsy for diagnosis. The test may be falsely negative on the first day or two of the illness and after the second week. Tests for HSV antibody in the CSF are rarely positive early in the disease; cultures for HSV are almost always negative. The electroencephalogram may point to the presence of a temporal lobe abnormality; however, it is not highly specific for HSV infection. Nonetheless, a normal electroencephalogram weighs against a diagnosis of HSV encephalitis.

Treatment with intravenous acyclovir should be instituted as soon as the diagnosis is suspected, because delay in treatment is associated with a poorer outcome. With early, specific therapy, the mortality and morbidity are substantially reduced, and there is little risk from the drug except in patients with renal failure.

### **Arbovirus-Induced Encephalitis**

A variety of arthropod-borne viruses (togaviruses) cause encephalitis, often in localized outbreaks associated with summertime increases in mosquito populations. The treatment of these encephalitides requires excellent supportive care until the patients improve on their own; there are no currently available specific antiviral compounds that are effective against arboviruses.

### **Brain Abscesses**

A variety of bacterial infections must be considered in producing the brain abscess symptom complex. Brain abscesses commonly cause seizures, focal deficits, and, as they enlarge, progressive obtundation. Although many patients with brain abscesses have no evident primary source of infection, it is imperative to search carefully for a primary focus in the paranasal or mastoid sinuses with contiguous spread to the brain. These sites may yield the organism(s) causing the brain abscess. Additionally, metastatic (or "hematogenous") abscesses, ones seeded via the bloodstream, can arise from infection in skin or lung, by IV drug use, in association with endocarditis, or in association with dental procedures.

Brain abscesses are usually recognized by contrast-enhanced CT or MRI scans. The importance of performing CT or MRI scans with contrast enhancement when testing for brain abscesses is demonstrated in [Figure 7-1](#). Brain abscesses may be confused with brain tumors but are usually more spherical with thinner walls; gas, if present, is a valuable diagnostic feature indicating their bacterial etiology. Brain abscesses are often associated with marked degrees of cerebral edema.

Management of patients who have brain abscesses usually involves a combination of surgery for diagnosis and drainage or excision, antibiotic therapy, and treatment of cerebral edema. The bacterial flora causing brain abscesses are highly variable and are often composed of mixed aerobic and anaerobic bacteria. Staphylococci, anaerobic streptococci, and *Bacteroides* species predominate, but gram-negative bacilli may also be found in brain abscesses. Initial treatment should include a penicillinase-resistant penicillin such as nafcillin or oxacillin to treat a staphylococcal component, a third-generation cephalosporin for gram-negative organisms, and metronidazole for anaerobic streptococci and *Bacteroides* species. Some authors include an anti-*Pseudomonas* drug if the abscess complicates chronic otitis.

Stereotaxic surgical aspiration is advisable to establish bacteriologic diagnosis and is often useful to decompress large abscesses or abscesses that block or threaten to rupture into the ventricular system. Repeated aspirations may be necessary to control a mass effect. Abscesses tend to enlarge by extending toward the ventricular system, and they pose a risk for rupture into the ventricles with an often fatal outcome. Thus, drainage efforts must be especially vigorous with abscesses enlarging toward the ventricular surfaces. Extirpation of abscesses should be considered when they are solitary, well encapsulated, and surgically accessible. Surgical extirpation should be considered for posterior fossa abscesses because of their propensity to compress the brainstem and to obstruct the ventricular system.

Management of the cerebral edema that accompanies brain abscesses should include dexamethasone administered intravenously. Mannitol may be used, especially as a temporizing measure prior to surgical drainage. Note that the cessation of steroid therapy, used to diminish cerebral edema, may allow an increase in the inflammatory component of the abscess, with a resulting increase in the degree of enhancement of the abscess wall on contrast-enhanced CT scans. This phenomenon may unnecessarily raise alarm that the abscess is not yielding to therapy; but this conclusion may be erroneous in the face of steroid withdrawal.

### **Subdural Empyemas**

Abscesses in the subdural space (subdural empyemas) are often associated with frontal, sphenoid, or ethmoid sinus infection. For reasons that are not understood, these empyemas are seen almost exclusively in males. Because the subdural space is continuous over the entire surface of the brain and between the hemispheres, large amounts of pus can be contained within it, causing widespread irritation and edema of the underlying brain. The organisms responsible are similar to those in brain abscesses, with aerobic streptococci, anaerobic streptococci, *S aureus*, and *Bacteroides* species predominating. In addition, *S pneumoniae* and *H influenzae* may cause these empyemas. Often there is associated meningitis if organisms and/or cells spread through the arachnoid into the subarachnoid space. In addition, involvement of cortical veins and venous sinuses in the inflammatory process and possibly with associated thrombosis can be seen.

Seizures are common. Because the CSF is usually abnormal and under raised pressure in these cases, the hazard of a spinal tap often outweighs the potential value of the

information that can be gained. The diagnosis is most readily established by MRI or CT scan with contrast enhancement. The treatment consists of prompt surgical drainage through bilateral or multiple burr holes or by means of formal craniotomy. Provisional antibiotic choices can then be modified on the basis of Gram staining and culture of the aspirated pus.

### **Cerebral Venous Sinus Infections**

Infections of the cerebral venous sinuses can be seen in association with any of the above purulent infections (meningitis, brain abscess, or subdural empyema) or as a consequence of mastoid or sinus infection. Usually the venous sinus involved is contiguous to an infected structure such as an infected sinus. The lateral venous sinuses thus may be involved when there is mastoid or ear infection, and cavernous sinus thrombosis may be associated with ethmoid or sphenoid sinus infection or with facial cellulitis. With extension of infective thrombus into cortical veins, seizures and cortical venous infarction are common. Infections of the cavernous sinus may produce proptosis and chemosis of the eye and palsies of the third, fourth, and sixth cranial nerves because these nerves traverse the cavernous sinus. This constellation of signs is also seen in diabetics with nasal or sinus infection caused by *Mucor* or *Rhizopus* fungal species. Involvement of the superior sagittal sinus frequently produces cortical vein thrombosis with seizures and may result in infection of the upper convexities of the brain with consequent leg paralysis.

The diagnosis of thrombosis of these venous structures is best made by MRI scanning, which can demonstrate the presence or absence of flow voids, clotted blood, engorgement of these structures, or some combination of these findings. The diagnostic certainty can be further enhanced by the use of magnetic resonance venography.

Treatment consists of antibiotics as for the treatment of brain abscesses or for other specific causative microorganisms that may be identified. Consideration should be given to administration of anticoagulants to inhibit the propagation of clots within the venous sinuses. However, the use of anticoagulants must be weighed against the possibility of worsening the process by hemorrhage, accompanying venous occlusion and infarction of brain.

### **Fungal Infections**

Fungi may cause focal disease in the brain with a constellation of signs and symptoms similar to those considered above. Fungal infections are most often encountered in hosts with compromised cell-mediated and other types of immunity. They are thus seen more often in patients with AIDS, lymphoma, Hodgkin's disease, leukemia, or advanced diabetes or in patients receiving cytotoxic or immunosuppressive regimens. Cryptococcal infection usually presents as severe meningitis and should be considered in the differential of acute bacterial meningitides discussed earlier. Infection caused by *Mucor* or *Rhizopus* species occurs most frequently in diabetics with multiple episodes of acidosis. The infection may spread from the oropharynx or paranasal sinuses into the skull base, involving the orbit, cranial nerves two through six, and the cavernous sinus as well as the carotid artery. The clinical picture of a red or proptotic eye with third or sixth nerve paralysis in a diabetic should prompt aggressive biopsy and culture of

affected tissues as well as culturing of the nasopharynx and sinuses for *Mucor* or *Rhizopus* species. Optimal management requires a combination of surgical debridement and therapy with high-dose amphotericin B or lipid-formulated amphotericin B.

The most frequent fungi associated with parenchymal infection of brain are *Aspergillus* and *Candida* species. These infections are seen most frequently in immunocompromised hosts, particularly in those with neutropenia. *Aspergillus* infections usually have their origins in pulmonary or sinus infections whereas *Candida* infections are often seen in patients with indwelling intravenous lines, in intravenous drug users, or in patients who have previously been treated with corticosteroids or broad-spectrum antibiotics.

These organisms, especially *Aspergillus* and *Mucor* or *Rhizopus* species, share a predilection for invading the walls of cerebral blood vessels with resulting thrombosis of the blood vessel. Thus, in addition to causing cerebral abscesses and meningitis, they often produce strokelike events as a result of thrombi forming in inflamed vessels. Treatment of these fungal infections is with high-dose amphotericin B or lipid-formulated amphotericin B. Therapy for *Candida* infection is amphotericin B or lipid-formulated amphotericin B with or without 5-fluorocytosine, depending on the patient's underlying disease and the species of the *Candida* strain (some strains of certain species of *Candida*, such as *parapsilosis*, are exquisitely susceptible to the synergism of amphotericin B with 5-fluorocytosine).

## **Toxoplasmosis**

Toxoplasmosis in the CNS presents most commonly with multifocal lesions, causing focal deficits, seizures, and impairment of cognitive functions over a period of days to weeks. Before the advent of AIDS, CNS toxoplasmosis was encountered only rarely, and then usually in the setting of Hodgkin's disease, lymphoma, or other states of severe immunosuppression. It has become a frequent complication in AIDS patients and should be immediately considered in the AIDS patient who develops multifocal neurologic deficits over a period of a few days to weeks.

The disease is often easily visualized by contrast-enhanced CT or (preferably) MRI scans, most often appearing as multicentric solid or ringlike enhancing lesions in the brain; the appearances are often quite characteristic but can be mimicked by cerebral lymphoma, also an AIDS-associated condition. A negative immunoglobulin G antibody test for *Toxoplasma gondii* makes the diagnosis unlikely. If the immunoglobulin G antibody test is positive, some experts advocate a therapeutic trial of sulfadiazine pyrimethamine, and folinic acid, in association with monitoring the clinical course as well as the size of the cerebral lesions on MRI scan. If there is no response in 10-14 days or if there is deterioration, a brain biopsy to examine other diagnostic possibilities should be strongly considered.

## **INFECTIOUS DISORDERS INVOLVING CRANIAL NERVES**

### **Essentials of Diagnosis**

- History: antecedent meningeal infection; infections of paranasal sinuses or skull base.

- Signs: cranial nerve deficits, especially nerves two, four, five, six, and seven.
- Laboratory: evidence of meningeal infection in CSF studies; MRI imaging of skull base and paranasal sinuses showing signs of an inflammatory process.

Involvement of the cranial nerves by infectious processes is usually the result of infection in the subarachnoid space at the base of the brain or in structures at the base near or through which cranial nerves course (eg, the cavernous sinus, as discussed previously). In the differential diagnosis, one must be aware that cranial nerves are also commonly involved by neoplastic processes, by inflammatory processes of other types (eg, sarcoidosis), or by vasculitic diseases, especially those affecting medium and small size vessels (eg, giant cell arteritis, polyarteritis nodosa, and diabetes mellitus).

Involvement of cranial nerves three, four, and six and the first division of five can be seen together because they traverse the cavernous sinus. Thus infections or infective thrombosis in the cavernous sinus can involve these nerves together.

Any meningeal infection, particularly if prolonged, can involve the cranial nerves at the base of the brain, so that palsies, particularly of the third, sixth, seventh, and eighth cranial nerves, can be seen in the course of pyogenic meningitis of any type or in more slowly evolving meningitides caused by tuberculosis, fungal infections, syphilis, or Lyme disease. Lyme disease seems to have a particular affinity for the seventh nerve; unilateral or bilateral facial paralysis is commonly seen. Involvement of the fifth nerve can be seen from reactivation of varicella-zoster virus in the trigeminal ganglion producing the well-known shingles eruption in one or more divisions of the nerve. Involvement of the intracranial portion of the carotid artery may occur in the course of ophthalmic zoster with thrombosis of the vessel and a middle cerebral distribution stroke. In contrast, reactivation of HSV in the same ganglion usually results only in the production of fever blisters on the lip.

The common Bell's palsy involving the facial nerve is tenuously associated with herpes simplex infections, prompting some authorities to recommend treatment of such cases with acyclovir. Involvement of the facial nerve by varicella results in the Ramsey-Hunt syndrome, with the appearance of vesicles in the ear. The facial nerve is susceptible to a variety of infections; in addition to those mentioned above, it is vulnerable to bacterial infections in the petrous apex. It, along with the eighth nerve, can be involved in *Pseudomonas* infections of the ear in diabetics (malignant external otitis).

## **INFECTIOUS DISORDERS WITH DYSPHAGIA & DYSARTHRIA AS DOMINANT FEATURES**

### **Introduction**

Involvement of cranial nerves nine through twelve is less frequent in meningeal infections, perhaps because their dysfunctions are less obvious, and they are less carefully examined. Involvement of their nuclei in the brainstem is, however, common in polio, leading to severe dysphagia, dysarthria, and respiratory difficulties. Thus, polio must be considered in unvaccinated individuals who have traveled abroad.

## Botulism & Pseudobotulism

Although botulism is a disorder of the neuromuscular junction rather than peripheral nerves, patients with botulism commonly present with dry mouth, dysarthria, dysphagia, diplopia, and impaired ocular accommodation. Rapid recognition of this disease is important. Prompt administration of antitoxin along with ventilatory support is essential in the management of botulism. In addition, recognition of the disease should prompt an intensive search for contaminated foodstuffs, which are most often the cause of the condition in adults. Victims who have only early symptoms may be recognized only because they were identified as sharing certain foodstuffs with individuals who have clear-cut disease.

A cluster of signs and symptoms similar to those in botulism may occur after ingestion of any part of the plant, Jimson weed (*Datura stramonium*); the syndrome may mimic botulism in patients who present with dysphagia; dilated, fixed pupils; and dry mouth (pseudobotulism), which is often accompanied by visual or auditory hallucinations. The *Datura* plant contains the anticholinergics atropine and scopolamine, which are highly concentrated in the seeds and can cause serious illness or death. Teenagers seeking mind-altering experiences sometimes experiment with *Datura*, only to die, probably from the cardiotoxic principle in the plant. They usually present with the pseudobotulism syndrome (fixed, dilated pupils and dry mouth), which is distinguishable from true botulism primarily by the history of contact with the *Datura* plant or its seeds and by the hallucinations, which are not a feature of true botulism. If the cardiovascular system is stable, the patients usually improve over time without therapy, other than emptying the stomach, using activated charcoal, or both; however, if the patients manifest profound toxicity, including bradycardia or tachycardia, the use of the antidote physostigmine should be considered.

*Datura* poisoning might also suggest rabies to the initial observer, if the hallucinations are mistaken for encephalopathy and if the dysphagia is mistaken for hydrophobia.

## Rabies

Rabies should also be considered in the differential diagnosis of patients presenting with dysphagia and dysarthria, with or without hydrophobia and laryngeal spasms. Rabies must be considered in any patient who has traveled to third-world countries and who has had any contact with potentially infected animals. Skunks, raccoons, and bats are the main animal reservoirs of rabies in the United States.

Treatment with human immune globulin and diploid cell-derived vaccine is very effective for individuals exposed to or bitten by rabid animals, but it is ineffective once neurological symptoms have developed. It is important for persons in close contact with the victims, whose body fluids may be infectious or for others who have had contact with the same or other infected animals to receive postexposure prophylaxis. A detailed review of the indications and procedures for postexposure prophylaxis has been provided by the Centers for Disease Control and Prevention (CDC/MMWR, 1999).

INTRODUCTION
-

**Table 7-1.** Polysynaptic thought process for managing infectious diseases.

Diagnosis/Disease	?	Most Likely Organism	?	Best Antimicrobial
eg, Meningitis		<i>Consider:</i> a. Patient's personal risk factors b. Community risk factors (what's going around) c. Physical examination d. Laboratory: (Gram stain) cultures and imaging studies		<i>Consider:</i> a. Which antimicrobial is likely against the most likely organism? b. Which antimicrobial is delivered to site of the infection? c. Which antimicrobial has a best mode of action? d. Which antimicrobial avoids special vulnerabilities (eg, allergy, myasthenia gravis, young age)?

<sup>1</sup>In known or suspected meningitis, the antimicrobial therapy should be initiated as soon as possible, ideally within 30 min after strongly suspecting or confirming the diagnosis.

 TABLES  
 Table 7-4. Value of CSF findings in predicting the most likely cause of meningitis.
-

**Table 7-5.** Management of the patient with obvious meningitis.

If the patient has obvious meningitis (fever, stiff neck, and confusion or coma), set an ideal goal of allowing yourself 30 min to have an IV infusing the best antibiotic for the most likely organism to be causing the meningitis.

**Suggested Use of the 30 Min**

**10 min** to confirm the diagnosis and get history (eg, drug allergy, previous meningitis, recent sinusitis or trauma) and assure that there is no papilledema and that there are no focal neurological deficits that might suggest a mass lesion (such findings indicate that a spinal tap may result in a herniation syndrome)

**5 min** to start an IV and draw blood cultures

**10 min** to do a spinal tap (if no signs of a mass lesion are present)

*Do not examine the CSF yet.*

**5 min** to start an intravenous antibiotic appropriate for the most likely organism as judged by the patient's age and other risk factors (see Tables 7-2 to 7-4 and 7-6).

**Now Examine the Spinal Fluid**

Change antibiotics if necessary; it rarely will be necessary if guidelines for predicting the most likely organism (see Tables 7-2 and 7-3) are followed in conjunction with picking the best antimicrobial agent for the most likely organism (see Table 7-6).

**Table 7-6.** Best antimicrobial regimens for specific most likely organisms.

Organism	Regimen <sup>1,2</sup>
<i>N meningitidis</i>	<ul style="list-style-type: none"> <li>• Adults: Penicillin G,<sup>3</sup> 4 million U by volutrol over 30 min every 4 h</li> <li>• Children older than 28 d: Penicillin G,<sup>3</sup> 50,000 U/kg IV every 6 h</li> <li>• Children 7 d or younger: Penicillin G,<sup>3</sup> 50,000 U/kg IV every 12 h</li> <li>• Penicillin-allergic patients: Chloramphenicol</li> <li>• Some experts add dexamethasone (as described below for Hib)</li> </ul> <p>Penicillin may cure the meningitis but fail to eradicate the nasal carriage state of the patient. To prevent postdischarge transmission of meningococci from the patient to siblings or other contacts, eradicate the carrier state of the patient with rifampin before discharge.<sup>4</sup> <b>For children older than 1 m of age, give rifampin, 10 mg/kg (maximum dose, 600 mg) PO every 12 h for a total of 4 doses in 2 d. For children = 28 d old, the dosage is 5 mg/kg PO every 12 h for a total of 4 doses in 2 d. For teenagers or adults, the dosage is 600 mg PO every 12 h for a total of 4 doses in 2 d.</b></p>
Group B streptococci	<ul style="list-style-type: none"> <li>• Adults: ampicillin, 2.0 g IV every 4 h + cefotaxime, 2.0 g IV every 6 h</li> <li>• Neonates: ampicillin, 50 mg/kg IV every 12 h + cefotaxime, 50 mg/kg IV every 12 h</li> </ul> <p>With either regimen, repeat CSF exam/culture 24-36 h after starting therapy.</p>
<i>S pneumoniae</i> (pneumococcus)	<ul style="list-style-type: none"> <li>• Adults and children older than 1 m: If the pneumococcus is <i>known</i> to be susceptible to penicillin (MIC = 0.1 µg/ml), use penicillin as above; otherwise, begin therapy with vancomycin, 15 mg/kg IV every 6 h</li> </ul> <p><b>PLUS</b> either<sup>5</sup>:</p> <p>Cefotaxime, 50-75 mg/kg IV every 6 h (8-28 d &gt; old)</p> <p><b>OR</b></p> <p>Ceftriaxone, 100 mg/kg IV at diagnosis, 12 h, then per day thereafter (&gt;28 d old)</p> <p><b>OR</b></p> <p>(Adults) ceftriaxone, 2 g IV every 12 h</p> <p>Adjust the regimen when the susceptibility of the pneumococcus has been quantitated (eg, if the patient is responding well and the pneumococcus is susceptible to the cephalosporin, discontinue vancomycin).</p> <p>Some experts add dexamethasone (as described below for Hib).</p>

Hib

There are three major components of therapy:

1. Antibiotics:

- Adults: Cefotaxime, 2 g IV every 4-6 h
- Children >28 d old: Ceftriaxone, 100 mg/kg IV per day
- (8-28 days old) Cefotaxime, 50 mg/kg IV every 8 h<sup>6</sup>

Ampicillin can be used for therapy of Hib meningitis only if the infecting strain is demonstrated *not* to produce  $\beta$ -lactamase

2. Inhibition of TNF- $\alpha$  production:

Data from studies in children with *H influenzae* meningitis indicate that an inhibitor of TNF- $\alpha$  production, dexamethasone, 0.4 mg/kg IV every 12 h for 2 d of antibiotic therapy, reduces the neurologic sequelae of meningitis (Lebel et al, 1988). There are no completely comparable data in adults or in meningitis caused by other pathogens, but, if there were *no* possible contraindication, such as a history of TB, many experts would use dexamethasone in meningococcal, pneumococcal, and other bacterial meningitides in which the inflammatory reaction seems to be more deleterious than helpful to the patient.

3. Eradicate carrier state of treated patients with rifampin prior to discharge<sup>4</sup>:

**For children older than 1 mo, give rifampin, 20 mg/kg (maximum dose, 600 mg) PO daily  $\times$  4 d. For adults or teenagers, each dose is 600 mg. Some experts forego this therapy if the patient was treated with cefotaxime or ceftriaxone, either of which eradicate nasal carriage of Hib.**

*L monocytogenes*

- Adults: Ampicillin, 2 g IV every 4 h (some experts add gentamicin, 5 mg/kg loading dose, then 1.7 mg/kg every 8 h)<sup>7</sup>
- Children >28 d old: Ampicillin, 50 mg/kg per 6 h + gentamicin, 2 mg/kg IV per 8 h
- Neonates: Ampicillin, 50 mg/kg IV per 12 h + gentamicin, 2.5 mg/kg IV per 18-24 h

*S aureus*

- Adults: Nafcillin or oxacillin (2 g IV every 4 h)

**OR**

Vancomycin (1.0 g IV every 6-12 h) plus rifampin, 600 mg PO per day

- Children >28 d old: nafcillin or oxacillin (37 mg/kg IV per 6 h) or vancomycin (40-60 mg/kg IV divided every 6 h).
- Neonates: Nafcillin or oxacillin (25 mg/kg IV per 12 h).

Gram-negative bacilli (*not H influenzae*)

*Klebsiella* spp., *E coli*, etc

- Adults: Ceftazidime, 2.0 g IV every 8 h, PLUS gentamicin, 2 mg/kg IV loading dose, 1.7 mg/kg every 8 h thereafter
- Children: Seek pediatric infectious disease consultation

*Pseudomonas*, *Enterobacter*, and *Acinetobacter* species

Often develop resistance to cephalosporins during therapy; therefore, susceptibility testing should be done on each successive isolate. *If* cephalosporin resistance arises, some experts treat older children, teenagers, and adults with systemic plus intraventricular aminoglycosides, as follows (an infectious disease consultation is recommended): Give intraventricular gentamicin, 0.03 mg/ml of CSF volume (the total volume of the CSF can be estimated with reasonable accuracy by the neuroradiologist)

**OR**

Intraventricular amikacin, 0.1 mg/ml CSF volume

**PLUS**

Standard intravenous therapy with the same aminoglycoside

<sup>1</sup>Most of these therapeutic recommendations are from *The Sanford Guide to Antimicrobial Therapy 2000* (Gilbert et al. 2000), the American Academy of Pediatrics *Red Book*, or both. For therapy of children whose age or weight does not conform to the guidelines here, the reader is advised to refer to *The Sanford Guide to Antimicrobial Therapy 2000* [Tables 1 (3)-1 (5) and 16] and the pediatric *Red Book*.

<sup>2</sup>Use half normal saline or saline for IV diluent fluid; D<sub>5</sub>/water administration may result in cerebral edema or hyponatremic seizures if inappropriate antidiuretic hormone secretion accompanies the meningitis, often the case.

<sup>3</sup>Avoid bolus injection of penicillin, which may precipitate seizures or cause respiratory arrest.

<sup>4</sup>Chemoprophylaxis regimens to protect individuals exposed to an index patient with invasive disease caused by *N meningitidis* or Hib or to eradicate the carrier state in a treated patient are shown in boldface.

<sup>5</sup>Recent studies in children suggest that meropenem, 1 g IV every 8 h, can substitute for the vancomycin/cephalosporin regimen (see Odio et al, 1999). Many experts add dexamethasone to the antimicrobial regimen to decrease TNF- $\alpha$  production and help prevent nerve damage that may result in blindness, deafness, or both.

<sup>6</sup>A recent, prospective, randomized, multicenter trial showed meropenem to equal cefotaxime in efficacy and safety in meningitis of children (Odio et al, 1999). Further, in that study both drugs were administered without vancomycin. The *S pneumoniae* isolates with decreased susceptibility to penicillin or cefotaxime were susceptible to meropenem.

<sup>7</sup>Others prefer to treat *adults* with sulfamethoxazole-trimethoprim, 15-20 mg/kg, trimethoprim equivalent, in equally divided doses given every 6-8 h. Sulfamethoxazole-trimethoprim is contraindicated in infants < 6 months of age.

<sup>8</sup>Some clinical microbiology laboratories save the first isolate from an infected site, and when the same microorganism is subsequently isolated from that site, report the first set of susceptibility data. This practice may result in failure to detect the transition of an initially cephalosporin-susceptible isolate to a cephalosporin-resistant isolate during cephalosporin therapy. Thus, susceptibility testing should be done on each successive isolate in meningitis caused by *Pseudomonas*, *Enterobacter*, or *Acinetobacter* spp., if the patient is treated with a cephalosporin.

## 8 . Infections of the Eye & Orbit — *Marlene L. Durand, MD*

### Key Terms

**Chemosis:** edema of the conjunctiva

**Endophthalmitis:** infection of the vitreous

**Epiphora:** excessive tearing

**Follicles:** foci of lymphoid hyperplasia seen on the inner surface of the lids in viral or chlamydial conjunctivitis

**Hypopyon:** layer of white blood cells in the anterior chamber

**Keratitis:** infection of the cornea

**Limbus:** junction of the cornea and sclera

**Meibomian glands:** sebaceous glands of the lids

**Uveitis:** inflammation of the choroid, ciliary body, or iris; retinitis is often included in this term

### EYELID INFECTIONS

#### Essentials of Diagnosis

- Generalized or localized erythema of lids.
- No change in visual acuity.
- No limitation in extraocular movements.

#### General Considerations

The eyelids contain meibomian glands ([Figure 8-1](#)) that secrete sebum, an oily substance that helps lubricate and protect the corneal surface. Inflammation of these glands may produce a localized swelling in the lid (hordeolum and chalazion) or redness and irritation of the lid margins (blepharitis).

#### HORDEOLUM

A hordeolum is an acute infection of a sebaceous gland of the upper or lower lid characterized by a red, painful swelling. The swelling may be within the lid (internal hordeolum) or at the lid margin (external hordeolum or sty). The usual cause is *Staphylococcus aureus*. Treatment is with warm compresses and topical erythromycin or bacitracin ointment (see [Box 8-1](#)).

#### CHALAZION

A chalazion is a firm, nontender, chronic mass within the lid. It is a sterile granulomatous reaction to either an internal hordeolum or to inspissated sebum within a meibomian gland. It is best seen on the inner surface of the lid, where the overlying conjunctiva may

be reddened. Treatment is with either excision or with intralesional injection of steroids.

## **BLEPHARITIS**

Blepharitis is an inflammation of the lid margins. It is usually bilateral and chronic and is caused by dysfunction of the meibomian glands. Superinfection with *S aureus* seems to play a role. There is often associated rosacea or seborrheic dermatitis. The lid margins are red and irritated, often with skin scales clinging to the eyelashes. Symptoms are burning and itching of the lids. Treatment includes daily gentle lid scrubs with a baby shampoo to remove scales and application of topical bacitracin ointment at night. Tetracycline therapy may help if there is associated rosacea.

## **PRESEPTAL CELLULITIS**

Preseptal cellulitis, sometimes called periorbital cellulitis, is an infection of the skin of the lids, anterior to the tarsal plate or "septum" ([Figure 8-2](#)). It is more common in children than in adults. The patient has tender, swollen, red lids but no eye pain, no change in vision or limitation of ocular movement, and no proptosis. Preseptal cellulitis must be distinguished from orbital cellulitis (see below). Common causes include *S aureus*, (group A) *Streptococcus pyogenes*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*. Treatment should be with oral or intravenous (IV) antibiotics directed against these pathogens (eg, cefuroxime). Parenteral antibiotics are usually used in children as initial therapy, because some children with preseptal cellulitis are also bacteremic.

## **THE TEAR FILM**

The tear film lubricates and nourishes the corneal surface and helps to focus light. It is composed of three layers. The outer lipid layer, produced by the meibomian glands, helps prevent evaporation of the middle aqueous layer. Chronic meibomitis, as occurs in chronic blepharitis, may decrease this lipid layer, allowing excessive evaporation of the aqueous layer, corneal dryness, and subsequent corneal defects. The middle aqueous layer is the largest layer and is produced by the lacrimal gland. The inner layer is composed of mucin produced by goblet cells in the conjunctiva. Destruction of these goblet cells, as occurs in Stevens-Johnson syndrome, leads to severe dryness and corneal damage.

## **LACRIMAL SYSTEM INFECTIONS**

### **Essentials of Diagnosis**

- Epiphora (excessive tearing).
- No change in visual acuity.
- Dacryocystitis: swelling and redness below the medial canthus (nasal side of the orbit).
- Canaliculitis: "pouting puncta".
- Dacryoadenitis: swelling and redness in the orbit above and lateral to the orbit of the

eye.

## General Considerations

The lacrimal system produces and drains the aqueous middle layer of the tear film. Tears are produced by the lacrimal gland, located in the upper outer portion of the globe. They flow medially across the surface of the eye and drain via canaliculi into the lacrimal sac and the nose ([Figure 8-3](#)).

## DACRYOCYSTITIS

Acute dacryocystitis is the most common infection of the lacrimal system, and results from obstruction of the lacrimal sac and subsequent infection. Patients present with a unilateral acute, red, painful swelling near the bridge of the nose, just below the medial canthus. There is often a history of chronic epiphora (excessive tearing). The most common pathogens are *S aureus*, streptococci including *S pneumoniae*, and *H influenzae*. Treatment is with systemic antibiotics (eg, cefuroxime); incision and drainage may be necessary.

## CANALICULITIS

Infection of the canaliculi causes epiphora, and "pouting puncta" are seen on examination. *Actinomyces israelii* is the most common pathogen, and applying pressure near the punctum causes the "sulfur granules" characteristic of this organism to be expressed. Treatment includes expressing this material and irrigating through the punctum with penicillin.

## DACRYOADENITIS

Dacryoadenitis, or infection of the lacrimal gland, is rare. Acute dacryoadenitis causes redness and swelling in the upper outer portion of the orbit. Viral causes include Epstein-Barr virus, mumps, and adenovirus; bacterial causes include *S aureus*, *Streptococcus pneumoniae*, and *H influenzae*. Chronic enlargement of the gland may be caused by tuberculosis or syphilis, but tumors or autoimmune disorders (including sarcoidosis) are more likely causes and should be excluded first.

## ORBITAL INFECTIONS

### Essentials of Diagnosis

- Marked swelling, erythema, tenderness of lids.
- Proptosis (may be apparent only when measured).
- Pain with extraocular movements.
- Limitation of extraocular movements (except with early orbital cellulitis).
- Fever and leukocytosis.

- Concurrent sinusitis is common.

## General Considerations

The bony orbit (eye socket) is shaped like a cone placed horizontally in the skull, point inwards. The medial wall is formed by the paper-thin lateral wall of the ethmoidal sinus, the "lamina papyracea" bone. Because this barrier is so thin, infection in the ethmoidal sinus may spread into the orbit (see [Figure 8-4](#)). Hence, ethmoidal sinusitis is the most common cause of orbital infections.

## ORBITAL CELLULITIS

Orbital cellulitis is an infection of the orbital soft tissue contents, and usually results from sinusitis. The onset is acute, with symptoms often developing within 24 h. The patient complains of unilateral eye pain and lid swelling. It is more common in children than in adults. Fever and leukocytosis are common. The lids are red, tender, and edematous, and they may be swollen shut. There is chemosis (edema) and injection of the conjunctiva. There is proptosis, but this may not be noted until measured by an ophthalmologist. Visual acuity may be decreased, and there is pain with eye movement. With progression of the infection, there is limitation of extraocular movement. The characteristic findings on computed tomography (CT) are proptosis and stranding in the orbital fat. Evidence of sinusitis on the same side is often seen. Pathogens include *S aureus*, *Streptococcus pneumoniae*, anaerobes, and *H influenzae*, although the frequency of *H influenzae* infections has markedly decreased since the 1985 introduction of the *H influenzae* type b vaccine. Treatment includes IV antibiotics (eg, ampicillin-sulbactam or nafcillin plus ceftriaxone) and drainage of any sinus pus. Patients should be closely monitored by both an otolaryngologist and an ophthalmologist. Progression of symptoms despite IV antibiotics should be evaluated by a repeat CT to exclude a drainable orbital abscess.

## ORBITAL ABSCESS

An orbital abscess is a collection of pus within the orbit. This is most often found in the medial or superior part of the orbit because infection usually begins in the ethmoid or frontal sinus. There is marked limitation of eye movement, and the eye usually looks "down and out" (away from the site of the abscess). Other signs and symptoms are similar to those of orbital cellulitis. On CT scan, a low-density collection within the orbit is seen. Treatment requires immediate drainage of the abscess and IV antibiotics directed against *S aureus*, streptococci, anaerobes, and *H influenzae* (eg, nafcillin plus ceftriaxone or ampicillin-sulbactam).

## SUBPERIOSTEAL ABSCESS

A subperiosteal abscess is a collection of pus between the bony wall and periosteum of the orbit. Because this is usually an extension of infection from the ethmoidal sinuses, the medial wall is most often involved. It is difficult to distinguish a subperiosteal abscess from an orbital abscess on clinical grounds; both produce fever, leukocytosis, lid swelling, redness, warmth, tenderness, chemosis, decreased vision, and marked

limitation of extraocular movement. As with orbital abscess, the eye is usually nearly fixed in position looking "down and out." On CT scan, a subperiosteal collection is seen. The bacteriology and treatment are the same as for orbital abscess: immediate surgical drainage plus IV antibiotics (eg, nafcillin plus ceftriaxone).

## **CAVERNOUS SINUS THROMBOSIS**

Cavernous sinus thrombosis is a life-threatening complication of orbital infection and results from bacteria gaining access (via venous drainage of the orbit) to the cavernous sinus. It represents extension of the orbital infection (cellulitis or abscess) backwards. Because the cavernous sinus is a venous plexus that crosses the midline, inflammation in this region produces bilateral signs. Hence, bilateral signs of orbital cellulitis with systemic toxicity are very worrisome for cavernous sinus thrombophlebitis. The patient should be cared for in the intensive care unit; any drainable pus (eg, an orbital abscess or purulent sinusitis) should be drained, and nafcillin plus ceftriaxone should be given in meningeal doses (eg, in adults, 2 g of nafcillin every 4 h and 2 g of ceftriaxone every 12 h in patients with normal renal function).

## **CONJUNCTIVITIS**

### **Essentials of Diagnosis**

- Diffuse erythema (conjunctival injection).
- Discharge (watery or purulent).
- Eye discomfort but not pain (except in epidemic keratoconjunctivitis and in hyperacute conjunctivitis).
- No change in visual acuity.
- No change in pupillary reactivity.
- No limitation in extraocular movements.
- Conjunctival papillae or follicles may be seen.

### **General Considerations**

Conjunctivitis is the most common type of eye infection. It is characterized by an inflamed conjunctiva, with injection and exudate. The conjunctiva is the mucous membrane that lines the inner surface of the lids (palpebral conjunctiva) and the surface of the sclera (bulbar conjunctiva) (see [Figure 8-2](#)). It does not cover the cornea, but abuts the corneal epithelium at the limbus (corneal-scleral border).

In general, patients with conjunctivitis complain of discomfort or pruritus, but they do not have deep eye pain unless the cornea is also involved (eg, epidemic keratoconjunctivitis or gonococcal disease). Any patient with a red eye and eye pain should see an ophthalmologist immediately, so that more serious eye conditions can be excluded (eg,

acute glaucoma, uveitis, or endophthalmitis). Conjunctivitis may be classified by the speed with which symptoms develop: hyperacute, acute, and chronic ([Table 8-1](#)).

## **HYPERACUTE CONJUNCTIVITIS**

Hyperacute conjunctivitis is a medical emergency because it may progress to corneal perforation and visual loss. It is nearly always caused by *Neisseria gonorrhoeae*; the remaining cases are caused by *N meningitidis*. It affects neonates and sexually active adults. Patients have copious purulent discharge (which reaccumulates within seconds to minutes of wiping clean), marked chemosis, injection, and mild lid swelling. Bilateral involvement and preauricular adenopathy may occur. The cornea is involved in about two-thirds of patients, causing true eye pain. Without prompt treatment, perforation of the cornea may occur.

The diagnosis of hyperacute conjunctivitis is made by clinical appearance and finding the gram-negative diplococci ("kissing kidney beans") characteristic of *Neisseria* spp. on the Gram stain of the exudate. Treatment for gonococcal disease consists of a single 1-g IV or intramuscular injection of ceftriaxone. In highly penicillin-allergic patients, oral ciprofloxacin (500 mg) can be used, although efficacy data are lacking. Saline irrigation or ciprofloxacin eyedrops may be given to clear the exudate. Patients and their sexual partners should be screened for other sexually transmitted diseases and treated for possible coexistent infection by *Chlamydia* spp.

Meningococcal conjunctivitis is followed by systemic illness in 20% of patients. Blood cultures should be obtained and patients should be examined for signs of meningitis. Treatment is with ceftriaxone (2 g IV once or twice daily) or high-dose IV penicillin.

## **ACUTE CONJUNCTIVITIS**

### **INTRODUCTION**

Acute conjunctivitis may be bacterial or viral; viral is more common. Distinguishing features are given in [Table 8-1](#). In bacterial conjunctivitis, the discharge is purulent; in viral, it is usually watery. In bacterial conjunctivitis, papillae give the inner surface of the lids a velvety appearance. In viral conjunctivitis, follicles (larger than papillae) give the inner surface of the lids a pebbly appearance. Preauricular adenopathy is typical of viral conjunctivitis.

### **1. ACUTE VIRAL CONJUNCTIVITIS**

Most cases of acute viral conjunctivitis are caused by adenovirus. Pharyngoconjunctival fever is caused by adenovirus types 3 and 7. Sore throat and fever accompany the conjunctivitis. It is easily spread from person to person; transmission in poorly chlorinated swimming pools has been reported.

Epidemic keratoconjunctivitis is usually caused by adenovirus type 8, although other serotypes have been noted. It is highly contagious and may survive on fomites (eg, doorknobs) for = 2 mo. It has been associated with epidemics arising in ophthalmologists' offices where there has been inadequate disinfection. The name

implies involvement of the cornea ("kerato"), and indeed corneal involvement is common, causing eye pain and photophobia. Treatment is supportive, and patients should stay home from work or school for 2 wk. Symptoms may persist for 6 wk.

Acute hemorrhagic conjunctivitis is caused by enterovirus type 70 and coxsackievirus A24 and is characterized by conjunctival hemorrhages and a 5- to 7-d course.

## 2. ACUTE BACTERIAL CONJUNCTIVITIS

The most common bacteria involved in acute bacterial conjunctivitis are *S aureus*, *Streptococcus pneumoniae*, *H influenzae* (especially in children), and *Moraxella catarrhalis*. *Haemophilus aegyptius* has caused epidemic conjunctivitis in tropical countries and may be part of Brazilian purpuric fever.

Culture of the exudate is usually not required, but should be done in any patient who fails to respond to therapy. Symptoms are self-limited and will last 7-10 d if untreated or 3-5 d if treated. Topical preparations are listed in [Table 8-2](#); bacitracin, erythromycin, or bacitracin/polymyxin ointments are reasonable choices for empiric therapy.

## CHRONIC CONJUNCTIVITIS

### INTRODUCTION

Chronic conjunctivitis is either follicular or nonfollicular. Nonfollicular conjunctivitis is often associated with chronic blepharitis, and *S aureus* or *M lacunata* may be cultured. Rarely, anaerobes have caused chronic conjunctivitis, and patients have responded to amoxicillin plus metronidazole.

Chronic follicular conjunctivitis is nearly always caused by *Chlamydia trachomatis*. There are two syndromes, depending on the serotype: trachoma (serotypes A-C), and inclusion conjunctivitis (serotypes D-K). Diagnosis for either is by isolation of *C trachomatis* on tissue culture, demonstration of chlamydial antigen by enzyme immunoassay or fluorescent monoclonal antibody stain (eg, MicroTrak, Chlamydiazyme), or nucleic acid hybridization (Gen-Probe). Giemsa staining, an older technique, is less sensitive.

### 1. TRACHOMA

Trachoma is a potentially blinding disease because repeated infections lead to scarring of the cornea and corneal vascularization. It is the most common infectious cause of blindness in the world and is prevalent in parts of Africa, the Middle East, and northern India. Follicles are seen inside the upper lid. Transmission occurs by flies, fomites, or person-to-person contact. Treatment with tetracycline for 3-6 wk or azithromycin is effective, but reinfection is difficult to prevent in endemic areas. Hand washing significantly reduces the frequency of infection.

### 2. INCLUSION CONJUNCTIVITIS

Inclusion conjunctivitis occurs in ~ 1 in 300 sexually active adults with genital chlamydial

infection. It is a chronic bilateral conjunctivitis with minimal discharge. Follicles are seen inside the lower lids. Unlike trachoma, corneal scarring does not occur. Treatment is with doxycycline, 100 mg orally 2 times/d (or erythromycin 500 mg orally 4 times/d) for 2 wk; sexual partners should also be examined and treated for chlamydial disease.

Inclusion conjunctivitis also occurs in neonates exposed to the infected mother during birth. Because neonates lack conjunctival lymphoid tissue, however, no follicles are seen. Treatment is with oral erythromycin (50 mg/kg/d) for 10-14 d.

## **KERATITIS (CORNEAL ULCER)**

### **Essentials of Diagnosis**

- Red, painful eye.
- Decreased vision.
- Photophobia.
- No fever or leukocytosis.

### **General Considerations**

The cornea is only 0.5-1.0 mm thick, but it and the overlying tear film account for 75% of the refractive power of the eye. It has no blood vessels, but has many nerve fibers (hence corneal abrasions are painful). Its barrier to infection is a 5-cell-layer-thick epithelium that is contiguous with the conjunctiva. Microbes may infect this epithelium (epithelial keratitis), the corneal stroma or interstitium (interstitial keratitis), or both (ulcerative keratitis).

### **BACTERIAL KERATITIS**

In the United States, ~ 30,000 cases of bacterial corneal ulcers are treated annually. Bacteria usually cause a craterlike ulcer when they infect the cornea (ulcerative keratitis). The patient complains of a red, painful eye; the redness is more intense near the limbus. A flashlight alone may show the defect in the cornea and a focal opacity. There may be a sterile hypopyon (layer of leukocytes in the anterior chamber) (see [Figure 8-5](#)).

A major risk factor for ulcerative keratitis is contact lens wear. Most bacteria (except gonococci) cannot penetrate an intact corneal epithelium. Contact lenses can cause breaks in this epithelium. Soft contact lenses worn overnight carry an especially high risk of keratitis: > 10- to 15-fold the risk with daily-wear lenses. Other risk factors for keratitis include corneal abrasions, previous corneal graft, dry eyes, neurotrophic keratitis (absence of normal sensation), and exposure keratitis (eg, in comatose patients in the intensive care unit).

Patients with keratitis must be promptly evaluated by an ophthalmologist. For identification of the bacteria involved, the ophthalmologist will view the cornea with the

slit lamp, carefully scrape the ulcer with a Kimura spatula, and directly plate the scrapings onto agar; a swab of the ulcer should be placed in broth.

Although coagulase-negative staphylococci are the most common organisms isolated from corneal ulcers, they may be surface colonizers rather than pathogens. Pathogens include *S aureus*, *Streptococcus pneumoniae*, viridans streptococci, and *Pseudomonas aeruginosa*. *P aeruginosa* is the most common pathogen in patients who wear contact lenses.

Empiric treatment is begun with a topical quinolone (eg, 0.3% ciprofloxacin or ofloxacin solution) or with cefazolin (50 mg/ml) plus fortified gentamicin or tobramycin (14 mg/ml) eyedrops. Of note, most eyedrops used to treat keratitis must be made up by the hospital pharmacy (the quinolones are exceptions). These are listed in [Table 8-3](#). Antibiotic drops can be tailored to specific therapy when culture results are known. Drops must be given every hour. Patients with advanced ulcers require hospitalization, as drops should be given around the clock. IV antibiotics are needed only for extension into the sclera or for impending perforation.

## **INTERSTITIAL KERATITIS**

In interstitial keratitis, the interstitium or stroma of the cornea is involved rather than the surface. On examination, there is no craterlike ulcer, but rather a haze within the cornea. Vision is decreased, and there may be photophobia, but there is usually no pain. Syphilis, Lyme disease, and mycobacteria (tuberculosis, atypical mycobacteria, and leprosy) are the most common bacterial causes; herpes infections are the most common viral causes.

## **VIRAL KERATITIS**

### **1. HERPES SIMPLEX KERATITIS**

Herpes simplex virus is the most common cause of keratitis in the United States, causing 500,000 cases per year. Most cases are from reactivation of latent infection, acquired during an earlier subclinical primary ocular or orofacial infection. Herpes simplex virus type 1 is the cause of most ocular infections in adults, whereas type 2 is the major cause in neonates.

The hallmark of herpes keratitis is a dendritic (branching) defect of the epithelium. The deeper corneal stroma is not initially involved. Diagnosis may be confirmed by viral culture. Treatment includes debridement of the involved epithelium and frequent eyedrops with a topical antiviral such as trifluridine (Viroptic).

One-third of patients have recurrent episodes within 2 y. Each recurrence carries a greater risk of stromal involvement, which may lead to permanent corneal scarring. Although topical steroids should never be used in the epithelial disease, they are helpful in treating stromal keratitis. Oral acyclovir suppressive therapy (400 mg twice a day) decreases recurrences of both epithelial and stromal disease.

### **2. HERPES ZOSTER KERATITIS**

Herpes zoster keratitis occurs in two-thirds of patients with herpes zoster ophthalmicus, the involvement of the ophthalmic division of the trigeminal nerve seen in ~ 10% of cases of zoster. An epithelial keratitis occurs at the time of the rash and consists of punctate or dendritic lesions. Treatment is with oral acyclovir (800 mg 5 times/d) or valacyclovir (1 g orally 3 times/d) for 10 d (doses assume normal renal function). Stromal keratitis may follow by several weeks. This is thought to be immune mediated and is treated with topical steroids.

## **PARASITIC KERATITIS**

### **1. ACANTHAMOEBA KERATITIS**

Acanthamoeba is an amoeba that lives in fresh water. It is a rare cause of keratitis, but is the most common cause of parasitic keratitis in the United States. Nearly all cases occur in contact lens wearers. Acanthamoeba may contaminate contact lens cases or lenses rinsed with water or homemade lens solutions. Acanthamoeba keratitis is characterized by pain out of proportion to clinical findings and a ring corneal infiltrate. Symptoms may be chronic, with relentless progression, while the patient is mistakenly treated for presumed herpes keratitis.

Diagnosis may be difficult. A calcofluor white stain of corneal scrapings may show the cysts. For culture, corneal scrapings should be transported in Page's saline, then plated on a nonnutrient agar overlain with a lawn of *Escherichia coli*. The organisms usually grow in 48 h and may be seen by viewing the agar plate under a light microscope.

Treatment is also difficult, and must be continued for weeks to months to prevent recrudescence of disease. The preferred drug is a swimming pool cleaner, the disinfectant Baquacil (polyhexamethylene biguanide). This is applied topically around the clock. Brolene (propamidine 0.1%) has also been used with success; it is available in England but not in the United States.

### **2. ONCHOCERCIASIS**

Onchocerciasis is caused by a filarial parasite, *Onchocerca volvulus*, that is transmitted by *Simulium* blackflies. The flies breed in fast-moving streams in savannahs and rain forests in Africa, and hence the disease is called "river blindness." The worms (microfilariae) infect 20 million Africans and cause 290,000 cases of blindness. Microfilariae that invade the cornea and anterior chamber of the eye cause keratitis and uveitis. Treatment is with ivermectin. A major control program is underway in West Africa.

## **FUNGAL KERATITIS**

Fungal infections of the cornea cause < 2% of corneal ulcers in this country, but are very difficult to treat. Infections caused by molds are more common in the southern United States, especially in agricultural workers. On examination, one sees a gray, plaquelike infiltrate with feathery edges and satellite lesions. *Fusarium* and *Aspergillus* spp. are the most common molds cultured. Treatment is with topical natamycin or

amphotericin.

## **ENDOPHTHALMITIS**

### **Essentials of Diagnosis**

- Eye discomfort.
- Decreased vision.
- Hypopyon.
- Hazy or no view of retina.
- No fever or leukocytosis.

### **General Considerations**

Endophthalmitis means infection within the eye and specifically the vitreous (see [Figure 8-6](#)). The vitreous is a gel-like substance that fills the posterior segment of the eye (volume ~ 6 ml). It is present at birth and becomes liquified with age. It is not reformed once removed, but may be replaced by saline, oil, etc.

Endophthalmitis is a medical emergency as it may quickly lead to blindness in the involved eye. Patients complain of eye discomfort (some have no pain) and a rapid decrease of vision. Patients feel otherwise well, are afebrile, and usually have a normal leukocyte count. On examination, the eye is injected and a hypopyon may be apparent. The view of the retina is hazy or obscured by the intraocular inflammation.

There are four major predisposing factors for endophthalmitis: cataract surgery, the presence of a filtering bleb for glaucoma, penetrating eye trauma, and bacteremia.

### **POSTCATARACT ENDOPHTHALMITIS**

Endophthalmitis after cataract surgery is the most common type of endophthalmitis. It occurs as a complication of only 0.1-0.2% of cataract surgeries, but this is a large number because there are 2 million cataract surgeries performed annually in the United States. Onset of symptoms usually occurs 2-7 d after surgery, although it may occur later. Cultures of the vitreous are positive in ~ 70% of cases. The major pathogens are coagulase-negative staphylococci (70% of culture-positive cases). *S aureus* and streptococci each cause ~ 10%, whereas Gram-negative bacilli cause only 6% of cases.

### **BLEB-RELATED ENDOPHTHALMITIS**

Patients with severe glaucoma may need a permanent "filtering bleb" created to reduce intraocular pressure. A bleb is a tunnel from the anterior chamber through the sclera, through which excess aqueous humor can leak. Endophthalmitis may occur abruptly months to years after surgery and is usually fulminant. The major pathogens are streptococci (including pneumococci), *M catarrhalis*, and *H influenzae*. The visual

outcome is usually poor.

## POST-TRAUMATIC ENDOPHTHALMITIS

Endophthalmitis develops in ~ 5% of patients who have penetrating eye injuries. The major pathogens are coagulase-negative staphylococci and *Bacillus cereus*. *Bacillus* produces a fulminant infection, and the eye is frequently lost. All penetrating eye trauma patients therefore should be given prophylactic antibiotics (eg, vancomycin plus ceftazidime) to prevent this complication.

## ENDOGENOUS ENDOPHTHALMITIS

### Introduction

Endogenous endophthalmitis means that bacteria (or fungi) have seeded the eye from the bloodstream. Endocarditis is the major risk factor, but cases have occurred in patients with urinary tract/kidney infections, abdominal abscesses, cellulitis, and meningitis and even after upper gastrointestinal endoscopy. *S aureus* and streptococci account for ~ 50% of cases. Patients should be treated with intravitreal as well as IV antibiotics.

Candidemia is associated with intraocular infection in 5-30% of cases. Most intraocular infections produce chorioretinitis rather than vitreal infection, but endophthalmitis does occasionally occur. Vitrectomy with injection of intraocular amphotericin (10 ug) is indicated, along with prolonged therapy with fluconazole (assuming normal renal function, 400 mg orally every day if the *Candida* species is sensitive).

### Diagnosis

For diagnosis of endophthalmitis, an ophthalmologist will either use a syringe to aspirate and culture a sample of vitreous (a bedside procedure) or perform a vitrectomy in the operating room. A vitrectomy uses a cutting instrument (vitrector) to remove most of the vitreous, which is simultaneously replaced by saline. The dilute vitreous washings are filtered, and the filter paper is cut up and plated on agar.

### Treatment

All patients should have antibiotics injected into the vitreous as soon as the vitreous sample is taken ([Box 8-2](#)). All patients should receive intravitreal vancomycin (1 mg in 0.1 ml) plus either amikacin (0.4 mg in 0.1 ml) or ceftazidime (2.25 mg in 0.1 ml). Amikacin is chosen because it has the least amount of retinal toxicity of the aminoglycosides, although a rare complication of any intravitreal aminoglycoside is macular infarction and loss of vision.

The role of systemic antibiotics in treating endophthalmitis is controversial. Some antibiotics, such as aminoglycosides, do not penetrate the blood-eye barrier well and do not achieve therapeutic levels in the vitreous. Vancomycin, quinolones, penicillins, third-generation cephalosporins (especially ceftazidime), and fluconazole are among the antimicrobials that can achieve therapeutic levels in inflamed eyes. A recent multicenter

randomized trial (the Endophthalmitis Vitrectomy Study) concluded that systemic antibiotics did not affect outcome in postcataract endophthalmitis, although the study was criticized because the antibiotics used (ceftazidime and amikacin) have poor activity against coagulase-negative staphylococci, the major pathogens. Vancomycin plus ceftazidime is the standard empiric IV antibiotic therapy to treat endophthalmitis.

The need for a vitrectomy to "debride" the vitreous (vs a vitreous aspirate only) is also controversial. In the Endophthalmitis Vitrectomy Study of postcataract endophthalmitis, patients who presented with severe loss of vision (light perception only) had a better visual outcome with vitrectomy than with vitreous aspirate. This difference was not apparent for patients who presented with a milder loss of vision. There were potentially confounding factors, however (patients in the vitreous aspirate group could have a subsequent vitrectomy and still be counted in the aspirate group).

A reasonable approach to the treatment of endophthalmitis would be intravitreal antibiotics for all patients with endophthalmitis, plus vitrectomy for any patient who presents with poor vision, fulminant eye symptoms and signs, or non-postcataract endophthalmitis. Intravitreal steroid (dexamethasone, 400 ug) may also be helpful. We favor using IV antibiotics for the initial 48 h until culture results are known. Therapy may be stopped then if the eye is improving and cultures are negative or reveal coagulase-negative staphylococci. For more virulent organisms, we favor 5-10 d of systemic therapy. Repeat intraocular injections of vancomycin or ceftazidime (depending on the organism) may be helpful after the first 48 h, because antibiotic levels in the vitreous fall 24-48 h after injection.

## **UVEITIS & RETINITIS**

### **Essentials of Diagnosis**

- Uveitis and retinitis nearly always cause a decrease in vision.
- Anterior uveitis is usually painful.
- Posterior uveitis and retinitis are usually painless.
- In anterior uveitis, the conjunctiva is often injected (red) near the limbus.

### **General Considerations**

The eye is made up of three coats: (1) the outer coat is composed of sclera plus cornea; (2) the middle coat is composed of the uvea (choroid, ciliary body, and iris); and (3) the inner coat is composed of the retina (see [Figure 8-6](#)). Uveitis is an inflammation of the middle, vascular layer. The term usually includes retinitis as well, because the retina is often involved when there is inflammation of the underlying choroid (a part of the uvea). Uveitis affects 1.2 million people and causes 10% of all blindness in the United States.

### **ANTERIOR UVEITIS**

In anterior uveitis, the iris (iritis) or iris plus ciliary body (iridocyclitis) is involved. The

patient has eye pain, photophobia, a red eye, and usually decreased vision. A slit lamp examination shows cells in the anterior chamber; some may coalesce on the back of the cornea ("kps" or keratic precipitates).

Of all anterior uveitis cases, ~ 10% have a known infectious etiology (eg, herpes simplex or zoster, syphilis, Lyme disease, or mycobacteria). The eye findings will regress when the underlying disease is treated. The remaining ~ 90% of cases are idiopathic or autoimmune (eg, ankylosing spondylitis, Reiter's disease, or systemic lupus erythematosus).

## **POSTERIOR UVEITIS**

### **INTRODUCTION**

Unlike anterior uveitis, posterior uveitis usually produces no pain. The main symptom is gradual visual loss. Both choroid and overlying retina are usually involved (chorioretinitis).

#### **1. TOXOPLASMA**

Toxoplasma is the leading cause of posterior uveitis in normal hosts (see [chapter 81](#), "Toxoplasma"). It usually represents reactivation of latent toxoplasma infection. On viewing the retina, new large yellow-white lesions are seen near old black scars. The vitreous often has inflammatory cells, so the view of the retina may be hazy—a "headlight in the fog" appearance. Diagnosis is by clinical appearance. Serology is helpful only if negative (usually excluding the diagnosis), because 50-70% of the general population is seropositive. Treatment is with pyrimethamine (with folinic acid "rescue"), sulfadiazine, and clindamycin. Corticosteroids are also used if there are lesions that threaten the macula.

#### **2. CANDIDA SPECIES**

Although *Candida* spp. may cause endophthalmitis, they more typically cause chorioretinitis, with fluffy white lesions seen on funduscopic examination. Treatment is with oral fluconazole (400 mg orally every day) if the *Candida* species is sensitive.

#### **3. SYPHILIS**

Syphilis may cause almost any retinal appearance, but typically produces a "salt and pepper" retina. Diagnosis is by clinical appearance and serology. Serology must include a fluorescent treponemal antibody test, because ocular syphilis may occur in tertiary syphilis when the nonspecific tests (eg, rapid plasma reagin test or Venereal Disease Research Laboratory test) are often negative. Ocular syphilis may also result from congenital infection. Any patient with ocular syphilis should have a lumbar puncture (to exclude neurosyphilis), as well as a test for human immunodeficiency virus [HIV (there is a higher incidence of ocular syphilis in patients with this viral infection)]. Treatment consists of high-dose IV penicillin (4 million U every 4 h, assuming normal renal function).

## 4. TUBERCULOSIS

Tuberculosis, like syphilis, may cause either an anterior or posterior uveitis. In posterior uveitis, the typical appearance is of bilateral multifocal choroid nodules. Treatment is the same as for other forms of extrapulmonary tuberculosis.

## 5. CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is the most common cause of retinitis. Cytomegaloviral retinitis usually occurs in immunosuppressed patients and, until recently, occurred in 20-40% of patients with AIDS. The incidence is now much lower, owing to highly active antiretroviral therapy. The typical appearance is of retinal hemorrhages (red) and exudates (white), giving the retina a "brush-fire" appearance. Unlike toxoplasmosis, CMV does not usually cause inflammation in the vitreous, so the view of the retina is clear. Diagnosis is by clinical appearance of the retina. Serology is helpful only if negative, although patients with advanced AIDS may have falsely negative serologies. Treatment is with ganciclovir or foscarnet. Systemic therapy is favored because direct ganciclovir intraocular injections or implants treat the ocular disease but do not treat the systemic CMV disease. In patients with AIDS, life-long maintenance therapy has been required to prevent recrudescence of retinitis. Recently, however, a study of seven patients on potent combination antiretroviral therapy (and with very low HIV viral loads) reported no recrudescence of retinitis when observed for 9-12 mo after maintenance CMV therapy was stopped.

## **9 . Upper Respiratory Tract Infections — *Abinash Virk, MD, & Nancy K. Henry, PhD, MD***

### **THE COMMON COLD**

#### **Essentials of Diagnosis**

- Acute rhinorrhea, sneezing, sore throat, burning eyes, cough, malaise, headache, anosmia.
- Usually there is no or low-grade fever in adults, higher fever in infants and children.
- Examination may demonstrate serous nasal discharge, conjunctival and/or pharyngeal congestion, and rhonchi.
- Diagnosis is made clinically, can be confirmed by serology or nasopharyngeal viral cultures in selected cases.
- Imaging is helpful if bacterial superinfective complications suspected (ie, sinusitis).

#### **General Considerations**

A "cold" is a self-limited viral infection of the upper respiratory tract presenting with a coryzal syndrome. It is the most common cause for physician visits and absenteeism in school and industry. Infection rates increase sharply during the fall through spring months with peak activity being in the winter. During these months, adults and children have an average of 2-4 and 6-8 colds per year, respectively.

Rhinoviruses are the most common cause of colds, accounting for one third of all colds ([Box 9-1](#)). Parainfluenza 1-4 viruses, coronaviruses, influenza types A and B, adenovirus, respiratory syncytial virus (RSV), and their numerous serotypes also are predominant viruses that induce colds. These viruses share a common property of frequent antigenic variation and evasion from the host humoral defense mechanisms, thereby permitting their persistent survival in the community. Other viruses can present with coldlike symptoms during the prodromal period, but their primary syndrome may be localized to another organ system(s).

Transmission is via aerosol, droplet, or direct contact with infected saliva or fomite from an infected person. The rate of infection increases in families with school-age children and in overcrowded and poorly ventilated living spaces. Cigarette smokers are more likely to develop severe disease as compared with nonsmokers.

Once the virus enters the cell, replication and subsequent shedding of the virus occur. The cytopathic effect of the virus on the epithelium varies depending on the virus, being relatively mild in rhinovirus and more marked with influenza virus infection. There is an acute inflammatory response, increased vascular permeability, tissue edema, mucus production, and serum transudation, resulting in the typical cold symptoms of

rhinorrhea, nasal obstruction, and cough. After the initial neutrophilic response, there is immunoglobulin M (IgM), IgG antibody, and cytokine production such as interferon, tumor necrosis factor- $\alpha$ , interleukin 8, interleukin 6, and others. Cytolytic T-cell response is more marked and significant in the immune response against influenza viruses than rhinoviruses. Antibody neutralization is the predominant immune mechanism for the latter. Production of antibodies coincides with the cessation of viral replication and waning of the inflammatory response and symptoms. This period may vary depending on the infecting virus. Viral shedding may occur for a few days to weeks.

## **Clinical Findings**

**A. Signs and Symptoms.** Onset of symptoms is between 24 and 72 h after the infectious contact. Symptoms include malaise, rapid progression to serous nasal discharge and obstruction, sneezing, throat irritation, and cough. There may be nasal intonation of voice with nasal obstruction or hoarseness with laryngeal involvement, or both. Patients may complain of burning of the eyes. Fever usually is low-grade or absent in adults but can be much higher in infants and children. Loss of smell and taste occurs as a result of nasal mucosal edema and obstruction. Overall, the symptoms can last for 1-2 wk.

Associated clinical findings can suggest a specific viral diagnosis; for example, the presence of conjunctivitis suggests an adenoviral upper respiratory infection; myalgias and lower respiratory symptoms such as pneumonia or bronchiolitis may suggest an influenza or RSV infection. Mild disease suggests rhinovirus or coronaviruses. Symptoms of complications such as sinusitis, otitis media, or lower respiratory tract infection may be present. Patients with previous hyperactive airways or asthma can develop exacerbations.

The patient usually appears tired, with thin serous nasal discharge, mild tenderness over the sinuses, and mildly suffused conjunctiva without frank conjunctivitis, and the skin over the nostrils may be red from recurrent blowing of the nose. Pharyngeal erythema without any exudates or lymphadenopathy may be present. Lung examination may reveal evidence of bronchitis or bronchiolitis.

**B. Laboratory Findings.** Most colds are diagnosed clinically and do not need any further investigations. Mild leukocytosis or leukopenia with or without thrombocytopenia may be noted. Serologies and viral cultures can make a specific viral diagnosis; however, this should be attempted only in selected cases. Rapid RSV or influenza type A antigen detection enzyme immunoassays are very sensitive for nasopharyngeal specimens. Influenza, parainfluenza, adenovirus, cytomegalovirus (CMV), and other viruses can be isolated on cell line cultures. Serologies are available for influenza, parainfluenza, RSV, adenovirus, CMV, and Epstein-Barr virus (EBV). The serologic test is considered positive for active infection if an IgM is present during acute infection or a fourfold rise in IgG in paired sera is detected. Patients with equivocal histories for colds versus group A streptococcal (GAS) pharyngitis should have a rapid antigen detection test (RADT) and bacterial cultures for group A streptococcus.

**C. Imaging.** No imaging is recommended for uncomplicated colds. However if bacterial or viral complications such as sinusitis or pneumonia are suspected, then appropriate

radiographs should be done. A computed-tomography (CT) scan study in patients with a common cold shows frequent involvement of the sinuses.

## **Differential Diagnosis**

A common dilemma is clinically differentiating the common cold from GAS pharyngitis and prodromal symptoms related to systemic syndromes caused by other viruses such as measles, chickenpox, EBV, or CMV. The presence of high fever, chills, severe pharyngeal congestion with exudate, and tender lymphadenopathy is more likely to suggest GAS pharyngitis. An RADT and bacterial culture may be able to confirm this. An exposure history to chickenpox or other viral disease may be a helpful clue to the correct diagnosis. A diagnosis of allergies is evident with rapid resolution and no recurrences in the absence of exposure.

## **Complications**

A complication of the common cold is viral or bacterial sinusitis. A common cold CT scan study by Gwaltney et al (1994) showed that sinus involvement occurs in > 60% of patients with a cold, with 79% of these resolving spontaneously in 2 wk without antibiotics. However, bacterial superinfections of the sinuses, middle ear, or both are potential complications. Viral pneumonia or worsening of bronchospastic airway disease is seen, particularly in children or immunocompromised hosts.

## **Treatment**

The old idiom of "prevention is better than cure" is certainly true for the treatment of the common cold. Multiple different viruses, their many serotypes, and rapid mutations pose a considerable challenge in the development of one vaccine or drug for cold prevention or treatment. Symptomatic support is the only therapy because no effective antiviral therapy is available.

Treatment is directed to rhinorrhea, nasal obstruction, sore throat, and cough. Sneezing, rhinorrhea, and nasal blockage improve markedly with topical or systemic decongestants that decrease edema by vasoconstriction. Topical decongestants such as phenylephrine (0.5% or 0.25%) or ephedrine (1%) nasal spray or drops should be used for a short period. Rebound congestion particularly with use of decongestant sprays beyond 3-4 d can occur. Systemic decongestants include pseudoephedrine hydrochloride, ephedrine, phenylephrine hydrochloride, propylhexedrine hydrochloride, phenylpropanolamine hydrochloride, xylometazoline hydrochloride, oxymetazoline hydrochloride, naphazoline hydrochloride, and tramazoline hydrochloride. Decongestant side effects include tachycardia, elevated blood pressure, fatigue, and dizziness. These should be used cautiously in patients with hypertension and dysrhythmias.

Nasal anticholinergics are effective in inhibiting the parasympathetic activation that contributes to rhinorrhea. Ipratropium bromide nasal spray reduces rhinorrhea and sneezing in the first 3 d of the cold.

Antitussives such as codeine, dextromethorphan, hydrocodone bitartrate, and diphenhydramine hydrochloride suppress the cough reflex in the medullary cough

center. Analgesics can be used to improve the myalgias, headache, and sore throat that accompany the common cold. Antihistaminics have no role in the treatment of common cold. The majority of the above mentioned drugs are available over the counter in combination with antihistaminics, analgesics, or antitussives.

Nonspecific measures such as warm saline gargles are encouraged. The role of vitamin C in the common cold is controversial. Studies with dosages of 1-30 g/d demonstrate a 5-29% decrease in severity and duration of symptoms. However, these studies had significant variations for conclusive evidence. Similarly, despite numerous studies of the role of zinc in the management of cold, zinc's role is still controversial and needs further confirmation. Antibiotics have no role in colds unless patients have evidence of bacterial superinfection of the upper respiratory tract.

## Prevention & Control

Handwashing is key in the prevention of common colds. Minimizing aerosol or droplet transmission with tissues or covering the mouth should be taught to children and adults. Experimental therapies with interferon- $\alpha$ 2 and leukocyte A interferon show some role in the prevention of cold. Producing vaccines for these viruses is difficult because of their numerous serotypes. However, active vaccination can be used for influenza types A and B along with the prophylactic use of amantadine or rimantadine.

## PHARYNGITIS

### Essentials of Diagnosis

- Pharyngeal discomfort or pain, pain on swallowing (odynophagia).
- Associated symptoms such as myalgia, fever, rhinorrhea, and lymphadenopathy depend on the etiologic agent.
- Pharyngeal erythema with or without exudate or lymphadenopathy.
- Leukocytosis, GAS RADT, and bacterial culture or other serologies may provide the definitive microbiologic diagnosis.

### General Considerations

Pharyngitis is an acute infection of the pharyngeal mucosa caused by a variety of pathogenic microorganisms, the majority of which are viral ([Box 9-2](#)). A minority of pharyngitis episodes are bacterial and, of those, group A streptococcus is the most common cause. Viral pharyngitis is caused by respiratory viruses such as rhinoviruses, coronaviruses, adenoviruses, influenza, and EBV. Bacteria causing pharyngitis include group A and non-group A streptococci, *Corynebacterium diphtheria*, *Corynebacterium pseudodiphtherium*, *Neisseria gonorrhoeae*, *Yersinia enterocolitica*, *Arcanobacterium hemolyticum*, and anaerobic bacterial species. Persons infected with the human immunodeficiency virus (HIV) may present with an HIV-induced exudative pharyngitis during the acute retroviral syndrome or with *Candida*-induced pharyngitis. The etiology of pharyngitis remains obscure in 40% of cases. Most pharyngitis occurs as result of

respiratory or contact transmission; few cases are foodborne. Outbreaks are common in winter or in crowded living situations, especially in families with children who serve as reservoirs by acquiring infections in daycare centers or school.

## Clinical Findings

**A. Signs and Symptoms.** The severity of the pharyngitis may vary from mild to life threatening depending on the etiologic agent. Symptoms of mild pharyngitis are irritation or sore throat. With increasing severity there may be severe pain that increases on swallowing or talking, plus cervical lymphadenopathy with or without fever. Pharyngitis can be life threatening with inflammatory edema of pharyngeal walls and extension to the larynx leading to respiratory distress.

An erythematous pharynx with or without exudates or cervical lymphadenopathy is the common finding on examination. Because it impacts therapeutic decision-making, it is important to attempt clinical differentiation between viral and bacterial pharyngitis. However, this may be difficult. Associated clinical signs and symptoms provide diagnostic clues to formulate a differential diagnosis. Mild pharyngeal symptoms with rhinorrhea usually suggest a viral etiology. Pharyngeal exudates suggest streptococcal pharyngitis, HIV, or EBV. Presence of vesicles and ulcers is seen with herpes simplex and coxsackievirus. Coxsackievirus-related vesicles often occur on the hard palate. Adenoviral pharyngitis is associated with conjunctival congestion. EBV, HIV, *A hemolyticum*, and streptococcal toxic shock can present with pharyngitis and a generalized rash. Pharyngitis with elevated transaminases, splenomegaly, and atypical lymphocytosis is the typical manifestation of EBV-induced infectious mononucleosis. Aseptic meningitis along with pharyngitis should suggest an acute HIV or enteroviral syndrome. Systemic viral infections with CMV, measles, and rubella, among others, can present with acute pharyngitis.

Sore throat with cough and signs of pneumonia may suggest influenza, *Chlamydia pneumoniae* or *Mycoplasma pneumoniae*. Diphtherial pharyngitis is associated with a grayish pseudomembrane.

GAS (*Streptococcus pyogenes*) pharyngitis frequently presents with fever of  $> 38.3^{\circ}\text{C}$ , chills, sudden-onset sore throat, painful and difficult swallowing, and tender cervical lymph nodes. Lymphadenopathy is more likely to be anterior and tender in GAS pharyngitis, unlike viral pharyngitis, which is more likely to be generalized and nontender. Exudate with intense pharyngeal and tonsillar pillars erythema is seen. Occasionally patients, especially children, present with systemic symptoms of nausea, vomiting, and headache. Symptoms of non-group A, such as group C or G, streptococcal pharyngitis are very similar to GAS and clinically indistinguishable. These symptoms and signs are nonspecific for GAS pharyngitis. However, absence of fever or presence of other symptoms such as rhinorrhea, cough, oral ulcers, and viral exanthema strongly suggests a viral rather than a GAS pharyngitis.

**B. Laboratory Findings.** Laboratory values may not be of considerable help. Testing for GAS should be done in all patients in whom GAS pharyngitis cannot be confidently excluded on clinical grounds. Diagnosis of GAS pharyngitis can be made by RADT, which has a sensitivity of 80-95% and specificity of 95%. Use of RADT significantly

increases the number of patients receiving appropriate antibiotic treatment. Because of its relatively lower sensitivity, a negative test should be confirmed with a throat culture. Throat cultures taken from the tonsillar fossae and posterior pharyngeal wall are 90-95% sensitive for the diagnosis of GAS pharyngitis. Follow-up cultures are not generally recommended except in patients with histories of acute rheumatic fever or poststreptococcal glomerulonephritis or in outbreaks. Asymptomatic contacts of the patient do not need to be screened unless there is an outbreak or the patient has a history of acute rheumatic fever.

Special culture media for *N gonorrhoeae* or *C diphtheria* should be specifically requested when these bacteria are suspected. Serologic testing can establish the diagnosis of EBV, HIV, CMV, influenza, *M pneumoniae*, and *C pneumoniae*. During acute HIV retroviral syndrome, HIV RNA polymerase chain reaction, or HIV culture can help make a diagnosis because HIV serology may be negative.

**C. Imaging.** A lateral neck x-ray should be done if the patient has associated symptoms of stridor or respiratory compromise, to rule out laryngeal obstruction.

### Differential Diagnosis

In children, Kawasaki's syndrome can present with a clinical picture similar to an infectious pharyngitis. Noninfectious causes of pharyngitis include chemotherapy-induced mucositis, drug reactions, agranulocytosis, or connective-tissue disorders.

### Complications

Local complications of bacterial pharyngitis include peritonsillar or retropharyngeal abscesses or *Fusobacterium necrophorum* jugular vein thrombophlebitis and its embolic complications (Lemeire's syndrome). In the United States, appropriate and timely antibiotics have decreased nonsuppurative complications of *S pyogenes* such as rheumatic heart disease or poststreptococcal glomerulonephritis. *C diphtheria* pharyngitis may become complicated by acute upper-airway obstruction, myocarditis, or neuritis. Viral pharyngitis may be complicated by secondary bacterial infection of the sinuses or lower respiratory tract.

### Treatment

In patients with a clinical picture consistent with GAS pharyngitis, empirical therapy should be started to prevent suppurative and nonsuppurative complications, to decrease infectivity and transmissibility, and to induce clinical improvement of symptoms ([Box 9-3](#)). Patients with a high index of suspicion for GAS pharyngitis but negative or pending RADT/culture results can be given empirical antibiotics until the results are available. An alternative approach is to withhold antibiotics until the culture is positive for *S pyogenes*. Delaying therapy against GAS does not increase the incidence of rheumatic heart disease or recurrences with the same strain of *S pyogenes*. Following the latter course will decrease inappropriate antibiotic use and control the increase in antibiotic resistance.

Antibiotic selection is based on efficacy, ease of administration, cost, compliance, and spectrum of the antibiotic. The treatment of choice is penicillin V or amoxicillin for 10 d to treat and eradicate carriage. Intramuscular benzathine penicillin G may be given in patients unlikely to complete a 10-d course. Shorter courses are not recommended until more definitive studies are available. Erythromycin or other macrolides (such as clarithromycin or azithromycin), or oral cephalosporins are the recommended alternatives for bacterial pharyngitis in patients who are allergic to penicillin. Absence of penicillin-resistant GAS and limited (5%) resistance to erythromycin make it imperative to choose a cheaper alternative to the newer more expensive antibiotics. In some patients with recurrent GAS pharyngitis, penicillin is unable to eradicate nasopharyngeal carriage. In such patients, rifampin, clindamycin, or amoxicillin/clavulanate use may decrease colonization. Patients with negative throat RADT/cultures should have antibiotics discontinued.

Pharyngitis caused by anaerobic bacteria may respond to penicillins, amoxicillin/clavulanate, or clindamycin. *A hemolyticum* is susceptible to erythromycin. *Yersinia* pharyngitis requires treatment with a third-generation cephalosporin, an aminoglycoside or trimethoprim-sulfamethoxazole (TMP-SMX). Effective therapies for gonococcal pharyngitis include ceftriaxone, cefixime, or fluoroquinolones such as norfloxacin, ofloxacin, or ciprofloxacin. Treatment of choice for *Mycoplasma* pharyngitis is either doxycycline or macrolides. Doxycycline is contraindicated in children < 8 y old because it causes discoloration of teeth.

Symptomatic oropharyngeal herpes simplex ulcers, particularly in an immunocompromised host, should be treated with acyclovir for 7-10 d. Influenza type A pharyngitis can be treated with amantadine or rimantadine or the neuraminidase inhibitors if the patient presents within 48-72 h of onset of symptoms. HIV acute retroviral syndrome should be considered for treatment with combination antiretroviral therapy.

General measures for symptomatic relief include fluids, warm saline gargles, and nonsteroidal anti-inflammatory drugs. Aspirin should be avoided in children with viral infections, particularly varicella-zoster virus infection, to prevent Reye's syndrome. Patients that appear toxic or patients with suppurative complications should be hospitalized for parenteral or surgical management.

## **Prognosis**

Uncomplicated pharyngitis results in no sequelae. Prognosis of GAS pharyngitis complicated by rheumatic heart disease or poststreptococcal glomerulonephritis is good with penicillin prophylaxis in rheumatic heart disease and spontaneous remission in poststreptococcal glomerulonephritis. Suppurative complications have minimal long-term adverse effects.

## **Prevention & Control**

Active immunization plays a role in prevention with regard to diphtheria and influenza types A and B ([Box 9-4](#)). Tonsillectomy is recommended in selected patients. Penicillin prophylaxis is required in patients at risk for recurrent rheumatic fever.

# ACUTE LARYNGITIS

## Essentials of Diagnosis

- Hoarseness or loss of voice (aphonia).
- Associated symptoms of rhinitis, pharyngitis, or cough.
- Children tend to develop airway obstruction.
- On direct examination, the larynx is hyperemic and edematous, with or without ulcerations.
- Mostly viral, occasionally bacterial.
- Persistent hoarseness lasting > 10 d should prompt laryngoscopy to exclude other etiologies.

## General Considerations

Laryngitis is the infection of the larynx that results in an inflammatory reaction and consequential symptoms and signs. Common cold viruses such as rhinovirus, influenza virus, adenoviruses, RSV, or parainfluenza viruses may cause acute laryngitis. It usually presents in winter as part of an upper respiratory tract infectious syndrome. Bacterial laryngitis is less common and is caused mainly by *S pyogenes* or *Moraxella catarrhalis*. Rarely laryngitis may be caused by *Mycobacterium tuberculosis*, syphilis, or fungi such as *Histoplasma capsulatum*, *Blastomyces dermatitidis*, or *Candida albicans*.

## Clinical Findings

**A. Signs and Symptoms.** Hoarseness, aphonia, and symptoms of associated upper respiratory tract infection such as rhinitis or pharyngitis may accompany acute laryngitis. Respiratory obstruction may occur particularly in children. Direct examination when done shows the larynx to be hyperemic and edematous, with or without ulcerations. An exudate or membrane may be seen in diphtheria, streptococcal, or EBV laryngitis.

**B. Imaging.** Lateral x-ray of the neck may be helpful to exclude acute bacterial epiglottitis or bacterial tracheitis. If symptoms of hoarseness persist beyond 2 wk, patients should be evaluated by direct visualization of the larynx by laryngoscopy.

## Differential Diagnosis

Voice abuse is the most frequent noninfectious cause of hoarseness. Differential diagnosis includes tumors, paralysis of the vocal cords, chemical irritants, or gastroesophageal reflux. Patients with laryngitis must also be differentiated from those with acute epiglottitis or bacterial tracheitis, which usually present with more systemic symptoms.

## Complications

Respiratory obstruction in children is the most serious complication.

## Treatment

Because the majority of laryngeal infections are viral, therapy is mostly supportive with voice rest, warm saline gargles, and increased humidity. If specific microbiologic diagnosis is made with positive microbiologic cultures, then therapy should be directed at the organism isolated.

## Prognosis

Long-term prognosis is excellent with no residual symptoms.

## Prevention & Control

Preventive measures for laryngitis are similar to those for common cold and pharyngitis.

## ACUTE LARYNGOTRACHEOBRONCHITIS (CROUP)

### Essentials of Diagnosis

- Most often in children ages 6 mo to 6 y, peak is at 2 y.
- Fever, hoarseness of voice followed by paroxysms of nonproductive, brassy cough that ends with a characteristic inspiratory stridor.
- The child appears anxious and has tachypnea, inspiratory stridor, retraction of intercostal muscles, and associated rhonchi or wheezing.
- Anterior-posterior x-ray view of the neck shows the subglottic obstruction.
- Microbiologic diagnosis can be established by serology, viral or bacterial cultures from the pharynx, or rapid antigen detection enzyme immunosorbent assays such as for RSV or influenza type A.

### General Considerations

Acute laryngotracheobronchitis (LTB) or croup is subglottic inflammation and edema caused by a viral or bacterial infection of the larynx, trachea, and bronchi ([Box 9-5](#)). Croup is the most common cause of upper respiratory tract obstruction in children between the ages of 6 mo and 6 y, with the peak occurrence at 2 y old. It is caused mostly by viruses, primarily parainfluenza virus types I and II, although others, such as influenza type A or B, RSV, and adenovirus are also implicated. Occasionally *M pneumoniae* can cause LTB.

### Clinical Findings

**A. Signs and Symptoms.** Most children have hoarseness of voice and a brassy cough with an associated inspiratory or even an expiratory stridor. Fever, rhinorrhea, sore throat, and cough usually precede this. Symptoms may vary in intensity and last ~ 3-4 d if mild. Patients appear apprehensive and tend to lean forward. The child may have tachypnea and might be using accessory respiratory muscles. Inspiratory or expiratory stridor is prominent. Pulmonary examination may reveal rhonchi, crepitations, or wheezing. Breath sounds may be diminished if upper airway obstruction is severe and air entry is greatly decreased.

**B. Laboratory Findings.** The white blood cell count may be normal or mildly elevated. Noninvasive pulse oximetry to monitor the oxygen saturation is recommended. Arterial blood gas assessment shows hypoxemia and/or hypercapnia, depending on the severity of the disease.

**C. Imaging.** Lateral neck x-rays show overdilated hypopharynx, subglottic narrowing that is wider on expiration than inspiration, thickened vocal cords, and a normal epiglottis. Anterior-posterior views of the neck show edematous subglottic walls converging to create a characteristic "steeple sign" ([Figure 9-1](#)). There may also be diffuse narrowing of the trachea and bronchi ([Figure 9-2](#)).

### Differential Diagnosis

Acute epiglottitis is a major differential diagnosis to be considered when a child presents with these symptoms. Radiographs of the neck can easily help differentiate the two conditions. Other causes of similar symptoms include foreign-body aspiration, which can be determined by history, x-rays, or endoscopic evaluation. Membranous croup or bacterial tracheitis should also be considered if the child presents with a clinical picture similar to croup but appears more toxic and has subglottic narrowing on radiographs of the neck.

### Complications

Severe croup, as may occur with influenza type A, may require tracheotomy or intubation in = 13% of patients and have an associated mortality of 0-2.7%. A small percentage of children with prolonged intubation or severe disease may develop subglottic stenosis. A few follow-up studies have shown an increase in hyperactive airways in children with a history of croup.

### Treatment

Antibiotics are not routinely recommended for the treatment of croup unless the patient has symptoms or cultures suggestive of bacterial etiology ([Box 9-6](#)). Cool air humidification and supportive care are essential to keep the child calm, to prevent further tachypnea and distress. Respiratory rate is the best predictor of hypoxemia. Noninvasive pulse oximetry or arterial blood gas testing for PaO<sub>2</sub> or PaCO<sub>2</sub> should aid in assessment of the patient's condition and response to therapy. Noninvasive monitoring is preferred to prevent further anxiety in the child.

Nebulized racemic epinephrine is important in the therapy for croup because the a and

$\beta$  agonists decrease edema and relieve obstruction by vasoconstriction. Racemic epinephrine nebulization is well tolerated, even by the younger children, and may decrease the need for intubation. Children receiving racemic epinephrine should be observed for relapse because epinephrine has a short half-life and rebound vasodilatation and edema can occur. Racemic epinephrine nebulization should be used cautiously in children with left ventricular outflow tract obstruction such as tetralogy of Fallot or idiopathic hypertrophic subaortic stenosis. In severe croup, corticosteroids (eg, dexamethasone) decrease subglottic edema, the number of racemic epinephrine treatments, and intubations.

Some children will fail medical management and require intubation. Intubation should be done in fully equipped units and preferably via the nasotracheal route. Extubation is usually attempted in ~ 5-7 d if extubation criteria are met. Extubation criteria include decreased secretions, decreased leakage around the endotracheal tube (which indicates decreased edema), and an alert child. Failure to extubate should prompt further endoscopic evaluation.

### **Prognosis**

Croup is mostly a self-limited disease with complete uncomplicated resolution. As mentioned above, some children may develop hyperactive airways or become predisposed to recurrent croup. A few may develop subglottic stenosis caused by severe disease or prolonged intubation.

### **Prevention & Control**

Good handwashing and cleanliness can help decrease transmission from an infected patient, particularly at daycare centers or even in the home environment.

## **ACUTE EPIGLOTTITIS**

### **Essentials of Diagnosis**

- Occurs in children between 2 and 6 y , can occur in adults although it presents with less severity.
- Irritable, febrile, sore throat; odynophagia, dysphonia, and dyspnea.
- Sits forward drooling, toxic appearing, tachypneic
- Examination of the larynx should not be attempted. Direct examination should be performed only by a trained person and in a unit where immediate intubation or tracheotomy can be performed.
- Direct laryngoscopic examination reveals a "cherry red" edematous epiglottis.
- Polymorphonuclear leukocytosis is common. Blood and epiglottis cultures are often positive for *Haemophilus influenzae* type b, *Staphylococcus aureus*, or other bacteria.

## General Considerations

Acute epiglottitis is a true respiratory emergency. An epiglottic infection leads to acute inflammation and edema of the epiglottis and can cause upper airway obstruction. Acute epiglottitis can occur at any age, however it is more common in children between 2-6 y and most often occurs in the winter and spring. Unlike croup, which is predominantly a viral disease, acute epiglottitis is a bacterial disease caused mainly by *H influenzae* type b, *S aureus*, or streptococcal species ([Box 9-7](#)). *H influenzae* type b was the most common organism isolated from children with acute epiglottitis, but widespread use of the *H influenzae* type b vaccine has dramatically decreased the incidence of *H influenzae* type b acute epiglottitis.

## Clinical Findings

**A. Signs and Symptoms.** The child presents with a short (6- to 12-h) rapidly progressive febrile illness, sore throat, pain on swallowing, and shortness of breath. There is usually no antecedent history of a viral infection. Adults have a similar clinical presentation with sore throat being a predominant symptom.

The patient looks anxious, appears toxic, and assumes a forward-leaning, neck-extended posture. Drooling of oral secretions and muffled voice are the sine qua non. The child has marked tachypnea and may have an inspiratory stridor from the supraglottic mucosa prolapsing into the glottis. Lung auscultation may reveal crepitations or bronchial breath sounds if there is associated pneumonia.

**B. Laboratory Findings.** The white blood cell count is elevated with a polymorphonuclear reaction. The blood and epiglottis cultures are frequently positive. Bacteremia occurs in almost all of the children with *H influenzae* type b acute epiglottitis. Serum latex agglutination tests against *H influenzae* type b may be helpful in making a rapid microbiologic diagnosis in patients from whom cultures were not obtained before starting antibiotics.

**C. Imaging.** Caution must be exercised in sending these patients for tests or x-rays without adequate supervision and to avoid a delay in intubation. Radiographs of the neck show an enlarged edematous epiglottis with a normal subglottic space. Some x-rays may be negative or show subglottic obstruction, and the diagnosis may be obscured. ([Figure 9-3](#)). Chest x-rays may show evidence of pneumonia. Laryngoscopic evaluation should be carried out by trained personnel in a controlled setting such as an operating room or unit equipped for immediate intubation.

## Differential Diagnosis

Croup or acute LTB presents with a clinical picture similar to that of acute epiglottitis. Croup has slower-onset, viral prodromal symptoms, a nontoxic appearing child, and absence of drooling. Anterior-posterior x-rays of the neck confirm the diagnosis. Other conditions that have a similar presentation include angioedema, foreign-body aspiration, and retropharyngeal or peritonsillar abscesses. Angioedema and foreign-body aspiration are suspected based on history and imaging or endoscopic evaluation. Radiographs or laryngoscopic evaluation identifies retropharyngeal or peritonsillar

abscesses.

## Complications

Mortality associated with untreated obstructive acute epiglottitis is ~80%. Respiratory failure from upper-airway obstruction is the most common complication. Occasionally patients will develop pulmonary edema along with the respiratory distress.

## Treatment

Acute epiglottitis is a medical emergency. Once acute epiglottitis is suspected, the child should be kept in an upright position and be accompanied at all times by personnel trained in advanced cardiopulmonary life support. Diagnosis should be expeditiously established clinically or radiographically. Laryngoscopic examination should be attempted only in a unit equipped for immediate intubation and only by experienced personnel. Maintenance of a patent airway is of foremost importance in the care of a patient with acute epiglottitis. Patients with impending respiratory failure who cannot be intubated may require an emergency subglottic tracheotomy. All pediatric patients with acute epiglottitis should be intubated preferably via a nasotracheal or an uncuffed endotracheal tube. Observation alone is not recommended in pediatric patients because of high associated mortality. Management of adult patients depends on the severity of clinical symptoms and signs of upper-airway obstruction.

Blood and epiglottic cultures should be obtained once the airway is secured. Patients should be started on parenteral antibiotics that are active against *H influenzae* type b, *S aureus*, and streptococci (Box 9-8). Because of the high degree of  $\beta$ -lactamase-mediated resistance in *H influenzae* type b, third-generation cephalosporins such as ceftriaxone or cefotaxime or a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combination antibiotic such as ampicillin/sulbactam should be started. Patients with acute epiglottitis usually improve within 12-48 h with appropriate antibiotics, and these should be continued orally or parenterally for 7-10 d. The average period of intubation is ~ 2 d, and direct visualization is the most effective way to determine time of extubation.

## Prognosis

Expeditious diagnosis, immediate management of upper-airway obstruction, and institution of antibiotics decreases morbidity and mortality related to acute epiglottitis. Full recovery without sequelae is expected in such patients.

## Prevention & Control

*H influenzae* type b polysaccharide vaccination can further decrease the incidence of acute epiglottitis (Box 9-9). However, patients can still be susceptible to non-type-b *H influenzae* and other bacterial etiologies of epiglottitis.

The secondary attack rate of *H influenzae* type b among all household contacts, especially in children < 4 y old, can be decreased by a prophylactic 4-d course of rifampin (20 mg/kg/d in a single daily dose). Rifampin prophylaxis should be given to the patient and all household contacts regardless of previous immunization status, to

prevent carriage state.

## OTITIS MEDIA

### Essentials of Diagnosis

- Commonest cause of office visits in children between 6 mo and 2 y.
- Irritability, fever, earache, discharge from the ear, occasional vertigo.
- On otoscopic examination, the tympanic membrane is erythematous and has decreased mobility on pneumatic otoscopy, which demonstrates the presence of middle ear fluid.
- There may be diminished hearing.
- Laboratory values may show leukocytosis. Cultures of the ear are not routinely recommended.

### General Considerations

Acute otitis media (AOM) is the middle ear inflammation that results in collection of fluid in the middle ear and associated local and systemic symptoms.

AOM is the most common reason for physician office visits for children under age 15 y. Children < 3 y and those at the age of school entry (5-6 y) are most vulnerable to AOM. Predisposing and recurrence factors for AOM include daycare attendance, particularly at large (> 6 children per room) centers, a sibling with AOM, parental smoking, and drinking from a bottle while lying flat on the back. Boys, Native Americans, and Alaskans have a higher incidence of AOM. A small percentage of children have an identifiable risk factor for recurrences such as congenital orofacial deformities and congenital or acquired immunodeficiencies such as HIV/AIDS. Recurrences occur in normal children with no apparent anatomic defects. A large percentage of AOM is viral, which may explain recurrences.

The most common bacterial organism responsible for otitis media is *Streptococcus pneumoniae*, which accounts for ~ 30-40% (Box 9-10) of cases. Cultures from the middle ear in various studies have demonstrated *S pneumoniae*, nontypable strains of *H influenzae* (21%), *M catarrhalis* (12%), *S aureus*, GAS (2-6%), and other less common gram-negative organisms including *Pseudomonas aeruginosa*. Penicillin-resistant *S pneumoniae* (PRSP) is increasing in the community and contributes to recalcitrant cases of AOM. PRSP is common in children < 6 y old, children who have received recent antibiotics, children with previous AOM, and children attending group daycare. Gram-negative organisms should be considered in neonates with AOM. Rare causes include *M pneumoniae*, which has a classic bullous lesion on the tympanic membrane, and *Chlamydia trachomatis* may be seen in very young infants. Occasionally mycobacterial or diphtheria middle-ear infections can occur.

### Clinical Findings

**A. Signs and Symptoms.** Young infants or children may present with crying, irritability, anorexia, lethargy, or a history of pulling at the affected ear. Earache with or without associated drainage from the ear is the most common symptom in older children and adults. They may be febrile and occasionally present with vertigo, tinnitus, or decreased hearing.

Otoscopic examination reveals an erythematous tympanic membrane. The tympanic membrane may be bulging, retracted, or perforated and occasionally exuding purulent drainage from the perforation. Fluid in the middle ear is demonstrated by air-fluid levels, bulging, and decreased mobility of the tympanic membrane demonstrated by pneumatic otoscopy. Pneumatic otoscopy should be attempted in all children unless it is too painful. Other otologic techniques such as tympanometry and acoustic reflectometry can help assess the amount of fluid in the middle ear. Audiologic evaluation is necessary in children with hearing loss.

**B. Laboratory Findings.** Laboratory values are not helpful in the management of AOM. There may be polymorphonuclear leukocytosis. Routine middle ear cultures via tympanocentesis are not recommended unless the patient is toxic, has recurrent infections, or is not responding to empirical therapy. Swab cultures from the external auditory canal (EAC) do not accurately reflect the organism causing AOM because the EAC cannot be adequately decontaminated. Nasopharyngeal cultures are not specific in identifying the causative bacteria in AOM.

**C. Imaging.** Imaging is not of considerable help in otitis media. CT scans of the head should be done if mastoiditis or other complications are suspected.

### **Differential Diagnosis**

Noninfectious causes of AOM, such as Wegener's granulomatosis, must be considered in a patient with recurrent and nonresponding disease. A foreign body in the EAC can present with earache and minimal erythema of the tympanic membrane. History and otoscopic visualization should identify a foreign body. A viral infection, fever, or crying or earwax removal can also cause a red tympanic membrane.

### **Complications**

Chronic otitis media, effusion, mastoiditis, and intracranial extension may result from recurrent otitis media and persistent middle ear effusion. In the preantibiotic era, mastoiditis and intracranial extension occurred in ~ 20% and 2.5%, respectively, of AOM patients. Now that the use of antibiotics is common, these rates have decreased to 2.8% and 0.13%, respectively. Contiguous spread to the cranial fossae, temporal or petrous bone, or sigmoid or lateral sinuses results in suppurative complications. Conductive hearing loss because of chronic otitis media and effusion can potentially impair language development and academic functioning of the child.

### **Treatment**

A large number of AOM cases are viral in nature with or without bacterial superinfection.

Approximately 30% of AOM cases are bacterial. Studies have also demonstrated spontaneous resolution in 16% of *S pneumoniae* infections, 50% of *H influenzae* infections, and ~ 80% of *M catarrhalis* AOM, particularly in children older than 2 y. Because of concerns regarding suppurative complications, parental expectation, and perhaps convenience, antibiotic therapy has become the norm for most AOM treatment ([Box 9-11](#)). Numerous studies have now demonstrated that antibiotics benefit defervescence and otalgia, decrease suppurative complications, and improve tympanic membrane healing, but they have no significant benefit in long-term outcomes such as recurrence rates or chronic middle ear effusion. These studies and the recent increase in multi-drug-resistant organisms that have no or minimally efficacious treatment have brought this practice of judicious antibiotics use for AOM into question.

The approach to patients with AOM should be individualized. A delayed antibiotic approach can be considered in children older than 2 y with no immunodeficiency, no craniofacial anatomic abnormalities, intact tympanic membrane, and no previous AOM. The child should be scheduled for a follow-up visit. If a follow-up visit is not possible, an antibiotic can be started at the initial evaluation. The initial empirical antibiotic regimen should be active against the common organisms. Despite the emergence of resistance in these bacteria, amoxicillin is still the preferred and effective initial antibiotic of choice. In children with a history of antibiotic use in the preceding month, the initial antibiotic is still amoxicillin but given at a higher dose.

Antibiotics effective in the treatment of AOM include amoxicillin/clavulanate, cephalosporins such as cefaclor, cefixime, cefprozil, cefuroxime, cefpodoxime, loracarbef, or macrolides such as erythromycin, azithromycin, or clarithromycin, TMP-SMX, and erythromycin/sulfisoxazole (Pediazole). The newer expensive antibiotics do not have a significant benefit as first-line agents when compared with their cheaper counterparts (eg, amoxicillin and TMP-SMX). In patients with penicillin allergy, cephalosporins, macrolides, or TMP-SMX can be prescribed. Cephalosporins should be avoided in patients with histories of anaphylactic reaction to penicillin. Studies report mean clinical cure rates of 85-94% with amoxicillin.

Most patients start responding in 48-72 h. Causes for slower response or recurrence with lower-dose amoxicillin therapy include resistant organisms such as intermediate- or high-grade PRSP or  $\beta$ -lactamase-producing *H influenzae* or *M catarrhalis*, suppurative complications, or noncompliance. Treatment failure is defined as lack of improvement in fever, ear pain, and persistent tympanic congestion, bulging, or otorrhea. It is important not to mistake a persistent middle ear effusion without signs of active infection as treatment failure. Treatment failure may be early (3 d) or late (10-25 d). If a child requires further treatment, high-dose (80 mg/kg/d) amoxicillin, a cephalosporin, amoxicillin/clavulanate, or a macrolide (either azithromycin or clarithromycin) may be prescribed. The choice of retreatment antibiotic depends on the risk of PRSP in the patient. Higher-dose amoxicillin or amoxicillin/clavulanate is still efficacious against intermediate-penicillin-susceptible *S pneumoniae*. Cefaclor and cefprozil are not good alternatives as second-line therapy because of their lower efficacy against nonsusceptible *S pneumoniae* and *H influenzae*. Because of the lack of activity against PRSP, clarithromycin, azithromycin, TMP/SMX, cefixime, ceftibuten, and loracarbef are recommended only as second-line antibiotics for patients at low risk for PRSP AOM.

Patients suspected of having PRSP AOM who fail high-dose amoxicillin should be considered for tympanocentesis for culture and susceptibilities. If empiric therapy is decided, the antimicrobial therapy should be effective against the  $\beta$ -lactamase-producing *H influenzae* and *M catarrhalis* in addition to being active against PRSP. Options include oral cefuroxime axetil, cefpodoxime or clindamycin, or parenteral cefotaxime, ceftriaxone or vancomycin. In children receiving clindamycin for PRSP, the addition of a  $\beta$ -lactamase-stable cephalosporin may be required to cover for  $\beta$ -lactamase-producing *H influenzae*. One parenteral dose of ceftriaxone 50 mg/kg/d is approved for AOM caused by susceptible *S pneumoniae*. However, ceftriaxone given daily for 3 d is likely to be more efficacious for AOM failing the first-line antimicrobial-agent therapy. Parenteral therapy is usually needed only for patients with severe AOM or those failing their second regimen. Middle ear aspirates should be sent for culture and susceptibilities to guide therapy in children failing second-line therapy. These patients should be reevaluated in 2 wk to ascertain that no suppurative complications have developed. A severely ill child failing initial therapy should be considered for admission and treatment with parenteral vancomycin and a third-generation cephalosporin, such as cefotaxime or ceftriaxone. A thorough evaluation for complications should also be conducted.

Symptomatic treatment is primarily pain control with analgesics such as acetaminophen or nonsteroidal anti-inflammatory drugs. On occasion, myringotomy (incision of the tympanic membrane) may be required to relieve the middle ear pressure. In most studies, myringotomy did not improve outcome even when combined with antibiotics. Antihistaminics and decongestants have equal efficacy as a placebo in AOM, and they are not recommended.

Treatment of recurrent otitis media includes prevention of recurrent attacks, a second course of antibiotics with broader antibacterial spectrum as mentioned above or specific treatment depending on middle ear cultures. Secondary antibiotic prophylaxis, surgical drainage or adenoidectomy, and active immunization are some of the measures used to prevent AOM. Children with three new episodes in 6 mo or four episodes in 1 y should be considered for antibiotic prophylaxis with amoxicillin or erythromycin/sulfisoxazole. Antibiotic prophylaxis decreases recurrences = 44%. The patient should be regularly evaluated for middle ear effusion. Middle ear effusion is seen in ~ 50% of children with AOM and usually resolves in 3 mo in the majority of patients. Persistent middle ear effusion or otitis media with effusion (OME) beyond 3-4 mo requires further management. Children with OME should have an audiologic test to detect any hearing loss. Patients with OME with normal hearing should be retreated with a 2- to 3-wk course of an antibiotic. If the effusion resolves, then a prophylactic antibiotic course of 3 mo may be of benefit to prevent recurrences. Children with OME and conductive hearing loss should be evaluated by an otorhinolaryngologist for surgical drainage procedures such as myringotomy and tympanostomy tubes (tubes placed in the tympanic membrane for permanent drainage).

## **Prognosis**

Recurrent AOM or OME may impair hearing, language development, and learning capabilities of the patient. The prognosis is worsened in patients with intracranial extension of infection. Uncomplicated AOM resolves without significant sequelae.

## Prevention & Control

Currently available 23 polyvalent pneumococcal polysaccharide vaccine produces poor immunologic responses in children < 2 y old but can be used for children > 2 y . The Advisory Committee on Immunization Practices advises that this vaccine be given to children with higher likelihoods of pneumococcal infections such as HIV-positive, asplenic, or sickle cell anemia patients. Conjugated pneumococcal vaccine is available and is more efficacious in children < 2 y old and may contribute to lowering the incidence of pneumococcal otitis media.

## OTITIS EXTERNA

### Essentials of Diagnosis

- Infection and inflammation of the external auditory canal causing pain and itching, similar to infections of the skin and soft tissue.
- *S aureus* or group A *Streptococcus* often causes acute localized otitis externa, similar to furunculosis.
- Main symptoms are localized pain and itching.
- "Swimmer's ear" or acute diffuse otitis externa is often caused by *P aeruginosa* or by *Aspergillus* spp.
- Chronic otitis externa results from persistent drainage caused by chronic suppurative otitis media. This may present as chronic itching.
- "Malignant" otitis externa is a severe necrotizing *P aeruginosa* infection of the external auditory canal and adjacent tissues. Severe pain, tenderness, and other signs of complications may be present.

### General Considerations

Inflammation of the EAC is particularly symptomatic because of the limited space for expansion of edematous tissue in the narrow external auditory canal.

### Clinical Findings

**A. Signs and Symptoms.** Infection of the EAC is divided into four different categories ([Box 9-12](#)):

1. Acute localized otitis externa is the most common form of otitis externa. It is similar to staphylococcal infections of the skin and hair follicles. Because of limited area for expansion, inflammation and edema of the EAC wall cause intense pain and tenderness. The canal has local erythema, heat, and tenderness over the tragus. There may be associated preauricular lymphadenopathy.

2. Acute diffuse otitis externa or "swimmer's ear" is caused mainly by gram-negative organisms, particularly *P aeruginosa*. It occurs in hot, humid climates or may be associated with contaminated hot-tub baths. Fungal organisms such as *Aspergillus* spp. may also cause symptoms of pain and itching in the ear. The canal is erythematous, edematous, and, in some severe cases, hemorrhagic.

3. Chronic otitis externa is a complication of persistent chronic otitis media and resultant drainage into the EAC leading to chronic irritation. Itching of the EAC is the main symptom.

4. "Malignant" or invasive otitis externa is a severe, necrotizing infection of the EAC with invasion into the surrounding tissues including blood vessels, cartilage, and bone. *P aeruginosa* is the most frequently isolated organism. Immunocompromised hosts, elderly, and particularly diabetics are predisposed to this disease

**B. Laboratory Findings.** Laboratory findings are not helpful in the diagnosis and management of otitis externa. The white blood cell count and sedimentation rate may be elevated in malignant otitis externa. Cultures from the EAC or involved tissue in malignant otitis externa are frequently positive for *P aeruginosa* or other bacteria.

**C. Imaging.** Imaging is not required for otitis externa but CT or magnetic resonance imaging of the head delineates the extent of damage in malignant otitis externa and its complications. This could potentially aid in the further management of this condition.

## Complications

Complications develop by local invasion such as temporal bone osteomyelitis, septic thrombophlebitis of the sigmoid or lateral sinus or jugular bulb, cranial nerve palsies, meningitis, or brain abscess.

## Treatment

Gentle cleaning is recommended for most otitis externa. Local heat, topical antibiotic solutions such as neomycin, polymyxin, or ofloxacin, or systemic antibiotics, or some combination of these are effective in the treatment of acute otitis externa ([Box 9-13](#)). Irrigation with hypertonic (3%) saline and cleansing with alcohol and acetic acid mixed 1:1 are recommended for acute diffuse otitis externa, whether it is bacterial or fungal. Fungal otitis externa may also be amenable to treatment with *m*-cresyl acetate. Topical antibiotics combined with steroids are sometimes used for 1-2 d to decrease edema. Severe infections may require systemic antibiotics with activity against *P aeruginosa*. Malignant otitis externa may be treated with parenteral antipseudomonal antibiotics such as ceftazidime or penicillins with antipseudomonal activity such as piperacillin with aminoglycoside or oral antipseudomonal antibiotics such as the fluoroquinolones. Topical antipseudomonal antibiotics, such as neomycin, polymyxin, or ofloxacin, are used for 4-6 wk.

## ACUTE & CHRONIC SINUSITIS BR> Essentials of Diagnosis

- Fever, facial pain or pressure, headache, purulent nasal or postnasal discharge (PND), cough.
- Tenderness over the sinuses, PND, other signs of complications may be seen such as meningismus or periorbital cellulitis.
- Leukocytosis in some cases, sinus or blood cultures may be positive for *S pneumoniae*, *H influenzae*, or other bacteria.
- CT scan is a very sensitive method of detecting sinusitis.

## General Considerations

Inflammation of the pseudostratified epithelium of the sinuses may occur as a result of an infection, allergy, toxin, or an autoimmune disorder. The paranasal sinuses (maxillary, ethmoid, frontal, and sphenoid) are sterile under normal conditions. Any one or all of them may become infected resulting in inflammation and edema of the pseudostratified epithelium that leads to an increase in tenacious secretions and the symptoms of acute sinusitis. The maxillary sinus is most commonly involved because its ostium is located at the highest part of the medial wall of the sinus. This leads to inadequate drainage and pooling of excess secretions, increased tenacity of secretions, and a drop in oxygen tension creating a more favorable environment for bacterial growth. Acute sinusitis occurs in all ages.

Infectious sinusitis may be bacterial, fungal, or viral. A large percent of acute sinusitis results from viral infection of the sinuses with or without bacterial superinfection. The latter is more symptomatic and patients are more likely to present to the physician. Episodes of sinusitis that occur all year round may be associated with allergies, polyps, or swimming.

The microbiology of acute bacterial sinusitis is similar to that of otitis media ([Box 9-14](#)). *S pneumoniae* and *H influenzae* account for > 50% of the sinusitis cases. Other pathogenic bacteria include *M catarrhalis*,  $\alpha$ - and  $\beta$ -hemolytic streptococci, *S aureus*, *C pneumoniae*, anaerobic bacteria, and occasionally gram-negative bacteria such as the Enterobacteriaceae or *P aeruginosa*. The  $\beta$ -lactamase-producing *H influenzae* and *M catarrhalis* and intermediate or PRSP have proportionally increased in the microbiology of sinusitis and have important implications for management of sinusitis. Anaerobic bacteria, such as *Peptostreptococcus*, *Fusobacterium*, or *Prevotella* species, are implicated in ~ 8-10% of cases of acute sinusitis. These are usually polymicrobial and result from contiguous spread from the roots of the teeth.

Patients with craniofacial fractures have a higher incidence of sinusitis. *P aeruginosa* is a frequent cause of sinusitis in HIV-positive and in cystic fibrosis patients and must be considered in a patient who fails empirical antibiotic therapy that does not include antipseudomonal activity. *S aureus* is slightly more common in frontal or sphenoidal sinusitis. Fungi such as *Aspergillus* spp., Zygomycetes (*Mucor* spp.), and *Pseudallescheria* spp., among others, can occur in normal hosts or in immunocompromised hosts. *Aspergillus* sinusitis may occur in normal hosts or present as an allergic syndrome. Zygomycetes infection is more common in people with

diabetes (particularly during acidosis), neutropenic patients, and patients on deferoxamine treatment. Viruses such as rhinovirus, influenza virus, adenovirus, coronavirus, and occasionally CMV, among others, account for sinusitis that presents with the primary rhinitis or upper respiratory tract infection syndrome. Coinfections of viruses and bacteria have a higher rate of prolonged duration of symptoms. Recurrent sinusitis may occur as a result of allergies, enlarged adenoids (especially in children), anatomic obstruction such as septal deviation, polyps, tumors, or craniofacial abnormalities, congenital primary or acquired immunodeficiency syndromes, or coexisting disease such as cystic fibrosis, asthma, or gastroesophageal reflux disease.

Chronic sinusitis, infection of the paranasal sinuses for 3 mo or more, may occur in patients with persistently impaired sinus drainage, immunodeficiency, or inadequately treated previous sinusitis episodes. The microbiology of chronic sinusitis is difficult to interpret with previous antibiotic use. However, chronic sinusitis is more often polymicrobial in etiology. There is a higher incidence of *S aureus*; anaerobes such as *Peptostreptococcus*, *Fusobacterium*, or *Prevotella* species (25-80%); gram-negative bacilli, such as *P aeruginosa*; and fungi in chronic sinusitis as compared with acute bacterial sinusitis.

## Clinical Findings

**A. Signs and Symptoms.** The symptoms may vary with the severity, cause of the infection and presence of complications. Acute uncomplicated bacterial sinusitis presents with high fever, facial pain, headache, and nasal discharge predominantly. Nasal discharge or PND is purulent and may have a foul smell. Cough secondary to the PND may be present. A more common presentation is sinusitis associated with a viral upper respiratory tract infection. The course is usually milder and presents with "flu-like" symptoms such as myalgias, rhinorrhea, and sore throat.

The symptoms of sinusitis may last longer than a viral syndrome and ~ 60% of these patients will have positive sinus cultures. Headache is common and may be frontal, temporal, vertex, or retro-orbital depending on the sinus involved. Sphenoidal sinusitis predominantly causes a vertex headache. Eustachian tube blockage caused by local edema and nasopharyngeal secretions may cause the sensation of "blocked ears." Patients may give a history of a predisposing condition such as sneezing or nasal itching with allergies. History of recurrent sinusitis or sinopulmonary disease, arthritis, and other organ disorders is important to identify immunodeficiencies and noninfectious etiologic diagnosis. Chronic sinusitis symptoms are occasional headaches, fatigue, irritability, low-grade temperature, facial pressure, and PND.

In acute uncomplicated bacterial sinusitis, there is severe tenderness overlying the affected sinuses. There may be swelling, erythema, and induration of the overlying area. Cloudy, yellow-to-green purulent drainage is noted. Intranasal examination should be conducted to attempt identifying the site of purulent discharge. Percussion examination of teeth should be done in patients with unilateral sinusitis or with a history of dental pain. Patients may have signs resulting from complications of sinusitis such as erythema, edema, and proptosis in orbital cellulitis. Purulent discharge and elevated temperature may be the only signs of acute sinusitis. Transillumination of the maxillary sinuses may demonstrate the presence of fluid.

**B. Laboratory Findings.** Acute sinusitis is usually associated with leukocytosis of > 10,000 cells/mm<sup>3</sup>. The sedimentation rate may be elevated. Cultures obtained by sinus puncture are regarded as the standard for an accurate microbiologic diagnosis and yield bacteria in ~ 60% of cases. Bacterial growth of > 10<sup>5</sup> colony-forming units (CFU)/mL suggests an etiologic role of those specific bacteria whereas growth of < 10<sup>5</sup> CFU/mL may represent contamination. Sinus puncture is recommended in patients who are severely ill; have intracranial or orbital complications, compromised immune systems, nosocomial sinusitis; or are not responding to standard empirical therapy. Newer endoscopic methods of collection of secretions are technically more difficult than puncture, especially from the maxillary antrum because of the location of its ostium. Endoscopic cultures obtained from the middle meatus may be contaminated with nasal secretions. In comparison with sinus puncture cultures, endoscopic cultures have a sensitivity of 65% and specificity of 40%, but this increases when evaluated specifically for *S pneumoniae*, *H influenzae*, and *M catarrhalis*.

**C. Imaging.** Standard radiography is useful for evaluating frontal and maxillary sinusitis with an anterior-posterior and Waters' view. Ethmoid sinuses are poorly seen on plain x-rays and difficult to interpret. Although standard radiography is less sensitive than CT, it may still be helpful in acute disease or determining bony erosion. The presence of air-fluid levels, opacification, and mucosal thickening is suggestive of acute disease. The coronal CT scan is a very sensitive imaging technique for sinus disease and is the imaging method of choice for accurate assessment. Findings on CT scan may include typical air-fluid levels that have a good correlation with acute bacterial sinusitis. Other findings such as membrane thickening, presence of polyps, and anatomic variations predisposing to or complicating sinusitis may help in defining the disease. Magnetic resonance imaging of the sinuses is also very sensitive in identifying mucosal disease. Both CT and magnetic resonance imaging are sensitive in detecting a fungus ball in the sinuses. Intracranial complications will require evaluation of the head with CT, especially if there are focal neurologic findings, or lumbar puncture for cell count, chemistry, and culture, and susceptibilities in a patient presenting with meningitis.

## Differential Diagnosis

Patients with noninfectious sinusitis such as that related to Wegener's granulomatosis, tumors, or allergic rhinitis may present with signs and symptoms similar to those of infectious sinusitis.

## Complications

The proximity of the orbits to the sinuses accounts for orbital complications. Orbital complications include periocular edema, orbital cellulitis, abscess, and further extension into the cavernous sinus leading to cavernous sinus thrombosis. Infection of the bone by direct spread or septic thrombophlebitis may occur. Frontal bone osteomyelitis and subperiosteal abscess cause a swelling and doughy feeling of the frontal bone called Pott's puffy tumor. Intracranial extension results in meningitis or epidural, subdural, or brain abscess. The incidence of these complications has declined, but they present as medical emergencies and require immediate attention. Cough or bronchitis from

aspiration of postnasal drainage into the respiratory tract may also occur.

## Treatment

Therapy of acute bacterial sinusitis includes symptomatic care along with an appropriate antibiotic regimen ([Box 9-15](#)). It may be helpful to stratify patients by the severity of symptoms. Patients who present with complicated sinusitis with evidence of intracranial or orbital extension should be hospitalized, undergo immediate appropriate diagnostic tests, and start on a parenteral empirical antibiotic regimen. Therapy should be guided by diagnostic sinus fluid aspiration. The recommended empirical antibiotic regimen in complicated sinusitis should include vancomycin, which is active against intermediate and highly PRSP, and a high-dose, third-generation cephalosporin (ie, cefotaxime or ceftriaxone) with activity against other usual pathogens. Empirical therapy should continue until culture and susceptibility results from sinus aspiration are available. Surgical consultations should be sought for possible drainage procedures. The increasing incidence of intermediate and highly PRSP and  $\beta$ -lactamase-producing organisms has led to a decrease in the efficacy of amoxicillin for sinusitis.

Current recommendations for empirical antimicrobial therapy for acute uncomplicated bacterial sinusitis include amoxicillin/clavulanate or oral cephalosporins such as cefuroxime for 10 d. Other efficacious antibiotics include cefprozil, cefaclor, loracarbef, or cefpodoxime. TMP-SMX achieved 95% cure rates in older sinusitis studies; however, it is less effective against GAS and *S pneumoniae*.

Alternative antibiotics include macrolides such as clarithromycin (15 mg/kg/d for children, 500 mg every 12 h in adults) or azithromycin. Erythromycin has poor activity against *H influenzae* and is not recommended. Newer fluoroquinolones, such as levofloxacin or gatifloxacin (not approved for use in children and adolescents < 18 y old), have good activity against PRSP and are approved for use in adults with upper respiratory tract infections. TMP-SMX, cephalosporins or macrolides could be used for penicillin allergic patients. Odontogenic sinusitis treatment should include anaerobic coverage with either a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combination or the alternative regimen should include clindamycin or metronidazole. Fungal sinusitis requires aggressive surgical debridement along with parenteral or oral antifungal therapy.

Supportive measures for symptomatic relief may be considered. Decongestants provide symptomatic improvement by decreasing the nasal edema and obstruction. Oral decongestants are preferred over topical ones to avoid rebound vasodilatation. Steroid inhalers are not recommended unless the patient has significant allergy history and symptoms. Most symptoms will resolve in 7-10 d. Indiscriminate use of antibiotics is strongly discouraged to prevent the emergence of resistant strains of bacteria, particularly if the symptoms are consistent with a viral upper respiratory tract infection.

Persistent symptoms after an appropriate course of treatment may result from retained secretions, resistant or unusual organisms, presence of allergies, or possible immunodeficiency. Recurrent bacterial sinusitis should prompt further evaluation of the paranasal anatomy; immunoglobulin levels; neutrophil function analysis; HIV serology; sinus aspiration; and cultures for aerobic and anaerobic bacteria, fungi, and mycobacteria. Sinus aspiration and lavage or other drainage procedures may be more

efficacious in relieving symptoms in these patients. Sinus aspirate should be sent for aerobic and anaerobic bacterial, mycobacterial and fungal culture, and susceptibilities. Patients with chronic sinusitis may require retreatment with a second course of broad-spectrum antibiotics to include antimicrobial activity against *S aureus* and anaerobes. This could be achieved with amoxicillin/clavulanate or combination therapy of a cephalosporin with clindamycin or metronidazole given for 4-6 wk. Occasionally antipseudomonal therapy may need to be added particularly in patients with cystic fibrosis, patients who are hospitalized, or patients who are HIV positive. Acute or chronic sinusitis exacerbations should be treated similarly to acute sinusitis.

## Prognosis

Most community-acquired bacterial sinusitis episodes respond well to antimicrobial therapy. Complicated sinusitis or sinusitis in an immunocompromised host may require aggressive treatment including surgery. Such patients may continue to have recurrences and the attendant morbidity. Mortality in sinusitis is related mostly to complications such as meningitis.

## Prevention & Control

Proper hygiene measures such as handwashing can reduce the incidence of acute sinusitis by decreasing transmission of infectious particles between persons ([Box 9-16](#)). Simple actions like covering the mouth with a handkerchief or tissue when sneezing or coughing can prevent aerosol or droplet transmission. Active immunization with pneumococcal polysaccharide vaccine or influenza vaccine may further decrease the incidence of these infections.

### ACUTE BRONCHITIS

#### Essentials of Diagnosis

- Acute inflammation of the tracheobronchial tree.
- Occurs more often in adults than in children.
- Most often caused by viruses; occurs most frequently in winter.
- Cough and low-grade fever are prominent symptoms; auscultation of lungs reveals rhonchi and/or wheezes.
- Diagnosis is on clinical basis; laboratory investigations and chest radiography are usually not helpful.
- Most patients require only symptomatic treatment; patients with chronic cardiopulmonary disease may require aggressive care including hospitalization, oxygen therapy, and occasionally mechanical ventilation.

#### General Considerations

Acute bronchitis is a common inflammatory condition of the tracheobronchial tree that results in many physician visits worldwide. By definition the inflammation is limited to the trachea and large and medium-sized bronchi, with absence of infection of the alveoli or lower respiratory tract.

Community-acquired respiratory viruses, such as respiratory syncytial virus (RSV), rhinovirus, coronavirus, adenovirus, influenza viruses, and parainfluenza viruses, are the most common causes of acute bronchitis ([Box 10-1](#)). Occasionally, herpes viruses and, more rarely, measles virus cause acute bronchitis. Less often, nonviral etiologies are implicated, such as *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and, more rarely, *Bordetella pertussis*. Sputum cultures from patients with acute bronchitis may be positive for *Streptococcus pneumoniae* or *Haemophilus influenzae*; however, the role of these organisms in pathogenesis is unclear and may represent oral or upper respiratory tract colonization with no etiologic role. A small proportion of acute-bronchitis cases may be caused by noninfectious injury to the bronchial epithelium, eg, by exposure to pollution or other toxic substances.

Infection of the tracheobronchial epithelium results in various degrees of epithelial injury (depending on the infecting organism), which in turn results in a local acute polymorphonuclear (PMN) inflammatory response, edema, and hyperemia of the mucous lining. The mucous and serous glands of the bronchial lining secrete abundant mucus during this inflammation. Normally, ciliated epithelium of the bronchi aid in the

upward passage of mucus, thereby preventing infection of the bronchioles and alveoli. This protective mechanism may not occur in infants or patients with other comorbid conditions such as chronic obstructive pulmonary disease. Smoking or exposure to air pollutants can increase the severity of attack.

## Clinical Findings

**A. Signs and Symptoms.** Cough is the most prominent symptom of acute bronchitis. Cough is accompanied by mucoid expectoration, which may or may not be discolored and usually is worse in the morning. Fever is not a prominent symptom. If present, it is usually low grade. Some patients may complain of substernal discomfort with coughing and associated wheezing. Physical examination usually reveals a patient who is not in obvious respiratory distress. Respiratory distress is more likely to occur among patients with a history of smoking, multiple previous episodes or in those with comorbid diseases such as chronic cardiopulmonary diseases. On auscultation of the lungs, rhonchi or wheezes—particularly on expiration—are most often heard. These findings result from congested bronchial walls and partial obstruction caused by luminal mucus. Inspiratory or expiratory coarse crepitations may be heard. Complete occlusion of a bronchus by a mucus plug may result in absence of breath sounds in the area of atelectasis. Most acute bronchitis episodes are self-limited and resolve in 1-2 weeks.

**B. Laboratory Findings.** Diagnosis is based on clinical symptomatology. Laboratory investigations are not helpful. Complete blood counts are likely to be normal or include mildly elevated leukocyte counts. Sputum cultures usually do not accurately reflect the etiology of acute bronchitis. A sputum Gram stain may show many mononuclear or polymorphonuclear cells in viral or bacterial infections, respectively. Rapid diagnostic antigen detection by enzymatic immunoassay for RSV and influenza may be useful in selected patients. Serological studies that detect the acute-phase immunoglobulin M (IgM) response to viruses, *Mycoplasma* spp., or *C pneumoniae* may be useful diagnostically, but these are expensive tests and are usually not necessary. In the acute phase, IgG is not helpful unless a fourfold increase or decrease in titer can be demonstrated in paired sera. However, these tests require serum samples that are obtained several weeks apart, and therefore not practical.

**C. Imaging.** Chest radiographs do not demonstrate specific abnormalities in acute bronchitis. However, because there are many causes of cough, chest radiographs may help exclude other causes.

## Differential Diagnosis

Cough is a common symptom of a number of cardiopulmonary diseases. Diagnosis of acute bronchitis should be made after appropriate evaluation and exclusion of other causes of cough. New onset of cough caused by pneumonia, presence of a foreign body, toxic-fume injury, drug side effects such as angiotensin-converting enzyme inhibitors, endobronchial malignancy, or congestive heart failure may be mistaken initially for acute bronchitis. Tuberculosis should be excluded in cases with chronic cough, particularly in patients with high-risk profiles, including immigrants, intravenous drug abusers, homeless populations, and those with previous tuberculosis exposure or immunocompromised status.

## Complications

Most episodes of acute bronchitis resolve spontaneously. However, patients with underlying chronic cardiopulmonary diseases, such as chronic obstructive lung disease (COPD), congestive heart failure, or severe immunosuppression, may develop respiratory compromise that requires hospitalization and, in severe cases, mechanical ventilation. Cough in otherwise healthy persons may persist for 6-8 weeks because of increased airway reactivity.

## Treatment

Because acute bronchitis is most often a viral infection, the majority of the episodes of community-acquired acute bronchitis require only symptomatic therapy and do not need antibiotic therapy. Nonetheless, studies have shown that 66% of patients with acute bronchitis are prescribed antibiotics for this self-limited disease. Antibiotic therapy for acute bronchitis should be reserved only for select patients, including the elderly, those with underlying cardiopulmonary disease and persistent cough (lasting > 7-10 days), or immunocompromised patients. The choice of antibiotics in such patients should be directed against *S pneumoniae*, *H influenzae*, *Mycoplasma* spp., or *C pneumoniae*. Antibiotics that can be administered on an outpatient basis and adequately cover these organisms include newer-generation macrolides such as clarithromycin, azithromycin, and doxycycline or a fluoroquinolone such as levofloxacin, administered for a 7- to 10-day course ([Box 10-2](#)). Hospitalized patients with acute bronchitis warrant antimicrobial therapy more often than do ambulatory patients. The choice of empiric antimicrobial therapy is the same for outpatients and inpatients.

Symptomatic therapy includes cough suppressants, adequate hydration, and antipyretics as necessary. Occasionally, patients may require  $\beta$ -adrenergic bronchodilators such as albuterol inhalers for bronchospasm associated with acute bronchitis.

## Prognosis

Prognosis for patients with acute bronchitis is excellent. Morbidity and mortality are higher among patients with an underlying comorbid condition.

## Prevention

Hand washing is an important measure in preventing the acquisition of viruses that cause viral lower respiratory tract infections (LRTIs) ([Box 10-3](#)). Care must also be taken in handling fomites from a person who is ill. Annual administration of influenza A/B vaccine is important for the prevention of influenza virus infection. Amantadine or rimantadine should be administered to exposed nonimmunized individuals. Active immunization with 23 polyvalent pneumococcal vaccine should be administered to high-risk patients. Droplet isolation for hospitalized patients, especially for infants and children, with *Mycoplasma*, influenza, RSV, and parainfluenza infections is recommended.

# CHRONIC BRONCHITIS & ACUTE EXACERBATIONS

## Essentials of Diagnosis

- Productive cough present for 3 months during 2 consecutive years.
- Exacerbations may be viral or bacterial; bacteria associated with chronic bronchitis with acute exacerbations (AECB) include *Haemophilus* spp., *S pneumoniae*, and *M catarrhalis*.
- Affects 10-25% of the adult population.
- Chronic cough productive of mucoid sputum, dyspnea, and signs of cor pulmonale in severe cases.
- Acute exacerbations are manifested by increases in volume and changes in the character of sputum production with or without fever; often accompanied by increased dyspnea and fatigue.
- Symptomatic therapy and a course of antimicrobial therapy are often required for acute exacerbations.

## General Considerations

Chronic bronchitis is defined as chronic productive cough present for = 3 months during 2 consecutive years. Chronic bronchitis and acute exacerbations are clinical syndromes associated with COPD. COPD is characterized by obstruction to airflow in the distal airways. Pulmonary-function tests, especially forced expiratory volume at 1 s, are used to assess the severity and prognosis of the disease.

The essential pathological change in chronic bronchitis is the alteration of the epithelial lining of the bronchi. Initially, because of cigarette smoking, dust, or other chemical irritants, attacks of acute bronchitis occur. The initial airway changes include acute inflammatory PMN cell infiltration, hyperemia, edema, and increases in mucous and serous gland secretion that lead to mucus production. Over time and with repeated attacks of bronchitis, loss of the serous glands and hypertrophy of mucous secreting glands occur. The increase in tenacious secretions and ongoing destruction of the ciliated epithelium of the bronchi lead to inability to clear the bronchial lumen and further retention of mucus. The retained secretions encourage bacterial growth, which may result in repeated attacks of infection and inflammation.

The role of bacterial infection in chronic bronchitis and exacerbation is unclear. Bacteria do not seem to cause the initial bronchitis; however, they may play a role in acute exacerbations ([Box 10-4](#)). Randomized, placebo-controlled studies evaluating the role of antibiotic therapy and of bacteria in acute exacerbations show improved outcomes with antibiotic therapy, which suggests a causal relationship of the bacteria with AECB. Pathogenic bacteria may be recovered from normally sterile bronchi in the majority of patients with chronic bronchitis or during exacerbations. Chronic pathologic changes in the bronchi occur as cycles of recurrent bronchitis continue and are worsened by

persistent exposure to noxious agents such as cigarette smoking or air pollutants. Ciliated epithelium disappears; goblet cells, which are normally not present, appear, resulting in partial obstruction of bronchi and atelectasis or consolidation distal to the obstructed lumen. Pathologically, severity of disease is measured by the Reid index, which is the ratio of the submucous layer (layer containing the mucous glands) to the thickness of the bronchial wall. The normal Reid index is 0.3; in chronic bronchitis the index is higher. In the later stages of the disease, the bronchial wall may become atrophic and thin.

Sputum may be chronically colonized with *Haemophilus* spp., *S pneumoniae*, or *M catarrhalis* in more than half of these patients. Bacteria such as *Staphylococcus aureus* or gram-negative bacilli occur less frequently. AECB may be precipitated by a viral infection. Viruses account for 25-50% of the acute exacerbations. These are usually the seasonal community-acquired viruses, such as influenza, parainfluenza, adenovirus, or RSV. Other microorganisms such as *M pneumoniae* or *C pneumoniae* are infrequent causes of infection.

## Clinical Findings

**A. Signs and Symptoms.** Persistent cough is a hallmark of chronic bronchitis. Coughing spells can be triggered by conversation or laughing. Patients clear their throats frequently. On most days cough is productive of mucoid sputum. Expectoration of sputum is greater in the morning and during winter. Sputum is usually mucoid, clear to yellow in color, and green or purulent with an AECB. Patients often complain of postnasal drip. The voice may be raspy from chronic cough and cigarette smoking.

Patients have accompanying symptoms and signs of COPD. In some patients, chronic bronchitis predominates, whereas others have symptoms of emphysema alone or a combination of both. Patients with chronic bronchitis develop severe functional, bronchitis-mediated structural damage to bronchioles and alveoli and have minimal compensatory mechanisms or increase in lung capacity. Spasm and stenosis of the bronchioles lead to difficulty in inspiration, hyperinflation, reduced inspiratory flow, and reduced oxygen tension in the alveoli. Patients with these changes that result in chronic reduced oxygenation, cyanosis, and severe dyspnea are referred to as the "blue bloaters." Patients complain of dyspnea, lethargy, and somnolence. Daily cough is accompanied by copious amounts of sputum. On physical examination, clubbing of the extremities and cyanosis are common. Rhonchi, coarse crepitations, and wheezing may be heard on chest auscultation. Eventually, chronic hypoxemia and respiratory acidosis lead to increased pulmonary vascular resistance and pulmonary artery hypertension, which may result in right-heart failure or cor pulmonale. On physical examination, cor pulmonale results in peripheral edema, jugular venous engorgement, and hepatomegaly.

Patients with primarily emphysema, as opposed to those with primarily bronchitis, lose alveolar elasticity, which results in increased lung capacity, slowing of alveolar gas movement, and diminished oxygen exchange. Compensatory mechanisms lead to an increase in the respiratory rate to maintain normal oxygen and carbon dioxide exchange. As a result, these patients are described as "pink puffers," who are dyspneic but not cyanotic. Eventually, with progressive destruction of the alveoli, this

compensatory mechanism fails. These patients are characteristically thin and barrel-chested, and they have hypertrophied accessory respiratory muscles. Expiration is prolonged and may be through pursed lips. Percussion of the chest is hyperresonant. Auscultation reveals diminished breath sounds, prolonged expiration, and often wheezing. Cor pulmonale is relatively uncommon in these patients but occurs in terminal stages.

**B. Laboratory Findings.** Blood test findings are often normal during chronic bronchitis. There may be mild leukocytosis with a left shift during an AECB, but most patients will not develop leukocytosis. Arterial blood gases are important in evaluating and managing patients during an AECB. Blood cultures are usually negative.

**C. Imaging.** Chest radiographs may show evidence of COPD with hyperinflated lungs, but findings are nonspecific. Chest radiography should be performed in AECB to exclude pneumonia, pneumothorax, and significant atelectasis caused by a mucus plug or a mass. Chest radiographs should be compared with previous images.

### Differential Diagnosis

Congestive heart failure or acute myocardial infarction can be mistaken for AECB. An electrocardiogram, cardiac enzymes, and echocardiography can help to exclude cardiac causes of symptoms. Pulmonary malignancy should be considered in smokers. Other conditions that may present in a manner similar to chronic bronchitis are chronic aspiration or recurrent asthma attacks. In younger patients, cystic fibrosis, epithelial ciliary defect, immunoglobulin deficiency (IgA or subclasses of IgG), or defects in neutrophil function should be considered in the differential diagnosis.

### Complications

Repeated attacks of chronic bronchitis can lead to right-heart failure or cor pulmonale. In acute cases, patients with minimal pulmonary reserve may develop respiratory failure that requires mechanical ventilation. Mechanical ventilation is required for 20-60% of hospitalized patients with AECB.

### Treatment

Management of chronic bronchitis can be divided into two broad categories—symptomatic and antimicrobial therapy.

**A. Symptomatic Therapy.** Symptomatic therapy is directed toward smoking cessation measures and management of airway secretions and bronchospasm. Smoking cessation decreases the continual irritation of the epithelial lining, thereby decreasing mucus production within weeks of stopping.

Airway management includes clearance of secretions and use of bronchodilators. Secretions may be tenacious and difficult to clear. A good cough is the best mechanism for clearing secretions. Mobilization of secretions can be increased by the use of bronchodilators followed by chest physiotherapy and postural drainage. Mucolytics and cough suppressants are not recommended. Mucolytics can be irritants and can increase

sputum production.

Inhaled-bronchodilator therapy with  $\beta$ -adrenergic or anticholinergic agents, either alone or in combination, is useful in patients with chronic bronchitis, particularly during acute exacerbations. Aerosol nebulization can be used to administer bronchodilators such as albuterol and ipratropium bromide. Patients with acute exacerbations may require supplemental oxygen. However, excessive oxygen may cause hypercarbia by overriding the hypoxic ventilatory drive. Therefore, if oxygen is used, levels of partial arterial  $O_2$  ( $PaO_2$ ) and partial arterial  $CO_2$  ( $PaCO_2$ ) should be carefully monitored.

Parenteral corticosteroids have been shown to improve pulmonary-function tests more rapidly than placebos among patients with acute exacerbations.

**B. Antimicrobial Therapy.** Antibiotic therapy in patients with chronic bronchitis is appropriate during acute exacerbations or occasionally as prophylaxis against acute exacerbations ([Box 10-5](#)). Risk assessment may help with the choice of antibiotics and route of administration. A patient stratification by risk factors and history has been suggested for empiric antibiotic management of acute exacerbations. In patients with no previous pulmonary problems and recent onset of acute bronchitis, who are otherwise healthy, no antibiotics are recommended. For patients with a short history of symptoms, infrequent exacerbations, and normal pulmonary function tests, empiric therapy with oral doxycycline, amoxicillin, a macrolide, or trimethoprim/sulfamethoxazole is recommended. For older patients with longer histories of COPD, multiple previous exacerbations (> 4/year), and impaired lung function tests, empiric therapy with a cephalosporin, fluoroquinolone, or amoxicillin/clavulanate is recommended. Choice of empiric antibiotic therapy for hospitalized patients or patients with comorbid conditions, severe impairment of lung function tests, or frequent previous exacerbations should include a fluoroquinolone, parenteral third-generation cephalosporin, or amoxicillin/clavulanate. It is important to consider regional antimicrobial resistance patterns and the possibility of colonization when selecting antibiotic therapy. Empiric therapy should be directed against *S pneumoniae*, *H influenzae*, and *M catarrhalis*. Penicillin resistance among *S pneumoniae* strains is increasing, with geographic variations in the percentage of resistance. Worldwide, penicillin resistance among *S pneumoniae* strains ranges from 20% to > 60%. Most cases of penicillin-resistant *S pneumoniae* ACEB may be treated adequately with high-dose penicillin, a new fluoroquinolone such as levofloxacin or gatifloxacin, or a third-generation cephalosporin.  $\beta$ -Lactamase-mediated resistance to amoxicillin among *H influenzae* isolates is ~ 30-40%; intrinsic non- $\beta$ -lactamase-mediated resistance among nontypable strains of *H influenzae* to penicillin and amoxicillin is > 20% worldwide. Similarly, > 90% of strains of *M catarrhalis* demonstrate  $\beta$ -lactamase-mediated resistance. Treatment with a second- or third-generation cephalosporin, amoxicillin/clavulanate, trimethoprim/famethoxazole, a macrolide such as clarithromycin or azithromycin, or a new fluoroquinolone is optimal. Owing to resistance to macrolides among *H influenzae*, higher failure rates may be observed. Antimicrobial therapy should be modified depending on the patient's sputum culture and susceptibility results. Antibiotics are usually continued for 7-10 days.

Patients with progressive disease and repeated hospitalizations are more prone to colonization with nosocomial gram-negative bacilli instead of or in addition to the usual oropharyngeal bacteria. It is prudent to choose empiric antibiotics to cover these

organisms in such circumstances. Use of a fluoroquinolone such as levofloxacin or gatifloxacin is appropriate until sputum culture and susceptibility data can help guide further modification.

Administration of prophylactic antibiotics in patients with chronic bronchitis is usually not recommended unless a high-risk patient has > 4 exacerbations/year. Options include monthly rotation of antibiotics, daily antibiotic therapy during winter, or antibiotics started as soon as there is a change in pulmonary symptoms or onset of an upper respiratory infection. The use of prophylactic antibiotics should be individualized for each patient, based on factors such as the development of antimicrobial resistance, cost, and side effects. Patients on chronic antibiotic therapy are likely to become colonized with resistant bacteria that reduce therapeutic options for subsequent oral antibiotic therapy.

## **Prognosis**

Advanced age (> 65 years), presence of other underlying diseases such as cardiac disease, multiple previous episodes of AECB, especially those requiring steroids, and severity of underlying COPD are poor prognostic factors. The mortality of hospitalized patients with AECB is ~ 10-30%.

## **Prevention**

Smoking cessation is the most important factor in prevention of AECB ([Box 10-6](#)). Patients should be immunized with influenza vaccine and the 23 polyvalent pneumococcal vaccine.

# **BRONCHIOLITIS**

## **Essentials of Diagnosis**

- Inflammation of bronchioles.
- More common in younger children < 2 years of age, usually those 2-6 months of age.
- Symptoms of a viral upper respiratory tract infection followed by cough, tachypnea, and wheezing.
- Chest radiographs show diffuse hyperinflation, patchy perihilar infiltrates, peribronchial cuffing.
- Supportive care, bronchodilatation, and occasional ventilatory support required.

## **General Considerations**

Bronchiolitis is defined as inflammation of the bronchioles as a response to injury because of infections, vasculitis, chemical exposure such as that from cigarette smoking, or transplant-associated airway injury. Infectious bronchiolitis is mainly a disease of infants and young children. Of infants < 1 year of age, ~ 1-6% will develop viral bronchiolitis. Viruses are the most common infectious causes of bronchiolitis ([Box](#)

[10-7](#)). These include RSV, parainfluenza virus types 1 and 3, influenza virus types A and B, adenovirus, rhinovirus, and enteroviruses. RSV is the most common cause, accounting for 45-75% of all bronchiolitis among infants, followed by parainfluenza virus. RSV is the most common cause of nosocomial bronchiolitis. Bronchiolitis has seasonal distribution with highest incidence in the winter, when RSV activity increases. Parainfluenza infections occur during the fall and spring. Risk factors for severe bronchiolitis and possible hospitalization include male sex (male:female = 1.5:1), prematurity, overcrowding, comorbidities such as congenital heart disease or chronic lung disease such as bronchopulmonary dysplasia, and lack of breast-feeding.

Acute bronchiolar inflammation occurs. Peribronchial mononuclear inflammation and resultant edema of the submucosa and adventitia may develop, resulting in bronchiolar epithelial necrosis. These changes may result in partial or complete bronchiolar obstruction and distal atelectasis, especially in infants. Positive pressure during expiration increases the degree of obstruction in the bronchioles. Inflammation and bronchospasm may be the result of virus-specific IgE, leukotriene C<sub>4</sub>, or other inflammatory mediators.

## Clinical Findings

**A. Signs and Symptoms.** Prodromal symptoms include rhinorrhea, low-grade fever, and irritability. Increasing cough, lethargy, and anorexia follow the prodromal symptoms. As the disease progresses, the infant becomes dyspneic, has an audible wheeze, and is in obvious respiratory distress. Tachycardia and tachypnea with chest wall retractions and flaring of the nasal alae may be present. Diffuse fine crepitations and expiratory wheezes are heard on auscultation. In severe progressive disease, auscultatory findings may be minimal owing to obstruction. Other findings on examination include manifestations of the infecting virus or pathogen such as otitis media (10-30% of children) or diarrhea. The symptoms usually last for 3-7 days, with improvement occurring in the first 3-4 days and overall clinical resolution taking 1-2 weeks.

**B. Laboratory Findings.** Complete blood count is usually normal in mild infections, but leukocytosis with a left shift may be present in severe cases. Hypoxemia and hypercarbia may occur with a severe progressive infection. A specific viral diagnosis may be established with viral cultures or by rapid diagnostic procedures such as the enzyme immunoassay (EIA) for RSV or influenza virus on respiratory secretions—obtained either by nasopharyngeal swab or wash or from an endotracheal sample if the child is intubated. Although bacterial cultures may be positive for *S pneumoniae*, *H influenzae*, or other bacteria, secondary bacterial infection is infrequent. Serologic studies are helpful if an IgM antibody is positive or a fourfold increase or decrease in titers is detected. In general, serologic tests are of minimal value and should not be performed on a routine basis.

**C. Imaging.** Radiographic findings in bronchiolitis may not correlate with the clinical severity of the disease. On a chest radiograph, bronchiolitis appears as hyperinflation of the lungs, with decreased costophrenic angles and depressed diaphragms ([Figure 10-1A](#) and [1B](#)). Prominent bronchovascular markings radiating from the hila appear as perihilar infiltrates with prominent peribronchial cuffing. Areas of atelectasis or consolidation may be seen. Occasionally, an associated pneumonic infiltrate may be

present.

## Differential Diagnosis

The differential diagnosis of bronchiolitis includes asthma or aspiration. The diagnosis is more likely to be bronchiolitis if wheezing occurs at < 1 year of age, RSV is detected, and there is no prior history of wheezing or family history of atopy. Other conditions that may simulate bronchiolitis include cystic fibrosis, lymphoid interstitial pneumonia as seen in HIV/AIDS patients, and congestive heart failure in very young infants.

## Complications

Immediate complications include apneic spells, dehydration, hypoxia, and respiratory failure. Apnea occurs more frequently among premature or very young infants. Dehydration results from diarrhea, anorexia, or repeated coughing spells that cause vomiting. Mucus plugging, atelectasis, pneumonia, and ventilation-perfusion mismatch may cause respiratory failure. Immunocompromised children or those with comorbidities such as chronic pulmonary or cardiac disease or prematurity are more likely to develop a severe infection that requires ventilatory support.

Late complications include an increased tendency to develop recurrent hyperactive airways. This may occur in as many as two-thirds of the patients and persist = 2-7 years after the episode, but this tendency gradually resolves. The risk of this late complication is less in children with mild disease that does not require hospitalization.

## Treatment

Therapy of bronchiolitis is based on the severity of disease ([Box 10-8](#)). In mild cases, outpatient management can be initiated with adequate hydration, feeding, and close follow-up. Children should be hospitalized if there is a history of underlying disease or prematurity; they are < 3 months of age; or they have pulse oximetry of < 93% on room air, apnea, severe dehydration, or signs of severe respiratory distress.

The cornerstone of inpatient management of bronchiolitis is the judicious use of oxygen and supportive care, including hydration and feeding. Oxygen saturation should be maintained above 95%. Some high-risk infants will require mechanical ventilation.

The use of bronchodilators in bronchiolitis is controversial. Some studies show a benefit; others do not. Numerous studies have shown no benefit from corticosteroid therapy.

There is considerable debate regarding the use of aerosolized ribavirin for patients with RSV bronchiolitis. Ribavirin inhibits viral protein synthesis and is active in vitro against RSV. Initial studies that compared ribavirin with a placebo indicated significant improvement in oxygenation and decreased length of hospitalization in patients treated with aerosolized ribavirin. However, recent studies comparing ribavirin with a placebo did not show the same benefits for ribavirin therapy and, in fact, indicated that ribavirin therapy may prolong hospitalization. Accordingly, because of lack of clear benefit, high cost, and difficult delivery systems, the American Academy of Pediatrics recommends use of ribavirin only for a select population and at the discretion of the physician caring

for the child with RSV bronchiolitis. Aerosolized ribavirin may be considered for high-risk patients such as those with a chronic underlying disease (pulmonary or cardiac), those in a severe immunocompromised state (organ transplant patients or patients with AIDS), those with severe RSV disease either with or without the need for mechanical ventilation, and those born prematurely at < 37 weeks gestational age or for infants < 6 weeks old.

## **Prognosis**

Overall, the prognosis of patients with bronchiolitis is good. The prognosis is worse in an immunocompromised host or in children with chronic cardiopulmonary diseases. Mortality among hospitalized infants with RSV bronchiolitis ranges from 0.5% to 1.5%.

## **Prevention**

Children, especially those with high-risk factors, should avoid contact with individuals with respiratory infections ([Box 10-9](#)). The American Academy of Pediatrics recommends the use of RSV immunoglobulin prophylactic therapy (RSV-IGIV) for patients at high risk for severe RSV disease. These include premature infants (infants with a gestational age < 28 weeks or between 29 and 32 weeks may benefit from RSV-IGIV therapy until 12 months or 6 months of age, respectively), children with bronchopulmonary dysplasia who are < 24 months postnatal age and are currently using oxygen or have used oxygen within in the last 6 months, or severely immunocompromised children. RSV-IGIV has been shown to decrease RSV-related hospitalizations by 41-63%. RSV-IGIV is given monthly at the onset of the RSV season between October and April. RSV-IGIV is not approved or recommended for children with cyanotic heart disease because of possible higher mortality associated with RSV-IGIV prophylactic use in these patients. A new humanized RSV monoclonal antibody, palivizumab, is being studied as prophylaxis for high-risk patients. Palivizumab was effective in reducing the incidence of RSV hospitalization from 10.6% in the placebo group to 4.8% in the palivizumab group (a 55% decrease in RSV hospitalizations) and decreasing intensive-care unit admissions. The Food and Drug Administration has approved palivizumab for preventive use in patients at high risk of severe RSV infections.

Hospitalized patients with bronchiolitis should be placed in contact isolation to prevent nosocomial spread of the virus.

## **PNEUMONIA**

### **Essentials of Diagnosis**

- Affects any age group.
- Productive or nonproductive cough, fever, dyspnea, pleuritic chest pain.
- On examination, patient may have hyper or hypothermia, tachypnea, crepitations, rhonchi, and evidence of consolidation; some patients present with signs of septic shock.

- Laboratory findings usually include leukocytosis with an increase in neutrophilic response; hypoxemia, azotemia, and acidosis occur in severe cases; when positive, blood cultures are diagnostic of a specific microbiologic etiology; Gram stain of a good sputum specimen can be helpful diagnostically.
- Chest radiography demonstrates patchy, segmental lobar or multilobar consolidation or other patterns; false-negative chest radiographs can occur.

## General Considerations

Entry of a pathogen into the lower respiratory tract induces a host inflammatory response that results in a fibrino-cellular exudate and consolidation of alveoli and smaller airways. This process is referred to as pneumonia. Patients present with symptoms and signs of an acute infection with associated radiographic findings. Pneumonia may be classified by microbiologic etiology, community versus hospital or nursing home setting, severity of onset (acute or chronic), or histologic appearance.

**A. Epidemiology.** In the United States, ~ 3 million individuals develop pneumonia annually. Pneumonia accounts for 10 million physician visits, 600,000 hospital admissions, and 45,000 deaths annually in the United States. The annual frequency of pneumonia varies by age, host factors, and season. It is more common in the winter and increases during influenza A season in the community. LRTIs are infrequent in infants < 6 months of age but increase in the second year of life. Overall, annual rates of pneumonia are highest in children 0-4 years of age. The rate increases during the childbearing years in parents who are exposed to children and in persons > 65 years old.

Certain host factors predispose patients to LRTIs. These include extremes of age; underlying diseases such as congestive heart failure, chronic renal disease, diabetes mellitus, chronic obstructive pulmonary disease, malnutrition, alcoholism, malignancy, cystic fibrosis or tracheobronchial obstruction; and institutionalization. Cerebrovascular diseases, dementia, and seizure disorders are also associated with an increased risk for LRTI. Risk factors for pediatric pneumonia include attendance at a day-care center, low birth weight, low maternal age, absence of breast-feeding, or a previous history of pneumonia or wheezing.

**B. Microbiology.** Pneumonia may be bacterial, viral, mycobacterial, or fungal. Certain host factors and exposures predispose patients to specific types of pneumonia.

**1. Community-acquired pneumonia.** Community-acquired pneumonia (CAP) is defined as pneumonia acquired in the patient's home or in a nonhospital environment such as a nursing home ([Box 10-10](#)). In general, viruses are the most common cause of LRTI.

Neonates are at an increased risk of CAP caused by gram-positive cocci, particularly group B streptococcal or staphylococcal pneumonia. There is also a predisposition to gram-negative bacillary pneumonia in this population. The risk for *S aureus* or gram-negative bacilli decreases with age. In children > 1 month old, viruses such as

RSV, adenovirus, and influenza viruses play an important role in LRTI. Bacterial causes of pneumonia in children include *S pneumoniae*, *H influenzae*, and, occasionally, group A streptococci. The latter may complicate primary varicella infection. *M pneumoniae* is an important etiology of CAP, especially in school-aged children.

Among adults, no pathogen is identified in 33-47% of patients with CAP. *S pneumoniae* (30%) is the most common bacterial cause of CAP. Elderly patients, HIV-infected patients, and immunosuppressed, asplenic patients with immunoglobulin deficiencies or chronic cardiovascular, pulmonary (COPD, chronic bronchitis), or renal diseases are particularly predisposed to pneumococcal pneumonia. CAPs by encapsulated organisms like *S pneumoniae*, *H influenzae*, and *Neisseria meningitidis* are more common among patients with sickle cell disease, AIDS, asplenia, and immunoglobulin deficiencies.

*C pneumoniae* is the second most common cause of CAP requiring hospitalization. *H influenzae* type B or nontypable *H influenzae* is a common cause of CAP. *M pneumoniae*, *M catarrhalis*, and *L pneumophila* are other bacterial etiologies of CAP. Occasionally, *S aureus*, *Chlamydia psittaci*, *Coxiella burnetii* (the agent of Q fever), anaerobes, or aerobic gram-negative bacilli are the etiologic agents for CAP. Legionnaires' disease is caused by various *Legionella* spp., *L pneumophila* being the most common. *Legionella* spp. probably account for 2-6% of all hospitalized cases of CAP. They are associated with exposure to contaminated air-conditioning cooling towers or other contaminated water sources. *S aureus* pneumonia usually results from bacteremic spread to the lung and is often associated with endocarditis.

*S pneumoniae*, *H influenzae*, or *M catarrhalis* often causes pneumonia among patients with chronic pulmonary disease (COPD, chronic bronchitis). Nursing home residents are predisposed to pneumonia caused by *S pneumoniae*, gram-negative bacilli, influenza virus, RSV, and *S aureus*. Patients with structural pulmonary disease (cystic fibrosis or bronchiectasis) are commonly colonized and infected with gram-negative bacilli such as *P aeruginosa*, *Stenotrophomonas maltophilia*, or *Ralstonia (Burkholderia) cepacia* ([Box 10-11](#)). Alcohol use is also associated with pneumonia and colonization with aerobic gram-negative organisms such as *Klebsiella pneumoniae*; however, *S pneumoniae* is the most common cause of CAP among alcoholics. Children and adults with recurrent sinopulmonary infections should be suspected of having specific congenital or acquired conditions, such as abnormal leukocyte function, mucociliary defect (Kartagener syndrome), or immunoglobulin deficiencies.

Influenza virus accounts for 7-8% of all CAP, whereas community viruses such as RSV, cytomegalovirus (CMV), adenovirus, and others such as hantavirus are seen in specific epidemiologic settings. RSV pneumonia is more common in young infants, particularly those with cardiopulmonary diseases, or in patients with severe immunosuppression, as in bone marrow transplantation. CMV pneumonia is most often associated with patients with bone marrow transplantation, solid organ transplantation, or, occasionally, AIDS. Seasonal variation such as the predilection of RSV and influenza viruses for winter may help differentiate the etiology. Influenza pneumonia has a higher incidence of secondary infection with *S pneumoniae* or *S aureus*.

HIV-infected patients have predisposition for pneumonia caused by unusual pathogens

such as *Pneumocystis carinii*, *Rhodococcus equi*, or fungi such as *Histoplasma capsulatum* or *Cryptococcus neoformans*. *Mycobacterium tuberculosis* causes CAP and should be considered among HIV-infected patients, homeless populations, intravenous drug abusers, immigrants, and institutionalized and nursing home patients.

Specific exposures provide clues to the microbiologic agent, such as *Coccidioides immitis* pneumonia in the southwest United States. Histoplasmosis is associated with exposure to bird droppings or bats. Psittacosis, caused by *C psittaci*, occurs after exposure to birds. Exposure to parturient cats or other animals is an epidemiological risk for *C burnetii* pneumonia. Hunting and skinning of rabbits, deer, or other wild animals are associated with *F tularensis* pneumonia. Recent or remote travel to Southeast Asia is associated with *Pseudomonas pseudomallei* pneumonia.

**2. Nosocomial and aspiration pneumonia.** Nosocomially acquired pneumonia (NAP) is pneumonia that occurs 48 h after hospitalization. Nosocomial pneumonia most often occurs in an intensive-care unit setting, especially among mechanically ventilated patients or patients at risk of aspiration. NAP is a leading cause of morbidity and mortality among patients with nosocomial infections, with an estimated annual incidence of 300,000 cases. Mortality from NAP is higher among patients with bacteremic pneumonia or pneumonia caused by resistant microorganisms. The microbiology of NAP is different from CAP ([Box 10-12](#)). The etiology of NAP varies geographically and by patient risk factors, duration of stay in the hospital, and severity of pneumonia. Patient risk factors include advanced age (> 70 years); coexisting diseases such as diabetes, renal, or pulmonary disease; malnutrition; and impaired consciousness. Violations of infection-control practices, such as lack of hand washing or the use of contaminated devices, also increases the risk of NAP. Additional important risk factors for NAP are procedures that increase the risk of microaspirations. These include mechanical ventilation, nasogastric intubation, particularly when a patient is supine, sinusitis associated with nasogastric or nasotracheal tubes, use of sedatives, and use of H-2 blockers that increase the pH of the stomach acid, which results in gastric colonization with gram-negative bacilli. Certain surgical procedures, such as thoracic, abdominal, or head and neck surgery, predispose patients to NAP. Patients with minimal or no risk factors are likely to develop NAP with nonpseudomonal enteric gram-negative bacilli such as *K pneumoniae*, *Escherichia coli*, *Enterobacter* spp., *Serratia* spp. or with *S pneumoniae* or *S aureus*. However, with increased host risk factors, invasive procedures, severity of pneumonia, or prolonged duration of hospitalization, the microbial flora change toward *P aeruginosa* and other more virulent multi-drug-resistant gram-negative bacilli. Gram-negative bacilli such as *Klebsiella* spp., *P aeruginosa*, *Acinetobacter* spp., *Enterobacter* spp., and *S aureus* (methicillin-susceptible or methicillin-resistant) are the predominant microorganisms that cause NAP. Microaspiration of oropharyngeal secretions containing these bacteria results in the development of pneumonia. NAP is occasionally caused by *Legionella* spp., influenza A and B, RSV, and, rarely, *Aspergillus* spp. or by nosocomial spread of *M tuberculosis*.

Aspiration pneumonia is predominantly caused by the oral flora, including aerobes and anaerobes such as *Peptostreptococcus* spp., *Prevotella* spp., and *Bacteroides* spp., that form a large percentage of the microorganisms found in the mouth. Aspiration pneumonia must be considered among patients with seizures, neurological disease that

impairs swallowing, altered mentation, vomiting, gastroesophageal reflux disease, and periodontal disease.

**C. Pathogenesis.** Pathogenesis of pneumonia depends on the interplay of host defense mechanisms and microbial factors. The normal defense systems of the respiratory tract play an important role in preventing LRTIs. These include anatomic barriers, humoral and cell-mediated immunity, and phagocytic function. Disruption of any of these mechanisms predisposes patients to respiratory tract infection. The first step in pneumonia pathogenesis is colonization of the upper respiratory tract mucosa with a microorganism capable of causing pneumonia. The nasal mucociliary barrier efficiently filters out particles by expulsion or by swallowing. Swallowing of saliva, local complement activity, local humoral immunity (IgA), and competition between normal oral flora and pathogens inhibit oropharyngeal colonization. Local IgA, adherence receptors, or fibronectin excretion normally prevents colonization of bacteria. Bacteria overcome these initial barriers because of large inoculum or virulence factors. The glottis and cough reflex help clear bacteria that reach the mucociliary lining of the tracheobronchial tree. The mucus overlying the ciliated columnar epithelial cells traps the bacteria, and the movement of the cilia pushes this mucus upward toward the glottis, to be either coughed up or swallowed. Humoral and cell-mediated immunity help clear the bacteria that reach the terminal airways and alveoli. Alveolar macrophages are the first line of defense in terminal airways and alveoli. The alveolar macrophages exhibit phagocytic function and induce chemotactic substances such as complement components, interleukin-1 (IL-1), IL-6, IL-8, IL-10, IL-12, and tumor necrosis factor (TNF). These mediate a local monocytic and neutrophilic influx. IL-8 is considered the most important chemokine that induces this neutrophilic response in the infected lung. In animal models, a neutralization of the IL-8 murine homolog macrophage inflammatory protein 2 resulted in decreased numbers of PMN cells, increased bacterial counts, and a higher incidence of bacteremia and dissemination. TNF- $\alpha$  is critical in orchestrating cytokines and chemotaxis. Circulating immunoglobulins and complement are incorporated into an inflammatory response. The pathologic appearance of the lung during this leukocytic influx into the alveoli is referred to as gray hepatization of the lung. The alveoli are filled with fluid containing the pathogenic bacteria, leukocytes, and macrophages. Subsequently, a slow resolution of the pneumonic process occurs.

Mechanical factors that impair cough and epiglottic reflexes predispose patients to aspiration. These include an impaired gag reflex that may be caused by neurologic disease, seizures, gastroesophageal reflux disease, anesthesia, or mental retardation.

## **Clinical Findings**

**A. Signs and Symptoms.** Clinical presentation depends on the microbiologic agent and host factors such as age, immune status, exposures (geographic, animal, or sexual), and other comorbid conditions. Studies have confirmed that microbiologic differentiation by clinical criteria alone is extremely difficult. Some historical associations may suggest a microbiologic agent but cannot be relied on entirely for therapeutic decisions. A detailed history of exposures, travel, hobbies, and past medical history is helpful in suggesting a microbiologic etiology. Severity and presentation of CAP range from mild to life-threatening. Although the symptoms vary, most patients with CAP present with fever, chills, cough, dyspnea, and occasionally chest pain. Cough is the most common

presenting symptom of CAP. Cough may be dry, productive, and associated with hemoptysis. Sputum is mucopurulent in bacterial pneumonias; classically, rusty-colored sputum is associated with pneumococcal pneumonia, whereas sputum may be like currant jelly (dark red mucoid) with *K pneumoniae* infection. When associated with a lung abscess, pneumonia may result in foul-smelling sputum that is indicative of the anaerobic or polymicrobial flora.

Lack of temperature elevation and confusion may occur in elderly patients. Patients with pneumococcal pneumonia typically develop sudden shaking, chills, fever, and mucopurulent, blood-tinged sputum, and they often have pleuritic chest pain. Gastrointestinal symptoms such as diarrhea may occur in pneumonia caused by *Chlamydia* or *Legionella* spp. A dry cough, an earache, aural discharge, and occasionally the presence of altered mental status may suggest pneumonia caused by *M pneumoniae*. Headache is common in patients with *Legionella* pneumonia. Patients with *Chlamydia* pneumonia may have a protracted upper respiratory infection with laryngitis that resembles a viral infection.

On examination, patients with a mild infection may not have acute distress, whereas patients with severe pneumonia often have severe respiratory distress and may appear toxic. The most common signs of pneumonia are tachycardia (heart rate > 100/min) and tachypnea. Temperature is commonly elevated but does not have a specific pattern. Pulse-temperature dissociation may be noted in viral, *Legionella*, mycoplasmal, or chlamydial pneumonia. To decrease pleuritic pain, splinting of the involved side may be noted. Pulmonary auscultation reveals crepitations and rhonchi. Signs of consolidation, such as dullness to percussion, increased vocal fremitus, bronchial breath sounds, and egophony, may be present. Signs of lobar consolidation are more likely in bacterial pneumonia. A pleural effusion may be detected. Use of accessory respiratory muscles, cyanosis, confusion, and severe tachypnea indicates severe respiratory distress. Hypotension and circulatory collapse occur in severe cases.

Assessment of the severity of infection and need for hospitalization must be done for all patients. Certain clinical signs predict higher morbidity and mortality. These include respiration rate > 30 breaths/min, diastolic blood pressure = 60 mm Hg or a systolic blood pressure = 90 mm Hg, temperature = 38.3 °C, extrapulmonary complications (such as the presence of septic arthritis or meningitis), confusion and altered mental status, requirement for vasopressors for > 4 h, need for mechanical ventilation, decreased urine output to < 20 mL/h or total urine output < 80 mL in 4 h (except in patients with chronic renal disease), or acute renal failure. Occasionally, physical signs may suggest specific etiology such as bullous myringitis, central nervous system symptoms, or erythema multiforme in *M pneumoniae* infection; erythema nodosum is associated with *C pneumoniae*, *M tuberculosis*, or fungal infections. Physical findings among patients with *Mycoplasma*, *P carinii*, or viral pneumonia may be minimal despite significant changes on the chest radiographs. Pulmonary histoplasmosis may be associated with oral ulcers and is frequent among patients with AIDS.

**B. Laboratory Findings.** Complete blood counts reveal leukocytosis or leukopenia. Thrombocytopenia and evidence of disseminated intravascular coagulation may be present in severe pneumonia. HIV testing should be offered to patients with HIV risk factors. The selection of diagnostic tests is determined by the clinical severity of

infection. Minimal laboratory investigation is necessary with mild disease. In critically ill patients, more extensive testing is necessary and includes, but is not limited to, serum chemistries, arterial blood gases, liver and renal function tests, and serum lactate. Poor prognosis is associated with leukocyte counts  $< 4 \times 10^9/L$  or  $30 \times 10^9/L$  or an absolute neutrophil count  $< 1 \times 10^9/L$ ,  $PaO_2 < 60$  mm Hg or  $PaCO_2 > 50$  mm Hg at room air, hematocrit  $< 30$  or hemoglobin  $< 9$  g/dL, evidence of disseminated intravascular coagulation, and elevated creatinine  $> 1.2$  mg/dL.

Gram stain examination and culture of sputum should be done in most outpatients and in all hospitalized patients. Sputum Gram stain provides a rapid and inexpensive method for a microbiologic diagnosis and aids in the selection of an appropriate management of pneumonia. A satisfactory sputum specimen is one that has  $< 10$  epithelial cells and  $> 25$  neutrophils in a low power ( $\times 100$ ) field. Sputum specimens that do not meet these strict criteria should be rejected for culture and the Gram stain results disregarded. For optimum sputum collection, patients must be alert and able to follow instructions. They should first rinse their mouths with water to decrease the oropharyngeal contamination and then collect expectorated material from a deep cough. Induced sputum is a more appropriate sample in patients unable to expectorate. Sputum induction is done with hypertonic saline aerosol. This method is useful for the diagnosis of *P carinii* pneumonia, *M tuberculosis*, or fungal disease.

Interpretation of the Gram stain of a sputum sample is dependent on knowledge of the normal flora of the mouth. Normal mouth flora includes abundant aerobic and anaerobic bacteria. Asymptomatic patients frequently harbor potentially pathogenic bacteria such as *S pneumoniae*, *H influenzae*, *S aureus*, and *N meningitidis* in the oropharynx. In healthy persons,  $\approx 9\%$  are colonized with *S pneumoniae*, and the carrier rate is higher in persons with preschool-aged children. Colonization with *S aureus* and gram-negative bacilli increases after 2 weeks of hospitalization and is frequent among nursing home residents and patients with chronic illnesses such as alcoholism, diabetes, or malignancies. Oropharyngeal colonization by gram-negative organisms increases the likelihood of a gram-negative bacillary pneumonia. However, isolation of gram-negative bacilli from sputum does not always implicate these organisms as the etiologic agent. Similarly, although *Candida* spp. are frequently recovered from sputa of normal individuals or from patients in intensive-care units, it rarely if ever causes LRTI.

Direct examination of the sputum is done by a Gram stain, by special stains such as acid fast (AFB) or KOH stain, or by immunofluorescence. Predominance of an organism on the sputum Gram stain examination sometimes identifies the causative agent. Abundant pathogenic bacteria with a characteristic morphology, such as the small lancet-shaped gram-positive diplococci of *S pneumoniae*, gram-negative coccobacillary forms of *H influenzae*, or gram-negative cocci of *M catarrhalis*, help in making the diagnosis. Polymicrobial bacteria suggest anaerobic gram-negative bacillary or aspiration pneumonia. Using an adequate sputum specimen, the sensitivity and specificity of the Gram stain approaches 50-60% and  $> 80\%$  respectively, especially for *S pneumoniae*. Special stains must be performed on specimens to identify organisms not ordinarily seen on the Gram stain. *P carinii* is identified by using either methenamine silver staining or fluorescent Calcofluor stain. Mycobacteria are visualized with AFB, Kinyoun stain, or fluorescent auramine rhodamine stain. Modified AFB is required for the detection of *Nocardia* spp. Direct fluorescent antibody stains may detect *Legionella*

spp.; KOH preparations may be necessary to identify fungi such as *Histoplasma*, *Blastomyces*, or *Coccidioides*.

Sputum cultures are not as sensitive or specific as Gram stains and are likely to be nondiagnostic in 50% of instances despite a highly suggestive Gram stain. In bacteremic pneumococcal pneumonia, only 40-50% of cases have a positive sputum culture for *S pneumoniae*. The recovery of some microorganisms from sputum culture usually implies their definitive role in pneumonia, and they do not usually represent contamination. These organisms include *L pneumophila*, *M tuberculosis*, *H capsulatum*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Blastomyces* spp., *C burnetii*, *Nocardia* spp., *Francisella tularensis*, and *Yersinia pestis*. Anaerobic cultures of sputum are of no value owing to oropharyngeal contamination. *M pneumoniae* isolation from sputum cultures is technically difficult, and it may take = 30 days to grow the microorganism.

Direct immunofluorescence assay (DFA) and EIA of sputum are useful in rapid diagnosis. DFA can detect *Legionella* spp. in respiratory secretions from 25% to 75% of patients with pneumonia caused by this organism. The sensitivity of the DFA varies with the antibody used, pathogenic species, and expertise of the personnel performing the test. Throat or nasopharyngeal swabs are the preferred specimens for DFA and cultures in suspected viral or *Chlamydia* pneumonia. DFA for *C trachomatis* has a sensitivity of 90%. Antigen detection tests for influenza A and B, parainfluenza, and RSV viruses have a sensitivity of 80%. DFA for RSV is more sensitive than cultures.

Blood cultures should be obtained from all hospitalized patients with pneumonia. Bacteremia occurs in 20-30% of patients with pneumococcal pneumonia. Positive blood cultures have a high specificity in providing a definitive diagnosis. Blood cultures are particularly useful in chronically ill, immunocompromised patients and in patients with a history of alcoholism or malignancies. Positive cultures from other infected body fluids such as pleural, joint, or cerebrospinal fluid also may be diagnostic.

Thoracentesis should be performed in patients with a pleural effusion who are not responding to appropriate antibiotics, or in seriously ill patients who are suspected of having empyema. Small pleural effusions should be considered for aspiration if fever persists for > 3 days on appropriate antimicrobial therapy. Pleural effusions occur more frequently in infections caused by group A streptococci, gram-negative bacilli, anaerobes, *S aureus*, or *S pneumoniae*. Pleural fluid should be promptly analyzed for pH, glucose, protein, and lactate dehydrogenase (LDH) and should be Gram stained and cultured for bacteria, mycobacteria, and fungi.

Serologies are not helpful in rapid etiologic diagnosis of pneumonia. They may be important in hospitalized patients with undiagnosed pneumonia, in which serology may be the only practical way to diagnose infections such as hantavirus or Q fever. Serologic tests are available for *Chlamydia* spp., *Legionella* spp., *Mycoplasma* spp., *C burnetii*, leptospirosis, and viruses such as influenza A and B, parainfluenza, RSV, adenovirus, hantavirus, CMV, herpesvirus, and varicella virus. Serologies may be useful for the diagnosis of histoplasmosis, coccidioidomycosis, blastomycosis, and cryptococcal pneumonia. Serologic diagnosis must be confirmed with an appropriate clinical picture and a positive IgM or a fourfold increase or decrease in the IgG titer in paired sera. A negative serology does not exclude the presumptive diagnosis. Delay in diagnosis and

cost are the major disadvantages of serologic testing. Serologies are not practical or cost-effective in outpatient pneumonia.

Antigen detection by EIA, counterimmunoelectrophoresis, bacterial antigen test, or radioimmunoassay may be used to detect *S pneumoniae*, *H influenzae*, or *L pneumophila*. Urine, pleural fluid, or cerebrospinal fluid may be used to detect pneumococcal antigens. Pneumococcal antigen detection has the highest yield in sputum and persists for an extended period of time after an acute infection. Rapid EIA detection of RSV, influenza virus, or parainfluenza viruses has a sensitivity of > 80% and is useful in clinical practice. EIA detection of *L pneumophila* serogroup I antigen in urine may provide a rapid diagnosis. EIA has a 70-80% sensitivity and a specificity of > 95%, but the test currently detects only serogroup I. *Legionella* antigenuria persists for a considerable length of time after the initial infection. The presence of cold agglutinins in serum is insensitive (sensitivity of 30-60%) and nonspecific for the diagnosis of *M pneumoniae* infection.

Patients with unexplained pulmonary infiltrates who fail empiric therapy, have a fulminant clinical course, are immunocompromised, or are mechanically ventilated should be considered for fiber optic bronchoscopic examination and quantitative bronchoalveolar lavage (BAL) or sample collection with the protected specimen brush (PSB). Bronchoscopic aspiration with PSB has a sensitivity of 70-97% and a specificity of 95-100% in the diagnosis of bacterial pneumonia. Gram staining of the bronchoscopic specimen is important in early presumptive diagnosis and, when positive, predicts growth of > 10<sup>3</sup> organisms/mL. A BAL specimen is considered diagnostic if it has 10<sup>3</sup>-10<sup>5</sup> cfu/mL growth of bacteria, especially if the Gram stain shows > 25 neutrophils and < 1% squamous cells. The diagnostic yield may be slightly less than with PSB. BAL is particularly helpful in the diagnosis of *P carinii* pneumonia (sensitivity of > 95%). Detection of CMV and *M tuberculosis* increases with BAL. Antibiotic use or a history of pulmonary diseases such as chronic bronchitis or cystic fibrosis decreases the diagnostic yield from bronchoscopic specimens.

Occasionally, fine-needle lung aspiration, transbronchial biopsy, or open-lung biopsy may be necessary for diagnosis. The risk of bleeding and pneumothorax (~ 20%) and variable diagnostic yields have decreased the utility of fine-needle lung aspiration. The diagnostic yield of a transbronchial biopsy is low. Thoracoscopic evaluation of the pleura and underlying lung is useful for the diagnosis of *M tuberculosis* infection, particularly when done in conjunction with a pleural biopsy. Finally, open-lung biopsy may be necessary when other procedures fail to yield a diagnosis. Open-lung biopsy is important in severely ill, immunocompromised patients or in patients not responding to empiric therapy. The diagnostic yield varies from 60% to 100%. The tissue should be examined for histopathology, Gram stained for bacteria, stained for acid fast bacilli, fungi, and *Legionella* spp., and cultured for these organisms. The lung tissue can also be subjected to molecular analysis by DNA probes or polymerase chain reaction techniques for rapid diagnoses of bacteria including mycobacteria, *C pneumoniae*, *Legionella* spp., or viruses. Open-lung biopsy alone may be useful for the diagnosis of noninfectious conditions such as malignancy, hemorrhage, vasculitis, bronchiolitis obliterans, drug-induced pulmonary injury, and others.

**C. Imaging.** Although chest radiographs alone cannot make a definitive diagnosis, they

are essential in the evaluation of pneumonia ([Figures 10-2](#), [10-3](#), [10-4](#), [10-5](#), and [10-6](#)). In general, chest radiographs can help characterize pneumonia as probably of bacterial origin, atypical, or complicated and help to assess the severity and extent of disease. Consolidation of one or more lobes with or without pleural effusion or cavitation suggests a bacterial pneumonia. Multilobar involvement, rapidly increasing infiltrates, or the presence of cavities in CAP is an indicator of higher morbidity and mortality. Staphylococcal pneumonia results in multiple patchy infiltrates, which may cavitate and result in air-fluid levels from hematogenous spread, although occasionally gram-negative bacillary lung infections may present with similar findings. Cavitory pulmonary infiltrates may represent tuberculosis, particularly in the appropriate clinical setting such as the homeless population, immigrant population, or HIV-infected patients. Cavitation in the dependent area of the lung, such as the superior segment of the right lower lobe or posterior segments of the upper lobe, suggests aspiration pneumonia. Less commonly, chronic aspiration can result in bilateral infiltrates.

Diffuse bilateral interstitial infiltrates are seen in pneumonias caused by *P carinii* or *Legionella* spp. and in viral, *Mycoplasma*, or *Chlamydia* pneumonia. These are usually present without a pleural effusion.

## Differential Diagnosis

A large number of diseases and clinical syndromes can mimic pneumonia. These conditions include pulmonary manifestations of systemic vasculitis, hypersensitivity pneumonitis, bronchiolitis obliterans with organizing pneumonia, drug reactions, alveolar hemorrhage, chronic eosinophilic pneumonia, and pulmonary alveolar proteinosis. Malignancies or lymphoproliferative disorders can mimic CAP.

Distinguishing an infectious from a noninfectious etiology for pulmonary infiltrates may be difficult. The clues that suggest a noninfectious cause are an insidious onset, nonproductive cough, a relatively less toxic-appearing patient, a normal or only mildly elevated leukocyte count, and a lack of response to broad-spectrum-antibiotic therapy. The presence of extrapulmonary manifestations such as arthralgias or arthritis, rash, and multiorgan involvement in the absence of sepsis suggests a noninfectious process such as vasculitis.

An immune response to inhaled antigens results in pulmonary infiltration with lymphocytes, plasma cells, eosinophils, and neutrophils, with the development of sarcoidlike granulomas in the airways and pulmonary parenchyma, called hypersensitivity pneumonitis. Establishing a compatible exposure history, usually to farm animals or plants, suggests the diagnosis of hypersensitivity pneumonitis. Specific examples include thermophilic *Actinomyces* infection (eg, farmer's lung), fungi (maltworker's lung), or avian protein antigens (pigeon breeder's lung). Symptoms of hypersensitivity pneumonitis usually resolve within 24-48 h after removal of the offending antigen. Chest radiographic features and high-resolution chest computed tomography (CT) reveal bilateral mixed interstitial and alveolar infiltrates with some fibrosis in chronic cases. Of patients with chronic eosinophilic pneumonia, 60-80% present with radiographic findings of peripheral infiltrates with central clearing. Transbronchial biopsy and presence of eosinophilia, often > 40% in BAL fluid, establish the diagnosis. Bronchiolitis obliterans-organizing pneumonia is suspected in patients

presenting with a clinical picture similar to CAP that does not respond to antimicrobial therapy. Chest radiographs demonstrate multifocal segmental or lobar alveolar infiltrates with air bronchograms in 60-80% of patients. There may be a peripheral predilection for pulmonary infiltrates similar to chronic eosinophilic pneumonia; 20-30% of patients have reticulonodular infiltrates. Although open-lung biopsy is considered the most effective test for the diagnosis of bronchiolitis obliterans-organizing pneumonia, occasionally transbronchial biopsy may establish the diagnosis. Drug-induced acute pneumonitis caused by nitrofurantoin, amiodarone, methotrexate, and other drugs should be considered in the differential diagnosis of CAP that does not respond to antimicrobial therapy. Systemic vasculitis may affect the lung, either primarily or as part of multiorgan involvement. Wegener's granulomatosis and Churg-Strauss syndrome are granulomatous forms of vasculitis that have a striking affinity for lung manifestations. Pulmonary cavitation and severe extrapulmonary symptoms such as upper-airway, renal, or ocular symptoms suggest Wegener's granulomatosis. Although serum antineutrophil cytoplasmic antibody (ANCA), especially c-ANCA (diffuse granular cytoplasmic staining pattern), has a reported sensitivity of > 90% in patients with Wegener's granulomatosis, biopsies of involved organs are essential to confirm the diagnosis. Diagnosis of alveolar hemorrhage is supported by anemia and bronchoscopic evidence of blood-tinged BAL fluid with hemosiderin-laden macrophages.

Other conditions that simulate CAP include pulmonary embolism, which may present with cough, fever, and chest pain. Clinical history, physical findings such as calf tenderness, and the rapidity of onset of symptoms should suggest pulmonary embolism.

## **Complications**

Pleural effusion and empyema are potential complications and may cause failure to respond to appropriate therapy. Lung abscess is another suppurative complication that can occur among patients, particularly after aspiration or in the presence of a pulmonary structural problem such as a malignancy. Patients can develop respiratory failure with or without septic shock and subsequent death. Respiratory failure and shock are more likely to occur in elderly, diabetic, alcoholic, or immunocompromised patients. Preexisting pulmonary disease is a risk factor for respiratory failure and ventilatory support. Young infants with RSV pneumonia can develop hyperactive airway disease later in childhood. Occasionally, *P carinii* pneumonia is associated with spontaneous pneumothorax.

## **Treatment**

Severity of illness and risk factor assessment is essential in evaluating a patient for outpatient therapy compared with hospitalization. The presence of coexisting illnesses, immunosuppression, respiratory rate of > 30/min, hypotension, multilobar involvement, hypoxemia, acidosis, electrolyte abnormalities, leukopenia (leukocytes < 4.0/mm<sup>3</sup>) or leukocytosis (leukocytes > 20/mm<sup>3</sup>) are indices of severe pneumonia that warrant hospitalization. This assessment should be conducted expeditiously, because these patients can progress rapidly to circulatory collapse and respiratory distress necessitating mechanical ventilation. They should receive immediate antimicrobial therapy, because delay in onset of antimicrobial therapy may increase morbidity and mortality. Patients with some but not all of the poor prognostic signs may also warrant

admission to a hospital, but not necessarily to an intensive-care unit. Patients without any underlying comorbidity and with normal or mildly abnormal physical findings represent low-risk individuals who may be treated with antimicrobial therapy as outpatients.

In addition to risk factors and objective findings, such factors as patient compliance and competence and the presence of a caregiver at home should be considered in making the decision for outpatient versus inpatient care. Patients with minimal or no home support may warrant hospitalization until outpatient support can be organized.

The choice of empiric antimicrobial therapy depends on the severity of disease, host factors, likely microorganism(s), epidemiological factors, and local antimicrobial resistance patterns. For instance, patients with a history of structural lung disease (cystic fibrosis, bronchiectasis) or nursing home residents require therapy with an antipseudomonal antibiotic (ceftazidime, cefepime, or antipseudomonal penicillin, or a carbapenem or fluoroquinolone). Aztreonam and a fluoroquinolone with or without an aminoglycoside are antibiotic options for  $\beta$ -lactam-allergic patients with gram-negative bacilli or NAP.

## **A. Community-acquired pneumonia.** (See [Boxes 10-13A](#), [10-13B](#), and [10-13C](#).)

**1. Outpatient therapy.** For outpatient empiric therapy of CAP, a macrolide such as clarithromycin or azithromycin, a newer fluoroquinolone with enhanced activity against *S pneumoniae* such as levofloxacin or gatifloxacin, or a tetracycline such as doxycycline is appropriate for pneumococci, *H influenzae*, and atypical organisms. Oral amoxicillin, a second-generation oral cephalosporin, or a macrolide is appropriate for outpatient treatment of CAP caused by penicillin-susceptible *S pneumoniae*. Amoxicillin or a fluoroquinolone such as levofloxacin or gatifloxacin is adequate for most mild outpatient CAP caused by *S pneumoniae* with intermediate resistance. Oral cephalosporins do not have adequate bactericidal activity to treat CAP caused by intermediate resistant *S pneumoniae* appropriately. Also, owing to multidrug resistance among these isolates, a macrolide, trimethoprim/sulfamethoxazole, or clindamycin may not be effective therapy. In vitro macrolide resistance among *S pneumoniae* isolates is ~ 10-25%. Therefore, these antibiotics should be used cautiously in patients with suspected *S pneumoniae* pneumonia. Outpatient treatment options for patients with high-level penicillin-resistant *S pneumoniae* pneumonia (PRSP) are limited. A new fluoroquinolone such as levofloxacin or gatifloxacin may be appropriate therapy. Ciprofloxacin has marginal activity against penicillin-susceptible *S pneumoniae*. Because multidrug resistance increases among penicillin-resistant pneumococci, susceptibilities to fluoroquinolones, macrolides, and other agents should be determined. Because penicillin resistance in pneumococci is caused by decreased affinity to altered penicillin-binding protein,  $\beta$ -lactam/ $\beta$ -lactamase inhibitor antibiotics such as amoxicillin/clavulanate are no more effective than penicillin against these microorganisms. Patients with additional risk factors such as advanced age or comorbidities and suspected penicillin-resistant pneumococcal pneumonia should be considered for hospitalization for parenteral antimicrobial therapy.

Doxycycline is appropriate therapy for younger (17- to 40-year-old) individuals with pneumonia because of the likelihood of *M pneumoniae* infection.

**2. Inpatient therapy.** Severity of illness at presentation and host factors, including age, comorbidities, and drug allergies, help determine the empiric antimicrobial therapy for a hospitalized patient with CAP. A third-generation cephalosporin (eg, cefotaxime or ceftriaxone) with or without a macrolide is appropriate as the initial therapy for hospitalized patients with moderate illness not requiring admission into the intensive-care unit. Alternative antimicrobial therapies for such patients include a second-generation cephalosporin such as cefuroxime, a macrolide alone (eg, clarithromycin or azithromycin), or a newer fluoroquinolone with activity against *S pneumoniae* (eg, levofloxacin or gatifloxacin). Fluoroquinolones are not approved for use in children < 18 years of age. Patients with serious CAP requiring management in an intensive-care unit require a broader-spectrum initial empiric antibiotic regimen with activity against PRSP, *P aeruginosa*, *S aureus*, or members of the *Enterobacteriaceae*. Empiric antimicrobial therapy should include a third- or fourth-generation cephalosporin or an extended-spectrum  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combination such as piperacillin/tazobactam or ticarcillin/clavulanate, with a fluoroquinolone or macrolide.

Broad spectrum empirical antimicrobial therapy of severe CAP should also include therapy against atypical organisms such as *Legionella*. Co-administration of a macrolide or a fluoroquinolone together with a  $\beta$ -lactam antibiotic (a third- or fourth-generation cephalosporin such as cefotaxime, ceftriaxone, or cefepime; or piperacillin/tazobactam) has been shown to decrease mortality in patients with severe CAP. Monotherapy with either a macrolide or a fluoroquinolone are not recommended in such patients. Patients with severe CAP with underlying chronic structural lung disease, frequent hospitalizations, or history of long-term care facility stay, the use of antimicrobials with anti-pseudomonal activity (such as cefepime, ceftazidime, or a fluoroquinolone with enhanced activity against *S pneumoniae* and *P aeruginosa* such as levofloxacin or gatifloxacin) is recommended.

Empiric antibiotic therapy may be modified once identification of a specific microorganism(s) and its susceptibilities is available. Parenteral penicillin G is the drug of choice for in-patient penicillin-susceptible pneumococcal pneumonia. Studies demonstrate that *S pneumoniae* strains that are penicillin-susceptible and intermediately penicillin-resistant (minimal inhibitory concentration < 2 ug/mL) may be treated with a penicillin or a third-generation cephalosporin such as ceftriaxone or cefotaxime. Penicillin-resistant pneumococcal pneumonia may be successfully treated with high-dose penicillin or a third-generation cephalosporin, vancomycin, a fluoroquinolone such as levofloxacin or gatifloxacin, or a carbapenem such as imipenem/cilastin or meropenem.

A second- or third-generation cephalosporin;  $\beta$ -lactam/ $\beta$ -lactamase inhibitor antibiotics such as amoxicillin/clavulanate, ampicillin/sulbactam, and piperacillin/tazobactam; carbapenems such as imipenem or meropenem; macrolides such as azithromycin; and fluoroquinolones are effective therapy for CAP caused by *H influenzae* or *M catarrhalis*.

*C pneumoniae*, *M pneumoniae*, and *Legionella* pneumonia respond to therapy with a tetracycline, macrolide, or fluoroquinolone. Rifampin is active in vitro against *L pneumophila* and may be used as adjunctive therapy for severe *Legionella* pneumonia. Parenteral therapy with either a fluoroquinolone or high-dose erythromycin is

recommended for moderate to severe *Legionella* pneumonia. Azithromycin and clarithromycin are more active in vitro than erythromycin against *L pneumophila*. Treatment failures have been reported with erythromycin. Oral therapy with azithromycin or clarithromycin or with a fluoroquinolone such as ciprofloxacin, ofloxacin, or levofloxacin may be considered for mild to moderate infection. There is no evidence to suggest that the addition of rifampin or erythromycin to fluoroquinolone therapy is more effective than a fluoroquinolone used alone. Therapy is usually continued for 3 weeks for *Legionella* pneumonia.

Parenterally administered antibiotics should be switched to oral therapy once the patient has demonstrated clinical response, is hemodynamically stable, is able to tolerate medications administered orally, and has no evidence of malabsorption. The switch from parenteral to oral antibiotics also depends on the availability of an oral equivalent of the parenteral drug being administered.

Most patients defervesce and show improvement of cough, tachycardia, and tachypnea within 3-5 days of onset of effective antimicrobial therapy. Patients with bacteremic pneumococcal pneumonia or with *Legionella* pneumonia usually take longer to improve (6-7 days). The optimum duration of antimicrobial therapy for CAP has not been studied in controlled clinical trials. Most studies have administered antimicrobial therapy for 10-14 days. Studies have demonstrated that a 5-day course of azithromycin is effective for outpatient CAP.

**B. Nosocomial and aspiration pneumonia.** Early and appropriate empiric antimicrobial therapy may reduce the mortality of NAP ([Box 10-14](#)). Guidelines for empiric antimicrobial therapy for NAP developed by the American Thoracic Society recommend the use of antibiotics depending upon risk factors and severity of disease. For patients with no underlying risk factors who develop mild to moderate NAP early or late during hospitalization or for patients with severe early onset NAP, the guidelines recommend that therapy should be directed against nonpseudomonal enteric gram-negative bacilli, *S pneumoniae*, *H influenzae*, or methicillin-susceptible *S aureus*. Appropriate empiric antibiotic therapy for these patients includes a third- (cefotaxime or ceftriaxone) or fourth-generation (cefepime) cephalosporin, a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combination, or a fluoroquinolone. Patients with multiple risk factors, such as mechanical ventilation, coexisting underlying disease, or impaired consciousness, who develop moderate or severe NAP should receive empiric antimicrobial therapy directed against *P aeruginosa*, *Acinetobacter* spp., *Enterobacter* spp., *K pneumoniae*, and *S aureus*. These bacteria are more likely to be multidrug resistant and require broader-spectrum initial empiric antimicrobial therapy. Empiric antimicrobial therapy for such patients should include an antipseudomonal cephalosporin such as ceftazidime or cefepime or an extended-spectrum antipseudomonal  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combination such as piperacillin/tazobactam or ticarcillin/clavulanate, or a carbapenem such as imipenem or meropenem. For patients with  $\beta$ -lactam allergy, aztreonam may be used as an alternative antipseudomonal drug. Because aztreonam is not active against gram-positive cocci, clindamycin or vancomycin should be added if such coverage is required. An aminoglycoside or ciprofloxacin should be added to  $\beta$ -lactam therapy for patients with serious NAP, particularly when *P aeruginosa* is suspected or documented. Patients with suspected methicillin-resistant *S aureus* require the addition of vancomycin therapy. Patients with suspected or witnessed aspiration should receive

therapy active against anaerobic microorganisms such as clindamycin, metronidazole, a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combination, or a carbapenem. Antimicrobial therapy may be modified once blood or tracheal culture and susceptibility results are available. Duration of antimicrobial therapy for NAP depends on severity, etiology, and response to antimicrobial therapy. Response to therapy is guided by defervescence, respiratory status, sputum production, gas exchange, and leukocyte counts. For patients with mild to moderate NAP, a 7- to 10-day course of antibiotics may be enough, whereas patients with severe NAP or NAP caused by *P aeruginosa* or other resistant gram-negative bacilli may require a longer course of therapy. Patients with slow or no response to appropriate antimicrobial therapy should undergo further diagnostic investigations for other infectious or noninfectious processes such as an empyema, cholecystitis, sinusitis, or catheter-associated infections. Patients with progressive pulmonary deterioration despite appropriate therapy may require bronchoscopy with PSB or BAL cultures.

**C. Infections in patients with cystic fibrosis.** Patients with cystic fibrosis (CF) who are early in their disease process are more likely to be colonized with *H influenzae*, *S pneumoniae*, or *S aureus*. Appropriate empiric antimicrobial therapy for CF patients early in this disease includes a second-, third-, or fourth-generation cephalosporin, trimethoprim/sulfamethoxazole, or a macrolide ([Box 10-15](#)). As CF progresses, patients become colonized with more virulent and resistant gram-negative bacilli such as *P aeruginosa*, *Ralstonia (Burkholderia) cepacia*, *S maltophilia*, *Achromobacter (Alcaligenes) xylosoxidans*, and *Enterobacter* spp. Empiric antimicrobial therapy for patients with progressive disease should include an antipseudomonal cephalosporin such as ceftazidime, cefepime, an antipseudomonal  $\beta$ -lactam/  $\beta$ -lactamase combination piperacillin/tazobactam, or a carbapenem. Owing to the severity of disease, repeated courses of antibiotics, frequent colonization with resistant microorganisms, and the presence of tenacious secretions, the use of combination therapy with an aminoglycoside together with an agent listed above is recommended. Because CF patients have an increased clearance of drugs, higher dosages of most antimicrobial agents are required. Aerosolized tobramycin has been approved for use as suppressive therapy in CF. Use of aerosolized tobramycin has been shown to improve pulmonary function, decrease *P aeruginosa* bacterial density in sputum, decrease hospitalizations, and reduce the use of other antipseudomonal drugs. It may be considered for bacterial suppression in patients who are > 6 years of age, have a forced expiratory volume in 1 s of = 25% and =75% predicted, are colonized with *P aeruginosa*, and are able to comply with the recommended regimen. Such therapy may not be effective if the *P aeruginosa* or other gram-negative bacilli are resistant to tobramycin. Preservative-free 300-mg tobramycin is delivered by using a PARI LC PLUS nebulizer with a De Vilbiss PulmoAide compressor with doses administered 12 h apart for 28 days and then suspended or discontinued for 28 days. The average sputum concentration of tobramycin 10 min after an inhalation dose of 300 mg is 1237 ug/g (range, 35-7414 ug/g). The efficacy of aerosolized tobramycin as adjunctive therapy for CF exacerbations is unknown. Although fluoroquinolones are not approved by the Food and Drug Administration for persons < 18 years of age, their use in CF patients may be warranted because of drug resistance, where a fluoroquinolone may be the only alternative.

**D. Follow-up.** Radiologic clearance of pulmonary infiltrates takes ~ 4 weeks in

immunocompetent patients and may be considerably slower for elderly patients or patients with comorbidities. Resolution of *L pneumophila* pulmonary infiltrates occurs in ~ 55% of patients by 12 weeks. Accordingly, chest radiographic findings should not be used to determine duration of antimicrobial therapy. However, a follow-up chest radiograph should be obtained in 6-8 weeks after completion of antimicrobial therapy to document clearance and to identify an underlying process such as malignancy or, in children, a foreign body or congenital malformation.

## Prognosis

Pneumonia is associated with an average mortality rate of 14% in hospitalized patients and an estimated mortality of < 1% in nonhospitalized patients. Mortality from pneumococcal pneumonia among patients > 60 years of age varies from 5% to 25% and is ~ 20% in bacteremic pneumococcal pneumonia. It is the sixth most common cause of death in the United States. Risk factors for increased mortality include extremes of age and underlying diseases such as malignancy, diabetes, chronic lung disease, chronic renal failure, alcoholism, immunosuppression, congestive heart failure, and neurological disease. Previous episodes of pneumonia contribute to higher mortality. Gram-negative bacilli, *S aureus*, or polymicrobial pneumonia, as in aspiration or postobstructive pneumonia, are associated with a higher mortality. Asplenia and severe malnutrition are also associated with a high mortality.

## Prevention

**A. Community-Acquired Pneumonia.** Immunization with the influenza A/B, 23 polyvalent pneumococcal, and *H influenzae* type B vaccines decreases the incidence of infections caused by these microorganisms ([Box 10-16](#)). Susceptible populations, such as the elderly (> 65 years of age) or those with comorbid conditions such as diabetes, immunocompromise, sickle cell disease, or asplenia, should be routinely immunized with influenza A/B and pneumococcal vaccines. *H influenzae* type B vaccine is recommended for infants and individuals of any age with sickle cell disease or asplenia.

The pneumococcal vaccine has an efficacy of > 60% in preventing bacteremic pneumococcal infection caused by vaccine strain bacteria and reduction of severity in immunocompetent patients, but this rate declines with advancing age and immunosuppression. Pneumococcal vaccine is repeated once in 6 years for asplenic patients and for patients > 65 years old who received their initial dose before the age of 65 years.

Appropriate identification and decontamination of water sources may prevent *Legionella* pneumonia. Control measures include hyperchlorination of water supplies and decontamination of air-conditioning cooling units.

**B. Nosocomial Pneumonia.** The Centers for Disease Control's Hospital Infection Control Practices Advisory Committee (HICPAC) has published guidelines for the prevention of NAP ([Box 10-17](#)). To prevent aspiration, elevation of the head end of the bed at a 30°-45° angle is recommended unless contraindicated. Aspiration of gastric contents may be decreased by verifying the proper placement of enteral tubes, regular assessment of intestinal motility, and use of the appropriate volume and rate of oral or

enteral feeding. Improved pulmonary toilet in postoperative patients may be accomplished by the use of frequent suctioning, incentive spirometry, and non-cough-suppressant analgesia. In addition, HICPAC recommended strict infection control surveillance measures, universal infection precautions for select patients, and the use of appropriate sterilization, disinfection, and handling of all devices and equipment used for respiratory therapy and mechanical ventilation. HICPAC strongly recommended hand washing after contact with mucous membranes or respiratory secretions, regardless of whether gloves were worn. Studies have shown that changing the ventilatory circuit every 24 h increases the risk of NAP when compared with ventilatory circuits that are changed every 48 h. In addition to these measures, use of cytokines such as filgrastim and sargramostim in neutropenic patients may decrease chemotherapy-related neutropenia. Selective decontamination of the digestive tract has not been proven to decrease the incidence of nosocomial pneumonia and is not recommended.

**C. Infections in CF Patients.** Patients with CF ([Box 10-18](#)) should receive pneumococcal and influenza vaccines regularly. Avoiding contact with persons with a respiratory illness may prevent acquisition of new viral infections and subsequent exacerbations. Prompt and aggressive treatment of the initial *P aeruginosa* infection may delay but not completely prevent colonization. Despite multiple courses of appropriate antibiotics and pulmonary toilet, chronic colonization and recurrent infections with *P aeruginosa* or other multidrug-resistant bacteria are inevitable in CF patients. There are some data to suggest that the use of rhDNase is associated with lower rates of pulmonary exacerbations and improved forced expiratory volume.

## PARAPNEUMONIC EFFUSION & PLEURAL EMPYEMA

### Essentials of Diagnosis

- Collection of effusion or pus in the pleural space.
- Persistent fever, chills, chest pain, and dyspnea.
- Examination reveals dullness, increased vocal fremitus, and decreased breath sounds.
- Chest radiographic or CT scan evidence of fluid collection in the pleural space.
- Pleural empyema fluid usually has pH < 7.0, LDH > 1000 IU/L, glucose < 40 mg/dL, leukocyte count > 50,000/mm<sup>3</sup>, and positive Gram stain or culture.
- Mainstay of treatment is drainage of pus followed by antimicrobial therapy for 2-4 weeks.

### General Considerations

A parapneumonic effusion is defined as a pleural effusion that occurs secondary to a pulmonary infection. An empyema is defined as a collection of pus in a normally sterile body cavity, such as between the visceral and parietal pleurae. Empyema usually results from contiguous spread of an infection from the lung or other neighboring sites.

The pleural space is a sterile space, which normally contains a scant amount of fluid, between the visceral and parietal pleurae. The pleural space is a relatively immunodeficient space, because it does not contain a high number of phagocytes and lacks opsonins and complements.

Microorganisms enter the pleural space either by contiguous spread from an infected lung, perforated esophagus, mediastinum, or subdiaphragmatic structures or by direct entry as a result of trauma, thoracic surgery, or thoracentesis. The most common cause of a parapneumonic effusion or empyema is an underlying pneumonia. Less often, infection may spread from a retropharyngeal, retroperitoneal, vertebral, or paravertebral source. Once bacteria enter the pleural space, an inflammatory response results in migration of PMN leukocytes and induction of cytokines such as TNF. Because of the relative inefficiency of the defense mechanisms in the pleural space, the bacteria multiply rapidly. This leads to a fibrinopurulent effusion with increased chemotaxis of PMN leukocytes, increased inflammatory response, fibrin deposition, and loculations. With increasing bacterial growth, accumulation and lysis of inflammatory cells, the fluid pH, and glucose levels decrease, and LDH increases. This may be followed by fibroblast proliferation and scar formation.

The response to adjacent infection may result in either a parapneumonic effusion or an empyema. Parapneumonic effusions are classified by size and laboratory parameters. Small (< 10-mm-thick effusion on a decubitus radiograph) or larger effusions that have glucose > 40 mg/dL, pH > 7.00, and LDH < 1000 IU/L and that are culture-negative are considered parapneumonic effusions. These effusions usually respond to antibiotic therapy and require no surgical intervention. Empyema is defined by positive Gram stain or cultures, glucose < 40 mg/dL, pH < 7.00, and multiloculated collections of pus.

The microbiology of empyema depends on the source of infection and host factors ([Box 10-19](#)). Because an empyema usually is a complication of pneumonia, *S pneumoniae*, *S aureus*, and streptococci are the most common organisms isolated. *S aureus* is a common cause of empyema, particularly in children < 6 months of age or in postsurgical or trauma patients, and it occasionally occurs in association with hemothorax. Overall, *S aureus* accounts for 29-35% of all cases of pediatric empyema. In older children, *S pneumoniae*, *S aureus*, and *H influenzae* most often cause empyema. Aerobic gram-negative bacilli may cause empyema in alcoholics or after thoracic surgery or trauma not confined to alcoholics. Postsurgical or traumatic empyema may also be caused by *S aureus*, a polymicrobial infection, or, rarely, by *Aspergillus* spp. Polymicrobial empyema may result from aspiration pneumonia, lung abscess, or perforation of the esophagus or stomach. Anaerobic empyema is uncommon in young children < 6 years of age. An empyema can develop as an extension of a subdiaphragmatic abscess. Less common etiologies of empyema include *M tuberculosis*, *C neoformans*, *C immitis*, rupture of an echinococcal cyst, or an *Entamoeba histolytica* liver abscess that ruptures into the pleural cavity. Rarely, an empyema may erode and drain spontaneously through the chest wall. This condition is called empyema necessitatis and is typically associated with *Actinomyces*, *Nocardia* spp., or *M tuberculosis*.

## Clinical Findings

**A. Signs and Symptoms.** Patient presentation depends on the underlying disease and organism. Symptoms usually resemble those of pneumonia. Fever, chills, cough, and chest pain are common. Persistent fever or leukocytosis and diaphoresis in a patient with pneumonia who is receiving appropriate antimicrobial therapy may be suggestive of an empyema. In chronic cases, patients develop low-grade fever, night sweats, and weight loss. On physical examination, dullness to percussion and increased vocal fremitus over the area of effusion or empyema are usually present. Auscultation of the corresponding area demonstrates decreased breath sounds; egophony or bronchophony is heard above the effusion.

**B. Laboratory Findings.** Leukocytosis with a left shift is common. Anemia is present in chronic empyema. Hypoxemia, azotemia, acidosis, and disseminated intravascular coagulation may occur in severely and acutely ill patients. Thoracentesis may show cloudy or grossly purulent fluid. The empyema fluid has a pH < 7.0, glucose < 40 mg/dL, LDH > 1000 IU/L, and leukocyte count > 50,000 × 10<sup>9</sup>. High pleural fluid protein or specific gravity is not helpful in the diagnosis of empyema. Detection of amylase in the fluid suggests an esophageal rupture. Chylous effusion is characterized by the presence of high triglycerides and pH in pleural fluid that appears cloudy or milky after centrifugation. Gram stain, AFB, modified AFB for *Nocardia* spp., KOH, and direct fluorescent microscopy for *L pneumophila* or smears for parasites should be performed. Overall, 18-30% of empyemas are sterile. The yield of positive bacterial cultures decreases with the administration of antimicrobial therapy or because of bacterial cell lysis in the acidic medium of the pus. Pleural tuberculosis usually results in an effusion; however, occasionally a purulent tuberculous empyema may occur. In the former, a positive AFB smear of pleural fluid is unlikely, whereas many AFB are typically present on stain in patients with tubercular empyema. Stains and cultures are more likely to be positive for mycobacteria when performed on pleural biopsy specimens than on pleural fluid. A positive tuberculin skin test in patients with pleural effusion or empyema suggests a mycobacterial etiology. Molecular methods of diagnoses such as polymerase chain reaction are currently under investigation.

**C. Imaging.** A posterior-anterior and lateral chest radiograph is useful for the detection of pleural effusion or empyema ([Figure 10-7](#)). A decubitus chest roentgenogram may detect =5 mL of pleural fluid. Approximately 200 mL of fluid produces a concave obliteration of the costophrenic angle in an upright radiograph. Larger effusions may cause complete opacification of the hemithorax with a contralateral shift of the mediastinum and trachea. An empyema is typically a loculated, homogenous opacity with sharp margins. The fluid appears as an opaque density in the chest radiograph. A decubitus film helps to identify a free-flowing or a loculated fluid collection. Ultrasonography or CT scan may be required to differentiate this density from a solid parenchymal mass or to detect small fluid collections in patients in whom a decubitus radiograph is difficult to obtain. Ultrasonography has a 92% accuracy in correctly identifying a solid mass or a fluid collection. This accuracy increases to 98% when used in conjunction with chest radiographs. Ultrasonography may be superior to CT scan in visualizing septations within a complicated parapneumonic effusion, particularly in children. A CT scan is the optimal method to differentiate a loculated fluid collection from parenchymal consolidation or peripheral lung abscesses, particularly when the opacity has an atypical location. The characteristic CT appearance of an empyema is a

lenticular shape, enclosed within enhancing thickened pleurae (the "split-pleura" sign), which forms an obtuse angle with the chest wall and causes displacement of vessels and bronchi around the fluid collection.

## Differential Diagnosis

Noninfectious causes of pleural effusion must be differentiated for accurate therapy and response. Exudative effusions may result from congestive heart failure, malignancies, collagen vascular diseases, thoracic duct tears, or pancreatitis. Malignant effusion is often hemorrhagic and may be differentiated by cytological evaluation of the pleural fluid.

## Complications

In children, empyema may result in pneumatoceles, pneumothorax, or scoliosis as a result of scarring. Other complications result from the local spread of infection to surrounding structures such as the lung, pericardium, and myocardium. Some patients develop a severe, overwhelming infection that results in multisystem organ failure and death. Empyema-associated mortality is low and varies from 1% to 19%. Mortality increases with age > 50 years, immunosuppression, comorbidities, and NAP.

## Treatment

Gross appearance, biochemical composition, and the radiographic appearance of the fluid guide the management of an infected effusion. The goals of treatment include appropriate antimicrobial therapy, removal of infected fluid, and re-expansion of the underlying lung.

Empiric antimicrobial therapy depends on the putative etiology of parapneumonic effusion or empyema ([Box 10-20](#)). When it is the result of CAP, empiric antimicrobial therapy should be directed against *S pneumoniae*, and the use of a third-generation cephalosporin is appropriate. A specific antimicrobial agent may be administered for known pathogens recovered from the sputum, blood, or pleural fluid. Broad-spectrum antimicrobial therapy is indicated if the empyema is thought to be caused by a ruptured lung abscess, postobstructive pneumonia from an endobronchial lesion, postoperative complication, trauma, or a nosocomial infection. In such situations, therapy should include a drug or combination of drugs with activity against gram-negative bacilli, gram-positive cocci, and anaerobes. Duration of antimicrobial therapy is usually 4-6 weeks.

Parapneumonic effusions with pH > 7.20 should be treated with antimicrobial therapy and drainage. Parapneumonic effusions with pH between 7.0 and 7.20 and elevated LDH may require repeated thoracentesis or chest tube drainage, together with antimicrobial therapy. Chest tube drainage, open drainage, or decortication is required for adequate therapy of empyema.

## Prognosis

The prognosis is extremely good, with cure rates of > 90% for uncomplicated

parapneumonic effusions when treated with an appropriate antimicrobial agent and with drainage as necessary. Patients with loculated pleural effusions or leukocyte counts of < 6400 are associated with treatment failure if not managed with nonsurgical measures. With the advent of surgical and nonsurgical intervention techniques and the vast majority of antimicrobial agents, mortality from empyema is low, ranging from 4% to 10%. Mortality varies with the causative organisms, such as *Aspergillus* species, underlying risk factors such as malignancy or other comorbid conditions, older age, and delay in appropriate therapy. Chronic empyema with a thick pleural wall requires a surgical approach. These types of empyema may take months to resolve and are more likely to result in treatment failures.

## Prevention

Early administration of effective antimicrobial therapy for LRTIs and early recognition and drainage of infected parapneumonic effusions are most important for the prevention of empyema ([Box 10-21](#)). Careful closure and inspection of the bronchial stump after pneumonectomy may prevent empyema that results from a postoperative bronchopleural fistula.

## LUNG ABSCESS

### Essentials of Diagnosis

- Infection resulting in destruction of lung parenchyma and formation of a cavity with an air-fluid level.
- Polymicrobial, mostly anaerobic microorganisms; often related to aspiration; symptoms: fevers, chills, cough, fatigue, weight loss.
- Appears radiographically as a cavity with air-fluid levels, with or without surrounding infiltrate.
- Prolonged course of appropriate antimicrobial therapy is necessary, with or without surgical intervention.

### General Considerations

Lung abscess is defined as an acute or chronic suppurative infection of the lung parenchyma caused by a single microorganism or multiple microorganisms, predominantly oral anaerobes, that results in destruction of the lung tissue and eventual cavity formation. Lung abscesses are classified as primary or secondary, depending on the pathogenesis and host factors. Primary lung abscesses occur because of aspiration or as the result of an infection of the lung caused by virulent organisms. Lung abscesses may be caused by microorganisms that cavitate, such as *Nocardia* spp., *M tuberculosis*, *S aureus*, or *S pyogenes*. Primary lung abscesses occur more frequently than secondary abscesses. Secondary lung abscesses are those that occur as a result of a remote primary infection with bacteremic spread to the lung or as an extension from a subphrenic abscess. Secondary infections may also include bacterial superinfection after a pulmonary infarct or as a complication of an underlying process, such as an

endobronchial lesion or bronchiectasis.

Aspiration of infectious material is the most common cause of lung abscesses. Oropharyngeal fluid containing multiple aerobic and anaerobic microorganisms is aspirated and carried to the most dependent portions of the lung, which are usually the right upper lobe or the superior segment of the right lower lobe. However, other parts of the lung may be involved. After the initial localized pneumonitis, there is bacterial proliferation, extensive inflammation, necrosis, and destruction of the lung tissue. This destruction may erode into a bronchiole or bronchus, leading to expectoration and partial emptying of the cavity, which creates an air-fluid level. The lung abscess may involve the pleural space by rupture or direct extension.

The microbiology of lung abscesses varies by the cause ([Box 10-22](#)). Because aspiration is the most common cause, it results in a polymicrobial infection that includes gram-negative bacilli, gram-positive cocci, and anaerobes. Anaerobes encountered in lung abscesses are oral anaerobic gram-negative bacilli and gram-positive cocci or bacilli. Anaerobes that are commonly isolated include *Prevotella* spp., *Bacteroides* spp., *Fusobacterium* spp., *Peptostreptococcus* spp., *Clostridium* spp., and, rarely, *Actinomyces* spp. Aerobic gram-negative bacilli such as *K pneumoniae*, *Enterobacter* spp., or *P aeruginosa*, along with anaerobes, predominate among nursing home residents with NAP, alcoholics, and trauma patients. Patients with lung abscesses tend to have poor oral hygiene and dental and gingival disease. Lung abscesses occur less commonly in edentulous patients. Lung abscess may develop from a metastatic infection as seen with *Fusobacterium necrophorum* septicemia or thrombophlebitis complicating an anaerobic pharyngitis (Vincent's angina, Lemierre's syndrome).

A process similar to lung abscess is a severe nonlocalized necrotizing pneumonia caused by anaerobic or aerobic bacteria, involving one or more lobes, that presents as severe pneumonia and multiple small cavities. Anaerobic bacteria and *S aureus* are the most common causes of necrotizing pneumonia. Other microorganisms that may cause necrotizing pneumonia include *S pyogenes*, gram-negative bacilli such as *Proteus* spp., or, rarely, *Legionella* spp. *S aureus* is the most common cause of bacteremic spread to the lungs that results in multiple lung abscesses.

Fungi may also cause lung abscesses and include *Aspergillus* spp., *C immitis*, *B dermatitidis*, and *H capsulatum*. Unusual causes of lung abscess include *Rhodococcus equi* and nontyphi strains of *Salmonella* spp.

Lung abscesses may result from direct extension of an intra-abdominal process. Examples of this include the direct extension of an amebic liver abscess or subphrenic abscesses.

The microbiology of lung abscess in children differs from that of adults. The most common cause of lung abscess in children is *S aureus*, followed by *S pyogenes*, *H influenzae*, and *S pneumoniae*. Abscesses in children may be polymicrobial and include anaerobes. In neonates, lung abscesses are usually caused by gram-negative bacilli.

## Clinical Findings

**A. Signs and Symptoms.** Patients with lung abscess present with symptoms of pneumonia, including cough producing copious amounts of foul-smelling expectoration. The symptoms may persist despite antibiotic therapy. Patients may have a history of weight loss, fatigue, and a chronic illness lasting weeks to months before diagnosis. In such patients, it is important to elicit a history of either gastroesophageal reflux, vomiting, or aspiration related to a period of unconsciousness.

Examination often reveals a chronically ill-appearing patient with poor dental hygiene, signs of neurologic disorder with an impaired gag reflex, and putrid-smelling expectorated sputum. Clubbing of the fingers may be present. Pulmonary examination is similar to that of patients with pneumonia. Breath sounds overlying the cavity may be bronchial in character, with an intense, high-pitched tone called "amphoric breathing." However, if the cavity is completely filled, breath sounds may be faint or absent. There may be signs of consolidation with dullness to percussion, increased vocal and tactile fremitus, and bronchial breath sounds. A pleural effusion may be present. Signs of an underlying condition may be present, such as spider naevi, palmar erythema, and splenomegaly suggestive of hepatic cirrhosis.

**B. Laboratory Findings.** The diagnosis of lung abscess is based on the clinical appearance and radiographic findings. The sputum Gram stain is not specific and usually demonstrates mixed oral flora. Routine sputum cultures and anaerobic cultures of sputum are not helpful in diagnosis. The most reliable cultures are those obtained by percutaneous image-guided transthoracic aspiration or by PSB lavage and aspiration. Fungal and mycobacterial stains and cultures should be done in patients with an unusual presentation or who are in an immunocompromised status. In patients suspected of having an amebic lung abscess, cysts and trophozoites of *E histolytica* may be seen in a wet mount of the sputum. Serological tests are not helpful.

**C. Imaging.** On chest radiographs, a lung abscess appears as a cavitary infiltrate with or without an air-fluid level ([Figures 10-8, 10-9, and 10-10](#)). There may be multiple cavities with air-fluid levels as seen with *S aureus* hematogenous lung abscesses. Severe necrotizing pneumonia presents as extensive parenchymal infiltrates with multiple small cavities. Lung abscesses caused by *H capsulatum* are likely to appear as small nodules with cavities. CT may delineate lung abscess more clearly than a chest radiograph. CT helps differentiate a lung abscess from an empyema and may identify pleural involvement and an underlying lung mass. Extension of the CT scan into the abdomen may identify an intra-abdominal cause. Periodic CT scans may be used to assess response to therapy or development of complications such as empyema.

## Differential Diagnosis

Wegener's granulomatosis, bronchogenic carcinoma, or a metastatic malignancy may cause cavitary lung infiltrates. Echinococcal cysts, *Paragonimus westermani* infection, emphysematous bullae, or a pulmonary infarct may be mistaken for a lung abscess. Occasionally, an empyema may be difficult to differentiate from a lung abscess in chest radiographs.

## Complications

Complications of lung abscess primarily result from direct extension of infection into neighboring structures. Pleura-based lung abscesses may extend into the pleural cavity and result in an empyema, which occurs in about one-third of patients with a lung abscess. Bronchopleural fistula with resultant pyopneumothorax may occur. Some abscesses that are in close proximity to a large pulmonary vessel may erode into the vessel and cause massive or fatal hemorrhage. Systemic dissemination of infection to other locations, such as the brain, may occur.

## Treatment

The principles of treatment for a lung abscess are the same as for abscesses elsewhere in the body—effective antimicrobial therapy and drainage.

Initial empiric antibiotic therapy should be directed against polymicrobial oropharyngeal flora, especially anaerobes ([Box 10-23](#)). This may be achieved with either a combination of a parenteral penicillin or a third-generation cephalosporin with clindamycin or metronidazole; or a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combination such as piperacillin/tazobactam or ampicillin/sulbactam. Alcoholics, nursing home residents, or patients with a nosocomially acquired lung abscess should receive therapy with a third- or fourth-generation cephalosporin with antipseudomonal activity, such as ceftazidime or cefepime, together with clindamycin or metronidazole; or a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combination or a carbapenem (imipenem or meropenem); or a fluoroquinolone such as levofloxacin or ciprofloxacin together with clindamycin or metronidazole. The duration of antibiotic therapy is usually 4-6 weeks, with reassessment at intervals for complications or lack of response. Clinical improvement is usually apparent within 1-2 weeks; however, there is a delay of = 8-12 weeks before resolution of the cavity occurs on chest radiograph or CT scan.

Medical therapy is effective in 80-90% of patients with a lung abscess < 5 cm in diameter. The majority of lung abscesses spontaneously drain into a bronchus. Postural drainage is strongly encouraged, and this may be improved with chest physiotherapy. Patients who do not respond to medical therapy or those with enlarging cavity size, ongoing sepsis, or associated empyema require drainage. Drainage of the lung abscess can be performed with transthoracic radiographic guidance or with open surgical drainage. Open surgical drainage is required in < 15% of patients. Indications for surgery include extent and severity of disease, underlying malignancy, large-volume hemoptysis, bronchopleural fistula with empyema, and inaccessibility of transthoracic drainage of the abscess.

## Prognosis

The prognosis of patients with lung abscesses depends on severity of disease, underlying host factors, and promptness of treatment. Poor prognostic indicators include a large cavity, multiple abscesses, abscesses caused by *S aureus*, *P aeruginosa*, or *K pneumoniae*, necrotizing pneumonia, and underlying host factors such as an immunocompromised status, including that caused by HIV infection, extremes of age, and malignancy. Overall, mortality from lung abscess is ~ 15%, and it increases to 25% with the presence of necrotizing pneumonia.

## Prevention

It is important to identify patients susceptible to aspiration and to institute aspiration precautions promptly in these patients ([Box 10-24](#)). Lung abscess should be suspected in patients with a slow response or progression of infection despite appropriate therapy for CAP.

## **BOX 10-9. Control of Acute Bronchiolitis**

### **Prophylactic Measures**

- Avoid contact with ill persons
- Respiratory syncytial virus (RSV) immunoglobulin, 750 mg/kg/mo during the RSV season (October to April) should be considered for select high-risk infants and children, including premature infants (gestational age < 28 wk or 29-32 wk, who are < 1 y or 6 mo of age, respectively), infants with bronchopulmonary dysplasia, or those who are severely immunocompromised
- Droplet isolation for hospitalized patients with RSV infection, influenza, parainfluenza, and *Mycoplasma* infection

## 11 . Infective Endocarditis — James M. Steckelberg, MD, & Walter R. Wilson, MD

### Essentials of Diagnosis

- Persistent bacteremia with typical microorganisms: for native valves, viridans group streptococci, *Streptococcus bovis*, HACEK group microorganisms, or community-acquired *Staphylococcus aureus* or enterococci in the absence of a primary focus.
- Bacteremia, typically continuous in the absence of antimicrobial therapy.
- Evidence of endocardial involvement: a new regurgitant murmur or echocardiographic demonstration of valvular vegetations, prosthetic valve dehiscence, or perforation.
- Supporting findings: predisposing cardiac risk factors or intravenous drug use, vascular phenomena such as emboli, immune-mediated phenomena such as glomerulonephritis.

### General Considerations

The term "infective endocarditis" refers to infection involving the endocardial surfaces of the heart. Typically, valvular surfaces are affected together with adjacent areas subject to trauma or shear forces from turbulent blood flow. Endocarditis has been recognized as a distinct clinical entity for well over 100 years but continues to be an important diagnostic and therapeutic challenge for clinicians in the modern era.

In studies in geographically defined populations, endocarditis occurs at a frequency of 4-5 cases/ 100,000 person years. Endocarditis occurs ninefold more frequently among people = 65 years old than among younger persons. The incidence rate is two- to threefold higher in men than in women at all ages. Cardiac abnormalities associated with turbulent blood flow increase the risk of endocarditis ([Table 11-1](#)). Although the association between dental infection or procedures and infective endocarditis has been recognized since the 1930s, only a minority of cases have a clearly implicated dental procedure. Intravenous drug abuse may be associated with endocarditis which most often affects the tricuspid valve but may cause infection of the aortic or mitral valve as well. Endocarditis associated with intravenous drug abuse is most often caused by *S aureus*, gram-negative bacilli (including *Pseudomonas* spp.), or *Candida*.

Unlike most other bacterial infections, untreated endocarditis is uniformly fatal, typically within weeks to months. Accurate diagnosis and prompt therapy are therefore paramount.

### Clinical Findings

The clinical manifestations of endocarditis are highly varied ([Table 11-2](#)). Patients may experience a prolonged, insidious onset of flulike symptoms over weeks to months,

especially if partially treated with oral antibiotics empirically or for an erroneous diagnosis of minor infection. Other patients present with a more abrupt, devastating onset of flagrant sepsis with rapid cardiac valvular destruction and cardiac decompensation, typically with *S aureus* infection.

**A. Signs and Symptoms.** Most patients with endocarditis have daily fever. Other nonspecific symptoms include rigors; night sweats; malaise; anorexia; muscular, joint, or back pain; and weight loss. Physical examination may reveal evidence of preexisting (Table 11-1) or new cardiac abnormalities, including murmurs or congestive heart failure. Splenomegaly is present in a minority of patients. Osler nodes are painful nodules, typically on the pulps of the toes or fingers. Janeway lesions are painless erythematous macules characteristically on the soles of the feet or palms. Roth spots are hemorrhagic retinal or conjunctival lesions with central pallor.

Osler nodes, Janeway lesions, and Roth spots, if found, are highly suggestive of infective endocarditis but will be absent in 80-90% of cases.

**B. Laboratory Findings.** Blood cultures should always be obtained promptly when endocarditis is suspected, before antimicrobial therapy is begun. For most microorganisms that cause endocarditis (Box 11-1), bacteremia is continuous, and = 90% of the first two sets of blood cultures obtained will be positive in the absence of recent antimicrobial therapy. Occasionally, endocarditis is caused by fastidious organisms (such as the HACEK group of oral gram-negative microorganisms or nutritionally variant viridans streptococci), which require longer periods of incubation of blood cultures or special culture techniques for optimal growth. Alerting the microbiology laboratory to the suspicion of endocarditis will aid in optimizing culture techniques.

In established endocarditis, anemia and an elevated sedimentation rate are present in the majority but not all patients. The leukocyte count typically is normal or mildly elevated despite the presence of ongoing bacteremia, except in fulminant *S aureus* infection, in which leukocytosis is the rule. Polyclonal hypergammaglobulinemia, hypocomplementemia, and false-positive rheumatoid factor, Lyme serology, or syphilis serology may be found and reflect ongoing immunologic activation. Microhematuria or elevated creatinine and urinary sediment findings suggesting glomerulonephritis may be seen in advanced, late infection. Glomerulonephritis is caused by the deposition of circulating immune complexes on kidney basement membranes.

**C. Imaging.** Echocardiography demonstrates cardiac valvular vegetations in from < 60-95% of patients. Transesophageal echocardiography, while more invasive, is more sensitive for detecting valvular vegetations or perforations (especially in patients with prosthetic valves) as well as intracardiac complications of endocarditis such as myocardial abscesses. Although echocardiographic examination is frequently helpful, the absence of vegetations as seen by echocardiography does not completely exclude a diagnosis of infective endocarditis. Among patients with right-sided cardiac involvement, chest x-ray may show multiple, migratory pulmonary infiltrates resulting from septic pulmonary emboli.

## Differential Diagnosis

The differential diagnosis of infective endocarditis is broad and includes many diseases discussed in [Chapter 18](#). In addition to many infectious etiologies, rheumatologic conditions such as systemic lupus erythematosus or vasculitides and malignancies are the main categories to be considered. Numerous noninfectious processes may cause marantic (noninfectious) cardiac valvular vegetations or false-positive echocardiographic studies ([Table 11-3](#)).

## Complications

**Intracardiac Complications.** Cardiac valvular destruction with resulting valvular insufficiency and cardiac failure is the most common intracardiac complication of infective endocarditis. Valvular dysfunction can occur from perforation of a valve leaflet, destruction of supporting apparatus such as an infected ruptured mitral chordae, or dehiscence of a prosthetic valve. Alternatively, large, bulky vegetations may occasionally result in valve outflow obstruction mimicking valvular stenosis.

Perivalvular extension of infection with abscess formation is associated more commonly with *S aureus* infections, infections of the aortic valve, and infections of prosthetic valves. Perivalvular extension may be clinically silent or manifested by conduction delays, persistent bacteremia or fever on appropriate therapy, fistulous tracts between cardiac chambers or the pericardial space, or prosthetic valve dehiscence. As noted above, transesophageal echocardiography is more accurate (positive predictive value, 87%; negative predictive value, 89%) than transthoracic echocardiography for the detection of perivalvular abscesses. The development of new atrioventricular block on electrocardiography has 88% specificity for abscess but poor sensitivity (45%).

**Extracardiac Complications.** Arterial emboli occur in 20-40% of patients with infective endocarditis. Symptomatic emboli occur most frequently in the central nervous system; other sites include abdominal viscera (especially the spleen), kidneys, peripheral arteries, coronary arteries, and (in right-sided endocarditis) the pulmonary arteries. About half of the embolic events occur before diagnosis. Endocarditis therefore should be considered in the differential diagnosis of every patient who presents with fever and an embolic event, such as a stroke. Overall, the incidence of emboli falls from 13 events/1000 patient days during the first week of effective antimicrobial therapy to < 1.2 events/1000 patient days after 2 weeks of antimicrobial therapy.

The relationship between vegetation size, as measured by echocardiography, and embolic events is complex. Not all studies have distinguished between an association with past embolic events (due in part to a longer course of illness associated with larger vegetations) and the ability to predict future embolic events. Some studies have suggested that large vegetations (> 1 cm), especially in the mitral position, are associated with higher embolic risk. In one study, vegetations were predictive of future embolic events only in patients with viridans group streptococcal infection and not in patients with other microorganisms. Staphylococcal infections had the highest incidence of embolic events, irrespective of vegetations.

Mycotic (infectious) aneurysms occur in 1-5% of patients with endocarditis, most commonly at bifurcation points in the central nervous system, although aortic, visceral, and peripheral arterial mycotic aneurysms also occur. Mycotic aneurysms may be

caused by any of the microorganisms that cause endocarditis; the term "mycotic" in this context does not imply a fungal etiology. Clinically, the presentation of mycotic aneurysms in patients with endocarditis is highly variable.

In some patients, a sudden, catastrophic intracranial hemorrhage without premonitory symptoms is the first indication of an aneurysm. In others, severe, localized headache or neurological symptoms such as evidence of a mass lesion, altered sensorium, or focal deficits such as hemianopsia or cranial neuropathy may indicate an embolus preceding an aneurysm or a premonitory aneurysmal leak. Patients suspected of an intracranial mycotic aneurysm should undergo contrast-enhanced computerized tomographic scanning or magnetic resonance angiography. In selected cases or when surgical intervention is planned, four-vessel cerebral angiography is indicated.

Treatment of mycotic aneurysms is complex; more than half of intracerebral aneurysms resolve or decrease in size with antimicrobial therapy, whereas in other patients enlargement, rupture, or the formation of new aneurysms occurs. The decision to intervene surgically should be individualized and depends on the number of aneurysms, their location and course, as well as patient risk factors for surgery.

Abscess formation distant from the heart may complicate endocarditis as a consequence of the sustained and sometimes prolonged bacteremia. Identification of this complication is especially important, since a persistent metastatic focus of infection may cause relapse of the endocarditis or require an altered treatment regimen. Persistence of fever or intermittent bacteremia despite appropriate antimicrobial therapy, localized pain or tenderness, or laboratory abnormalities referable to the involved organ (such as abnormal liver function tests) provides clues to the diagnosis. Abscesses occur most frequently in the spleen, liver, brain, or disk spaces. Bacteremic seeding of muscle or single or multiple joint spaces may also be seen, most often associated with *S aureus* endocarditis.

Renal failure, once commonly seen in end-stage infective endocarditis, is now rarely seen. Microhematuria or red cell casts may be present in the urine. Renal failure may occur due to glomerulonephritis associated with endocarditis, renal infarcts due to emboli, or as complications of drug therapy. Renal failure due to immune complex deposition in glomeruli associated with infective endocarditis typically improves with the institution of appropriate antimicrobial therapy.

## **Treatment**

Effective medical treatment of infective endocarditis requires identification and susceptibility testing of the responsible microorganism; sustained bactericidal antimicrobial therapy singly or in combination, usually in high concentrations, based on the susceptibility of the microorganism ([Tables 11-4](#), [11-5](#), [11-6](#), [11-7](#), [11-8](#), and [11-9](#)); identification and treatment of complications, including abscesses and complications of drug therapy; identification and eradication of the original source of infection (such as a dental abscess) if possible; and patient education about future endocarditis antimicrobial prophylaxis ([Tables 11-1](#), [11-10](#), [11-12](#), and [11-13](#)).

Surgical intervention is necessary in about a third of patients with endocarditis and is

lifesaving in some situations. The most common indication for valve replacement or valve repair surgery is congestive heart failure or hemodynamic instability due to valvular dysfunction that is unresponsive to medical therapy. In this setting, immediate surgery is indicated; a delay to complete a longer course of antimicrobial therapy may increase surgical mortality. Other accepted indications for surgery include sustained, persistent bacteremia despite appropriate antimicrobial therapy, especially in the setting of resistant microorganisms (eg, fungi) or myocardial abscess, and relapse with highly resistant microorganisms. Some patients with multiple emboli despite effective antimicrobial therapy may benefit from surgery.

Echocardiographic appearance per se of vegetations should not be used as the sole criterion for surgical intervention. Patients at risk of emboli from valvular vegetations demonstrable on echocardiography may be considered candidates for surgical intervention if emboli continue to occur after 2 weeks of effective antimicrobial therapy, or in those patients with large mobile vegetations located on the anterior leaflet of the mitral valve. However, generalizations should not be made regarding surgical intervention in these patients, and the decision for cardiac surgery to prevent systemic embolization should be individualized for each patient.

## Prognosis

As noted above, untreated infective endocarditis is uniformly fatal. The prognosis with accurate diagnosis and treatment is highly variable, depending on the microorganism, the degree of valvular destruction before antimicrobial treatment, and whether prosthetic material is involved. In uncomplicated *viridans* group streptococcal infection of a native valve, outcome is frequently excellent, including prompt response of fever and systemic symptoms to antimicrobial therapy and cure rates exceeding 98% with approved regimens in patients who survive to complete therapy. In contrast, mortality in prosthetic valve infection with staphylococci, gram-negative bacilli, or fungi remains in the range of = 25-50%, despite aggressive medical and surgical therapy.

Even after cure of infective endocarditis, subsequent need for valve replacement because of valvular insufficiency is not uncommon, especially in the setting of aortic valve infection. Persons who have had infective endocarditis are at = 100-fold increased risk of recurrent infection, compared with the general population.

## Prevention

Patients with known cardiac risk factors for infective endocarditis should have regular professional dental care and practice good oral hygiene. The American Heart Association recommends specific antimicrobial prophylaxis for patients who have cardiac abnormalities associated with increased risk of endocarditis and who are undergoing certain invasive procedures associated with a risk of transient bacteremia caused by microorganisms commonly causing endocarditis ([Tables 11-1, 11-10, 11-11, 11-12, and 11-13](#)).

**Table 11-1.** Cardiac conditions associated with endocarditis.<sup>1</sup>

Endocarditis prophylaxis recommended

High-risk category:

Prosthetic cardiac valves, including bioprosthetic and homograft valves

Previous bacterial endocarditis

Complex cyanotic congenital heart disease (eg, single ventricle states, transposition of the great arteries, tetralogy of Fallot)

Surgically constructed systemic pulmonary shunts or conduits

Moderate-risk category:

Most other congenital cardiac malformations (other than above and below)

Acquired valvar dysfunction (eg, rheumatic heart disease)

Hypertrophic cardiomyopathy

Mitral valve prolapse with valvar regurgitation, thickened leaflets, or both

Endocarditis prophylaxis not recommended

Negligible-risk category (no greater risk than the general population):

Isolated secundum atrial septal defect

Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residua beyond 6 mo)

Previous coronary artery bypass graft surgery

Mitral valve prolapse without valvar regurgitation

Physiologic, functional, or innocent heart murmurs

Previous Kawasaki disease without valvar dysfunction

Previous rheumatic fever without valvar dysfunction

Cardiac pacemakers (intravascular and epicardial) and implanted defibrillators

**Table 11-4.** Suggested regimens for therapy of native valve endocarditis due to penicillin-susceptible *bovis* (minimum inhibitory concentration =0.1 µg/mL).<sup>1</sup>

<b>Antibiotic</b>	<b>Dosage and Route</b>	<b>Duration, wk</b>
Aqueous crystalline penicillin G sodium or Ceftriaxone sodium	12-18 million U/24 h IV either continuously or in six equally divided doses 2 g once daily IV or IM <sup>2</sup>	4 4
Aqueous crystalline penicillin G sodium With gentamicin sulfate <sup>3</sup>	12-18 million U/24 h IV either continuously or in six equally divided doses 1 mg/kg IM or IV every 8 h	2 2
Vancomycin hydrochloride <sup>4</sup>	30 mg/kg per 24 h IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored	4

<sup>1</sup>Dosages recommended are for patients with normal renal function. For nutritionally variant streptococci, use intravenous; IM, intramuscular.

<sup>2</sup>Patients should be informed that IM injection of ceftriaxone is painful.

<sup>3</sup>Dosing of gentamicin on a mg/kg basis will produce higher serum concentrations in obese patients than in lean patients. In obese patients, dosing should be based on ideal body weight. (Ideal body weight for men is 50 kg + 2.3 kg per inch over 5 feet; for women is 45.5 kg + 2.3 kg per inch over 5 feet.) Relative contraindications to the use of gentamicin include renal impairment, or impairment of the eighth nerve. Other potentially nephrotoxic agents (eg, nonsteroidal anti-inflammatory drugs) should be used cautiously in patients receiving gentamicin.

<sup>4</sup>Vancomycin dosage should be reduced in patients with impaired renal function. Vancomycin given orally has lower serum concentrations in obese patients than in lean patients. Therefore, in obese patients, dosing should be based on ideal body weight. Each dose of vancomycin should be infused over at least 1 h to reduce the risk of the histamine-release reaction. ## 12 . Intra-abdominal Infections — *Jeffery Loutit, MB, ChB*

### INTRODUCTION

The term intra-abdominal infection encompasses many inflammatory processes of the peritoneum and/or an intra-abdominal organs. Therefore, patients may present with a clinical syndrome ranging from peritonitis to a localized abscess. Most cases of intra-abdominal infection are secondary to changes in the structure and function of the bowel wall that allow passage of aerobic gram-negative organisms and anaerobes into the intra-abdominal cavity. Bacterial pathogens appear to predominate. In this chapter, primary, secondary, and tertiary peritonitis and other intra-abdominal infections such as liver, splenic, and pancreatic abscesses are discussed. In addition, cholecystitis, appendicitis, and necrotizing pancreatitis are reviewed.

Abdominal pain is a common feature of intra-abdominal infection. In evaluation of the patient with abdominal pain, three distinct patterns can be described: acute, chronic intermittent, and chronic intractable abdominal pain. Temporal features, quality, location, exacerbating/relieving factors, and, of course, physical examination are paramount in the diagnosis of patients with abdominal pain.

### ABDOMINAL PAIN

Abdominal pain is a common presenting complaint. To delineate the source of a patient's pain, the practitioner must be familiar with the neurologic innervation of the visceral organs. There are three levels of neurons that connect the abdominal organs with the cerebral cortex. The first-order neurons link receptors on the abdominal organs to the spinal cord; therefore, stimuli such as stretch, distention, or contraction of a hollow viscus will cause visceral pain. The second-order neurons in the dorsal horn of the spinal cord link the spinal cord and the brain stem; their fibers travel through the contralateral spinothalamic tract. The third-order neurons link the brain stem with the higher brain centers.

Visceral pain is often very poorly localized and vague. The neuronal fibers that carry painful stimuli to the central nervous system are relatively few and travel with the sympathetic nervous system. In addition, a relatively small number of fibers modify the stimulation of a majority of the second-order neurons. This is likely to be a cause of the imprecise localization of these stimuli, as well as a partial explanation for the observation that visceral pain is accompanied by a variety of autonomic responses, such as changes in muscle tone, pulse, blood pressure, and skin temperature. The gut itself begins to develop during embryologic development, as a midline structure; therefore, it has bilateral and symmetric innervation. Consequently, most visceral pain is felt as midline pain. In some areas of the gut, such as the ascending and descending colon, and in the biliary tree, nerve fibers from one side predominate over those from the other. Patients with pain that originates from these structures have a lateralized sensation that is appropriate to the predominant side of innervation. Other areas of pain localization in the abdominal wall also follow embryologic development. Nerves from foregut structures enter into the spinal cord at T/5-T/9 and cause pain in the epigastric

region, usually between the xiphoid process and umbilicus. Nerves of the mid gut structure enter into the spinal cord from T/8-T/11 and L/1, and pain is perceived in the periumbilical area. Nerves of the hindgut structure enter into the spinal cord from T/11 through L/1 and cause pain between the umbilicus and the pubic bone.

Somatic pain occurs when intra-abdominal conditions cause stimulation of the somatic or abdominal wall nerves rather than visceral nerves; therefore, the characteristics of the painful sensation become more like those expected from the skin. Referred pain is felt as a deep ache that is perceived near the surface of the body and is accompanied by skin hyperalgesia and increased muscle tone.

## CLINICAL SYNDROMES

### PERITONITIS

#### 1. SPONTANEOUS BACTERIAL PERITONITIS

##### Essentials of Diagnosis

- Presence of ascites.
- Fever in ~ 80% of cases.
- No symptoms or signs in 30% of patients at presentation.
- Abdominal tenderness in only 50% of patients.
- Ascitic fluid with  $> 250$  neutrophils/mm<sup>3</sup>.
- Ascitic fluid with  $> 10,000$  neutrophils/mm<sup>3</sup> and yielding  $> one$  microorganism by culture, suggests secondary peritonitis.

##### General Considerations

The peritoneum consists of a single layer of mesothelial cells that line the peritoneal cavity. The peritoneal cavity typically contains  $< 50$  mL of clear sterile fluid with  $< 3000$  cells/mm<sup>3</sup>, composed of 50% macrophages and 40% lymphocytes.

**A. Epidemiology.** Primary peritonitis or spontaneous bacterial peritonitis (SBP) refers to peritonitis that arises without an obvious explanation, which is seen almost exclusively in patients with ascites, usually secondary to hepatic dysfunction or, less commonly, to nephrotic syndrome. It is thought that opsonic activity of the peritoneal fluid is decreased in the setting of ascites and that lymphatic clearance mechanisms are also impaired. The mechanism by which the peritoneal fluid becomes infected is unclear, with bacteremia and translocation across the bowel wall postulated as possible mechanisms.

Primary peritonitis may also be seen in children without ascites, usually girls  $< 10$  years

of age. The source of the infection is usually unknown, and the infecting organism in this group of patients is usually *Streptococcus pneumoniae* or group A streptococcus. Gram-negative aerobic bacilli are rarely implicated. The presence of the above organisms would suggest that the peritoneum is seeded via a hematogenous route. For unknown reasons, the incidence of primary peritonitis in young girls has decreased markedly over the past several decades.

SBP has also been noted in patients with systemic lupus erythematosus and lupus nephritis, without obvious ascites. Many of those patients are receiving corticosteroid therapy at the time of diagnosis, and the most common etiologic agents in this group of patients are gram-positive cocci such as *S pneumoniae* and group B streptococcus.

In the adult population, as mentioned above, most SBP is secondary to advanced chronic liver disease and ascites. The exact prevalence of SBP is unknown, but it occurs in ~ 8-27% of patients with cirrhosis and ascites. The mortality of SBP in this population is ~ 50% or higher in many studies.

**B. Microbiology.** The organisms isolated from ascitic fluid from adults in the setting of SBP are *Escherichia coli* in 50% of patients and *S pneumoniae* and other streptococcal species in 15-20% of cases ([Box 12-1](#)). *Klebsiella* spp. and anaerobes are isolated in ~ 10% and 5% of SBP cases, respectively. Bacteremia is documented in ~ 50% of SBP cases when the infection is caused by a single aerobic species, whereas in cases involving anaerobes, multiple organisms are usually involved, and documented bacteremia is rare. Within the ascitic fluid, organisms are able to proliferate because of impaired local host defense mechanisms and decreased bactericidal activity.

## Clinical Findings

**A. Signs and Symptoms.** The clinical presentation of SBP is variable. On one hand, patients may be asymptomatic or complain of only mild, diffuse nonspecific abdominal pain. On the other hand, the process may produce signs of acute peritonitis. Fever is the most common sign, but may be absent in ~ 20% of cases. Approximately one-third of patients may be free of all signs and symptoms characteristic of intra-abdominal infection, and only 50% of patients will have abdominal tenderness on examination.

**B. Laboratory Findings.** The key to the diagnosis of SBP is a high index of suspicion in a patient with ascites, especially in those with an otherwise unexplained deterioration in hepatic or renal function; one should have a low threshold for performing paracentesis. The ascitic fluid should be cultured for bacteria, and a leukocyte count should be determined. A Gram stain of the fluid should also be performed, despite the fact that it often (60-80% of attempts) fails to reveal organisms. If the stain reveals organisms of a single morphologic type, then SBP should be suspected. If multiple bacterial types are observed, then secondary peritonitis is more likely, in which case a further search for the cause of the peritonitis should be performed. The polymorphonuclear (PMN) leukocyte count of the ascitic fluid is thought to be the best marker of SBP. PMN leukocyte counts of  $> 250$  cells/mm<sup>3</sup> suggest a diagnosis of SBP, and counts  $> 500$  cells/mm<sup>3</sup> should mandate antimicrobial therapy.

There are three variant forms of SBP ("typical" SBP, culture-negative neutrocytic

ascites, and bacterascites), each of which is defined by the combination of PMN leukocyte count and bacterial culture results ([Table 12-1](#)). The clinical prognoses of SBP and culture-negative neutrophilic ascites are indistinguishable, and they should be managed identically; however, bacterascites is often self-limited, and patients can be managed by repeating the paracentesis after 48 h and with careful observation. An ascitic fluid with  $> 10,000$  PMN leukocytes/mm<sup>3</sup> or the presence of multiple bacterial species, anaerobes, or fungal organisms should point the physician towards a diagnosis of secondary peritonitis.

## Differential Diagnosis

The diagnosis of primary peritonitis is one of inclusion and exclusion. Patients who develop primary peritonitis usually do so in the setting of ascites, and other intra-abdominal infections must be excluded. CT scanning has greatly enhanced the ability to detect other intra-abdominal sources of peritonitis.

## Prognosis

The mortality rate of spontaneous bacterial peritonitis in cirrhotic adults is high, with some studies reporting rates as high as 95%. The high mortality is mainly due to the accompanying end-stage cirrhosis, and more recent studies have reported mortality rates between 57% and 70%.

## Treatment

SBP should be treated with broad antimicrobial coverage until culture results are available. Third-generation cephalosporins, such as cefotaxime, are recommended, but many other agents, such as  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combinations or carbapenems, are also effective ([Box 12-2](#)). If SBP develops during hospitalization, consideration should be given to antipseudomonal coverage by using an aminoglycoside plus an antipseudomonal penicillin or cephalosporin. Intravenous antimicrobial agents should be given for 10-14 days. More recent data indicate that 5 days of therapy may be sufficient in those patients who are clinically well and in whom the ascitic fluid is culture negative and the PMN leukocyte count is  $< 250$  cells/mm<sup>3</sup>, after this period of therapy.

## Prevention

Recurrences of SBP occur in  $> 50\%$  of patients within 6 mo of the initial episode; therefore, prophylaxis is recommended ([Box 12-3](#)). Agents such as norfloxacin (400 mg/d) or trimethoprim-sulfamethoxazole (one double-strength tablet/d) are effective. These antimicrobial agents have been shown to decrease significantly the incidence of primary peritonitis, but they have not been shown to improve survival.

## 2. SECONDARY PERITONITIS

### Essentials of Diagnosis

- Spillage of gastrointestinal or genitourinary organisms into the peritoneal space.
- Severe abdominal pain, nausea, vomiting, fevers, chills, avoiding movement with hips/knees flexed.
- Abdominal tenderness, involuntary guarding, rebound tenderness, high temperature, tachycardia, hypotension, sepsis, hypovolemic shock.
- Elevated peripheral leukocyte count.

## General Considerations

**A. Epidemiology.** Secondary peritonitis occurs when there is gross soilage of the peritoneal space by contents (and organisms) from the gastrointestinal or genitourinary tracts. Appendicitis, diverticulitis, cholecystitis, and perforation of a peptic ulcer are settings in which this may take place. Postsurgical anastomotic leak is also a common cause of secondary peritonitis and intra-abdominal abscess. Secondary peritonitis can produce either a generalized peritoneal reaction or a localized abscess. Abscesses are usually restricted to the site of the perforation, and therefore are often pericholecystic, periappendiceal, or peridiverticular. They are also commonly restricted to peritoneal recesses such as the subdiaphragmatic or subhepatic regions.

**B. Microbiology.** Most cases of secondary peritonitis are polymicrobial ([Box 12-4](#)). The specific organisms that are involved reflect the segment of bowel or other hollow organ that perforates. The stomach contains few organisms because of low pH. In the proximal small bowel, the density of organisms increases and, in addition to a-hemolytic streptococci and lactobacilli, some *Enterobacteriaceae* and anaerobes are present. In the large bowel, anaerobic organisms predominate (1000-5000:1 aerobe), in particular, the *Bacteroides fragilis* group, other *Bacteroides* spp., *Bilophila wadsworthia*, *Peptostreptococcus* spp. and *Clostridium* spp. In one study of perforated appendicitis in which careful anaerobic techniques were used, 9.4 anaerobes were isolated per patient. *B fragilis* is consistently the anaerobe isolated most often; *B wadsworthia*, a newly characterized gram-negative anaerobe, was the fourth most common anaerobe isolated from a study of patients with a perforated or gangrenous appendix.

The aerobic organisms present in the large bowel usually include *E coli*, *Proteus* spp., and *Klebsiella* spp., along with various *Streptococcus* and *Enterococcus* spp. But the microflora can be altered by previous antimicrobial therapy or by the underlying illness. For example, the loss of gastric acidity allows colonization of the stomach by oral flora, aerobes, and anaerobes. In severely ill hospitalized patients who receive antimicrobial agents, organisms such as *Pseudomonas* and *Enterobacter* spp., as well as multidrug-resistant *Enterococcus* and *Candida* spp., may proliferate; they will therefore contribute to any peritoneal infection that occurs while a patient is in a hospital. This is often referred to as tertiary peritonitis, ie, peritonitis in patients with impaired host defenses and multiple organ dysfunction, and it is often a nosocomial event.

The role of *Enterococcus* spp. in secondary peritonitis is unclear. Most intra-abdominal abscesses can be cured without antimicrobial agents that have specific activity against the *Enterococcus* spp. However, in the case of pure growth of these organisms from an

infected intra-abdominal source, most experts would recommend an antibiotic regimen that includes enterococcal coverage, as well as coverage against the other typical aerobic and anaerobic organisms.

**C. Pathogenesis.** Generalized peritonitis may occur as a result of appendicitis, diverticulitis, penetrating abdominal wounds, blunt trauma to the abdomen, perforation of the gastrointestinal tract (eg, perforated peptic ulcer or neoplasm), or rupture of an intra-abdominal abscess. The prognosis is poorest in a patient with appendicitis or a perforated peptic ulcer, and best with postoperative peritonitis.

Weinstein and coworkers demonstrated the sequence of events after contamination of the peritoneum with fecal flora. They showed that *E coli* is responsible for sepsis and for the mortality of early peritonitis, whereas *B fragilis*, in conjunction with *E coli*, is responsible for the late abscess formation. Synergy between anaerobes and facultative aerobic organisms has long been recognized as a key pathogenic feature in these mixed infections. After initial peritoneal contamination, bacteria encounter host defenses in the form of lymphatic clearance, phagocytosis, and sequestration by fibrin. The lymphatic clearance mechanism is usually very efficient, but the presence of necrotic debris facilitates the development of peritonitis or abscess formation. Local resident macrophages are the predominant host defense cells initially, but, if bacterial proliferation continues, PMN leukocytes become more numerous. The systemic and abdominal manifestations of peritonitis are mediated by cytokines such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1 (IL-1), IL-6, interferon- $\alpha$ , and others. These cytokines are produced by macrophages and other host cells in response to bacteria or bacterial products such as lipopolysaccharide.

## Clinical Findings

The purpose of the clinical evaluation should be to delineate whether urgent or semiurgent surgical intervention is indicated. History and physical examination are paramount in that decision-making process.

**A. Signs and Symptoms.** Pain, nausea, vomiting, altered bowel habits, and fever or chills are often present in patients with peritonitis. As mentioned previously, owing to the innervation of the abdomen, pain from an intra-abdominal viscus infection is usually midline and poorly localized. Localized pain that is exacerbated by movement is more characteristic of an irritated parietal peritoneum that stimulates the somatic nerve system. The actual presentation will vary depending on the location, extent, and maturity of the inflammatory process. Patients with diffuse peritonitis will often present with hypovolemic shock, whereas those with a chronic localized abscess often present with minimal vital-sign abnormalities and pain that may not be well localized. This is especially true if the parietal peritoneum is not a component of the wall of the abscess. Therefore, physical findings will also be variable. Patients with peritonitis typically avoid movement and may have their hips and knees flexed. Abdominal exam may reveal tenderness to percussion and/or palpation. Involuntary spasm of the abdominal wall elicited by palpation is indicative of an inflamed parietal peritoneum.

**B. Laboratory Findings.** As part of the evaluation of a patient with a suspected intra-abdominal infection, a leukocyte count, urine analysis, and blood cultures should

be performed.

**C. Imaging.** An upright chest x-ray or left lateral decubitus radiograph may reveal free air ([Figure 12-1](#)) in = 70% of patients with a perforated gastric or duodenal ulcer, but will rarely reveal free air with other types of perforated viscus. Radiologic evaluation of patients with suspected peritonitis or localized abscess has become invaluable. In addition, computed-tomography (CT) or ultrasound-guided aspiration or drainage of a suspected intra-abdominal abscess has become standard practice in the evaluation and management of patients. Ultrasonography is usually less costly than CT; ultrasonography is also usually portable, it is noninvasive, and it may be obtained rapidly. It is very useful in the evaluation of gallbladder and biliary tract disease and is also useful for evaluating the pelvis in a female patient with signs of pelvic infection, in whom the pelvic and rectal examinations have not identified the cause. The weaknesses of ultrasonography include operator dependency and limitations imposed by bowel gas and fat in the abdominal wall and omentum. CT with intravenous, oral, and rectal contrast is the most definitive radiographic test ([Figure 12-2](#)). Its strengths include provision of a relatively complete picture of intraperitoneal and retroperitoneal anatomy, thereby revealing small or deep fluid collections and abscesses. CT can also detect and localize causes of bowel obstruction and detect free air trapped within the bowel wall better than any other method. Its drawbacks include the needs for ionizing radiation, intravenous contrast, and patient cooperation and its lack of portability.

### **Differential Diagnosis**

The differential diagnosis of patients with symptoms and signs of peritonitis includes pneumonia, sickle cell crisis, herpes zoster, diabetic ketoacidosis, porphyria, familial Mediterranean fever, lead poisoning, uremia, and systemic lupus erythematosus.

### **Prognosis**

Survival in a patient with secondary peritonitis depends on many factors including age, comorbid conditions, duration of peritoneal contamination, and the primary intra-abdominal process and bacteria involved. Mortality ranges from 3.5% in those with early infection caused by penetrating abdominal trauma to > 60% in established intra-abdominal infections and secondary organ failure. Outcome has been mainly linked to host factors as predicted by the acute physiologic and chronic health evaluation (APACHE2) scores rather than type and source of infection.

### **Treatment**

**A. General Management.** Based on the history, physical examination and initial laboratory data, patients with secondary peritonitis can usually be placed in one of two categories: those who should and those who should not undergo surgery in the next few hours. Those patients who do not undergo surgery should be observed and evaluated closely. Patients with ascites should have paracentesis performed and a PMN leukocyte count, along with bacterial cultures, obtained. The decision as to the most appropriate radiographic procedure is then made. Evaluation of each patient must be individualized and should be based on the patient's specific presentation. There is no concise set of infallible guidelines regarding when to order a test and which test or tests to order for

any given patient. The decision must be made as to the immediacy of investigation and intra-abdominal exploration or observation.

Surgical intervention is the mainstay of therapy for some patients and must be performed promptly for peritonitis that is secondary to bowel perforation or penetrating trauma. The underlying pathology should be corrected, necrotic tissue debrided, and further peritoneal seeding by microorganisms prevented. The duration of antimicrobial therapy after surgery is usually 5-7 d, depending on the severity of the infection, clinical response, and normalization of the leukocyte count. Although treatment of enterococcal or *Candida* infections is controversial, the identification of either type of organism in the blood or as a pure culture within an intra-abdominal site is an indication for specific antimicrobial therapy, in addition to surgery. The surgical approach to management of secondary peritonitis includes: (1) bowel decompression, (2) closure of any traumatic perforation and/or resection of diseased perforated viscus, and (3) drainage of any purulent collections to reduce the bacterial load and reduce levels of pro-inflammatory cytokines. Intraoperative peritoneal lavage with saline is standard procedure during laparotomy for peritonitis, but only limited data are available to support the practice of continuous postoperative peritoneal lavage.

Percutaneous drainage via interventional radiology has increasingly become an acceptable alternative to surgery in many patients. A safe drainage route must first be identified. Once this is accomplished, most patients in whom a drain is placed will show resolution of abscess radiographically and resolution of their symptoms within 48-72 h. Persistent fever or leukocytosis is an indication for repeat imaging to assess possible incomplete drainage. Published success rates with percutaneous abscess drainage range from 80% to 90%. Drainage of more complex abscesses, ie, loculated, large, and less well-organized abscesses, has been less successful. One group reported a 45% success rate for percutaneous drainage of complex abscesses vs 82% for simple abscesses. The complication rate was also higher in the group of patients with complex abscesses (21% vs 5%).

**B. Antimicrobial Therapy.** The selection of an antimicrobial regimen is made empirically, based on the likely pathogens that are present in the bowel at the site of peritoneal seeding. Clinical trials have not definitively established the superiority of one antimicrobial regimen over another, but it is clear that, in patients with polymicrobial infection, both anaerobic and aerobic organisms must be covered. Antimicrobial agents must penetrate the site of infection, in concentrations that are sufficient to overcome the effects of high bacterial density, metabolic inactivity, and slow growth rates. Low pH, low redox potential, necrotic tissue, and bacterial products may also interfere with the therapeutic efficacy of certain antimicrobial agents. Early clinical trials established the combination of ampicillin, clindamycin, and an aminoglycoside as a gold standard regimen, despite the relative inactivity of the last group of agents at an acid pH.

Aminoglycosides are frequently under-dosed because of concerns of nephrotoxicity or underestimation of the expanded volume of distribution in critically ill patients with intra-abdominal sepsis. Once-daily aminoglycoside therapy obviates these dosing problems, but limited data are available concerning the use of this dosing regimen in these patients. Substitution of a third-generation cephalosporin for ampicillin and aminoglycoside is also effective in the treatment of severe intra-abdominal infections.

Concerns about the emergence of drug resistance have limited the use of these agents somewhat. Selection of *Enterobacteriaceae* with stably derepressed  $\beta$ -lactamase production is sometimes seen after use of third-generation cephalosporins, and widespread use within an intensive care unit will often hasten the selection of these organisms. Traditionally, combination therapy has been the mainstay of treatment, but, in some settings, single antibiotics with broad-spectrum activity may be appropriate.  $\beta$ -Lactam/ $\beta$ -lactamase inhibitor combination agents such as ampicillin-sulbactam, ticarcillin-clavulanate, piperacillin-tazobactam, cephamycins such as cefoxitin and cefotetan, and the carbapenems, imipenem-cilastatin, and meropenem have all been shown to be as effective as traditional combination therapy. The choice of empiric antimicrobial agents should be dictated by the severity of illness and whether the infection was acquired in a community or hospital environment. Recommendations for empiric therapy of infections of mild to moderate severity acquired in a community setting include ampicillin-sulbactam, cefoxitin, cefotetan, and ticarcillin-clavulanate (Box 12-5). Recommendations for the treatment of severe infections or those acquired in a hospital environment include clindamycin or metronidazole plus a third-generation cephalosporin, ciprofloxacin, or an aminoglycoside, aztreonam plus clindamycin, or imipenem-cilastatin, meropenem, or piperacillin-tazobactam alone (Box 12-6).

### 3. TERTIARY PERITONITIS

Tertiary or nosocomial peritonitis is accompanied by the usual clinical signs of peritonitis, often with signs of sepsis, and occurs after treatment for secondary peritonitis. Organisms may gain access to the peritoneal cavity after intra-operative contamination or after selection by antibiotic therapy from an initial polymicrobial peritoneal inoculum or by translocation of bowel flora.

The organisms involved in tertiary peritonitis are usually those of low pathogenicity, such as *Candida* spp., enterococci, and coagulase-negative staphylococci. In addition, *Pseudomonas aeruginosa* is isolated in a significant portion of cases of tertiary peritonitis, owing to the selective pressure of broad-spectrum antimicrobial agents.

### 4. PERITONITIS COMPLICATING PERITONEAL DIALYSIS

Continuous ambulatory peritoneal dialysis (CAPD) was developed in the late 1970s, and this procedure creates a special predisposition for the development of peritonitis. The overall incidence of peritonitis is 1.3-1.4 episodes/CAPD patient per year. Organisms gain access to the peritoneal cavity in several ways. Most common is an organism traveling down the inside or the outside of the catheter, which can occur from a break in sterile technique or infection of the local exit site. Less common is seeding of the peritoneum through contaminated dialysate or bacteremia. Microbial factors that contribute to this disease include the ability of an organism to grow in dialysis fluids and the ability to produce an extracellular slime layer or biofilm. In most patients with CAPD peritonitis, there is a single pathogen. Gram-positive cocci are the cause in 60-70% of cases; 20-30% of cases are secondary to gram-negative bacilli. Coagulase-negative staphylococci are the single most common pathogen, followed by *Staphylococcus aureus* and *Streptococcus* spp. Among the gram-negative organisms, most of the *Enterobacteriaceae* have been associated with CAPD peritonitis, and no single species predominates. Fungi have become increasingly important. *Candida* spp. account for

80-90% of fungal cases, but *Aspergillus*, *Mucor*, and *Rhizopus* spp. have all been reported. *Mycobacterium* spp. are isolated in < 3% of CAPD peritonitis cases.

Clinical features of CAPD peritonitis include signs and symptoms of peritoneal irritation, cloudy dialysate fluid with a leukocyte count of > 100/mm<sup>3</sup>, and a positive fluid culture. Any two of these criteria may be sufficient to establish the diagnosis. Laboratory evaluation of the dialysate is critical. The percentage of PMN leukocytes in the dialysate fluid is usually > 50% in affected patients.

The use of intraperitoneal antibiotics as therapy for CAPD peritonitis has allowed most patients to be treated on an ambulatory basis. Antimicrobial agents that have been used with success include third-generation cephalosporins and glycopeptides such as vancomycin. Initial therapy should include coverage of gram-negative and gram-positive organisms while the culture results are awaited. Therapy is usually continued for 10-14 days, but may be extended if disease is severe or response is slow.

## **INTRAPERITONEAL ABSCESS**

### **Essentials of Diagnosis**

- Previous bowel perforation.
- History of recent intra-abdominal surgery, particularly pancreatic, biliary tract, colon, and stomach surgery.
- Present with either abdominal pain with fever or constitutional symptoms such as fever, nausea, or vomiting.
- Peripheral blood leukocyte count always elevated.
- CT scan is procedure of choice.
- Ultrasound and nuclear medicine scans are alternatives.

### **General Considerations**

Intra-abdominal abscesses form because of one of two processes: (1) diffuse peritonitis in which pus collects in dependent areas such as the pelvis, paracolic gutters, and subphrenic areas and (2) spread of infection from a local inflammatory process. A common example of the latter is an appendiceal or diverticular abscess after rupture of the appendix or diverticulum and localization of the inflammatory process.

**A. Epidemiology.** Almost half of all intraperitoneal abscesses occur in the right lower quadrant, after rupture of the appendix. Postoperative anastomotic disruption is also a common cause of abscess formation, with = 80% of all intra-abdominal abscesses falling into this category in some reports. Pancreas, biliary tract, colon, and stomach are the operative sites that are most likely to lead to postoperative abscess.

**B. Microbiology.** The organisms found within an intra-abdominal abscess reflect the

site of perforation. The microbiology of intraperitoneal abscess is similar to that of secondary and tertiary peritonitis ([Box 12-4](#)). Whereas a large number of bacterial species may contaminate the peritoneal cavity, only a few go on to cause abscess formation. Studies have shown that the capsular polysaccharide complex of *B fragilis* subspecies *fragilis* is the primary virulence determinant for abscess formation, but that a mixture of aerobic and anaerobic organisms must be present.

**C. Pathogenesis.** After the initial peritoneal soiling, many of the bacteria are cleared by the diaphragmatic lymphatic system. Peritoneal macrophages and mesothelial cells elaborate proinflammatory mediators with resultant hyperemia, exudation of protein-rich fluid containing fibrinogen, and massive influx of phagocytic cells. The fibrin deposition helps to sequester bacteria, localize the inflammation, and subsequently decrease the incidence of bacteremia and mortality. However, by walling off the organisms, the fibrin may also help to protect the organisms from the normal host clearance mechanisms.

Within an abscess, factors such as hypoxia, low pH, hyperosmolarity, and bacterial synergy impair host defenses and promote microbial persistence. A mature abscess consists of a central core of necrotic debris, dead cells, and bacteria; a surrounding ring of neutrophils and macrophages; and a peripheral ring of smooth muscle cells and fibroblasts within a collagen capsule.

## 1. SUBPHRENIC ABSCESS

### Introduction

A subphrenic abscess can result from four different processes. Over one half of these abscesses develop after surgery involving the duodenum or stomach, biliary tract, or appendix, and 20-40% develop after rupture of a hollow viscus, such as a perforated peptic ulcer or acute appendicitis. A smaller number of subphrenic abscesses develop after penetrating trauma, and < 5% occur without any obvious precipitating factor.

### Clinical Findings

**A. Signs and Symptoms.** Abdominal pain and tenderness in the right or left upper quadrants in conjunction with weight loss are common features of patients with subphrenic abscesses. They may present as an acute febrile illness with abdominal pain or as an insidious, chronic process. Patients may present with hiccups, jaundice, shoulder pain, chest pain, cough, dyspnea, tachypnea, or a pleural effusion. The chronic syndrome is seen more commonly in those patients who have previously received antimicrobial agents. Patients with the chronic presentation will often complain of intermittent fever, weight loss, anemia, and other nonspecific constitutional symptoms. Subphrenic abscess should always be considered in any patient presenting with fever of unknown origin, especially if the patient has had abdominal surgery within the previous few months.

**B. Laboratory Findings.** The pleural effusion is usually transudative in nature. A peripheral blood leukocytosis is almost always present.

**C. Imaging.** Radiographic techniques such as CT scan and ultrasonogram are the best

approaches for establishing the diagnosis. Plain radiographs often show a pleural effusion, decreased diaphragmatic movement in conjunction with an elevated hemidiaphragm, and concomitant lower-lobe pneumonia or atelectasis. An upright chest x-ray may reveal wide separation of the upper margin of the gastric air bubble and the diaphragm.

## **Treatment**

The primary treatment of a subphrenic abscess is drainage, either via a percutaneous approach or an open laparotomy. Antimicrobial therapy is aimed at the likely spectrum of organisms associated with the presumed pathogenic mechanism and may be modified after the receipt of culture results. Caution should be used when assessing culture results from patients who have already been receiving antimicrobial therapy.

## **2. DIVERTICULAR ABSCESS**

Diverticulitis and diverticular abscess occur in the setting of pre-existing colonic diverticula. The latter are mucosal outpouchings located at points of maximal weakness in the colonic wall, and they typically develop in the left colon with increasing patient age. When fecaliths become impacted in diverticula, an inflammatory process ensues, sometimes leading to erosion and perforation of the colonic wall. The spectrum and severity of acute diverticulitis and diverticular abscess vary in relation to the extent of involvement of the colonic wall and the extent of inflammation. Stage 1 lesions consist of microabscesses in the colonic wall and peridiverticular inflammation. Stage 2 lesions are small, well-defined macroabscesses contained within the mesentery and epiploic appendages of the colon. Patients with well-defined macroabscesses that are associated with diverticular perforation have stage 3 disease. Patients with generalized peritonitis resulting from a perforated diverticular abscess or from gross fecal soilage have stage 4 disease. CT has been useful in diagnosing and staging this disease.

The treatment of diverticulitis should be based on the severity of disease. A traditional approach for stage 1 or 2 disease has been conservative medical management with bowel rest, low-residue diet, and antimicrobial therapy ([Boxes 12-5](#) and [12-6](#)). Operative intervention, if it becomes necessary, may involve one-, two-, or three-stage resection procedures. Catheter drainage techniques may safely eliminate the need for surgery in some patients or may reduce the complexity of the required surgical procedure. Clinical studies report a 71-88% success rate for preoperative percutaneous drainage and subsequent primary anastomosis in selected patients. There are limitations to the use of percutaneous drainage. For example, if anastomotic dehiscence is suspected, open surgical drainage and repair are preferred. The presence of multiple loculations, excessive cellular debris, high fluid viscosity, or an inadequate drainage route may also prevent successful percutaneous drainage. The percutaneous catheter should remain in place until clinical evidence of infection has resolved and the drainage from the catheter ceases.

## **3. VISCERAL ABSCESSSES**

### **Liver Abscess**

## Essentials of Diagnosis.

- 15-30% are cryptogenic.
- Most common cause is biliary tract disease.
- Portal vein bacteremia accounts for 12-15%.
- Patients present with fever, chills, weight loss.
- Abdominal discomfort is uncommon, but 60% will have liver tenderness.
- Peripheral blood leukocytosis is present.
- Alkaline phosphatase serum levels are elevated.
- CT scan is the diagnostic test of choice.

## General Considerations

**A. Epidemiology.** The incidence of pyogenic liver abscess is 0.005% for all hospital admissions. Biliary tract disease, such as ascending cholangitis secondary to obstruction from stones, stricture, or malignancy, is the most common associated factor. Bacteremia, via the portal vein or less commonly the hepatic artery, is the cause of hepatic abscess in 12-15% of cases, and 15-30% of cases are considered cryptogenic.

**B. Microbiology.** Pyogenic liver abscesses principally contain enteric bacteria, such as *E coli* or *Proteus*, *Klebsiella*, or *Enterobacter* spp. (Box 12-7). Approximately two-thirds of these abscesses are polymicrobial, with one-third involving anaerobic organisms. *S aureus*, seen in 30% of cases, is a more common etiologic agent in children and in patients with bacteremia. Streptococci are seen in 7% of cases. Blood cultures are positive in 30-50% of patients with pyogenic liver abscess. *Entamoeba histolytica* accounts for only 10% of all liver abscesses.

## Clinical Findings

**A. Signs and Symptoms.** Fever is the most common symptom and is present in nearly 90% of patients with hepatic abscess. Chills and weight loss occur in about half of cases. The abdominal features are often less pronounced, and many patients will present with fever of unknown origin, without abdominal symptoms. Two-thirds of patients will have an enlarged tender liver; care should be taken in trying to identify an area of point tenderness. Pyogenic hepatic abscess must be differentiated from amebic liver abscess. Patients will often have a history of travel or of significant diarrhea.

**B. Laboratory Findings.** Peripheral blood leukocytosis is present in most cases. Serum alkaline phosphatase levels are elevated in almost all patients, but elevated bilirubin levels are infrequent.

The identification of *E histolytica* trophozoites or cysts in the stool can be helpful, but

stool examinations are negative in most patients. If there is concern about the possibility of amebic liver abscess, then serologic testing should be performed with an enzyme-linked immunosorbent assay.

**C. Imaging.** CT is the most accurate diagnostic technique and yields positive results in = 95% of confirmed cases. Ultrasound is helpful in = 80% of confirmed cases. A plain x-ray may provide an initial clue to the diagnosis by revealing an elevated right hemidiaphragm, a right pleural effusion, or an air fluid level within the abscess itself. An amebic abscess is more likely to be solitary and confined to the right lobe of the liver.

### **Differential Diagnosis**

The infectious differential diagnosis of pyogenic liver abscess includes amoebic abscess and hydatid cyst.

### **Prognosis**

The prognosis of pyogenic liver abscess depends on the rapidity with which the diagnosis is made and treatment started. Recent studies have shown very high cure rates, in the 80-100% range. The advent of percutaneous drainage has significantly affected treatment, because open surgical drainage is no longer necessary in every patient.

**Treatment.** Some small pyogenic liver abscesses respond to antibiotic treatment alone, but most experts advocate drainage of any such abscess. Percutaneous drainage is now the initial procedure of choice and is accompanied by success rates of = 89%. Surgical drainage is reserved for cases that fail to respond to the percutaneous approach. Antibiotics should be administered intravenously with broad coverage of enteric organisms such as anaerobes, *Enterobacteriaceae*, and streptococci, until the specific agents have been identified. Empiric therapy for pyogenic liver abscess is the same as that for peritonitis (see [Box 12-5](#)). Amebic liver abscess is treated with metronidazole, 750 mg three times per day for 5-10 days, plus a luminal agent such as diloxanide furoate, 500 mg three times per day for 10 days.

### **Pancreatic Abscess**

#### **Essentials of Diagnosis**

- Most occur as a complication of pancreatitis.
- 30-50% are polymicrobial.
- Abdominal pain radiating to the back; vomiting.
- Elevated amylase (80-90% of cases).

#### **General Considerations**

**A. Epidemiology.** Most pancreatic abscesses occur after an episode of pancreatitis,

which most commonly develops as a result of alcoholism, gallstones, or surgical trauma. Pancreatic abscess may also develop after a secondary infection of an established pancreatic pseudocyst. The spectrum of severity ranges from unapparent to fulminant. Two relatively distinct patterns can be distinguished. In the first, the patient recovers from an episode of pancreatitis, but 1-5 wk later develops fever, chills, leukocytosis, and abdominal pain. These patients usually have a well-defined abscess, as revealed by CT scan. The other group of patients is those who never recover from an episode of pancreatitis and continue to appear ill, with hemodynamic instability and fever. A CT scan is usually performed earlier in the course of disease than in the first group, and hence the infected tissues, as seen on CT scan, have not yet liquefied, and necrosis is seen without evidence of an abscess. Lesser sac abscesses also occur after pancreatitis. These involve an extensive collection of necrotic tissue and pus in the retrogastric area and in the region behind the gastrocolic ligament.

**B. Microbiology.** Organisms contained within pancreatic and lesser sac abscesses are predominantly *E coli*, *Enterococcus* spp., and other enteric organisms ([Box 12-4](#)). Anaerobic organisms are less common than in other types of intra-abdominal abscesses. Nonenteric organisms including *Staphylococcus* spp., *Pseudomonas* spp., and, less often, *Candida* spp. may also be involved.

**Clinical Findings.** The diagnosis of pancreatic abscess can be difficult, because patients may present with indolent disease or may be clinically indistinguishable from patients with a noninfected pancreatic inflammatory mass.

**A. Signs and Symptoms.** Pancreatic abscess should be suspected in any patient with pancreatitis and persistent fever and ileus or if clinical deterioration occurs < 4 wk after initial improvement. The classic presentation includes nausea, vomiting, abdominal pain, and abdominal tenderness on examination. A mass may be palpable.

**B. Laboratory Findings.** Peripheral blood leukocytosis is usually present. Pancreatic amylase levels are elevated in < 50% of cases; however, liver function tests are often abnormal.

**C. Imaging.** The abdominal CT scan is the key to diagnosis, and percutaneous aspiration is often the most effective method of diagnosis. Chest radiographs commonly show an elevated hemidiaphragm, atelectasis, and a pleural effusion. Ultrasound is useful in defining a pancreatic mass, but cannot reliably distinguish between a pseudocyst and an abscess.

**Differential Diagnosis.** The differential diagnosis of pancreatic and lesser sac infections includes other visceral infections such as hepatic abscess, cholecystitis/cholangitis, and other intra-abdominal infections such as subphrenic abscesses.

**Prognosis.** The mortality rate in untreated pancreatic abscesses is very high. Survival is dependent on early surgical drainage. Complications include erosion of the infections from the pancreas into major blood vessels with subsequent intra-abdominal hemorrhage. The abscess can also spread retroperitoneally, and fistulas may develop with the transverse colon, stomach, and duodenum.

**Treatment.** Pancreatic abscesses are highly lethal ([Boxes 12-5](#) and [12-6](#)); without drainage, the mortality is 100%. Surgical drainage is considered mandatory. Although percutaneous drainage may be helpful for diagnosis and for treatment of well-circumscribed infected pancreatic pseudocysts, it has been less successful in the treatment of true pancreatic abscesses than with other types of intra-abdominal abscess. Removal of necrotic debris, in addition to abscess cavity drainage, seems to be very important in decreasing morbidity. Broad-spectrum antimicrobial agents should be chosen that are directed against aerobic enteric gram-negative rods and anaerobic organisms. Therapy should be revised on the basis of cultures of the abscess material or blood, especially if *Pseudomonas* or *Candida* spp. are present.

## **Splenic Abscess**

Splenic abscesses are uncommon but appear to be increasing in incidence. Of all splenic abscesses, ~ 25% have no obvious source. The others are usually documented to be the result of bacteremia or septic embolization; infected splenic infarcts; or contiguous spread. Fevers (92%), chills, and left upper quadrant abdominal pain (39%) are the most common symptoms seen with this entity. Diaphragmatic, pleuropulmonary symptoms may predominate if the upper pole of the spleen is involved, whereas peritoneal symptoms may predominate if the lower pole of the spleen is infected. Causative organisms include *S aureus*, *Streptococcus* spp., *Salmonella* spp., and enteric bacteria. Mixed infections are common, and anaerobes such as *Bacteroides* spp. are often cultured. Fungi, such as *Candida* spp., are important causes of splenic abscess in immunocompromised hosts but rarely occur in immunocompetent hosts. CT is the most useful radiographic procedure. Antimicrobial therapy is mandatory. Although splenectomy has been regarded as the treatment of choice, percutaneous drainage has been increasingly used with significant success. Percutaneous drainage should be considered when the abscess is unilocular, when the patient has significant risks for a standard surgical approach, and when a safe drainage window is present.

## **APPENDICITIS**

### **Clinical Findings**

Appendicitis most commonly manifests as right lower quadrant abdominal pain accompanied by nausea and vomiting. Upon examination there is usually tenderness in the right lower quadrant, along with low-grade temperature. Initially, voluntary guarding may be present, followed by rebound tenderness and abdominal rigidity. Variations in the anatomic location of the appendix may result in variations in the location of pain and physical findings. For example, a retrocecal appendix may present as principally flank pain and tenderness, and a pelvic appendix may present with suprapubic pain. The findings of appendicitis are often nonspecific, and many patients are admitted and found to have another diagnosis.

The organisms associated with appendicitis are found in the normal colonic flora, such as *B fragilis*, *P melaninogenica*, *B wadsworthia*, anaerobic gram-positive cocci, and *Enterobacteriaceae*.

## Differential Diagnosis

The differential diagnosis of patients presenting with suspected appendicitis includes mesenteric lymphadenitis, rubeola, and infectious mononucleosis.

## Treatment

Therapy for appendicitis is surgical removal and drainage of any abscess that may be present. Antibiotics need only be started before surgery if it is felt that the appendix has been perforated.

## CAECITIS (TYPHLITIS)

### Introduction

Caecitis is inflammation of the cecum that occurs in immunocompromised patients such as those with HIV infection and severe neutropenia. Pathologically, the bowel wall is edematous with marked thickening. The luminal surface has discrete areas of ulceration, which may coalesce. The actual pathogenesis of this entity is unclear, but it is thought that bacteria opportunistically invade ulcerations in the bowel during periods of neutropenia. The organisms proliferate and cause local destruction by the production of exotoxins.

### Clinical Findings

Patients with caecitis may present with signs and symptoms similar to those of acute appendicitis with fever, abdominal pain, rebound tenderness in the right lower quadrant, and diarrhea.

Plain radiographs and CT scans are useful in delineating and identifying this entity.

### Treatment

Mortality rate is high and, although management is controversial, antimicrobial therapy, as outlined in [Boxes 12-5](#) and [12-6](#), together with surgical resection of necrotic bowel, is generally recommended.

## ACUTE CHOLECYSTITIS

### Clinical Findings

Of patients with acute cholecystitis, 90% have gallstones affecting the cystic duct. The initial clinical manifestations of obstruction of the cystic duct may be only epigastric pain, nausea, and vomiting. The duct obstruction may be transient, but if it persists, findings of acute cholecystitis may evolve. Most patients will report pain in the right upper quadrant and may have signs of peritoneal inflammation on examination. The gallbladder is palpable in 30-40% of cases, and most patients will have significant fever. Most patients will resolve their symptoms within 1-4 days. A patient presenting with repeated chills, fever, and jaundice or hypotension is likely to have suppurative

cholangitis as a consequence of the common duct obstruction.

Laboratory data usually show an elevated leukocyte count. In addition, ~ 50% of patients will have a markedly elevated bilirubin level, 40% will have a marked elevation in their AST levels, and 25% will have an increased serum alkaline phosphatase. Organisms causing cholecystitis include enteric gram-negative bacilli and enterococci plus anaerobic organisms such as *Bacteroides* sp. ([Box 12-4](#)).

Acute gangrenous cholecystitis is seen most commonly in elderly diabetic males. Systemic symptoms are more severe, and the classic radiographic picture of the abdomen reveals gas within the gallbladder, a gas fluid level within the lumen of the gallbladder, and gas in a ring along the contours of the gallbladder wall.

### **Complications**

Complications include perforation in 10-15% of cases. These patients are readily recognizable because they present with acute symptoms and signs of diffuse peritonitis.

### **Differential Diagnosis**

The differential diagnosis of acute cholecystitis includes myocardial infarction, perforating ulcer, right-lower-lobe pneumonia, intestinal obstruction, hepatitis, peri-hepatitis, and acute disease involving the right kidney.

### **Treatment**

Antibiotics to treat acute obstructive cholecystitis include those outlined in [Boxes 12-5](#) and [12-6](#). Coverage should be directed at the organisms already discussed ([Box 12-4](#)), although anaerobes play a lesser role in acute cholecystitis. Immediate surgery should be performed for gangrenous cholecystitis, perforation, or suspected peri-cholecystic abscess. The timing of surgery for patients with uncomplicated acute cholecystitis is controversial.

## **CHOLANGITIS**

### **Introduction**

Cholangitis is defined as various degrees of inflammation, infection, or both involving the hepatic and common bile duct.

### **Clinical Findings**

Patients with cholangitis usually have a history compatible with prior gallbladder disease and present acutely with high fever, chills, and diffusive pain and tenderness over the liver. Jaundice is usually prominent, and in many cases shock and other findings of gram-negative bacteremia may be present. Eighty-five percent of patients fulfill the classic triad of fever, chills, and jaundice.

Laboratory findings include marked leukocytosis with increase in immature forms, serum

bilirubin concentration of > 4 mg/dL, and serum alkaline phosphatase levels significantly higher than those encountered in acute cholecystitis. In contrast to uncomplicated cholecystitis, bacteremia is seen in 50% of patients with cholangitis, of which *E coli*, *Klebsiella* spp., *B fragilis*, and *E faecalis* are the most frequently isolated organisms.

Ultrasound and nuclear medicine scanning are the most useful imaging studies in the setting of acute cholangitis.

## Complications

Complications of bacteremia and shock occur more commonly in patients with obstructive cholangitis. Perforation of the gallbladder can occur leading to hepatic abscess, peritonitis, or a peri-cholecystic abscess.

## Differential Diagnosis

The differential diagnosis of patients with cholangitis includes acute cholecystitis, perforating ulcer, pancreatitis, intestinal obstruction, right lower lobe pneumonia, acute disease involving the right kidney, and bacteremic shock related to another focus of infection.

## Treatment BR>

Prompt antimicrobial therapy is mandatory with choices as outlined in [Boxes 12-5 and 12-6](#). Prompt operative intervention with decompression of the common duct is mandatory in most cases of cholangitis. In those patients who do undergo surgery, operative cholangiography should be performed.

## 13 . Skin & Soft-Tissue Infections — *Mark P. Wilhelm, MD, FACP, & Randall S. Edson, MD, FACP*

### General Considerations

Skin and soft-tissue infections range in severity from self-limited localized inflammation to rapidly progressive, life- and limb-threatening necrosis with severe systemic toxicity. The clinician must be alert to clinical symptoms and signs that help to distinguish between an inflammatory process that is likely to respond to antimicrobial therapy alone and one that is rapidly progressing and requires prompt surgical intervention. We address the following clinical entities: primary pyodermas (localized bacterial infections involving the skin and/or its appendages), necrotizing soft-tissue infections, infections associated with human or animal bites, and diabetic foot infections.

When evaluating a patient with soft-tissue infection, it is important to define the host (eg, immune status, integrity of integument, etc), obtain a detailed patient history, and examine the patient with careful attention to local features. For example, a patient with impaired cell-mediated immunity, due either to exogenous factors (eg, corticosteroid therapy) or an underlying immunosuppressive disease process (eg, late-stage HIV infection or hematologic malignancy), may be susceptible to infection from opportunistic microorganisms (eg, *Cryptococcus neoformans*, nontuberculous mycobacteria, and filamentous fungi), causing cellulitis which may be difficult to distinguish from typical staphylococcal or streptococcal cellulitis.

Historical features to be carefully investigated include symptoms of systemic toxicity (eg, fever, chills, or prostration), the rate of progression of the inflammatory process, the presence or absence of significant pain in the involved area, recent environmental exposures, the occurrence of a precipitating event (eg, a puncture injury or animal bite), and the presence of an associated underlying disease. Necrotizing infections occur most commonly in association with advanced age or underlying comorbidity (eg, peripheral vascular disease, diabetes mellitus, alcoholism, malignancy, organ failure, or immunosuppressive therapy).

The presence or absence of fever and other signs of systemic toxicity (eg, hypotension, confusion, or oliguria) should be noted during physical examination. A careful examination of the involved area should include an assessment of the presence of erythema, induration, lymphangitis, crepitus, tenderness, duskiness (evidence of ischemia), and bullae, as well as the presence and characteristics of any drainage. The presence of gas in soft tissues is not a pathognomonic sign for the presence of anaerobic bacteria; more common causes of gas include mechanical trauma and infection with aerobic/facultative gram-negative bacilli such as *Escherichia coli*. Because the disease may progress rapidly, frequent reassessment and monitoring are essential.

Soft-tissue infection syndromes are best understood and defined by considering the specific anatomic structures involved and the microbial etiology. [Figure 13-1](#) provides an overview of the anatomy of soft tissue that should help facilitate understanding of specific clinical syndromes.

# THE PYODERMAS

## IMPETIGO

### Essentials of Diagnosis

- A vesiculopustular or crusted superficial skin infection usually caused by *Streptococcus pyogenes* and/or *Staphylococcus aureus*.
- Absence of pain and constitutional symptoms
- Healing occurs without scarring.

### General Considerations

Impetigo is generally considered a disease of early childhood, although it is occasionally seen in the elderly and in immunocompromised patients of all ages. Impetigo is more common in warmer climates and is typically caused by group A streptococci (GAS) (ie, *S pyogenes*). *S aureus* may also cause impetigo, occasionally in combination with GAS ([Box 13-1](#)). A bullous form of impetigo, which occurs in newborn and very young children, is caused by *S aureus* of phage group II.

### Clinical Findings

Impetigo is a very superficial bacterial skin infection that begins with the formation of vesicles and pustules in the epidermis beneath the stratum corneum. These lesions eventually rupture and release a honey-colored liquid, which forms a yellowish-brown crust. Impetigo typically develops on the face or on the extremities in areas that have sustained minor trauma. Pruritus is common—scratching of lesions can result in the spread of infection to previously uninvolved sites. The infection remains superficial and generally does not result in ulceration or scarring. Fever or other constitutional symptoms are absent or minimal.

### Differential Diagnosis

Clinical entities that may be confused with impetigo include contact dermatitis, herpes simplex virus infection, and insect bites.

### Complications

Occasionally, infections caused by nephritogenic strains of GAS can result in poststreptococcal glomerulonephritis. Mentioned in treatment section.

### Treatment

Although impetigo may resolve spontaneously without anti-infective therapy, treatment is generally recommended for more rapid resolution of established lesions, deterring the formation of new lesions, preventing evolution to cellulitis, and possibly preventing the

development of post-streptococcal glomerulonephritis, which occasionally follows infection caused by nephritogenic GAS strains ([Box 13-2](#)). Treatment options include a 10-day course of oral dicloxacillin sodium, a first-generation cephalosporin (eg, cephalexin), clindamycin, or topical mupirocin. It has not been established conclusively that antibacterial therapy is effective in reducing the incidence of nephritis.

## **ERYSIPELAS**

### **Essentials of Diagnosis**

- Edematous, red, indurated, spreading lesion.
- Sharply demarcated, advancing, elevated margin.
- Occurs most commonly on the face.
- Pain, fever, and systemic toxicity are common.

### **General Considerations**

Erysipelas is distinguished from cellulitis in that it involves the more superficial layers of the skin and cutaneous lymphatics and is more sharply demarcated; cellulitis tends to extend more deeply into subcutaneous tissues. It most commonly occurs on the face or extremities and is almost always caused by GAS. Rarely, other  $\beta$ -hemolytic streptococci or even *S aureus* may cause erysipelas. Organisms generally gain access through a break in the skin. Erysipelas tends to recur in an area of previous infection, particularly in patients with lymphedema or venous insufficiency. Facial erysipelas occasionally occurs after a streptococcal upper respiratory tract infection.

### **Clinical Findings**

This lesion typically begins as a red spot, often at the nasolabial groove. Inflammation spreads, resulting in a tender, warm, glistening, red, edematous, and indurated area of skin. Vesicles or bullae are sometimes encountered on the surface, and there may be oozing of serous fluid. There is typically a distinct demarcation between involved and normal skin, and the area of inflammation is raised above the level of the surrounding skin. Desquamation of involved skin often occurs several days after the onset of symptoms. Skin necrosis does not occur, and healing is complete without scar formation. Associated symptoms include pain, malaise, fever, and chills. Occasionally, marked systemic toxicity is encountered.

### **Differential Diagnosis**

The differential diagnosis of erysipelas includes cellulitis, contact dermatitis, thermal injury, and noninfectious inflammatory lesions such as the malar rash of systemic lupus erythematosus.

### **Treatment**

In most cases of erysipelas, therapy is initiated with a parenteral agent active against  $\beta$ -hemolytic streptococci such as penicillin G or cefazolin (see [Box 13-2](#)). After clinical improvement is documented, therapy may be switched to an oral agent (eg, penicillin V or cephalexin). Parenteral therapy may not be necessary in mild cases with minimal systemic toxicity. Hot packs applied locally and aspirin are generally administered for symptomatic relief.

## Prognosis

Skin necrosis does not occur in cases of erysipelas, and healing is generally complete without scar formation. However, involvement of superficial lymphatics may result in recurrence of erysipelas in the same area.

## ECTHYMA

### Essentials of Diagnosis

- Punched-out ulcers appearing beneath adherent crusts.
- Typically occur on lower extremities.

### General Considerations

Ecthyma represents a deeper form of impetigo that begins as a vesicle and progresses to a punched-out ulcer that is surrounded by a violaceous border and covered by an adherent crust. It is most often caused by GAS, which either produce de novo lesions or infect preexisting skin lesions such as insect bites, eczema, or excoriations. Lesions with a similar clinical appearance may be encountered with bacteremia caused by *Pseudomonas aeruginosa* (ecthyma gangrenosum).

### Clinical Findings

Ecthyma typically occurs as a single erythematous ulceration or multiple erythematous ulcerations with overlying crusts on the lower extremities, especially in areas of minor trauma. Because of the deeper level of infection, ecthyma—unlike impetigo—often heals with scarring.

### Treatment

The approach to treatment of ecthyma is the same as for impetigo. Beyond removal of crusts and debris with warm compresses, surgery is generally not indicated. Ecthyma caused by *P aeruginosa* requires parenteral antipseudomonal therapy and occasionally debridement (see [Box 13-2](#)).

## CELLULITIS

### Essentials of Diagnosis

- Diffuse spreading infection of skin and subcutaneous tissue.

- Inflammatory lesion is hot, red, with diffuse or vague margins.
- Systemic toxicity is variable.

## General Considerations

Cellulitis is a superficial infection of skin and subcutaneous tissues characterized by erythema, induration, and tenderness. Local trauma or underlying skin lesions are common predisposing conditions. Because inflammation from an episode of cellulitis, erysipelas, or lymphangitis can result in obstruction of lymphatic drainage, initial episodes are associated in many cases with an increased predisposition to develop recurrent infections involving the same area. Most cases are caused by either *S pyogenes* or *S aureus*. Mixed streptococcal and staphylococcal infection may also occur. Less common bacterial etiologies include groups B, C, and G streptococci, *Haemophilus influenzae* (in children), *Streptococcus pneumoniae*, *Pasteurella multocida* (cat or dog bites), enteric bacilli (*Enterobacteriaceae*), anaerobic bacteria, *Legionella* spp., *P aeruginosa*, *Helicobacter cinaedi* (immunocompromised patients), *Aeromonas hydrophila* (freshwater exposure), and *Vibrio vulnificus* (seawater exposure). *Erysipelothrix rhusiopathiae* is the etiologic agent of erysipeloid, which is a violaceous cellulitis of the hands occurring in persons handling raw fish, meat, or poultry. Nonbacterial causes of cellulitis, such as *Cryptococcus neoformans*, filamentous fungi, and nontuberculous mycobacteria, should be considered in unusual cases, particularly with immunocompromised patients.

## Clinical Findings

**A. Signs and Symptoms.** Cellulitis typically presents with erythema, warmth, swelling, and local pain and tenderness. In contrast to erysipelas, the margins of the inflammatory erythematous lesion are neither elevated nor sharply demarcated from surrounding uninvolved tissue. The involved area is often quite extensive and may progress rapidly, particularly in patients with chronic dependent edema. Lymphangitis with regional lymphadenopathy is common. Although it is presumed that cellulitis often begins at the site of a break in the skin, this is often not clinically apparent. Systemic features of cellulitis vary considerably, ranging from the complete absence of systemic illness to severe systemic toxicity. Fever, chills, and malaise accompany most cases of significant bacterial cellulitis.

**B. Laboratory Findings.** Blood cultures should be obtained in most cases of cellulitis, before the initiation of empiric antimicrobial therapy. Although the culturing of a punch biopsy specimen or leading-edge aspirate has often been advocated, positive cultures occur in only ~ 20% of cases. This diagnostic approach is usually not necessary and is in practice rarely pursued in cases of uncomplicated bacterial cellulitis. However, material for culture should be obtained by aspiration, or biopsy should be considered in unusual cases, particularly in cases of necrotizing infection and in immunocompromised patients, who may develop soft-tissue infections that are caused by unusual pathogens.

**C. Imaging.** Most cases of simple bacterial cellulitis do not require radiologic investigations. Plain radiographs may disclose the presence of foreign bodies, adjacent

bony involvement, or gas in soft tissues.

## Differential Diagnosis

The differential diagnosis of cellulitis includes a wide variety of infectious and noninfectious inflammatory lesions, including erysipelas, erysipeloid, thermal injury, infiltrative malignancies, angioedema, neutrophilic dermatosis (Sweet's syndrome), erythema chronicum migrans, and cutaneous herpes zoster.

## Complications

Although many instances of limited cellulitis resolve without treatment, cellulitis can cause serious disease by spreading rapidly via lymph vessels and the bloodstream. Patients who have undergone saphenous venectomy for myocardial revascularization may develop recurrent acute cellulitis in the involved limb, often with associated lymphangitis. These episodes are generally caused by non-group A  $\beta$ -hemolytic streptococci and commonly occur in association with tinea pedis, which may serve as a nidus for streptococcal colonization. Episodes tend to recur over many months or even years. Treatment of the dermatophytic fungal infection may abolish recurrent cellulitis episodes. Recurrent streptococcal cellulitis also occurs in patients with lymphedema of a limb, which may be caused by mastectomy, radiation therapy, radical pelvic surgery, or neoplastic involvement of lymph nodes. Although most cases of cellulitis resolve without suppurative complications, localized inflammation may occasionally evolve into a subcutaneous abscess that requires drainage.

## Treatment

Uncomplicated bacterial cellulitis is most commonly caused by  $\beta$ -hemolytic streptococci or *S aureus*. Because the clinical features of streptococcal, staphylococcal, or combined infections are usually similar, in most cases therapy is directed against both streptococci and staphylococci without confirmation of the etiology. If the infection is mild, an oral agent such as dicloxacillin or a first-generation cephalosporin (eg, cephalexin) may be selected (see [Box 13-2](#)). Either a semisynthetic penicillin (eg, nafcillin or oxacillin) or a first-generation cephalosporin (eg, cefazolin) would be an appropriate first-line parenteral agent for mild cellulitis of undetermined etiology. Penicillin remains the drug of choice for streptococcal cellulitis, such as with recurrent cellulitis in a limb after saphenous venectomy.

## Prognosis

The prognosis of most cases of simple bacterial cellulitis is good with appropriate antimicrobial therapy. Scarring is generally not encountered, and suppurative complications occur in a minority of cases. Episodes of cellulitis may heal with the development of lymphedema, thereby potentially predisposing the patient to recurrent episodes in the same location.

## Prevention

Treatment of tinea and management of edema in involved limbs with appropriate

mechanical measures such as support hose may lessen the risk for the development of bacterial cellulitis.

## **CUTANEOUS ABSCESSSES**

### **Essentials of Diagnosis**

- A fluctuant, erythematous, tender, cutaneous nodule.
- Associated purulent drainage may occur.
- Features of systemic illness are variably present.

### **General Considerations**

Cutaneous abscesses most commonly evolve by local extension of a primary epidermal/dermal infection. Although localized suppuration occurs, host defenses prevent systemic spread of the infection. Thus, cutaneous abscesses tend to be superficial, single, and well localized, and are not associated with systemic toxicity. A subcutaneous abscess may also arise through trauma, such as from puncture injuries. Abscesses may occur by hematogenous seeding of cutaneous/subcutaneous tissue, as is occasionally seen in the setting of *S aureus* bacteremia. Cutaneous abscesses may occur in any location, although they most commonly involve the head, neck, extremities, and perineal region. Cutaneous abscesses usually contain organisms that reflect the flora of the overlying skin or adjacent mucous membrane. Abscesses on the trunk or extremities are commonly caused by *S aureus* or streptococci.

### **Clinical Findings**

Cutaneous abscesses are recognized clinically as tender, painful, erythematous nodules that become fluctuant. There may be evidence of surrounding inflammation or an overlying pustule.

### **Complications**

Complications of cutaneous abscesses include bacteremia and spread of infection into adjacent structures, including bone or joints.

### **Treatment**

Most cutaneous abscesses require incision and drainage when demonstrable fluctuance is present. If only a tender nodule is encountered, needle aspiration may be performed, followed by incision and drainage if pus is recovered. Because of the potential for extension to the cavernous sinus, lesions on the nose or lips should generally not be incised or otherwise manipulated. If the lesion is effectively drained surgically, antibiotic therapy may not be necessary. Antibiotic therapy is generally reserved for high-risk patients with impaired host defenses or for patients in whom there is evidence of bloodstream invasion or extension of infection to adjacent tissues (see [Box 13-2](#)). Because drainage of subcutaneous abscesses may cause transient bacteremia,

antibiotic prophylaxis should be given for patients with underlying cardiac valvular disease. Empiric adjunctive antibiotic therapy should be based on the most likely bacterial pathogen(s). In most cases, a first-generation oral cephalosporin or an antistaphylococcal penicillin would be an appropriate agent. Definitive treatment can subsequently be selected based on culture and susceptibility data.

## **FURUNCLES AND CARBUNCLES**

### **Clinical Findings**

Furuncles present as tender, firm, erythematous nodules that become fluctuant. They develop from folliculitis, spreading to the subcutaneous layers of the skin. Furuncles occur in moist areas of skin that contain hair follicles and are subject to friction (eg, neck, axillae, buttocks, and face). An inflammatory nodule becomes fluctuant with subsequent spontaneous drainage of pus. Predisposing conditions include diabetes mellitus, corticosteroid therapy, and use of injected drugs.

A carbuncle is a more extensive, multiloculated subcutaneous lesion that occurs most commonly at the nape of the neck. It often drains along hair follicles from deep, septate pockets of suppuration; multiple sinus tracts are frequently present. Carbuncles tend to occur in areas covered by thick inelastic subcutaneous tissue such as the nape of the neck, back, or thighs; they are generally quite painful.

Both furuncles and carbuncles are almost always caused by *S aureus*. Although systemic manifestations are not encountered with furuncles, fever and other systemic symptoms are frequently seen with carbuncles. Patients with recurrent furunculosis should be evaluated for the possibility of nasal carriage of *S aureus*.

### **Complications**

Manipulation of furuncles on the upper lip or near the nasolabial groove should be avoided, because it may result in cavernous sinus thrombosis. Staphylococcal bacteremia may be encountered with large, inflamed lesions, possibly resulting in metastatic abscesses.

### **Treatment**

For minor furuncles, moist heat should provide adequate therapy. Topical or systemic anti-infective therapy is generally not indicated. Larger furuncles and carbuncles require incision and drainage as well as oral or, occasionally, parenteral antistaphylococcal therapy.

## **FOLLICULITIS**

### **Clinical Findings**

Folliculitis is a bacterial infection that involves the ostium of a hair follicle, typically on the face, buttocks, or the extensor surface of an extremity. The lesions consist of small, tender erythematous papules or pustules that eventually drain, become crusted, and

spontaneously heal. Lesions in different stages of evolution are often present simultaneously. Most cases of folliculitis are caused by *S aureus*, although folliculitis caused by *P aeruginosa* may be encountered in the setting of contaminated swimming pools or hot tubs. Healing occurs spontaneously in most cases, either by drainage or regression. Scarring is distinctly uncommon.

## **Treatment**

Anti-infective therapy is generally not indicated. Local heat may provide symptomatic benefit.

## **NECROTIZING SOFT-TISSUE INFECTIONS**

### **Essentials of Diagnosis**

- Usually rapidly progressive infections with evidence of soft-tissue necrosis.
- Marked systemic toxicity generally but not invariably present.
- Multisystem organ failure may occur.
- Involved area generally painful.
- Variable microbiology—monomicrobial (eg, GAS, *Clostridium* spp.) vs polymicrobial.

### **General Considerations**

Necrotizing soft-tissue infections are characterized by rapidly progressive inflammation and necrosis variably involving skin, subcutaneous fat, fascia, and occasionally muscle. Many classification schemes have been proposed for necrotizing soft-tissue infections, but they are often inconsistent and imprecise. In many cases, a variety of terms have been given to closely related or essentially identical processes. Furthermore, the classifications have been difficult to apply clinically and have resulted in considerable confusion in clinical practice. In approaching this group of infections, emphasis should be placed on differentiating necrotizing infections, which require prompt surgical intervention, from non-necrotizing infections, which usually do not.

Early clinical signs of a necrotizing infection include the presence of bullae, edema that extends beyond the area of erythema, focal cutaneous ecchymosis/ischemia, crepitus, cutaneous anesthesia, and the absence of lymphangitis. Early in the course of a necrotizing infection, patients complain of severe pain, usually out of proportion to the physical findings. Although skin changes are usually present, cutaneous evidence of necrotizing fasciitis may be absent. The most clinically important distinctions to be made in defining necrotizing soft-tissue infection syndromes are the tissues/structures involved and the microbial etiology.

Most necrotizing soft-tissue infections are polymicrobial, although there are two important exceptions: clostridial myonecrosis and type-2 necrotizing fasciitis caused by invasive GAS. All necrotizing soft-tissue infections should be cultured and require

prompt surgical debridement and parenteral antimicrobial therapy ([Boxes 13-3](#) and [13-4](#)).

Ultrasonography is helpful in evaluating the possibility of complicating abscess formation and for providing imaging capability at the bedside in emergency situations. Although computed tomography scans provide considerable information about the extent of infection, magnetic resonance imaging provides the greatest resolution and level of detail in the definition of complex soft-tissue infection syndromes. In cases of suspected deep and/or necrotizing infections that are not clinically obvious, magnetic resonance imaging scans may provide substantial diagnostic benefit. However, pursuing imaging studies should not delay life-saving surgical intervention, which is also the most definitive mode of diagnosis. Detection of a significantly elevated serum creatine kinase level suggests involvement of muscle in the disease process.

The key to a successful outcome in the treatment of necrotizing soft-tissue infections is early diagnosis and treatment. Early findings of necrotizing infections may appear similar to nonoperative cellulitis; therefore, correct early diagnosis requires a high index of suspicion and an awareness of specific clinical findings that suggest a necrotizing infection.

Classification problems notwithstanding, several relatively well-defined necrotizing soft-tissue infection syndromes regularly encountered in the medical literature are discussed in the following sections.

## **CLOSTRIDIAL MYONECROSIS (GAS GANGRENE)**

### **General Considerations**

Clostridial myonecrosis (gas gangrene), usually caused by *Clostridium perfringens*, is an extremely serious, rapidly progressive infection that poses imminent risk to limb and life. It typically occurs in settings characterized by the presence of contaminated, devitalized tissue. Predisposing conditions include traumatic injuries such as compound fractures, penetrating wounds (eg, combat-induced wounds), surgical wounds after enteric surgery, and limb injuries in the setting of advanced arterial insufficiency.

### **Clinical Findings**

There is rapid destruction of muscle and usually severe systemic toxicity. Prompt debridement of all nonviable tissue, often leading to amputation, is essential for cure. At surgery, involved muscle is typically pale and edematous and does not contract when probed.

A variant syndrome, referred to as spontaneous nontraumatic gas gangrene, occurs in the absence of trauma in patients with underlying diseases such as colon cancer, leukemia, or diabetes mellitus. It is commonly caused by *Clostridium septicum* and is thought to occur via hematogenous seeding.

The onset of gas gangrene is sudden, with severe pain, hypotension, and systemic toxicity. The affected limb becomes edematous; the surrounding skin is pale; a

blood-tinged, serous discharge may be noted; and the surrounding tissue finally becomes dusky with fluid-filled bullae. In addition, gas may be palpable in the tissues.

## **Complications**

Severe tissue destruction is generally encountered with gas gangrene, which may lead to loss of limb or death.

## **Treatment**

When *Clostridium* spp. have been demonstrated or are highly suspected, high-dose penicillin G is generally considered the drug of choice (see [Box 13-4](#)). Although some studies have shown increasing resistance of clostridia to penicillin, almost all strains of *C perfringens* remain susceptible. Metronidazole, imipenem, clindamycin, and ampicillin/sulbactam or piperacillin/tazobactam are possible alternatives. It should be noted that clindamycin is relatively inactive in vitro against some strains of *Clostridia* spp. The combination of penicillin and clindamycin is often used in the setting of clostridial myonecrosis, largely based on experimental evidence in animals.

Although it is reasonable to use adjunctive hyperbaric oxygen therapy when available, under no circumstances should debridement be delayed to facilitate transport to a facility with hyperbaric oxygen facilities. Prompt surgical debridement should be performed, with removal of all devitalized tissue.

## **Prognosis**

Prompt recognition and adequate debridement of devitalized tissues are essential to minimize tissue loss. More proximal amputation may sometimes be necessary if initial debridement is inadequate.

## **Prevention**

Meticulous care of contaminated traumatic wounds, including thorough debridement of devitalized tissue and foreign material, is essential to lessen the likelihood of the development of gas gangrene.

## **NECROTIZING FASCIITIS**

### **General Considerations**

Necrotizing fasciitis is an infectious process that progressively destroys the subcutaneous fascia and fat with relative sparing of underlying muscle. Although it may affect any part of the body, including the abdominal wall and perineum, necrotizing fasciitis occurs most commonly on the extremities.

### **Clinical Findings**

Early findings of necrotizing fasciitis may resemble cellulitis. However, the process spreads rapidly and is usually associated with severe pain and significant systemic

toxicity. Edema may extend beyond the area of cutaneous inflammation. Infection spreads rapidly along fascial planes and through venous and lymphatic channels. Although there is often evidence of cutaneous necrosis, necrotizing fasciitis may occur with relatively intact overlying skin, particularly with an early presentation. Patchy cutaneous anesthesia, gangrene, or both may occur as a result of extensive undermining of subcutaneous tissue, which contains vascular structures and nerves. Patients generally appear "toxic," and hypotension and multiorgan failure often develop. The diagnosis is usually readily confirmed at surgery by the finding of gray necrotic fascia without frank pus and by easy dissection and undermining of the wound. Histopathologic findings include fascial necrosis, thrombosis of small arteries and veins, and the presence of microorganisms on Gram stains.

Based on microbial etiology, necrotizing fasciitis syndromes are classified into two types. Type-1 necrotizing fasciitis is a polymicrobial infectious process in which at least one anaerobic species (usually *Bacteroides* or *Peptostreptococcus* spp., or both) is isolated in combination with one or more facultative species, such as gram-negative bacilli of the *Enterobacteriaceae* family or streptococci (but not GAS). Fournier's gangrene represents a form of polymicrobial necrotizing fasciitis involving the male genitalia, typically occurring in diabetic patients. Synergistic necrotizing cellulitis represents essentially the same process as type-1 necrotizing fasciitis, although it often involves muscle. Type-2 necrotizing fasciitis, occasionally referred to as hemolytic streptococcal gangrene, is caused by invasive GAS, which may rarely be present in combination with another organism such as *S aureus*. There has been a marked increase in the reported incidence of invasive GAS infection over recent years. It often begins at the site of minor trauma. Although it typically occurs in the elderly and in patients with underlying medical conditions, it has also been encountered in otherwise healthy young patients. Varicella infection has also been shown to be a risk factor for the development of invasive *S pyogenes* infections. Although muscle involvement can occur, soft tissue gas is not seen. This type of necrotizing fasciitis is often seen in association with the streptococcal toxic shock syndrome. The use of nonsteroidal anti-inflammatory agents may adversely affect the clinical outcome, and there is a significant risk of nosocomial or domestic transmission.

### **Differential Diagnosis**

The differential diagnosis of necrotizing fasciitis includes cellulitis, clostridial myonecrosis, myositis, and anaerobic and other necrotizing forms of cellulitis.

### **Complications**

Complications of necrotizing fasciitis include compartment syndromes, progressive limb necrosis leading to amputation, bacteremia, multiorgan failure, and death.

### **Treatment**

In all instances where drainage is present, aerobic and anaerobic cultures and a Gram stain should be performed. Initial anti-infective therapy may then be based on the results of the Gram stain morphology (see [Box 13-4](#)). When only streptococci are seen on Gram stain in the setting of a necrotizing infectious process, then high-dose penicillin G

should be administered. It has been suggested, from limited experimental data and anecdotal clinical experience, that clindamycin should be administered in addition to penicillin in cases of invasive infection caused by *S pyogenes*, because of the theoretical ability of clindamycin to interfere with streptococcal toxin production. There is also anecdotal evidence supporting the use of intravenous gammaglobulin in cases of streptococcal necrotizing fasciitis. No controlled data are available to clearly define the potential additive benefit of this costly adjunctive therapeutic modality, however.

When the Gram stain reveals several bacterial morphologies, broad-spectrum antibacterial therapy should be directed at gram-positive and gram-negative anaerobic and aerobic/facultative organisms. Polymicrobial Gram stain findings may be encountered in many of the polymicrobial syndromes described above, including type-1 necrotizing fasciitis, progressive synergistic gangrene, and nonclostridial anaerobic cellulitis. Reasonable initial therapeutic regimens, pending definitive culture and susceptibility data, include (1) a third-generation cephalosporin (eg, cefotaxime or ceftriaxone) in combination with metronidazole or clindamycin; (2) ampicillin, gentamicin, and clindamycin or metronidazole; (3) piperacillin/tazobactam monotherapy; or (4) imipenem monotherapy.

## **Prognosis**

The prognosis of necrotizing fasciitis largely depends on early recognition, prompt institution of antimicrobial therapy, and early complete debridement of all devitalized tissue.

## **PROGRESSIVE BACTERIAL SYNERGISTIC GANGRENE**

This soft-tissue infection syndrome, also known as Meleney's synergistic gangrene, typically results from infection at the site of an abdominal surgical incision, around an enterostomy, in association with an abdominal fistula exit site, or in association with a chronic lower-extremity ulcer. As the term synergistic implies, this infection typically has a polymicrobial etiology and most commonly involves anaerobic or microaerophilic streptococci with *S aureus* or occasionally facultative gram-negative bacilli such as *Proteus* spp.

Progressive bacterial synergistic gangrene begins as a localized area of swelling, erythema, and tenderness that becomes ulcerated and gradually enlarges. Fever is usually minimal or absent. The ulcer is characteristically encircled by gangrenous skin with surrounding violaceous skin.

## **ANAEROBIC CELLULITIS**

Clostridial anaerobic cellulitis describes an infection, usually caused by *C perfringens*, that typically involves devitalized subcutaneous tissues that result from a contaminated or inadequately debrided traumatic or surgical wound. Nonclostridial anaerobic cellulitis is clinically similar to clostridial anaerobic cellulitis but is caused by non-spore-forming anaerobic bacteria (eg, *Bacteroides* spp., peptostreptococci, and peptococci) often in conjunction with facultative organisms such as *Enterobacteriaceae*, streptococci, or staphylococci. Gram stains and cultures of exudate aspirated from the lesion will

typically suggest the polymicrobial nature of this process.

Gas formation is evident in skin and subcutaneous tissue on examination and radiographically, and thin, malodorous drainage may emanate from the wound. There is no appreciable involvement of deeper structures such as fascia or muscle. The onset is generally gradual, and there is usually mild local pain and systemic toxicity, allowing clinical differentiation from the more fulminant clostridial myonecrosis.

## INFECTIONS ASSOCIATED WITH HUMAN OR ANIMAL BITES

### Essentials of Diagnosis

- Acute soft-tissue infection occurring at the site of a bite injury.
- May involve deeper structures such as joint space, tenosynovium, or bone.
- Etiology often polymicrobial—*P multocida* commonly seen with dog bite or cat bite infections.

### General Considerations

Human and animal bite wounds account for ~ 1% of emergency room visits. Half of all Americans at some time during their lives are bitten by a cat or dog. These wounds can be clinically quite deceptive, because what initially appears to be a minor wound may involve the subjacent joint space or bone, resulting in serious complications. [Box 13-5](#) summarizes the most common causes of each type of infection.

**A. Dog Bites.** Dog bites account for ~ 80% of animal bite wounds; 15-20% of these wounds become infected. The risk of infection is increased in the presence of associated crush or puncture injuries and involvement of the hand. Organisms generally encountered are found in the oral flora of dogs: *P multocida*, *S aureus*, streptococci, and occasionally *Capnocytophaga canimorsus*, *Eikenella corrodens*, other gram-negative bacilli, and anaerobes.

**B. Cat Bites.** Cats have slender and extremely sharp teeth that typically cause a puncture-type injury with potential involvement of bone or joint. The overall rate of wound infection after cat bites is > 50%, with a proportionate increase in the incidence of associated septic arthritis and osteomyelitis. *P multocida* is the most frequently isolated pathogen, occurring in > 50% of cases. Other organisms, similar to those associated with dog bite injuries, may also be recovered.

**C. Human Bites.** Human bites tend to be more serious and more prone to infection than animal bites, in part because of the typical mechanisms of injury (eg, clenched fist and occlusional injuries). Clenched-fist injuries typically involve trauma to the metacarpophalangeal joints, and thus are at high risk for complications such as deep soft-tissue infections, septic arthritis, and osteomyelitis. Potential pathogens include *S aureus*, *H influenzae*, *E corrodens*, and anaerobic bacteria, including strains that produce  $\beta$ -lactamases.

## Treatment

Wounds should be irrigated with saline and may require debridement and surgical repair depending on the severity of the injury. The risk for rabies infection should be assessed carefully and appropriate prophylaxis given, if indicated. Tetanus prophylaxis should also be addressed. If a wound is brought to clinical attention > 24 h after injury or if there are already signs of infection, it should be left open. If a patient presents with an infected wound, cultures for aerobic and anaerobic bacteria should be obtained. Radiography should be pursued if an underlying fracture is suspected. In general, relatively trivial bite wounds may not require antibiotic therapy, although it may be prudent to administer a short (3- to 5-day) course of a prophylactic oral antibiotic (eg, amoxicillin/ clavulanate) in the setting of a more significant bite injury (especially for cat bite injuries) ([Box 13-6](#)). For an infected wound requiring hospitalization, ampicillin/sulbactam would be a reasonable initial empiric therapeutic choice.

## DIABETIC FOOT INFECTIONS

### Essentials of Diagnosis

- Acute, subacute, or chronic soft-tissue infection of diabetic feet, often with associated ulceration.
- Commonly occurs in the setting of associated neuropathy and arterial insufficiency.
- Fever and other systemic symptoms may or may not be present.
- Need to exclude underlying osteomyelitis.
- Mild, non-limb-threatening infections usually caused by *S aureus* or  $\beta$ -hemolytic streptococci.
- Severe limb-threatening infections usually have a polymicrobial etiology.

### General Considerations

Foot infections are a serious complication of diabetes mellitus and result in more days of hospitalization than any other complication. Diabetic foot infections account for > 50% of all nontraumatic amputations. Underlying pathogenic factors include sensory peripheral neuropathy, macro- and microangiopathy, and systemic factors. Diminished sensation places the patient at risk for skin trauma and subsequent ulceration.

Infections typically start with a break in the skin, followed by penetration of bacteria into the skin and subcutaneous tissue ([Box 13-7](#)). This leads initially to a localized cellulitis that may spread to deeper structures including the deep fascia, tendon, joint space, or bone. Penetration by a foreign body is often asymptomatic and may lead to deep infection with limited involvement of superficial structures. Repetitive minor trauma caused by ill-fitting shoes may also lead to skin breakdown with subsequent infection. Hyperglycemia has been shown to result in polymorphonuclear cell dysfunction, which may contribute to the development and progression of infection. Diabetic foot ulcer is

not a common problem in pediatric diabetes.

**A. Mild Non-Limb-Threatening Infections.** Mild non-limb-threatening infections tend to be superficial, presenting with mild cellulitis and minimal systemic toxicity. They may be associated with an ulcer that, if present, does not traverse all layers of the skin. There is no subjacent bone or joint involvement and the involved limb generally has reasonably good arterial blood supply. These infections are monomicrobial in half the cases and are generally caused by *S aureus* or aerobic streptococci. Gram-negative bacilli and anaerobic bacteria are infrequently isolated.

**B. Severe Limb-Threatening Infections.** Limb-threatening diabetic foot infections are usually polymicrobial and involve both anaerobic and aerobic bacteria, including *S aureus*,  $\beta$ -hemolytic streptococci (often group B), *Enterobacteriaceae*, *Clostridium* spp., and *Bacteroides* spp. Although coagulase-negative staphylococci, enterococci, and *Corynebacterium* spp. are occasionally recovered in culture and may be pathogenic, the possibility of contamination or colonization should be considered, particularly when isolated from a superficial swab.

## Clinical Findings

Limb-threatening diabetic foot infections typically occur in the setting of significant limb ischemia and often with associated gangrene. The cellulitis is more extensive, and full-thickness skin ulcers are often present. There may be infection of contiguous bone and/or joint space. When fever is present, it is often seen in association with extensive soft-tissue infection, deep abscesses, bacteremia, or hematogenously seeded metastatic infection.

Diagnostic evaluation involves detailed definition of the extent of disease and the potential for wound healing. The vascular status of the involved limb should be documented by physical examination, noninvasive laboratory studies including transcutaneous oximetry, and angiography in selected cases. The possibility of concomitant subjacent osteomyelitis should be considered in all cases. Visualization of bone or the ability to "probe to bone" in infected diabetic foot ulcers has been shown to strongly correlate with the presence of underlying osteomyelitis.

All available radiographic diagnostic modalities, including plain radiographs, computed tomography scans, and technetium and radioactive leukocyte scans, have limited sensitivity and/or specificity for the definitive diagnosis of osteomyelitis. Magnetic resonance imaging is a valuable diagnostic tool for the detection of osteomyelitis in feet of diabetic patients and may be superior to radionuclide imaging.

## Complications

Complications of diabetic foot infections include persistence of infection, osteomyelitis, septic arthritis, progressive infection necessitating amputation, and systemic infection with severe toxicity.

## Treatment

Selection of antimicrobial therapy ([Box 13-8](#)) depends to a large extent on the nature and severity of infection. In cases of mild non-limb-threatening cellulitis without evidence of tissue necrosis and in the absence of a foul odor, therapy may be directed at gram-positive cocci (ie, *S aureus*) with a first-generation cephalosporin such as cefazolin. In select cases, oral therapy with an agent such as dicloxacillin or cephalexin may be appropriate. More severe infections, particularly those with associated tissue necrosis, generally require broader-spectrum therapy. Possibilities include piperacillin/tazobactam, imipenem or meropenem, or combination therapy such as cefepime with clindamycin or metronidazole. Therapy should be guided by culture and susceptibility data if appropriate specimens are available for culture. Duration of antimicrobial therapy depends on specific clinical circumstances. Cases of mild cellulitis are generally treated for 7-10 days.

More severe soft-tissue infection may require 2-3 weeks of therapy. If osteomyelitis is present and complete surgical resection of diseased bone is not performed, a minimum of 4 weeks of parenteral therapy is usually indicated. Surgical removal of devitalized tissue and drainage of pus are important components of therapy. If osteomyelitis is present, the surgical approach should be dictated by the extent of bone involvement and the vascular status of the limb. Revascularization should be pursued in ischemic limbs to facilitate healing, if technically feasible.

Considerable controversy exists concerning the surgical approach to diabetic foot infections and the extent of debridement required for treatment of infected bone. Limited ablative surgery to remove infected bone, such as with toe amputation or ray resection, often allows for a shortened course of antibiotic therapy, a shorter hospital stay, a greater likelihood of cure, and an earlier return to normal living. In cases of severe underlying arterial occlusive disease that is not amenable to surgical repair or in the presence of significant tissue necrosis, more proximal amputation may be necessary.

## **Prognosis**

The outcome of the treatment of diabetic foot infections is to a great extent related to the underlying vascular and neurologic status of the limb. In infections involving relatively well-perfused limbs, amputation is less likely to be necessary for ultimate cure. In general, severe infection in severely ischemic limbs requires amputation.

## **Prevention**

Preventive measures that may lessen the incidence of diabetic foot infections include meticulous foot care, the use of properly fitting footwear, early treatment of mild infections, and optimizing blood flow to ischemic feet through revascularization procedures, if possible.

### OSTEOMYELITIS

#### Essentials of Diagnosis

- Localized pain and tenderness of the involved bone is common.
- Purulent drainage from a sinus tract may or may not be present.
- Systemic symptoms and signs (eg, fever and chills) are often absent, particularly in chronic osteomyelitis.
- The erythrocyte sedimentation rate may be elevated.
- Plain radiographs may be negative. Computed tomography (CT) and magnetic resonance imaging (MRI) examinations are sensitive and specific tests for the presence of osteomyelitis but are expensive.
- Biopsy of the involved bone for pathologic examination and culture is diagnostic.

#### General Considerations

**A. Pathogenesis.** Osteomyelitis is an inflammatory disease of bone due to infection by a variety of different microorganisms ([Figure 14-1](#)). Normal bone is very resistant to infection unless there has been antecedent trauma or a foreign body is present. Certain organisms such as *Staphylococcus aureus* preferentially cause osteomyelitis because the organisms bind to bone through the expression of receptors for fibronectin, laminin, collagen, or bone sialoglycoprotein and because *S aureus* is a frequent colonizer of the skin and anterior nares. Osteomyelitis occurs by several mechanisms, including hematogenous seeding caused by bacteremia from a focus of infection elsewhere in the body, contiguous spread from adjacent soft-tissue or joint infection, or direct inoculation of microorganisms into the bone during penetrating trauma or surgery.

**Hematogenous Osteomyelitis.** Hematogenous osteomyelitis occurs most often in children and the elderly. In children it usually occurs in the metaphyses of the femur, tibia, and humerus because the blood supply to these bones is derived from small capillary branches of the nutrient artery, which have few phagocytic cells and are prone to vascular obstruction from minor trauma. Once the blood supply is diminished, small areas of bone necrosis develop that are susceptible to hematogenous seeding. These areas of infected avascular bone become sequestra. In children < 1 y of age, the infection can spread to the epiphysis and joint space through capillaries that cross the growth plate. In children > 1 y of age, the infection is confined to the metaphysis, with resulting lateral extension of the infection through the Haversian and Volkmann canal system, rupture of the cortex, and subperiosteal abscess formation. The exception to

this rule is the development of osteomyelitis in metaphyses that are intracapsular, such as the proximal femur, humerus, and radius.

Hematogenous osteomyelitis in adults is much less common than in children and most often involves two adjacent vertebrae and the intervertebral disc space (vertebral osteomyelitis). Hematogenous seeding occurs through the arterial and venous blood supply (retrograde flow through Batson's venous plexus) with the former thought to be more common. Common sources of a bacteremia that predisposes to vertebral osteomyelitis include infections of intravenous-access devices, pneumonia, and urinary tract infection.

**Contiguous-focus osteomyelitis.** Contiguous-focus osteomyelitis is much more common in adults than in children and is often seen in persons > 50 y of age. Contiguous-focus osteomyelitis occurs secondarily to spread of infection from adjacent soft tissue or joints or is caused by direct inoculation of microorganisms during trauma or surgery. Concomitant infection of orthopedic fixation devices is often present. Vascular insufficiency such as that seen in patients with longstanding diabetes mellitus often leads to recurrent soft-tissue infections and subsequent contiguous-focus osteomyelitis of the underlying bones.

**B. Classification Schemes.** Waldvogel has classified osteomyelitis as being of hematogenous origin or due to a contiguous focus of infection. Contiguous-focus osteomyelitis is further subdivided into osteomyelitis with or without vascular insufficiency. In addition, either type of osteomyelitis can be acute or chronic in its presentation. Acute infection is defined as a recently diagnosed bone infection of < 10-d duration, whereas chronic infection represents relapse of osteomyelitis at the same site or disease of > 10-d duration. Vertebral osteomyelitis can be acute or chronic and, depending on the pathogenesis of the infection, can be hematogenous in origin or caused by a contiguous focus of infection. Contiguous-focus osteomyelitis often occurs secondarily to a wound infection after surgery.

Cierney and Mader have proposed an alternative classification scheme ([Table 14-1](#)). This classification system is based on bone anatomy and the physiologic status of the host. This system is very useful in comparing medical and surgical treatment strategies in clinical trials. Examples of stage 1 disease include hematogenous osteomyelitis and infected intramedullary rods. Osteomyelitis of the surface of a bone at the base of a soft-tissue infection would be an example of stage 2 osteomyelitis. Osteomyelitis involving the full thickness of the bone, with or without cortical sequestration that can be debrided without endangering the stability of the bone, constitutes stage-3 disease. Osteomyelitis that involves the entire extent of bone and usually requires segmental resection to achieve adequate debridement (a debridement that often compromises the stability of the bone) is stage-4 osteomyelitis.

**C. Microbiology and Epidemiology.** The optimal selection of antimicrobial agents for the treatment of osteomyelitis depends on the definitive identification of the microorganism(s) causing infection and knowledge of its antimicrobial susceptibilities. Antimicrobial therapy should usually be withheld until all cultures from the involved tissue have been obtained.

Skin and serologic testing for unusual organisms such as mycobacteria and fungi should be done only if these infections are suspected clinically. Serologic tests to detect cell wall components of *S aureus*, such as teichoic acid, are not clinically helpful. Sinus tract swab cultures are not accurate in predicting polymicrobial infection but may be helpful if *S aureus* is the only pathogen isolated.

For culture, as much tissue and purulence as possible should be obtained at the time of bone biopsy and/or surgical debridement. All specimens should be sent immediately to the microbiology laboratory. Tissue specimens should be sent to both the pathology laboratory and the microbiology laboratory. Anaerobic cultures require anaerobic transport media.

The microbiologist should perform a Gram stain on all specimens. Stains for fungi or acid-fast bacilli may also be useful in selected cases. Cultures for aerobic and anaerobic bacteria should be routinely obtained. When the history, physical examination, or intraoperative findings suggest an unusual infection, special culturing techniques for organisms such as fungi, mycobacteria, *Mycoplasma* spp., *Brucella* spp., or other organisms may be required. Failure to obtain specimens for these cultures at the time of initial debridement may result in unnecessary procedures to obtain further culture material or ultimately treatment failure despite adequate debridement.

The pathologist, although primarily looking for the presence or absence of inflammation, may also find evidence of a specific type of inflammation, such as granulomas, that provide a clue to the etiology of the infection. In this circumstance, it is useful to perform additional tissue stains for fungi and mycobacteria.

Once the microorganism responsible for the infection has been identified, antimicrobial susceptibility tests should be performed. A minimal inhibitory concentration (MIC) obtained by broth or agar dilution is the best guide to therapy. When only disc diffusion (Kirby-Bauer disc sensitivities) results are available, drugs with intermediate or resistant results should not be used. Some investigators also advocate performing a serum bactericidal titer. This test quantitates the bactericidal activity of the patient's serum. It is the dilution of patient's serum that shows = 99.9% killing of the organism in vitro. However, these tests are difficult to reproduce within and among laboratories, and their use is not advocated.

**Hematogenous Osteomyelitis.** *S aureus* is the most common cause of hematogenous osteomyelitis in children and adults ([Box 14-1](#)). Hematogenous osteomyelitis caused by beta-hemolytic streptococci and aerobic gram-negative bacilli is much less common. Some patient groups are predisposed to hematogenous infection due to certain organisms: neonates (*Enterobacteriaceae*, group B streptococci), patients with sickle cell disease (*Salmonella* spp., *S aureus*), and injection drug users (*Pseudomonas aeruginosa*, *S aureus*). *Haemophilus influenzae* causes infection in infants and children, but the incidence of invasive disease caused by *H influenzae* is decreasing owing to the *H influenzae* type b-conjugated vaccine that is now routinely administered to children. Anaerobic and polymicrobial infections are uncommon.

**Vertebral Osteomyelitis.** *S aureus* is the most common cause of vertebral osteomyelitis. Aerobic gram-negative bacilli cause = 30% of infections, particularly those

associated with hematogenous seeding from a urinary tract infection. *P aeruginosa* and *S aureus* infections are common among injection drug users. Coagulase-negative staphylococci, *S aureus*, and aerobic gram-negative bacilli are common causes of vertebral osteomyelitis after spine surgery with or without spinal hardware implantation. Polymicrobial infection is uncommon. Candidal infection may occur after candidemia, due to infections of intravascular devices.

**Contiguous-Focus Osteomyelitis.** This infection is often polymicrobial, particularly in the setting of osteomyelitis of the phalanges or metatarsals in patients with diabetes mellitus or vascular insufficiency or in osteomyelitis of the long bones after a contaminated open fracture. *S aureus*, beta-hemolytic streptococci, enterococci, aerobic gram-negative bacilli, and anaerobes can all be pathogens. If soil contamination is present, *Clostridium* spp., *Bacillus* spp., *Stenotrophomonas maltophilia*, *Nocardia* spp., and rarely various mycobacteria and fungi may cause infection. If orthopedic fixation devices become infected, then monomicrobial infection due to *S aureus* or coagulase-negative staphylococci is more common. *Pasteurella multocida* osteomyelitis often complicates cat bites, and *P aeruginosa* is a common cause of osteomyelitis of the foot after puncture injuries by nails or other sharp objects. Normal oral flora and *Actinomyces* spp. cause mandibular or skull osteomyelitis after periodontal infection.

## Clinical Findings

### A. Hematogenous osteomyelitis.

**1. Signs and symptoms.** Children most often present with severe bone pain, limitation of motion of the extremity, and fever and chills of several days to 3 wk in duration, although, in = 40% of cases, vague symptoms of 1- to 2-mo duration occur. On examination, there may be soft-tissue swelling, erythema, and tenderness of the involved area. Neonates often have no fever and present with only a decreased range of motion of the involved limb and localized tenderness and swelling. The presence of a joint effusion is also common in neonates.

**2. Laboratory findings.** An elevated leukocyte count, erythrocyte sedimentation rate, and C-reactive protein are common, but the lack of any one or all of these laboratory abnormalities does not exclude the diagnosis of osteomyelitis. Blood cultures should be obtained and are positive in = 50% of cases. Aspiration of associated soft tissue or subperiosteal abscesses or biopsy of involved bone is diagnostic. Arthrocentesis should be performed if a joint effusion is present.

**3. Imaging.** Plain radiographs may be negative early in the disease. Soft-tissue swelling and subperiosteal elevation are the earliest abnormalities and may not be seen for several weeks. Before lytic lesions appear, 30-50% of the bone must be destroyed, and typically these lesions do not appear for 2-6 wk after the onset of the illness. Sclerotic changes occur later and, when seen in association with periosteal new-bone formation, suggest chronicity of the infection.

Radionuclide scanning may be helpful early in the course of the disease, but the usefulness of this test is often limited by its lack of specificity. CT scans and MRI are better able to distinguish soft-tissue infection from osteomyelitis, are more sensitive than

plain radiographs, and allow better identification of optimal areas for needle aspiration or biopsy.

## **B. Vertebral osteomyelitis.**

**1. Signs and symptoms.** Patients are often > 50 y of age, except injection drug users, and usually present with back pain of several-months duration. The pain is often described as a continuous dull ache that is exacerbated by movement, cough, or straining. If neurologic complications (30%) are present secondary to nerve root or spinal cord compression from epidural extension of the infection, these symptoms may dominate the clinical picture. On physical examination, a draining sinus or wound is usually not present unless the infection is secondary to recent surgery. Fever is present in 20-50% of patients. Paraspinal muscle spasm and percussion tenderness of the spine are often present. The lumbar spine is most commonly involved, followed by the thoracic and cervical regions.

**2. Laboratory findings.** An elevated leukocyte count is often present. The erythrocyte sedimentation rate is elevated in = 95% of patients. Blood cultures are positive in 25-50% of cases, and positive blood cultures negate the need for routine biopsy of the involved vertebra and intervertebral disc space. Needle biopsy of the involved intervertebral disc, vertebra, or associated epidural abscess is the diagnostic procedure of choice. In = 25% of cases, the cultures from the initial needle biopsy may be negative. A second needle biopsy, an open biopsy, or both should then be performed.

**3. Imaging.** Plain radiographs of the spine often do not show characteristic vertebral endplate destruction, particularly in patients with a short duration of symptoms or other underlying vertebral pathology such as severe osteoarthritis. However, nonspecific abnormalities (ie, loss of disk height) on plain radiographs will be detected in the majority of cases. Gallium scans are more sensitive and specific than three-phase technetium ( $^{99}\text{Tc}$ ) bone scans or indium-labeled leukocyte scans for the diagnosis of vertebral osteomyelitis. MRI, however, is the most sensitive and diagnostic imaging technique and, in addition, provides the best anatomic detail. Gallium scans should be used when spinal hardware is present that degrades the MRI images.

## **C. Contiguous-focus osteomyelitis.**

**1. Signs and symptoms.** The patient usually presents with localized bone pain and/or drainage from a wound or sinus tract, of several-months duration. Fever and constitutional symptoms are uncommon. Overlying cellulitis may be present. A pathologic fracture may be present if extensive disease is present.

**2. Laboratory findings.** The leukocyte and the erythrocyte sedimentation rates are often normal. Blood cultures are usually negative. A bone biopsy is diagnostic and is usually obtained at the time of surgical debridement.

**3. Imaging.** Because the time from onset of infection to diagnosis of osteomyelitis is often delayed with contiguous focus osteomyelitis, plain radiographs, including tomography, often show abnormalities consistent with osteomyelitis. In the proper clinical setting, such as the presence of a draining sinus tract, plain radiography may be

all that is required. In some circumstances, however, there are other pathologic processes present that mimic osteomyelitis (ie, neuropathic bone disease in patients with peripheral neuropathy), or there are partially healed fractures or orthopedic fixation devices in place that limit the usefulness of plain radiography. If the clinical situation warrants additional radiologic procedures to confirm the diagnosis of osteomyelitis or to help identify the optimal surgical therapy for the patient, MRI is the diagnostic test of choice. If orthopedic hardware is present that interferes with MRI examination, then the combination of a three-phase ( $^{99}\text{Tc}$ ) technetium bone scan and indium-labeled leukocyte scan can be performed.

## Differential Diagnosis

Acute hematogenous osteomyelitis in children must be distinguished from soft-tissue infection, infectious arthritis, and certain malignancies such as Ewing's sarcoma. Vertebral osteomyelitis should be distinguished from the multitude of disease entities that can cause acute to subacute onset of back pain in adults, including osteoarthritis, metastatic malignancy, and compression fractures. If recent surgery has been performed, it is often difficult to distinguish postoperative pain and radiographic changes from those secondary to infection. Contiguous-focus osteomyelitis must be distinguished from chronic soft-tissue infection and rarely malignancy. Contiguous-focus osteomyelitis of the feet in patients with diabetes mellitus must be distinguished from neuropathic bone disease.

## Complications

Failure of medical and surgical therapy of osteomyelitis invariably leads to a relapse of infection. If treatment is delayed, osteomyelitis can progress from superficial to diffuse disease or from Cierney/ Mader stage 1 or 2 to stage 3 or 4 and thus become much more difficult to eradicate. In severe cases, amputation may be required for control of infection. In addition, acute hematogenous osteomyelitis in children can spread to adjacent joints and cause infectious arthritis. Vertebral osteomyelitis in adults if untreated can cause neurologic sequelae including paralysis either through extension to the epidural space or spinal column instability. Rare complications of longstanding osteomyelitis include amyloidosis, squamous cell carcinoma at the site of chronic sinus tract or primary bone malignancies such as osteogenic sarcoma.

## Treatment

The treatment of osteomyelitis depends on the goals of therapy and requires a multidisciplinary team of physicians, which may include the orthopedist, neurosurgeon, oral surgeon, plastic surgeon, vascular surgeon, invasive radiologist, and infectious disease specialist. If eradication of infection is the goal, then, in most circumstances, extensive debridement and resection of dead and infected bone are required, in conjunction with appropriate dead-space and soft-tissue management, rigid fixation of fractures, local antimicrobial therapy with antibiotic-impregnated polymethylmethacrylate beads, and prolonged systemic antimicrobial therapy directed at the causative organisms. In addition, modification of any physiologic factors (see [Table 14-1](#)) that may promote treatment failure, such as cessation of smoking, enhancement of the local blood supply in the area of the infection, and improved control of diabetes mellitus,

should be accomplished. Often, delayed reconstructive orthopedic techniques such as bone grafting and distraction osteogenesis (Ilizarov technique) are also necessary.

Exceptions to the absolute requirement for extensive debridement to arrest osteomyelitis include acute hematogenous osteomyelitis of the long bones in children and vertebral osteomyelitis in adults. The duration of therapy is usually 3-4 wk in children and 4-6 wk in adults. In children, after 7-10 d of intravenous antimicrobial therapy, the last 2-3 wk of therapy are often administered orally. Indications for surgery for acute osteomyelitis include failure to make a specific microbiologic diagnosis with less invasive techniques, involvement of the femoral head, neurologic complications, the presence of sequestra, and failure to improve while on appropriate antimicrobial therapy. In addition, the consequences of aggressive surgical and medical treatment for chronic osteomyelitis may in selected cases be worse than the consequences of the disease itself, and local wound care with or without oral antimicrobial suppressive therapy may be an option in these situations.

There are no large randomized studies to help guide the clinician in the antimicrobial therapy of osteomyelitis. Although several clinical trials have been performed, their interpretation is limited by their small sample size, differences in inclusion and exclusion criteria, definition of treatment failure, failure to stratify patients by the type and severity of osteomyelitis present, and a short duration of follow-up. The overall failure rate among the 154 evaluable patients in these studies was 22%.

Most experts administer 4-6 wk of intravenous antimicrobial therapy after surgical debridement for the treatment of chronic osteomyelitis. This therapy can be completed as an outpatient in the majority of cases. Data from animal models of osteomyelitis suggest that the addition of rifampin to beta-lactams or vancomycin for osteomyelitis caused by *S aureus* may be beneficial, but confirmation in clinical trials is needed before this practice can be routinely recommended.

The choice of a specific antibiotic depends on the antimicrobial activity, pharmacokinetics, tissue penetration, and potential toxicities of the antimicrobial agents under consideration. Integration of this knowledge with information about drug allergies, current medications, concurrent remote infection, and hepatic and renal insufficiency allows for selection of the optimal antimicrobial agent and dosage. For antimicrobial agents that have potential toxicities at concentrations close to therapeutic concentrations, such as aminoglycosides or vancomycin, the dosage and frequency of administration are guided by measurement of their concentration in serum. Although the cost of an antimicrobial agent is an important consideration, it is secondary to the safety and efficacy of the antibiotic. Suggested antimicrobial agents for specific pathogens that cause osteomyelitis are shown in [Box 14-2](#).

For osteomyelitis caused by susceptible aerobic gram-negative bacilli, some practitioners use initial oral antimicrobial therapy with fluoroquinolones such as ciprofloxacin or levofloxacin or completion of antimicrobial therapy with oral agents after intravenous therapy. Hyperbaric oxygen therapy for chronic osteomyelitis remains controversial.

## **Prognosis**

Despite state-of-the-art medical and surgical therapy for osteomyelitis, relapse of infection occurs. Relapse is more common in cases of chronic osteomyelitis than acute osteomyelitis and can occur in = 25-30% of cases. Relapse of infection is most often caused by suboptimal surgical debridement rather than a failure of antimicrobial therapy. Therefore, it is probably best not to think in terms of a cure for osteomyelitis but prolonged arrest of the disease process.

## Prevention

Specific strategies to prevent osteomyelitis depend on the type of osteomyelitis. Decreasing the incidence of infections that predispose to transient or sustained bacteremia will prevent hematogenous osteomyelitis. Therefore, efforts to reduce the incidence of community- and nosocomially acquired infections such as pneumonia, urinary tract infections and soft-tissue infections through vaccination, infection control measures, and early treatment of established infection will prevent hematogenous osteomyelitis. The incidence of contiguous-focus osteomyelitis can be reduced through efforts such as improved foot care in patients with diabetes mellitus and infection control efforts to reduce the incidence of surgical-site infections after orthopedic and neurosurgical procedures.

## INFECTIOUS ARTHRITIS

### Essentials of Diagnosis

- Monoarticular arthritis of the knee, hip, or shoulder is most typical, but involvement of any joint can occur.
- Risk factors include systemic immune defects, a history of prior joint trauma or arthritis, or both.
- Fever and infection elsewhere in the body are common.
- Arthrocentesis commonly reveals a synovial-fluid leukocyte count of > 100,000/ul with a predominance of polymorphonuclear leukocytes.
- Gout and pseudogout must be excluded.

### General Considerations

Infectious arthritis is an inflammatory disease of a joint ([Figure 14-2](#)). It is usually caused by hematogenous seeding of the joint. Synovial tissue has a rich vascular supply and no basement membrane and therefore is at increased risk of hematogenous infection should bacteremia occur, owing to a focus of infection elsewhere.

**A. Epidemiology.** An estimated 20,000 cases, or 7.8 cases per 100,000 person years, of infectious arthritis occurred in the United States in 1993, of which 56% were male and 45% were = 65 y of age. Host factors that have been associated with an increased risk of acquiring infectious arthritis include systemic immune defects, as seen in patients

with rheumatoid arthritis, diabetes mellitus, and malignancy and local abnormalities of host defenses owing to the presence of prior joint damage, which predisposes the joint to hematogenous infection. In addition, factors that increase the risk of bacteremia, such as intravenous drug use and chronic skin infection, or that allow direct inoculation of microorganisms, such as therapeutic arthrocentesis, predispose to infection. Disseminated gonococcal infection is more common among sexually active menstruating women.

**B. Microbiology.** A multitude of microorganisms can cause infectious arthritis, although bacteria cause the majority of cases in children and adults. Fungi, mycobacteria, *Borrelia burgdorferi*, and viruses, as well as other microorganisms, also cause infectious arthritis and are discussed in their specific chapters. Group B streptococci and gonococci cause = 95% of community-acquired infections in neonates. In children, *S aureus*, *H influenzae*, and streptococci are the major pathogens. The frequency of disease caused by *H influenzae* is decreasing, owing to the use of the *H influenzae* b conjugate vaccine.

In persons 15-40 y of age, 94% of infectious arthritis cases are due to *Neisseria gonorrhoeae*. The most common pathogens among adults are shown in [Box 14-3](#). Infection in patients with rheumatoid arthritis or polyarticular infectious arthritis is caused by *S aureus* in = 90% of patients. Infectious arthritis caused by gram-negative bacilli is more common in the elderly and patients with other comorbid illnesses. Enterococcal or anaerobic infection is uncommon. *P aeruginosa* and *S aureus* are common pathogens among injection drug users. *Mycoplasma* spp. cause infection in patients who are hypogammaglobulinemic.

**C. Pathogenesis.** *S aureus* is the most common cause of joint infection, in part because of its ability to bind to sialoprotein, a glycoprotein found in joints. Direct inoculation of microorganisms caused by trauma, arthrotomy, arthroscopy, or arthrocentesis also occurs. Infection caused by contiguous soft-tissue infection or periarticular osteomyelitis is rare. The presence of bacteria in the synovial tissue results in an influx of polymorphonuclear leukocytes that release enzymes, which destroy the ground substance of the articular surface, erode the cartilage, and eventually narrow the joint space.

## Clinical Findings

**A. Signs and Symptoms.** Acute onset of an inflammatory arthritis of a weight-bearing joint over hours to days is typical. A chronic disease process is more common with infectious arthritis caused by mycobacteria or fungi. The knee, hip, and shoulder are the most commonly involved joints in adults. Infection of the hip or the knee is most common in children. Sacroiliac or sternoclavicular joint infection is common among injection drug users. Polyarticular infection occurs in ~ 10% of patients and is more common among patients with rheumatoid arthritis. Fever is often present but is mild.

Physical examination usually reveals a large effusion and a marked decrease in range of motion of the joint, although these findings may be minimal or absent in patients with rheumatoid arthritis. Tenosynovitis, a macular, vesicular, pustular or petechial rash, and polyarticular involvement are commonly seen with disseminated gonococcal infection,

whereas monoarticular involvement without rash or tenosynovial involvement is common in later stages of the disease.

**B. Laboratory Findings.** The erythrocyte sedimentation rate and leukocyte count are elevated in the majority of cases. The diagnostic procedure of choice is an arthrocentesis. Synovial fluid is often purulent, and the leukocyte count is usually  $> 50,000/\text{mm}^3$  and often  $> 100,000/\text{mm}^3$ , with  $> 75\%$  polymorphonuclear leukocytes. Unfortunately these findings can also be seen in patients with rheumatoid arthritis and crystal deposition arthritis. A low glucose is common but is not specific for infection. The Gram stain will be positive in 35-65% of patients. Synovial fluid should be cultured for both aerobes and anaerobes and other organisms depending on the clinical circumstances. All synovial fluid from adults should be examined for uric acid and calcium pyrophosphate dihydrate crystals. The role of the polymerase chain reaction in detecting bacterial pathogens remains to be defined although the technique seems a promising tool for the detection of infectious arthritis due to *B burgdorferi*. Synovial tissue cultures are indicated only for chronic infectious arthritis when mycobacterial or fungal arthritis is suspected. Blood cultures are positive in  $\approx 30\%$  of all patients and more often in patients with polyarticular involvement. In disseminated gonococcal disease, the blood cultures and/or cultures from the urethra, cervix, rectum, or pharynx are positive whereas synovial fluid cultures are negative. In monoarticular gonococcal arthritis, the synovial fluid cultures are usually positive, and the blood cultures negative.

**C. Imaging.** Periarticular soft-tissue swelling is the most common abnormality seen on plain radiography. Joint space narrowing from cartilage destruction occurs later. It is often difficult to distinguish infection from inflammatory arthritis by using radiographic methods in the setting of rheumatoid arthritis, but the development of a rapid destructive arthritis in one or two joints suggests infection. CT scans and MRI are more useful than radionuclide studies in identifying concomitant periarticular osteomyelitis. Sacroiliac or sternoclavicular joint disease can be evaluated with all three modalities.

## Differential Diagnosis

In adults, the differential of patients with an acute onset of fever, chills, and an inflammatory arthritis of one or more joints revolves around infectious arthritis, gout, pseudogout, rheumatic fever, reactive arthritis, and rheumatic illnesses such as rheumatoid and psoriatic arthritis. In children, as stated previously, concomitant osteomyelitis is common and must be excluded. In addition, a painful hip and fever in a child should raise the possibility of acute transient synovitis of the hip.

## Treatment

The principles in the management of infectious arthritis include drainage of the purulent synovial fluid, debridement of any concomitant periarticular osteomyelitis, and the administration of appropriate parenteral antimicrobial therapy. Experimental models of infectious arthritis suggest that early drainage and antimicrobial therapy prevent cartilage destruction. Local antimicrobial as opposed to systemic therapy is unnecessary. Joint immobilization and elevation are useful for symptomatic relief of pain early in the course of the disease, but early active range-of-motion therapy is beneficial for ultimate functional outcome.

The optimal method of drainage of an infected joint remains controversial, in part because no well-controlled randomized trials exist to guide therapy. Most children, except patients with infectious arthritis of the hip, and patients with gonococcal infection do not require repeated joint aspirations or arthrotomy. Historically, most adults with infectious arthritis have been managed with repeated joint aspirations, not surgical debridement. Arthrotomy has been reserved for cases in which there is failure to improve within 7 d of conservative therapy, inability to adequately drain the infected joint by aspiration either due to location (hip and shoulder) or loculations of purulence within the joint, and longstanding infectious arthritis. The exact role of arthroscopy remains unknown but is an attractive option for the initial therapy of infectious arthritis because of the minimal morbidity of the procedure and its improved ability to adequately drain purulent material from the joint compared with joint aspiration. Randomized trials are urgently needed to evaluate all of these modalities.

The principles of antimicrobial therapy, as well as the drugs of choice and their dosages for specific pathogens that cause infectious arthritis in adults, are the same as for osteomyelitis ([Box 14-2](#)). Most experts, however, recommend 2-4 wk of parenteral antimicrobial therapy for nongonococcal infectious arthritis instead of the usual 4-6 wk recommended for osteomyelitis. Oral antimicrobial therapy with an effective agent with excellent bioavailability, such as ciprofloxacin or cotrimoxazole, is also acceptable particularly if the patient has rapidly improved on intravenous therapy.

Up-to-date treatment guidelines for gonococcal arthritis can be obtained from the CDC but currently include 7-10 d of ceftriaxone (1 g IV daily) or intravenous penicillin (10 million U daily administered continuously or in divided doses) depending on in vitro susceptibility testing. If the patients improve substantially within 72 h, oral antimicrobial therapy with cefixime, ciprofloxacin, or amoxicillin, depending on in vitro susceptibility testing, can be substituted for intravenous therapy. As discussed previously children that are improving can usually be switched to oral antimicrobial therapy within 7-10 d. Compliance with therapy must be assured.

## Prognosis

Patients with infectious arthritis have an estimated case fatality rate of 9%, but, in patients with polyarticular infectious arthritis and rheumatoid arthritis, it is = 56%. Of patients who survive, = 42% will have a permanent loss of joint function. Predictors of morbidity and mortality include older age, the presence of rheumatoid arthritis, infection in the hip or shoulder, > 1-wk duration of symptoms before treatment, involvement of more than four joints, persistently positive cultures after 7 d of appropriate therapy, and the presence of bacteremia.

## Prevention

Infectious arthritis can be prevented in certain patient populations through promotion of efforts by state and national officials to eradicate injection drug use, decrease the incidence of animal bites and nosocomial infections, and promote improved foot care in patients with diabetes mellitus. The routine use of *H influenzae* b conjugate vaccine in children has been shown to decrease the incidence of infectious arthritis caused by this

microorganism.

## PROSTHETIC-JOINT INFECTION

### Essentials of Diagnosis

- Prosthetic-joint infection is most common in the first 2 y after prosthesis implantation.
- Clinical presentation can be one of either an acute infectious arthritis or chronic pain due to prosthesis failure without constitutional symptoms.
- A draining sinus is present in 30-40% of patients.
- Multiple positive cultures either from preoperative joint aspirations or intraoperatively obtained tissue are diagnostic.

### General Considerations

**A. Epidemiology.** The overall rate of prosthetic-joint infection among the ~ 430,000 total hip and knee arthroplasties is highest in the first 6 mo postsurgery and declines thereafter. At the Mayo Clinic, the postoperative incidence rates of total hip and knee arthroplasty during the first year, second year, and after 2 y are ~ 6.5, 3.2, and 1.4 per 1000 joint years, respectively.

Most prosthetic-joint infections occur in immunocompetent hosts. The primary factors predisposing to infection appear to be local abnormalities of host defenses caused by the presence of the foreign body itself. Well-known risk factors for prosthetic-joint infection include prior joint surgery, perioperative wound complications, and rheumatoid arthritis. Other less-well-documented risk factors include diabetes mellitus, the use of steroids, obesity, extreme age, joint dislocation, poor nutrition, distant infection, psoriasis, hemophilia, sickle cell hemoglobinopathy, joint implantation for malignancy, prior infectious arthritis, and the presence of a hinged knee prosthesis.

**B. Microbiology.** The microbiology of prosthetic-joint infection in a large case series is detailed in [Box 14-4](#). A common characteristic among the microorganisms that cause prosthetic-joint infection is their ability to adhere to foreign materials.

**C. Pathogenesis.** The majority of prosthetic-joint infections are acquired in the operating room either through direct inoculation during prosthesis implantation or as a result of airborne contamination of the wound. Hematogenous seeding during a bacteremia or through direct contiguous spread from an adjacent focus of infection also occurs but is much less common.

### Clinical Findings

**A. Signs and Symptoms.** Patients may present with a range of clinical signs and symptoms varying from a syndrome of acute infectious arthritis to a syndrome of chronic pain without constitutional symptoms, which is difficult to distinguish from aseptic loosening of the prosthesis. On physical examination, limitation of the range of motion of

the joint is present, and a draining sinus tract is present in 30-40% of patients. Virulent organisms such as *S aureus* or pyogenic beta-hemolytic streptococci more often cause the acute infectious arthritis syndrome, while infection with less virulent microorganisms such as coagulase-negative staphylococci often follows a more chronic course.

**B. Laboratory Findings.** As for all bone and joint infections, an elevated leukocyte count, erythrocyte sedimentation rate, or C-reactive protein is often present but is not sufficient to definitively make the diagnosis of prosthetic-joint infection. Multiple positive cultures from either a preoperative joint aspiration or an intraoperatively obtained tissue are diagnostic for prosthetic-joint infection. Blood cultures should be obtained if fever is present. In addition the presence of acute inflammation on a frozen section of periprosthetic tissue is an accurate way to identify infection intraoperatively at the time of revision surgery prior to the culture results. Because of the importance of making a microbiologic diagnosis antimicrobial therapy should usually be withheld until all aspirates have been obtained and/or the surgeon has obtained intraoperative cultures from the joint. If antimicrobial therapy has already been started, when possible it should be stopped for 10-14 d before any diagnostic procedure to avoid false-negative culture results. As much fluid for culture as possible should be obtained at the time of diagnostic joint aspiration.

**C. Imaging.** Plain radiographs, arthrograms, and radionuclide imaging are often useful in diagnosing prosthetic-joint infection ([Figure 14-3](#)). Abnormalities that can be seen on plain radiography include loosening of the prosthesis, lucency at the bone-cement interface, and periostitis or other evidence of osteomyelitis. An arthrogram can confirm the presence of a loose prosthesis and often allows for simultaneous aspiration of the joint for culture. The combination of a three-phase <sup>99</sup>Tc bone scan and an indium-labeled leukocyte scan is the most sensitive and specific radionuclide test for the presence of prosthetic-joint infection.

### Differential Diagnosis

When an acute infection occurs or if a draining sinus tract is present, the diagnosis of prosthetic-joint infection is clear. If only chronic pain is present then infection must be distinguished from aseptic loosening.

### Complications

Failure of diagnosis and treatment of prosthetic joint infection may lead to chronic pain, loosening and failure of the prosthesis, loss of limb function, and rarely amputation. Squamous cell carcinoma may rarely complicate a draining sinus tract.

### Treatment & Prognosis

A number of medical and surgical approaches have been described for the treatment of prosthetic-joint infection; however, there are no controlled trials to guide the clinician on which one may be best for the individual patient. The goal of treatment is a pain-free functional joint. Eradication of infection is the most direct method to achieve this goal but may not be possible in certain instances. Basic treatment options include chronic suppressive antimicrobial therapy, surgical debridement with retention of the prosthesis,

resection arthroplasty, arthrodesis, amputation, and one- or two-stage reimplantation.

Long-term eradication of infection can be achieved in between 85% and 95% of cases by removal of the infected prosthesis with or without subsequent staged reimplantation of another prosthesis, followed by 4-6 wk of intravenous antimicrobial therapy directed at the pathogens causing infection. The best functional results occur when another prosthesis can be reimplanted. Specific antimicrobial regimens are similar to those shown in [Box 14-2](#).

If removal of the prosthesis is not feasible, then 4- to 6-wk intravenous antimicrobial therapy is administered after debridement of the prosthesis. This treatment option has been successful in between 50% and 70% percent of patients when the debridement has occurred within 1 mo of prosthesis implantation or within several days of the onset of an acute infection. Overall, however, this technique has a success rate of only 20-30%.

Occasionally chronic suppressive antibiotics may be used. Proposed criteria for the selection of appropriate candidates for chronic antimicrobial suppression include the following: (1) removal of the prosthesis is not feasible; (2) the microorganism is of low virulence and is highly susceptible to orally administered antimicrobial agents; (3) there are no signs of systemic infection; (4) the patient is compliant and tolerant of the antimicrobial agent; and (5) the prosthesis is not already loose.

## Prevention

**A. Perioperative Infection.** The preponderance of evidence in multiple clinical trials favors the use of antimicrobial prophylaxis at the time of joint placement compared with no prophylaxis. Prophylactic antimicrobial agents should be directed against the common organisms that cause postoperative wound infection. Because staphylococci and streptococci are the most common organisms to cause these infections, agents directed against these pathogens, such as penicillinase-resistant penicillins and first-generation cephalosporins, are often used. Recent studies also suggest that antibiotic-impregnated cement may be effective in the prophylaxis of deep wound infection after total joint replacement. Further studies with longer follow-up periods are needed before this practice can be endorsed. The utility of laminar airflow devices in preventing prosthetic-joint infection remains controversial.

**B. Hematogenous Infection.** The majority of hematogenous infections are caused by *S aureus*, coagulase-negative staphylococci, and beta-hemolytic streptococci, presumably from a skin source. Urinary tract and respiratory tract infections have also been implicated as sources of infection. It seems prudent to aggressively diagnose and treat systemic infections in patients with a prosthetic joint, to prevent hematogenous seeding of the prosthesis. Optimal antimicrobial therapy for these infections will depend on the source of infection, in vitro susceptibility of the organism causing infection, and the patient's history of antibiotic allergies.

Antimicrobial prophylaxis is controversial for patients with a prosthetic joint who undergo a dental procedure or invasive procedures such as endoscopy and cystoscopy. Guidelines for this practice have recently been published.

**BOX 14-2. Antibiotic Therapy for Chronic Osteomyelitis in Adults**

<b>Microorganisms</b>	<b>Antibiotic Therapy<sup>1</sup></b>	<b>Alternative Therapy<sup>1</sup></b>
Staphylococcus aureus Methicillin sensitive	<ul style="list-style-type: none"><li>• Nafcillin sodium or oxacillin sodium, 1.5-2.0 g IV every 4 h for 4-6 wk.</li></ul> <p><b>OR</b></p> <ul style="list-style-type: none"><li>• Cefazolin (or other first-generation cephalosporins in equivalent dosages) 1 g IV every 8 h for 4-6 wk (cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin)</li></ul>	Vancomycin, <sup>2</sup> 30 mg/kg divided doses, not to exceed 2 g/24 h unless serum levels are monitored for 4-6 wk
Methicillin resistant	<ul style="list-style-type: none"><li>• Vancomycin,<sup>2</sup> 30 mg/kg IV in 2 equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored for 4-6 wk</li></ul>	Consult infectious disease specialist
Penicillin-sensitive streptococci or pneumococci (MIC, < 0.1 µg/mL)	<ul style="list-style-type: none"><li>• Aqueous crystalline penicillin G, 20 × 10<sup>6</sup> U/24 h IV either continuously or in six equally divided doses for 4-6 wk</li></ul> <p><b>OR</b></p> <ul style="list-style-type: none"><li>• Ceftriaxone, 2 g IV or IM for 4-6 wk<sup>2</sup></li></ul> <p><b>OR</b></p> <ul style="list-style-type: none"><li>• Cefazolin (or other first-generation cephalosporins in equivalent dosages), 1 g IV every 8 h for 4-6 wk (cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin)</li></ul>	<ul style="list-style-type: none"><li>• Vancomycin,<sup>2</sup> 30 mg/kg divided doses, not to exceed 2 g/24 h unless serum levels are monitored for 4-6 wk (vancomycin therapy is preferred for patients allergic to beta-lactams) (immediate-type hypersensitivity to penicillin)</li></ul>
Enterococci or streptococci with an MIC > 0.5 µg/mL or nutritionally variant streptococci (All enterococci causing osteomyelitis must be tested for antimicrobial susceptibility to select optimal therapy.)	<ul style="list-style-type: none"><li>• Aqueous crystalline penicillin G, 20 × 10<sup>6</sup> U/24 IV, either continuously or in six equally divided doses for 4-6 wk,</li></ul> <p><b>OR</b></p> <ul style="list-style-type: none"><li>• Ampicillin sodium, 12 g/24 h IV either continuously or in six equally divided doses (The addition of gentamicin sulfate,<sup>3</sup> 1 mg/kg IV or IM every 8 h for 1-2 wk is optional)</li></ul>	<ul style="list-style-type: none"><li>• Vancomycin,<sup>2</sup> 30 mg/kg divided doses, not to exceed 2 g/24 h unless serum levels are monitored for 4-6 wk (The addition of gentamicin sulfate,<sup>3</sup> 1 mg/kg IV or IM every 8 h for 1-2 wk is optional)</li></ul>

*Enterobacteriaceae* (based on in vitro susceptibility)

• Ceftriaxone, 2 g IV every day for 4-6 wk<sup>2</sup>

• Ciprofloxacin, 500-750 mg IV every day for 4-6 wk

*Pseudomonas aeruginosa* or *Enterobacter* spp.

• Most effective single drug or combination of drugs IV for 4-6 wk

<sup>1</sup>Dosages recommended are for patients with normal renal function. IV, intravenous; IM, intramuscular

<sup>2</sup>Vancomycin therapy is recommended for patients allergic to beta-lactams (immediate-type hypersensitivity). The concentration of vancomycin should be obtained prior to and 1 h after completion of the infusion and should be in the range of 20-40 µg/mL for a peak and 5-10 µg/mL for a trough for twice-daily dosing. Vancomycin should be given for at least 1 h to reduce the risk of the "red man" syndrome.

<sup>3</sup>Serum concentration of gentamicin should be obtained prior to and 30 min after completion of the infusion. The concentration should be in the range of 3-4 µg/mL for a peak and 0.5-1 µg/mL for a trough for synergistic therapy for enterococcal infections. Contraindications to the use of gentamicin are age > 65 y, renal impairment, or impairment of the eighth cranial nerve. Other potentially nephrotoxic agents should be used cautiously in patients receiving gentamicin.

### URETHRITIS

#### Essentials of Diagnosis

- Mucopurulent or purulent urethral discharge and dysuria.
- Gram stain of urethral discharge shows > five leukocytes per high-power field.
- Positive leukocyte esterase test on first-void urine.
- Presence of gram-negative diplococci on stain or culture does not exclude other coinfecting pathogens.

#### General Considerations

Urethritis is the most common sexually transmitted disease (STD) syndrome recognized in men and is frequently seen in women with coinciding cervicitis. Cases can be of two types, gonococcal urethritis and nongonococcal urethritis (NGU), based on the presence or absence of *Neisseria gonorrhoeae*. The two forms are not mutually exclusive. Coinfection with *N gonorrhoeae* and *Chlamydia trachomatis* or *Ureaplasma urealyticum* occurs in 15-25% of heterosexual men with urethritis. NGU that occurs soon after curative therapy for gonorrhea is called postgonococcal urethritis (PGU).

The Centers for Disease Control and Prevention estimates that NGU is 2.5-fold more prevalent than gonococcal urethritis in the United States and much of the developed world. However, gonococcal urethritis accounts for up to 80% of acute urethritis cases in certain underdeveloped regions of the world. Among people of higher socioeconomic status and college students, NGU is more common. In urban STD clinics, gonococcal urethritis is more common.

#### Etiology

[Box 15-1](#) lists causative organisms associated with various forms of urethritis. Noninfectious causes exist but should be considered only after infectious pathogens are excluded.

**A. Gonococcal Urethritis.** *N gonorrhoeae* is a gram-negative intracellular coccus that characteristically grows in pairs (diplococci). Two points deserve special mention. First, over the last 25 years, the prevalence of penicillin- and tetracycline-resistant gonococci has been increasing worldwide, requiring alternative treatment strategies. Second, *N gonorrhoeae* may not be limited to urethritis. Patients may present with coinfection of the cervix, rectum, or pharynx or have symptoms of disseminated infection.

**B. Nongonococcal Urethritis.** *C trachomatis* is the most common pathogen of NGU. It is isolated in 30-50% of patients with NGU. *U urealyticum* is found in 20-25% of cases. The other infectious causes of NGU account for 1-5% of cases and include *Trichomonas vaginalis*, herpes simplex virus (HSV), *Mycoplasma genitalium*, and *Candida* spp. The causes for the remaining 20-30% of NGU cases remain unclear.

*C trachomatis* is an obligate intracellular parasite. It causes > 4 million infections each year. However, a recent multicenter study reported a declining percentage of NGU cases caused by *C trachomatis*, < 25% in some centers. This may reflect the increasing use of faster diagnostic tests, enabling an earlier diagnosis and treatment. The result is a decrease in the reinfection rate and spread of disease.

The role of *U urealyticum* is less clear in NGU. *U urealyticum* may be found in the urethra of many asymptomatic sexually active men and is a common commensal organism in the genital tract of sexually active women. Nevertheless, *U urealyticum* is believed to have a pathogenic role. There is an increased prevalence and concentration of the organism in the urethra of men with NGU compared with those without NGU. Men with NGU and *U urealyticum* isolated from the urethra respond better to antimicrobial agents with antiureaplasma activity than to those without antiureaplasma activity.

The importance of *T vaginalis* as a cause of urethritis has been controversial. A recent study showed the organism to be present in 17% of patients with nonchlamydial NGU in one U.S. series, indicating a more epidemiological association between *T vaginalis* and NGU than previously thought. Furthermore, a favorable symptomatic response of men with trichomonad-positive NGU to metronidazole has been demonstrated.

There has been compelling evidence that *M genitalium* is another cause for urethritis. It is more prevalent in homosexual men and in individuals with persistent and recurrent NGU. Detection is more for epidemiological interest because recurrent urethritis is usually treated with agents that are active against *M genitalium*.

HSV is an uncommon cause of urethritis. When it occurs, it is usually in the setting of primary genital herpes infection. Urethral involvement is less common in recurrent disease.

## Clinical Findings

**A. Signs and Symptoms.** See [Table 15-1](#) for a comparison of the clinical findings associated with gonococcal urethritis and NGU. Distinguishing between them may be difficult. The incubation period for gonococcal urethritis is 2-7 days, after which an acute onset of purulent urethral discharge and dysuria usually develops. Of males with gonococcal urethritis, 5-10% are asymptomatic or have symptoms that are ignored.

The incubation of *C trachomatis* urethritis is longer, between 7 and 21 days. Symptoms of NGU tend to arise less abruptly, and the urethral discharge is less profuse and more mucoid in appearance. Dysuria may be present without urethral discharge. Urinary frequency, hematuria, and urgency are infrequent with either infection.

*Trichomonas* urethritis in men is often asymptomatic, making detection difficult. Acute

symptomatic trichomoniasis in men usually presents with signs and symptoms similar to chlamydial urethritis. Purulent urethritis and prostatitis are unusual.

In HSV urethritis, dysuria is usually more severe, and the urethral discharge may be diffuse and mucoid. There may be regional lymphadenopathy and constitutional symptoms present with primary HSV urethritis. Genital lesions are not always present.

## **B. Laboratory Findings.**

**Examination of the Urethral Discharge.** The diagnosis of urethritis can be made microscopically based on the presence of five or more leukocytes per high-power field in a sample of urethral exudate. The leukocyte esterase test is an alternative screening test for urethritis that can be used on first voided urine samples. It is nonspecific and has a sensitivity of 80%.

The diagnosis of gonococcal urethritis can be made on a stained slide of male urethral exudate if gram-negative diplococci are seen. This finding is present in >95% of symptomatic men with gonococcal urethritis. The presence of gram-negative diplococci, however, does not rule out the possibility of coinfection with NGU organisms.

**Detection of *N gonorrhoeae*.** If the urethral Gram stain is negative for gonococci, a culture should be done. *N gonorrhoeae* is a fastidious organism requiring a selective growth medium in a CO<sub>2</sub>-rich environment. Selective growth media include Thayer-Martin, Martin-Lewis, and New York City media.

Nonculture or rapid diagnostic tests for gonococcal infection include Gonozyne, the Gen-Probe Pace 2 and the ligase chain reaction (LCR). Gonozyne is an enzyme immunoassay that can detect gonococcal antigens within the urethra, cervix, and urine. The Gen-Probe Pace 2 uses nonisotopic probes to detect ribosomal RNA. LCR utilizes a DNA amplification technique to detect trace amounts of organism-specific nucleic acid sequences from urethral and endocervical swab specimens and urine samples.

**Detection of *C trachomatis*.** Cell culture is considered the gold standard for chlamydial testing. It has a sensitivity of 75-80% and a specificity approaching 100%. The addition of an enzyme immunoassay to culture increases the sensitivity to 95%. Cultures are expensive and may require 3-7 days for results.

Nonculture rapid diagnostic tests, including the direct fluorescence antibody (DFA) test, enzyme-linked immunoassay (EIA) test, and DNA probe tests, provide a more prompt diagnosis than culture with roughly an equivalent specificity. The sensitivity is 70-90%. The Gen-Probe Pace 2 and LCR assays detect rRNA and DNA sequences, respectively, of both *N gonorrhoeae* and *C trachomatis*. The sensitivity is higher than that of cell cultures without compromise in specificity.

**Detection of Other Pathogens.** Identification of *U urealyticum* requires culture. Because *U urealyticum* can be isolated in men without urethritis, a positive culture for *U urealyticum* does not necessarily identify the cause of the urethritis.

The gold standard for diagnosing trichomoniasis is isolating the protozoa in culture. A

more rapid and less expensive method is the direct microscopic wet mount examination of urethral discharge. The accuracy of the exam is based on identifying motile protozoa with characteristic morphology. The wet mount exam is routinely used to evaluate women for vaginal trichomoniasis (50-70% sensitive) but is less sensitive with urethral discharge from infected men.

## Differential Diagnosis

Noninfectious causes of urethritis should be considered only after infectious pathogens are excluded. Urethritis caused by Wegener's granulomatosis may be suggested by the findings of upper- or lower-respiratory-tract disease, mucosal ulcerations, cartilaginous destruction, and glomerulonephritis. Stevens-Johnson's syndrome may produce a urethritis associated with characteristic skin and mucosal lesions with systemic toxicity. Prior exposure to certain drugs (eg, sulfonamides, nonsteroidal anti-inflammatory drugs, and phenytoin) is typical. Urethral trauma from instrumentation and indwelling urinary catheters is a frequent cause of urethritis in hospitalized patients. Urethral irritation from renal stones, spermicides, and alcohol can also occur.

## Complications

Disseminated gonorrhea, which occurs in 0.5% of untreated cases of gonococcal infection, presents with fever, arthritis or tenosynovitis, and a skin rash. The rash may be scattered pustular lesions or hemorrhagic necrotic blisters on extensor surfaces of the extremities. Reiter's syndrome is a human leukocyte antigen B27-associated spondyloarthropathy that can follow a genitourinary infection with *C trachomatis*. It is characterized by urethritis, asymmetric oligoarthritis, conjunctivitis, and skin and mucous membrane lesions. Reiter's syndrome can also follow bacterial gastroenteritis caused by *Salmonella*, *Shigella*, *Yersinia*, and *Campylobacter* spp. Epididymitis and urethral strictures secondary to urethritis are rare with treatment. A small proportion of patients may develop conjunctivitis caused by either *N gonorrhoeae* or *C trachomatis*. This is most likely a result of autoinoculation with these organisms from a genital source.

## Treatment

**A. Gonococcal Urethritis.** In 1976, penicillin-resistant gonococci were identified and found to have acquired plasmids encoding for the production of beta-lactamase. Approximately 15% of all gonococci in the United States are now penicillin resistant. In some urban areas, the incidence is as high as 60-75%. In 1985, tetracycline-resistant gonococci were identified and also found to have plasmid-encoded resistance. Tetracycline-resistant gonococci are responsible for up to 15% of gonococcal infections along the eastern coast of the United States. *N gonorrhoeae* with chromosomal mutations conferring penicillin and tetracycline resistance has also been identified. Because of the increasing frequency of penicillin- and tetracycline-resistant gonococci, the penicillins and tetracyclines are no longer recommended by the Centers for Disease Control and Prevention for treatment. Quinolone-resistant gonococci have been identified but are rare in the United States and have not altered current treatment recommendations.

Gonococcal urethritis can be successfully treated with a number of single-dose

regimens ([Box 15-2](#)). Intramuscular ceftriaxone cures nearly 100% of genital infections and is effective for the treatment of gonococcal infection at all sites. Ceftriaxone is also active against incubating syphilis. Oral cefixime is nearly as active against *N gonorrhoeae* and is less expensive.

For the beta-lactam-allergic patient, oral ciprofloxacin or ofloxacin is highly effective. Both are less expensive and better tolerated than ceftriaxone but are contraindicated in pregnancy and for patients under age 18. Patients with disseminated gonococcal infection should be hospitalized for intravenous therapy.

Many patients who experience symptomatic relief after a single-dose treatment for gonococcal urethritis develop a prompt recurrence or persistence of milder symptoms. This syndrome is called postgonococcal urethritis (PGU) and is the result of dual infection of the urethra with *N gonorrhoeae* and organisms of NGU. *N gonorrhoeae* is eradicated by a single dose of the aforementioned cephalosporins and quinolones, but the organisms responsible for NGU are often spared. PGU should be suspected if signs, symptoms, or laboratory evidence of urethritis is found 4-7 days after a single-dose treatment for gonococcal urethritis. Unless chlamydial infection has been specifically ruled out through testing, all patients treated for gonococcal infections should also be treated for chlamydial infection.

**B. Nongonococcal Urethritis.** Empiric therapy is directed against the two most common pathogens, *C trachomatis* and *U urealyticum*. Oral doxycycline has been the traditional drug of choice for NGU. It is highly effective against *C trachomatis* and moderately effective against *U urealyticum*, and it is inexpensive. Azithromycin is a first-line drug that can be administered as a single oral dose. This offers a significant advantage of increased patient compliance, but is more expensive than doxycycline. For acute nongonococcal urethritis in men, single-dose oral azithromycin is as effective as the standard 7-day therapy with doxycycline. Alternative choices include ofloxacin and erythromycin. Ofloxacin remains the only single drug recommended for treatment of both gonococcal and chlamydial infections. Tetracycline/doxycycline-resistant *U urealyticum* exists and is the basis for treating patients with erythromycin who fail standard therapy.

Patients with recurrent or persistent symptoms should be retreated with the initial regimen if noncompliance is suspected; otherwise a wet mount and culture for *T vaginalis* can be done. Treatment of *Trichomonas*-caused urethritis with a single oral dose of metronidazole is usually sufficient.

## Prognosis

In early gonococcal infections, a single course of the appropriate antimicrobial agent is almost always curative. Recurrent disease is more common in NGU; however, patients failing therapy need to be questioned about drug compliance and the possibility of re-exposure to an infected partner. Complications are rare when infectious urethritis is treated early. To prevent reinfection and the spread of disease, patients should avoid sexual contact for 7 days after a single-dose treatment or during a 7-day treatment regimen. Sexual contact should also be avoided until infected partners have been adequately treated.

# CERVICITIS

## Essentials of Diagnosis

- Characterized by purulent or mucopurulent endocervical discharge.
- Gram stain of cervical discharge shows > 10 leukocytes per high-power field.
- Most common in adolescent females.
- Commonly presents without symptoms.
- Abdominal pain and adnexal tenderness may signify pelvic inflammatory disease.

## General Considerations

Cervicitis is the most common STD syndrome in women and is caused primarily by *N gonorrhoeae*, *C trachomatis*, HSV, and human papillomavirus (HPV). It represents an inflammation of the columnar and subepithelium of the endocervix and can involve any contiguous columnar epithelium that lies exposed on the ectocervix. In adolescent girls, the transition zone is frequently everted over part of the ectocervix, thereby increasing the amount of susceptible columnar tissue exposed to a pathogen. This biological circumstance, combined with an increased number of sexual partners without barrier methods of contraception, places adolescent girls at highest risk for cervicitis from an STD pathogen. Interestingly, oral contraceptives cause cervical eversion (ectropion) and may increase the risk of chlamydial infection but have not been shown to increase gonococcal infection.

Even though most of these organisms also cause male urethritis, there is a strong gender bias for infection in women. Male-to-female transmission of infection is more common than female to male.

## Clinical Findings

Infectious cervicitis has often been referred to as the "silent partner" of male urethritis. The lack of well-recognized symptoms and signs of cervical inflammation has largely impeded clinical recognition of sexually transmitted cervical infections.

**A. Signs and Symptoms.** Acute gonococcal cervicitis is characterized by a purulent cervical discharge and cervical edema. Nonspecific symptoms include increased vaginal discharge in approximately one-third of patients, increased menses, dysmenorrhea, dyspareunia, and dysuria. As many as 50 percent of women with gonococcal cervicitis also have gonococcal infection of the urethra, which may explain the urinary-tract symptoms reported by many female patients. Approximately 50% of women with uncomplicated gonococcal cervicitis are asymptomatic and may remain culture positive for 3-6 months after the initial infection.

*C trachomatis* typically causes a mucopurulent cervicitis, but nonspecific abdominal pain

and spotting with intercourse may occur. Cervical abnormalities are often subtle, and only one-third of women note a vaginal discharge that originates from the inflamed cervix. On examination, 20-70% of infected women will have a completely normal appearing cervix.

HSV cervicitis usually presents with a more mucoid, less commonly mucopurulent cervical discharge. Affected patients may complain of lower abdominal pain. The cervix usually appears friable with occasional frank ulcers or necrosis. External genital lesions are usually absent. Inguinal adenopathy is unusual unless accompanied by external genital lesions.

**B. Laboratory Findings.** The presence of cervicitis can be established by a variety of diagnostic procedures, including Gram stain of the endocervical mucus, cervical cytology, colposcopy, and cervical biopsy. The microscopic presence of 10 leukocytes per high-power field supports the diagnosis of mucopurulent cervicitis. Gram-negative intracellular diplococci on a stain of cervical discharge can suggest, but not diagnose, gonococcal cervicitis. Because the presence of commensal *Neisseria* spp. and morphologically similar organisms such as *Haemophilus* spp. decreases the specificity of cervical-discharge Gram stains, a positive stain should be confirmed with a positive culture for *N gonorrhoeae*. The same culture and rapid nonculture diagnostic tests described for urethritis can be used to identify *N gonorrhoeae* and *C trachomatis* in cervical specimens.

The diagnosis of HSV cervicitis can be made cytologically by observing multinucleated giant cells, often with intranuclear inclusions. The diagnosis can be confirmed by isolating the virus in culture or by immunofluorescent staining. Viral isolation will permit the differentiation of HSV-1 from HSV-2. This has prognostic significance because HSV-1 is less likely than HSV-2 to cause recurrent genital herpes.

### **Differential Diagnosis**

Symptoms of dysuria, vaginal discharge, and abdominal pain are not specific for cervicitis. Vulvovaginitis, pelvic inflammatory disease (PID), urethritis, and cystitis may produce a similar clinical picture. A speculum exam and urinalysis are indicated to rule out vaginitis, urethritis, and cystitis. Erythema around the cervical os can indicate infection or merely represent cervical ectropion.

### **Complications**

There are four categories of complications from cervical infections: (a) ascending intraluminal spread of infection producing endometritis, salpingitis, PID, ectopic pregnancies, and infertility; (b) ascending infection during pregnancy, producing premature rupture of the membranes, premature birth, low birth weight, spontaneous abortion, and intrauterine death; (c) initiation or promotion of cervical neoplasia; and (d) perinatal infections acquired during delivery through an infected birth canal, including ophthalmia neonatorum/inclusion conjunctivitis and neonatal herpes.

Gonococcal and chlamydial infections are the most common causes of PID, ectopic pregnancy, and impaired fertility in women. If not adequately treated, 20-40% of women

infected with *C trachomatis* and 10-40% of women infected with *N gonorrhoeae* develop PID. At least 25% of women with PID during their reproductive years develop a related complication, including infertility, ectopic pregnancy, and chronic pelvic pain.

## Treatment

The treatment options for gonococcal and chlamydial cervicitis are the same as those described for infectious urethritis ([Box 15-2](#)). The treatment program should always include activity against both *C trachomatis* and *N gonorrhoeae*. The tetracyclines, including doxycycline, and the quinolones are contraindicated during pregnancy. For pregnant patients, erythromycin (base or ethylsuccinate) or amoxicillin is recommended for anti-Chlamydia therapy. Treatments for HSV and HPV are described later.

## Prognosis

Early treatment of cervicitis is quite effective, usually with prompt resolution of symptoms. As with their male counterparts, women with recurrent disease need to be questioned regarding treatment compliance and reexposure. Asymptomatic disease remains a significant problem. Therefore, screening women is a major element in *Chlamydia* prevention. The recommendations for *Chlamydia* screening in women are listed in [Table 15-2](#). To prevent reinfection and the spread of disease, the same measures should be taken as described for urethritis.

# VULVOVAGINITIS

## Essentials of Diagnosis

- Clinical clues include vaginal discharge, vulvar pruritus, and dyspareunia.
- Microscopic exam with a cover slip can reveal motile trichomonads and clue cells.
- Potassium hydroxide (KOH) preparation enables identification of *Candida* spp. as yeast or pseudohyphae.
- Positive whiff test in trichomoniasis and bacterial vaginosis (BV).
- Vaginal fluid pH is > 4.5 in trichomoniasis and BV.

## General Considerations

The three most common types of vaginal infections in adult women are vulvovaginal candidiasis (20-25%), BV (30-45%), and trichomoniasis (15-20%). Other less common pathogen-related causes include ulcerative vaginitis attributed to *Staphylococcus aureus* toxins in women with toxic shock syndrome, clindamycin-responsive desquamative inflammatory vaginitis, group A streptococcal vaginitis, and idiopathic vulvovaginal ulceration associated with HIV infection.

**A. Vulvovaginal Candidiasis.** An estimated 75% of women experience at least one episode of vulvovaginal candidiasis during their lifetime, and 40-50% will have two or

more episodes. Recurrent vulvovaginal candidiasis is defined as four or more episodes of infection per year and occurs in < 5% of healthy women. The role of vulvovaginal candidiasis as an STD is controversial. *Candida* spp. are among the normal vaginal flora, and vulvovaginal candidiasis can occur in women who have never engaged in sexual activity. Nonsexual predisposing risk factors for the development of vulvovaginal candidiasis include the use of broad-spectrum antibacterial agents, oral contraceptives, corticosteroids, pregnancy, diabetes mellitus, and a decrease in cell-mediated immunity. There is, however, an increase in the frequency of vulvovaginal candidiasis at the time most women begin regular sexual activity. Penile colonization with *Candida* spp. is fourfold more prevalent among male sexual partners of infected women than among other men of the same population. The most common pathogens for vulvovaginal candidiasis include *C. albicans* (accounts for 80-90% of cases), *C. glabrata* (10%), and *C. tropicalis* (5%).

**B. Bacterial Vaginosis.** BV is the most common cause of infectious vaginitis. It signifies a change in the normal vaginal flora characterized by the replacement of hydrogen peroxide-producing lactobacilli with high concentrations of anaerobic bacteria (eg, *Bacteroides* spp., *Mobiluncus* spp., and *Peptostreptococcus* spp.), *Gardnerella vaginalis*, and *Mycoplasma hominis*. The cause of this microbial alteration is not fully understood. Most of these organisms are normally found in low numbers within the healthy vagina. The role of *G. vaginalis* as a pathogen remains unclear, but it may interact synergistically with vaginal anaerobes to produce disease. Sexual transmission of organisms associated with BV has been demonstrated; however transmission alone is not sufficient to cause disease. Additional risk factors for the development of BV include menstruation, poor hygiene, intrauterine devices, and previous pregnancies.

**C. Trichomoniasis.** *T. vaginalis* is a common sexually transmitted pathogen and, unlike *Candida* spp., is closely linked epidemiologically to other STDs. *T. vaginalis* can be identified in 30-40% of the male sexual partners of infected women. Risk factors associated with the acquisition of *T. vaginalis* include sexual activity, pregnancy, and menopause. During menses, blood raises the vaginal pH, which is more suitable for trichomonad replication.

## Clinical Findings

[Table 15-3](#) summarizes the clinical and microscopic findings associated with vaginitis.

**A. Vulvovaginal Candidiasis.** Patients with vulvovaginal candidiasis often report intense perivaginal itching or burning sensations. The vaginal discharge classically has a thick white "cottage cheese" texture that is odorless and adherent to the vaginal walls. If external vaginitis is present, dysuria may be the major complaint. Labial erythema and edema, linear perineal fissures or excoriations, and pustulopapular perineal dermatitis often develop.

A normal vaginal pH (4-4.5) and the microscopic finding of budding yeasts or pseudohyphae on a slide of vaginal discharge with 10% KOH can make the diagnosis. If the KOH is negative and clinical suspicion for candidiasis is high, a culture for *Candida* spp. can be performed.

**B. Bacterial Vaginosis.** Affected women usually complain of a slightly increased malodorous vaginal discharge that is gray-white in color, thin, and homogenous. Pruritus and vulvar inflammation are notably absent. Many women with BV are asymptomatic.

The pH of the vaginal fluid is elevated above 4.5 (usually in the range of 4.7-5.5). A characteristic "fishy" odor is produced when the vaginal fluid is mixed with 10% KOH. This is called a positive "whiff test" and is the result of volatilization of aromatic amines at an alkaline pH. A wet mount or a Gram stain of the vaginal fluid shows vaginal epithelial cells covered with coccobacilli. These characteristic epithelial cells are called "clue cells." Established diagnostic criteria for BV require three of the following four signs: (1) presence of clue cells, (2) homogenous noninflammatory discharge adherent to vaginal walls, (3) vaginal fluid pH > 4.5, and (4) positive whiff test.

**C. Trichomoniasis.** Trichomoniasis generally produces copious amounts of a thin, frothy, green-yellow or gray, malodorous vaginal discharge. Infected women may also complain of vaginal soreness and dyspareunia. However, a large proportion of women carrying trichomonads are asymptomatic.

On examination, the vaginal and exocervical epithelium may have an edematous and erythematous appearance with increased vascularity and petechiae formation. This is often referred to as the "strawberry cervix" of trichomoniasis. The vaginal pH is usually >5.0. The vaginal discharge contains many leukocytes and may elicit an odor when 10% KOH is added (positive whiff test). Confirmation of trichomoniasis is made when motile, pear-shaped trichomonads are seen on the wet mount; however, this occurs in only 50-70% of cases. In patients with an elevated vaginal pH, increased number of leukocytes, and an absence of motile trichomonads or clue cells on the wet mount, a culture for *T vaginalis* can be done to confirm the diagnosis.

### Differential Diagnosis

Toxic shock syndrome with *S aureus* can produce vaginitis along with characteristic symptoms of fever, rash, hypotension, multiorgan abnormalities, and often a polymucositis. Desquamative inflammatory vaginitis may produce prominent cell exfoliation and purulent vaginal discharge with an elevated pH. Patients may respond to clindamycin or corticosteroids.

Noninfectious causes of vaginitis must be distinguished from infectious ones. Atrophic vaginitis commonly affects postmenopausal women and is the result of decreased estrogen levels. There is thinning of the vaginal epithelium, reduced lubrication, an increase in vaginal pH, and an overgrowth of nonacidophilic coliforms. Symptoms include vaginal soreness, dyspareunia, postcoital burning, and occasional vaginal spotting. Treatment consists of topical vaginal estrogen. Other noninfectious causes include chemicals or irritants (eg, spermicides, topical antimycotic drugs, minipads, or topical fluorouracil), contact dermatitis, and collagen vascular disease.

### Complications

PID, plasma cell endometriosis, and posthysterectomy vaginal-cuff cellulitis are the

major complications of BV (see [Chapter 22](#)). In pregnant women, BV is associated with preterm labor, premature rupture of the membranes, chorioamnionitis, and postcesarean and postpartum endometritis. Asymptomatic high-risk pregnant women (eg, prior preterm delivery) should be screened for BV early in the second trimester. Trichomoniasis also may be associated with premature rupture of the membranes and preterm delivery.

## Treatment

**A. Vulvovaginal Candidiasis.** Vulvovaginal candidiasis can be successfully treated with topical antifungal agents in > 80% of cases ([Box 15-3](#)). There are a variety of topical agents, including butoconazole, clotrimazole, miconazole, nystatin, tioconazole, and terconazole. They are applied intravaginally for 1, 3, or 7 days. Fluconazole is the only oral azole to be approved by the FDA for vulvovaginal candidiasis; however, oral ketoconazole is also effective. Non-*albicans* species are less susceptible to fluconazole and may require alternative agents. Treatment of male sexual partners is not necessary unless balanitis is present.

The optimal treatment for recurrent vulvovaginal candidiasis is not yet established. The initial treatment of recurrent vulvovaginal candidiasis is usually the same as for an acute episode. The duration, however, may be extended to 10-14 days, followed by a lower-dose maintenance regimen for 6 months. It is unclear whether the pathogenesis of recurrent infections involves the persistence of risk factors, repeated sexual transmission, an immunologic deficit, or a treatment failure. Treatment failure is not uncommon with *C glabrata*.

**B. Bacterial Vaginosis.** Metronidazole is quite active against vaginal anaerobic bacteria while its hydroxy-metabolite is moderately active against *G vaginalis*. Although the 7-day regimen has a slightly higher cure rate (> 90%), patient compliance may be greater with the single, higher-dose format. Clindamycin is an alternative oral treatment. Effective topical formulations include 2% clindamycin vaginal cream and 0.75% metronidazole vaginal gel. Routine treatment of male sexual partners has not been shown to improve cure rates. Symptomatic women in the first trimester of pregnancy should use oral clindamycin.

If BV is discovered during screening of asymptomatic pregnant women, treatment should be given at the beginning of the second trimester with metronidazole or clindamycin. If treatment must be given during the first trimester, clindamycin is recommended. Although there is concern for the effects of metronidazole to the unborn fetus, evidence of definitive teratogenicity remains unclear and is considered minimal after the first trimester. The treatment of high-risk pregnant women may reduce preterm delivery.

**C. Trichomoniasis.** The treatment of choice for trichomoniasis is metronidazole. Similar cure rates are obtained with the 7-day regimen (cure rate 85-90%) compared with the single, higher-dose format (82-88%). Male sexual partners of infected women should also be treated. Pregnant patients can be treated with metronidazole after the first trimester.

## Prognosis

Although not usually considered as a life-threatening disease, the symptoms of vaginitis can be severe and recurrent disease problematic. Screening during pregnancy can help lower BV and *Trichomonas*-associated maternal and neonatal complications.

## GENITAL ULCER DISEASE

### Essentials of Diagnosis

- Syphilis: Average incubation period 21 days, painless ulcer (chancre), nontender, nonfluctuant adenopathy.
- Chancroid: Incubation period 2-7 days, painful ulcers, fluctuant adenopathy.
- Genital herpes: Incubation period 2-7 days, multiple vesicles, painful ulcers, can be recurrent.
- Lymphogranuloma venereum (LGV): Variable incubation period, characteristic "groove sign," fluctuant buboes can rupture.
- Donovanosis: Variable incubation period, painless ulcers, scar formation.

### General Considerations

Genital ulcer disease involves a disruption of the skin and mucous membranes of the genitalia and often is the presenting complaint of a sexually acquired infection. *Treponema pallidum* is the spirochete responsible for all stages of syphilis. It is the second most common cause of genital ulcer disease in both underdeveloped and developed countries, although it is more common in the latter. *Haemophilus ducreyi*, a gram-negative bacillus, is the organism responsible for chancroid. The disease is most prevalent in Africa and developing countries; however, a number of outbreaks have occurred in New Orleans and other large cities along the Gulf Coast. Genital herpes is the most common cause of genital ulcer disease in North America and Europe. It is an incurable and recurrent disease affecting an estimated 5 million-20 million Americans. Of all first-episode genital herpes lesions, 85% are produced by HSV-2 and the remaining 15% by HSV-1 (see [Chapter 33](#)). Recurrent infections are much more common with HSV-2. Sexual transmission of HSV can occur during asymptomatic periods. LGV is a chlamydial infection caused by the highly invasive L1, L2, and L3 serovars of *C trachomatis*. LGV is endemic in Africa, India, Southeast Asia, South America, and the Caribbean. Donovanosis is an ulcerative disease caused by the gram-negative bacillus *Calymmatobacterium granulomatosis*. Other names for this disorder include granuloma inguinale, granuloma venereum, granuloma donovani, chronic venereal sore, and granuloma inguinale tropicum. Although rare in the United States, donovanosis is a common cause of genital ulceration in southeastern India, New Guinea, the Caribbean, and parts of South America.

### Clinical Findings

[Table 15-4](#) summarizes the clinical findings associated with genital ulcer disease.

### A. Signs and Symptoms.

**Primary Syphilis.** After an incubation period of ~21 days (range 3-90 days), a painless ulcer appears at the site of inoculation. This ulcer is called a chancre and is the hallmark of primary syphilis. Typically a solitary chancre exists, but multiple chancres may be present in HIV patients. The base of the chancre is usually clean and the borders smooth. The most common locations include the glans penis, frenulum, and penile shaft in men and the labia, vagina, and cervix in women. Extragenital locations for chancres include the perianal region (especially in homosexual men), oral mucosa, and pharynx. Unilateral or bilateral adenopathy usually develops after the chancre. The adenopathy is firm, nontender, and never fluctuant.

**Chancroid.** After a short incubation period of 2-7 days, one to three (or more) painful ulcers appear in the genital region. The ulcer base is typically necrotic and purulent with ragged undermined borders. The lesion is not indurated and has historically been called the "soft chancre." Painful inguinal lymphadenopathy is much more common in men (> 50%) than in women. It is usually unilateral but occasionally can be bilateral. The lymph nodes can enlarge and become fluctuant. Although the findings of a painful ulcer and tender inguinal adenopathy are suggestive of chancroid, the addition of suppurative adenopathy is almost pathognomonic.

**Genital Herpes.** Genital herpes also has a short incubation period of ~2-7 days. The characteristic lesions are multiple vesicles on an erythematous base. In women, these lesions frequently involve the labia minora and majora, cervix, and occasionally the vagina. In men, the glans and shaft of the penis are common sites. Homosexual men may manifest herpetic lesions over the perianal area. Several days after the appearance of the vesicles, they rupture, creating shallow, intensely painful ulcers that subsequently become crusted. Urethritis may occasionally develop.

Primary genital herpes is the initial infection by HSV in a patient without anti-HSV antibodies. It may be preceded by constitutional symptoms of low-grade fever, chills, headache, malaise, and myalgia. These symptoms are likely related to a transient viremia and usually subside after 1 week. More localized symptoms then develop, including genital pain, itching, dysuria, and tender adenopathy. Localized paresthesia may develop in the outbreak site 24-48 h before the appearance of the vesicles. The skin lesions of primary genital herpes generally last 2-3 weeks. Nonprimary, first-episode genital herpes refers to patients previously infected with HSV, who have developed antibodies to HSV. The symptoms are usually milder, and the disease course shorter than in primary genital herpes. Systemic symptoms are generally absent. Recurrent genital herpes is a local disease without systemic symptoms and has a significantly milder presentation and shorter course than primary or nonprimary, first-episode genital herpes. These lesions generally resolve in 1 week.

**Lymphogranuloma Venereum.** Clinically, there are distinct stages of LGV. The first stage is marked by the formation of a primary genital skin or mucosal lesion in the form of a papule or herpetiform ulcer. It usually develops between 3 days and 3 weeks (up to 6 months) after exposure. It is painless and transient, and it heals rapidly without

scarring. It is often unnoticed. The second stage is characterized by enlarged painful lymphadenopathy, which is unilateral in two-thirds of cases. This often is the presenting complaint of LGV and usually develops 2-6 weeks after exposure. Enlargement of nodes above and below the inguinal ligament produces the characteristic "groove sign." It is pathognomonic for LGV and occurs in approximately one-third of cases. Lymph nodes may become fluctuant (buboes) and can spontaneously rupture, forming loculated abscesses, fistulas, or sinus tracts. Approximately one-third of inguinal buboes become fluctuant and rupture, whereas the other two-thirds involute over time to form a hard inguinal mass without suppuration. Systemic symptoms may include fever, chills, myalgia, and arthralgia.

**Donovanosis.** After a variable incubation period of 3-180 days, a small painless papule or nodule forms. It later erodes to form a beefy red, granulomatous ulcer. There are clinical variants of donovanosis classified by the appearance of the primary lesion: (1) ulcerative and ulcerogranulomatous, (2) hypertrophic or verrucous, (3) necrotic, and (4) sclerotic or cicatricial. Multiple lesions may coalesce to form large painless ulcers. Eventual healing occurs with scar formation. Classic buboes are absent in donovanosis.

## **B. Laboratory Findings.**

**Primary Syphilis.** An immediate diagnosis of primary syphilis can be made by identifying the corkscrew appearance of *T pallidum* on dark-field microscopy. A negative result on dark-field microscopy does not rule out primary syphilis. Nontreponemal serologic tests such as VDRL (Venereal Disease Research Laboratory) and RPR (Rapid Plasma Reagin) have a sensitivity in primary syphilis of 59-87% and can be falsely nonreactive. Nontreponemal titers usually correlate with disease activity and should become nonreactive after treatment. Specific treponemal tests such as the FTA-ABS (Fluorescent Treponemal Antibody Absorption Test) and the MHA-TP (Microhemagglutination—*Treponema pallidum*) are more specific serologic tests and usually remain positive indefinitely. Nontreponemal and treponemal tests should be interpreted together.

**Chancroid.** Because of the technical difficulty and specialized media required by *H ducreyi* for growth in the laboratory, the diagnosis of chancroid is made more frequently on clinical grounds. Culture media containing supplemented agar and vancomycin in a CO<sub>2</sub>-enriched atmosphere can successfully be used to grow *H ducreyi*. If confirmation by culture is not possible, then a clinical diagnosis of chancroid should be made and treatment begun only after genital herpes and primary syphilis have been excluded.

**Genital Herpes.** A Tzank smear of tissue scraped from a herpetic lesion can reveal the characteristic multinucleated giant cells of HSV infection. Viral culture has been the standard and most specific test for genital herpes, but requires 1-3 days for a result. Rapid nonculture techniques such as immunofluorescent staining and the enzyme-linked immunosorbent assay have become more widely used but are more expensive.

**Lymphogranuloma Venereum.** The isolation of *C trachomatis* from an inguinal lymph node aspirate is the most definitive test for the diagnosis of LGV. However, the recovery of *Chlamydia* spp. by this method is < 30%. Serologic testing is an alternative diagnostic

method.

**Donovanosis.** The diagnosis of donovanosis is usually made clinically based on the history and exam findings on a patient with recent sexual contact in an endemic part of the world. The diagnosis can be confirmed by demonstration of the typical intracellular "Donovan Bodies" in a Giemsa or Wright's stain of crushed tissue smears or biopsy specimens. Routine culturing and serologic tests are not widely available.

### Differential Diagnosis

Any genital ulcer pathogen can produce a "textbook picture" of another pathogen. A complete patient history (including travel), examination for other lesions or adenopathy, and laboratory testing are essential for an accurate diagnosis. Acute ulcers restricted to the genital area in sexually active patients strongly suggest a sexually transmitted pathogen or possibly trauma secondary to coitus. Ulcers involving both the genital and nongenital areas suggest a noninfectious process such as Behcet's disease, dermatitis herpetiformis, erythema multiforme or Stevens-Johnson syndrome, pemphigus, pemphigoid, fixed drug eruption, contact dermatitis, or squamous cell carcinoma. Fellatio can result in the simultaneous presentation of oral and genital lesions, such as HSV and syphilis. In tropical endemic regions, additional considerations include filariasis, cutaneous leishmaniasis, amebiasis, and schistosomiasis.

### Complications

All genital ulcers are prone to secondary bacterial infections with a variety of genital bacteria. Additionally, edema of the foreskin in uncircumcised men may produce phimosis. Without treatment, chancres of primary syphilis and lesions of genital herpes heal spontaneously. Patients with syphilis progress into the secondary stage, whereas those with genital herpes may later experience recurrence of their lesions. The ulcers of chancroid and LGV continue to grow slowly by local extension and can produce further tissue and organ damage. LGV may further lead to perianal abscesses and rectovaginal, rectovesical, and anal fistulas and strictures. Lymphatic obstruction and edema may occur. Rectal LGV is associated with an increased incidence of rectal cancer. Complications of donovanosis scarring include urethral, vaginal, and anal strictures and lymphedema of the external genitalia.

### Treatment

**Primary Syphilis.** Penicillin remains the treatment of choice for any stage of syphilis ([Box 15-4](#)). For early syphilis (primary, secondary, and latent syphilis of < 1 year's duration), a single intramuscular dose of benzathine penicillin G is recommended. Some authorities, however, recommend giving two or three doses 1 week apart, especially in the immunocompromised patient. For the penicillin-allergic patient, doxycycline or tetracycline may be used. Patients intolerant to the tetracyclines can use erythromycin or intramuscular ceftriaxone, although treatment failures and lack of clinical experience, respectively, have limited their use. Because *T pallidum* has been isolated in the cerebrospinal fluid in patients with only a chancre, a lumbar puncture with cerebral spinal fluid exam should be performed in primary or secondary syphilis if there are signs or symptoms of neurologic involvement (ophthalmic and/or auditory symptoms or cranial

nerve palsies) or treatment failures.

**Chancroid.** A single dose of intramuscular ceftriaxone or oral azithromycin or 7 days of erythromycin are recommended first-line treatments. Some HIV-positive patients require a more prolonged therapy than the single-dose formats. For these patients, the 7-day erythromycin regimen is preferred. Alternative therapies include amoxicillin/clavulanic acid or ciprofloxacin. Fluctuant adenopathy may require needle aspiration or drainage. Symptomatic improvement should occur within days, but complete healing of ulcers may require up to 1 month.

**Genital Herpes.** Uncomplicated genital herpes will heal spontaneously. Treatment is available to decrease viral shedding and shorten the duration of disease. For first-episode genital herpes, oral acyclovir, valacyclovir, or famciclovir is recommended for 10 days. For recurrent disease, any one of these regimens can be given for an additional 5 days. For immunocompromised patients, including HIV-positive patients, acyclovir should be given until clinical resolution. Suppressing therapy is recommended for patients with severe and frequent recurrent episodes of genital herpes. Acyclovir can be given for up to a year, after which a 1- or 2-month "drug-free" interval is recommended to assess recurrence rate. Valacyclovir or famciclovir can be used as an alternative agent for suppressive therapy.

**Lymphogranuloma Venereum.** The treatment of choice for LGV has been doxycycline or tetracycline. Alternative agents include erythromycin and sulfisoxazole. Fluctuant lymph nodes should be drained by needle aspiration to prevent rupture and sinus tract formation.

**Donovanosis.** There has been no general consensus regarding the optimal treatment of donovanosis because of the lack of controlled studies. Recommended oral treatments include doxycycline, tetracycline, or trimethoprim-sulfamethoxazole for at least 3 weeks or until visible healing has occurred. Alternative oral agents include ciprofloxacin and erythromycin base. The addition of an aminoglycoside should be considered if the lesions do not respond within the first few days of therapy.

## **Prognosis**

The individual and societal impact of genital-ulcer disease depends on timely recognition and treatment of disease. Acknowledging the frequency of coinfecting pathogens and the increased risk of HIV transmission maximizes the potential for individual cure and regional containment.

## **OTHER SEXUALLY TRANSMITTED DISEASES**

### **SKIN & MUCOUS MEMBRANE DISEASES**

#### **1. HUMAN PAPILLOMAVIRUS**

There are > 70 different HPV genotypes based on differences within the DNA structure. HPV types 6 and 11 cause condyloma acuminatum (anogenital warts), the most common viral STD in the United States, which is rarely associated with cervical

dysplasia. HPV types 16, 18, 31, 33, and 35 cause cervical infection, which is present in ~20% of reproductive-age women in the United States. Cervical infection is the most common source of squamous cell abnormalities on Pap smears and has a direct oncogenic association with cervical cancer.

Diagnosis is usually based on visual identification of genital warts, cytologic examination of scraped cervical cells, or cervical biopsy. Treatment options for genital warts include podofilox 0.5% solution, cryotherapy, podophyllin resin 10-25%, trichloro- acetic acid or bichloroacetic acid 80-90%, intralesional interferon, laser surgery, and surgical removal. Treatment of cervical HPV infection should be conducted through an expert to exclude high-grade squamous intraepithelial lesions.

## **2. MOLLUSCUM CONTAGIOSUM**

Molluscum contagiosum is a benign disease caused by a virus of the Poxviridae family. It is spread by close human contact, including sexual contact. There are classically 2- to 10-mm domed-shaped papules, often with a central depression (umbilication). They may occur anywhere on the body except the palms and are often grouped. In HIV infected patients, the infection is often generalized with skin lesions appearing on the face and upper body. The diagnosis is usually made clinically but can be confirmed with histopathologic examination. Local treatment includes curettage or cryotherapy. There is no systemic therapy available.

## **PELVIC INFLAMMATORY DISEASE**

PID includes endometriosis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. When PID develops as a complication of cervicitis, *N gonorrhoeae* and *C trachomatis* are the pathogens primarily responsible. Symptoms of PID include abnormal cervical or vaginal discharge, abdominal pain, and fever. On exam there may be cervical motion and adnexal and lower abdominal tenderness. It is important to diagnose and treat PID as early as possible. For patients requiring hospitalization, intravenous cefoxitin or cefotetan plus doxycycline (IV or oral) can be given ([Box 15-5](#)). Alternatively, intravenous clindamycin plus gentamicin can be given, followed by oral doxycycline. Outpatient treatments include oral ofloxacin plus metronidazole or ceftriaxone (or cefoxitin and oral probenecid) plus oral doxycycline. Duration of intravenous treatment is dependent on the severity of the clinical presentation.

## **EPIDIDYMITIS**

In men under age 35, the most common pathogens are *N gonorrhoeae* and *C trachomatis*. Homosexual men may have enteric pathogens from rectal intercourse. Unilateral testicular pain and tenderness are common. There is usually palpable swelling of the epididymis. The evaluation and diagnostic tests are the same as those for urethritis. Treatment regimens include ceftriaxone plus doxycycline or ofloxacin ([Box 15-5](#)).

## **PROCTITIS**

### **Introduction**

Proctitis acquired through receptive anal intercourse can be caused by *N gonorrhoeae*, *C trachomatis* (including LGV serovars), *T pallidum* (syphilis), and HSV. Treatment includes ceftriaxone plus doxycycline ([Box 15-5](#)).

## Prevention

STDs collectively rank as one of the most common groups of diseases throughout the world. There are ~150 million-300 million curable cases of STDs per year with 5 million-12 million cases in North America alone. The most significant global problem in STD management today is not one of treatment, but one of prevention. No single STD can be regarded as an isolated problem. The presence of an STD identifies high-risk behavior through which multiple infections, including HIV, can occur. The primary-care physician has a significant opportunity to not only rapidly diagnose and treat STDs, but also to reduce the risks of reinfection to the patient and spread of disease within a community.

STD prevention begins with the identification of high-risk patients by taking a sexual history. A risk factor assessment includes the patient's age during the first sexual encounter and first STD, number of previous STDs, number of partners, risk assessment of those partners, type of contraception used (if any), and future plans for sexual activity. Once the risk factors are identified, the educational process can begin.

Patient education is the most significant preventative measure against STDs. The goal is to educate patients about methods and behaviors that can reduce the potential for STD transmission. Male condoms, when used correctly, are the most effective method in preventing infections transmitted between mucosal surfaces and transmission of HIV disease. Condoms do not cover all exposed skin areas and may be less effective in preventing infections transmitted through skin-to-skin contact. Female condoms also serve as an effective mechanical barrier to prevent the transmission of infection. Diaphragms do offer protection against gonococcal and chlamydial cervicitis and trichomoniasis; however, they should not be assumed to protect against HIV infection. Vaginal spermicides may reduce the risk of gonococcal and chlamydial infections, but they offer minimal to no protection against HIV infection. Although nonbarrier contraceptive measures such as hormonal supplements, surgical sterilization, and hysterectomy prevent pregnancy, they offer no protection against HIV or other STDs.

Sexual contacts of infected patients must be evaluated. Partner identification enables the treatment of persons who may be infected but are asymptomatic. Not only will early diagnosis and treatment prevent the serious, long-term complications of STDs, but it will also help reduce the spread of disease within a community.

As stated earlier, all patients with an STD should be evaluated for other STDs. The presence of one pathogen doesn't eliminate the possibility of other coinfecting pathogens or an earlier untreated infection with a different pathogen. The physician must balance a high index of suspicion with screening programs to diagnose STDs as early as possible and to break the chain of STD transmission.

<sup>1</sup>The fluoroquinolones should not be used during pregnancy or in patients under age 18.

<sup>2</sup>Spectinomycin, once widely used for the treatment of gonorrhea, has the disadvantages of higher cost, intramuscular injection, and lack of sustained high-serum bactericidal levels.

<sup>3</sup>Ceftizoxime and cefuroxime are well tolerated but less active.

<sup>4</sup>Doxycycline should not be used during pregnancy.

<sup>5</sup>Metronidazole should not be given during the first trimester of pregnancy. Metronidazole may cause a disulfiram-like reaction with alcohol.

### BOX 15-3. Treatment of Infectious Vaginitis

#### Syndrome/ Microorganism

#### Microorganism

#### Vulvovaginal Candidiasis

#### First Choice

#### Intravaginal agents<sup>1</sup>:

- Butoconazole, 2% cream 5 g<sup>a</sup> intravaginally for 3 days
- Clotrimazole, 1% cream 5 g intravaginally for 7-14 days<sup>2,3</sup>
- Clotrimazole, 100-mg vaginal tablet for 7 days,<sup>2</sup> or two 100-mg tablets for 3 days,<sup>2</sup> or 500-mg vaginal tablet in a single application
- Miconazole, 2% cream 5 g intravaginally for 7 days<sup>2,3</sup>
- Miconazole, 200-mg vaginal suppository for 3 days<sup>2</sup> or 100-mg suppository for 7 days<sup>2</sup>
- Nystatin, 100,000 U vaginal tablet, one tablet for 7-14 days
- Tioconazole, 6.5% ointment 5 g in a single application<sup>2,3</sup>
- Terconazole, 0.4% cream 5 g intravaginally for 7 days<sup>2</sup> or 0.8% cream 5 g for 3 days<sup>2</sup>
- Terconazole, 80 mg vaginal suppository for 3 days<sup>2</sup>

#### Oral agents:

- Fluconazole, 150-mg oral tablet once

#### Bacterial Vaginosis

- Metronidazole, 500 mg orally twice daily for 7 days
- Clindamycin cream, 2% 5 g intravaginally for 7 days
- Metronidazole gel, 0.75% 5 g twice daily for 7 days

#### Trichomoniasis

- Metronidazole, 2 g orally once

#### Alternative Choice

#### Systemic agents

- Fluconazole, 150-mg oral tablet once
- Ketoconazole, 200 mg orally for 5-7 days or 400 mg orally for 3 days
- Itraconazole, 400 mg orally once, then 200 mg orally for 2 more days

- Metronidazole, 2 g orally once
- Clindamycin 300 mg orally twice daily for 7 days

- Metronidazole 500 mg twice daily for 7 days

<sup>1</sup>Topical azole regimens should be used to treat pregnant women. Many experts recommend treating for 7 days during pregnancy.

<sup>2</sup>Available over the counter.

<sup>3</sup>These creams and suppositories are oil based and may weaken latex condoms and diaphragms.

---

## BOX 15-4. Treatment of Genital Ulcer Disease

### Syndrome/ Microorganism

#### Primary Syphilis

#### First Choice

- Benzathine penicillin G, 2.4 million units once
- Tetracycline, 500 mg orally four times daily for 2 weeks<sup>1</sup>
- Erythromycin, 500 mg orally four times daily for 2 weeks<sup>2</sup>
- Ceftriaxone, 250 mg IV daily or 1 g IV every other day for 8-10 days<sup>1,2</sup>

#### Alternative Choice

- Doxycycline, 100 mg orally four times daily for 2 weeks<sup>1</sup>

#### Chancroid

- Ceftriaxone, 250 mg IM once
- Azithromycin, 1 g orally once
- Erythromycin, 500 mg orally four times daily for 7 days

- Ciprofloxacin, 500 mg orally twice daily for 3 days<sup>3</sup>
- Amoxicillin/clavulanic acid, 500 mg/125 mg orally three times daily for 7 days

#### Genital Herpes

##### First episode

- Acyclovir, 200 mg orally five times daily or 400 mg orally three times daily for 10 days<sup>4</sup>
  - Valacyclovir, 1 g orally twice daily for 10 days
  - Famciclovir, 250 mg orally three times daily for 10 days
- Any of the first line agents

##### Recurrent disease

- Acyclovir, 200 mg orally five times daily or 400 mg orally three times daily or 800 mg orally twice daily for 5 days
  - Valacyclovir, 500 mg orally twice daily for 5 days
  - Famciclovir, 125 mg orally twice daily for 5 days
- Any of the first line agents

##### Suppressive therapy

- Acyclovir, 400 mg orally twice daily for year(s)
- Famciclovir 250 mg orally twice daily

- Valacyclovir 500 mg orally twice daily

##### HIV/immunosuppressed patients

- Acyclovir, 400 mg orally three to five times daily until clinical resolution

- Famciclovir, 500 mg orally three times daily
- Valacyclovir<sup>5</sup>

##### Severe disease

- Acyclovir, 5-10 mg/kg IV every 8 h for 5-7 days

**Lymphogranuloma  
Venereum**

- Doxycycline, 100 mg orally twice daily for 21 days
- Tetracycline, 500 mg orally four times daily for 21 days
- Sulfisoxazole, 500 mg orally four times daily for 21 days

- Erythromycin, 500 mg orally four times daily for 21 days
- Azithromycin, 1 g orally for 3 weeks

**Donovanosis**

- Trimethoprim-sulfamethoxazole, DS orally twice daily for a minimum of 3 weeks
- Doxycycline, 100 mg orally twice daily for a minimum of 3 weeks
- Tetracycline, 500 mg orally four times daily for a minimum of 3 weeks<sup>1</sup>

- Ciprofloxacin, 750 mg orally twice daily for 21 days
- Erythromycin, 500 mg orally four times daily for 21 days

<sup>1</sup>The tetracyclines should not be used during pregnancy.

<sup>2</sup>Treatment failures reported with oral erythromycin and ceftriaxone.

<sup>3</sup>The fluoroquinolones should not be used during pregnancy or in patients under age 18.

<sup>4</sup>Current data suggest no increased risk for major birth defects after acyclovir treatment. Indications for acyclovir use during pregnancy include first episode of genital herpes and life threatening maternal infection (eg, encephalitis, disseminated disease, pneumonia, and hepatitis). There is insufficient data regarding the safety of valacyclovir and famciclovir during pregnancy.

<sup>5</sup>In immunocompromised patients, valacyclovir in doses of 8 g per day has been associated with a syndrome resembling hemolytic uremic syndrome or thrombotic thrombocytopenic purpura. However, in the doses recommended for treatment of genital herpes, valacyclovir is probably safe for use in immunocompromised patients.

## BOX 15-5. Treatment of other Sexually Transmitted Diseases

### Syndrome/ Microorganism

#### First Choice

#### Alternate Choice

### Pelvic Inflammatory Disease

Parenteral Regimen<sup>1</sup>  
• Cefoxitin, 2 g IV every 6 h or cefotetan, 2 g IV every 12 h **PLUS** doxycycline, 100 mg IV or orally every 12 h

Parenteral Regimen<sup>2</sup>  
• Clindamycin, 900 mg IV every 8 h **PLUS** gentamicin, 2 mg/kg IV loading dose followed by 1.5 mg/kg IV every 8 hours<sup>3,4</sup>

Oral Regimen  
• Ofloxacin, 400 mg orally twice daily for 14 days **PLUS** metronidazole, 500 mg orally twice daily for 14 days

Oral/Combined Regimen  
• Ceftriaxone, 250 mg IM once or cefoxitin, 2 g IM with probenecid 1 g orally once **PLUS** doxycycline 100 mg orally twice daily for 14 days

### Epididymitis

• Ceftriaxone, 250 mg IM once **PLUS** doxycycline, 100 mg orally twice daily for 10 days

• Ofloxacin, 300 mg orally twice daily for 10 days

### Proctitis

• Ceftriaxone, 125 mg IM once **PLUS** doxycycline 100 mg orally twice daily for 10 days

<sup>1</sup>Parenteral regimens should be continued for at least 24 hours after clinical improvement; doxycycline should be continued for 14 days.

<sup>2</sup>Additional alternative parenteral regimens include ofloxacin plus metronidazole; ampicillin/sulbactam plus doxycycline; ciprofloxacin plus doxycycline plus metronidazole.

<sup>3</sup>Single daily dosing of gentamicin may be substituted.

<sup>4</sup>Parenteral therapy with clindamycin and gentamicin should be followed by oral doxycycline or oral clindamycin if tubo-ovarian abscess is present, to complete 14 days of therapy.

## **16 . Urinary Tract Infections — *Walter R. Wilson, MD & Nancy K. Henry, PhD, MD***

### **COMMUNITY-ACQUIRED URINARY TRACT INFECTIONS**

#### **Essentials of Diagnosis**

##### **Acute Cystitis-Urethritis.**

- Women and girls older than 2 years.
- Acute onset dysuria, increased frequency urination.
- Pyuria = 5-10 erythrocytes/high-power field of centrifuged urine or positive leukocyte esterase test.
- Positive urine culture (1000-100,000 colony forming units/mL) for *Escherichia coli*, other *Enterobacteriaceae*, enterococci, or *Staphylococcus saprophyticus*.

##### **Acute Pyelonephritis.**

- Fever, chills, flank pain.
- Pyuria.
- Positive urine Gram stain for gram-negative bacilli.
- Positive urine culture (= 100,000 colony forming units) or blood culture with gram-negative bacilli.

##### **Acute Prostatitis (subjects older than age 35).**

- Fever, chills, dysuria, increased frequency of urination, low back or pelvic pain.
- Pyuria.
- Positive urine culture for gram-negative bacilli or enterococci.

##### **Chronic Prostatitis.**

- Middle-aged to elderly men.
- Chronic intermittent dysuria, increased frequency of urination, pelvic pain.
- Enlarged prostate.

- Positive culture of prostatic secretions or voided urine after massage for gram-negative bacilli or enterococci. The number of colony forming units of bacteria should be 10-fold greater than the number in urine obtained before prostatic massage.

## General Considerations

Infections involving the urinary tract are among the most common infectious diseases. Bacteriuria is defined as bacteria present in the urine. Bacteriuria may be asymptomatic or may be present in association with acute or chronic infection of the kidney, bladder, prostate, or urethra. Acute cystitis-urethritis is a syndrome consisting of dysuria, urgency, and increased frequency of urination with or without upper tract infection. Acute pyelonephritis is an infection of the kidneys and is described as a syndrome of fever and flank pain with or without dysuria. The term acute prostatitis describes a syndrome of fever, perineal and low-back pain, dysuria, urgency, and increased frequency of urination. Chronic urinary tract infection (UTI) refers to persistence or frequent reinfection of the kidney, bladder, or prostate.

### A. Epidemiology.

**1. Children.** During infancy, the frequency of bacteriuria is 1-2% and is more common in boys during the first 3 months; thereafter, it is more common in girls. Lack of circumcision increases the risk of UTI in infant males. Among preschool children, bacteriuria is more common in females than in males, and, when present in males, bacteriuria is usually associated with congenital abnormalities. The prevalence of bacteriuria among school girls is 1-2%, and = 5% have bacteriuria before finishing high school. Of these girls, ~ 3% develop symptomatic UTI. School girls with bacteriuria are at greater risk of developing bacteriuria in adulthood. Bacteriuria is rare among school boys, and, when present, it is associated with structural abnormalities.

**2. Adults.** Prevalence of bacteriuria in nonpregnant females is 1-3%. At least 10-25% of females develop symptomatic UTI during their lifetimes. The risk of subsequent UTIs is greater than the risk of the initial UTI. The prevalence of bacteriuria among adult men is low (< 0.1%) and is associated with anatomic abnormalities, such as obstruction.

**3. Pregnancy.** Pregnant women are at increased risk of bacteriuria, and the prevalence ranges from 4-7%. Beginning as early as the seventh week of gestation, dilatation of the uterus and renal pelvis occurs, and the bladder tone decreases, which may result in urinary stasis in the bladder. The majority of pregnant women with bacteriuria have bacteriuria detected at the first prenatal visit. Of pregnant women with bacteriuria, ~ 25% develop their infection during pregnancy.

Bacteriuria during pregnancy increases the risk of pyelonephritis during the latter stages of pregnancy. If untreated, ~ 20-40% of patients with bacteriuria early in pregnancy develop acute pyelonephritis later in pregnancy. Of pregnant women without bacteriuria early in gestation, < 1% develop acute pyelonephritis, which emphasizes the importance of early detection and treatment. Acute pyelonephritis is associated with premature delivery in 20-50% of patients. The eradication of bacteriuria probably reduces the frequency of prematurity and low birth weight. The association of bacteriuria and hypertension in pregnancy is not clear.

**4. Elderly.** Among individuals older than 65 years, = 10% of men and 20% of women have bacteriuria. Risk factors include prostatic hypertrophy in males, bladder prolapse in females, soiling of the peritoneum, neurogenic bladder, and the use of a chronic indwelling urinary catheter.

**B. Microbiology.** *E coli* is the most common cause of acute uncomplicated community-acquired UTI, accounting for ~ 95% of cases. In recurrent infections, especially in association with structural abnormalities, the relative frequency increases for infection caused by other microorganisms, such as *Proteus* species, *Klebsiella* species, *Enterobacter* species, and enterococci. Nosocomial acquisition, especially in association with urinary catheterization, is often caused by *E coli*, *Pseudomonas* species, or other gram-negative nosocomial microorganisms (see section on "Nosocomially Acquired Infection" later in this chapter). Urea-splitting microorganisms, such as *Proteus* species, are associated with calculus formation. *S saprophyticus* accounts for 5-15% of acute cystitis in young sexually active females. Type 2 adenovirus may cause acute hemorrhagic cystitis in children and is more common in young boys than in girls.

### C. Pathogenesis.

**1. Routes of infection.** Bacteria may cause UTIs by three possible routes: ascending, hematogenous, or lymphatic. Of these, the ascending route, especially in women, is probably the most common. Uropathogenic microorganisms colonize the vaginal introitus and periurethral area where they may ascend through the urethra, enter the bladder, multiply, and ascend the ureters to the renal pelvis and parenchyma. Urethral massage, sexual intercourse, or other factors enhance entry of microorganisms into the female urethra. In the male urethra, the mechanism of ascending infection is less understood than in females. Hematogenous infection of the kidney occurs uncommonly in gram-negative bacteremia, although gram-negative bacteremia originating from the urinary tract is one of the most common sources of bacteremia. *S aureus* bacteremia may cause intrarenal or perinephric abscess. Lymphatic spread of infection to the urinary tract is thought to be uncommon.

**2. Microbial factors.** Although virtually any microorganism is capable of causing UTI, *E coli* is responsible for the majority of infections ([Box 16-1](#)). Uropathogenic strains of *E coli* are selected from the fecal flora by the presence of virulence factors that enhance colonization of vaginal and periurethral cells, attachment to uroepithelium, and invasion of tissue. These factors include adhesions, resistance to serum bactericidal activity and phagocytosis, presence of a high amount of K antigen, and hemolysin production. Of these, adhesion is the most important property of uropathogenic *E coli*.

Fimbriae are the major type of surface adhesions of uropathogenic *E coli*. A number of specific, morphologic and functional *E coli* fimbriae have been identified. The two most important of these are P fimbriae and type 1 fimbriae. *E coli* expressing P fimbriae attach to globoseries, glycolipid receptors in the kidney, and are the strains most associated with acute pyelonephritis. These receptors are distributed throughout the urinary tract but are most prevalent in the kidney. The attachment of these strains is not inhibited by mannose, and the strains are referred to as mannose resistant. Type

1-fimbriaed *E coli* bind to mannose-containing receptors in the urinary tract and are more likely to cause cystitis than pyelonephritis. Attachment of these strains is inhibited in the presence of mannose, and these strains are referred to as mannose susceptible. Type 1 fimbriae increase the susceptibility of *E coli* to phagocytosis, but uropathogenic *E coli* fail to express type I fimbriae in renal parenchyma. Polymorphonuclear leukocytes lack a receptor for P fimbriae, which inhibits the phagocytosis of these strains. Nonfimbriated uropathogenic *E coli* bacteria express a variety of adhesions that bind to uroepithelium.

*Proteus mirabilis* and *Klebsiella* species also express fimbriae, which are responsible for attachment. *S saprophyticus* adheres more readily to uroepithelial cells than does *Staphylococcus epidermidis* or *S aureus*. The production of urease by *Proteus* species and other microorganisms increases the potential of these microorganisms to cause pyelonephritis. Bacterial K-antigen inhibits phagocytosis. Most uropathogenic bacterial strains produce hemolysins, which facilitate tissue invasion and enhance renal cell damage.

**3. Host factors.** Many host factors increase susceptibility to UTI. The most common of these is obstruction of normal urinary flow, resulting in stasis. This may occur as the result of extrarenal obstruction from congenital abnormalities, malignancies, calculi, vesicoureteral reflux, prostatic hypertrophy, neurogenic bladder, pregnancy, or other conditions.

Vesicoureteral reflux caused by congenital abnormalities or neurogenic bladder is highly associated with UTI. Reflux results in a residual pool of urine in the bladder after voiding which, when infected, predisposes to upper tract infection and renal scarring. Incomplete bladder emptying from any cause, such as prostatic hypertrophy, similarly results in residual urine in the bladder, which increases susceptibility to UTI.

Urinary tract instrumentation is another common cause of UTI. A single catheterization of the bladder results in bacteriuria in 0.1-1% of patients. Virtually all patients with a chronic indwelling urinary catheter develop UTI.

In sexually active women, the use of a diaphragm with spermicidal jelly increases the susceptibility to UTI. Spermicide may cause pH changes that increase colonization of the vagina with uropathogens. Diabetics are more susceptible to infection in general, including UTI. The presence of glucose in the urine enhances bacterial growth.

A variety of factors protect the host from UTI. With the exception of the urethral mucosa, the normal urinary tract is resistant to colonization by bacteria and rapidly clears most microorganisms that gain access to the bladder. High or low urine osmolality, high urea concentration, and low urinary pH inhibit the growth of microorganisms. Tamm-Horsfall protein secreted by cells in the ascending loop of Henle contains mannose, which binds type 1-fimbriated *E coli*. Mannose-bound strains prevent microorganisms from binding to uroepithelial cells, and the complexes are flushed from the urinary tract during micturition. Prostatic secretions contain zinc, which inhibits growth of bacteria in urine.

## **Clinical Findings**

**A. Signs and symptoms.** Many patients with bacteriuria, especially older patients, are asymptomatic. Among neonates and children < 2 years of age, symptoms may be nonspecific and include fever, vomiting, irritability, and failure to thrive. Children older than 2 years usually develop increased frequency of urination and dysuria; with acute pyelonephritis, nausea, vomiting, fever, chills, and flank and abdominal pain may occur.

**1. Acute cystitis-urethritis.** Adult women with acute cystitis-urethritis typically have acute onset of dysuria, urgency, and increased frequency of urination. Fever is usually not present in uncomplicated cystitis-urethritis. Physical examination in women with cystitis-urethritis may reveal suprapubic tenderness.

**2. Acute pyelonephritis.** Adults with acute pyelonephritis present with fever, chills, and flank or back pain. On physical examination, flank tenderness is common.

**3. Acute prostatitis.** Men with acute prostatitis complain of fever, chills, and perineal and low-back pain together with dysuria and increased frequency of urination. The prostate is exquisitely tender in men with acute prostatitis. Physical examinations of the prostate in acute prostatitis should be avoided because of severe pain and the risk of inducing bacteremia.

**4. Chronic prostatitis.** Men with chronic prostatitis describe chronic intermittent episodes of dysuria and increased frequency of urination. On physical examination, the prostate is often enlarged, and tenderness may be present but is often absent.

## **B. Laboratory findings.**

**1. Urinalysis and Gram stain.** A urinalysis should be performed in all patients suspected of having a UTI. The large majority of patients with symptomatic UTI have pyuria, described as 5-10 leukocytes/high-power field of centrifuged urinary sediment. A dipstick leukocyte esterase test is a rapid screening test and has a high sensitivity and specificity for detection of pyuria. Leukocyte casts are commonly present in patients with pyelonephritis. Microscopic or gross hematuria may occur in patients with cystitis-urethritis.

The presence on Gram stain of = 1 bacterium/high-power field, performed on a midstream clean-catch urine specimen, correlates with =  $10^5$  bacteria/mL of uncentrifuged urine. Automated screening tests for detection of bacteria are available to rapidly screen large numbers of specimens.

**2. Quantitative urine culture and antimicrobial susceptibility tests.** A quantitative urine culture with antimicrobial susceptibility tests is not necessary in most women with urethritis-cystitis. Urine culture and susceptibility studies should be performed in women who relapse after short-course antimicrobial therapy or in those with frequent recurrence of UTI. A quantitative urine culture and antimicrobial susceptibility tests should be performed in all patients that are suspected of having pyelonephritis. Patients with symptomatic UTIs typically have =  $10^5$  bacteria/mL of midstream clean-catch urine. However, = 40-50% of females with acute cystitis-urethritis have <  $10^5$  bacteria/mL of urine, and infection may be present with counts as low as = 1000 bacteria/mL. The

presence of < 1000 bacteria/mL of urine suggests a diagnosis other than UTI. Females with acute cystitis-urethritis and sterile pyuria should be suspected of having urethritis caused by *Chlamydia trachomatis* or *Neisseria gonorrhoeae*.

**3. Blood cultures.** Blood cultures are frequently positive in patients with acute pyelonephritis and should be obtained in all patients in whom this diagnosis is suspected.

### C. Laboratory diagnosis of prostatitis.

**1. Acute prostatitis.** Acute prostatitis is most often caused by *E coli* or another member of the family *Enterobacteriaceae*. Expressed prostatic secretions contain polymorphonuclear leukocytes, and microorganisms are usually present on Gram stain and may be recovered from culture. However, prostatic massage should be avoided in these patients because the prostate is exquisitely tender to palpation, and massage may result in bacteremia. The clinical presentation of acute prostatitis is highly suggestive of the diagnosis, and the microorganism may be recovered from cultures of midstream urine. Antimicrobial susceptibility tests should be performed.

**2. Chronic prostatitis.** Of chronic prostatitis cases, = 80% are caused by *E coli*; the remaining cases are caused by *Klebsiella*, enterococci, *Enterobacter* spp., and *P mirabilis*. Because bacteria in the urethra may contaminate prostatic secretions, the diagnosis requires simultaneous sequential quantitative cultures of four specimens: (1) urethral urine, (2) midstream urine, (3) prostatic secretions expressed by massage, and (4) voided urine after massage. Diagnosis is made by comparing the results of quantitative cultures. The diagnosis is suggested when the number of bacteria in the prostatic massage secretions exceeds those in specimens number 1 and 2 by = 10-fold. If no prostatic secretion fluid is obtained, the postmassage urine quantitative culture should exceed cultures from specimens 1 and 2 by = 10-fold. Antimicrobial susceptibility tests should be performed.

**D. Imaging.** Imaging studies should be performed in adult patients with complicated UTIs, such as those with urolithiasis or pyelonephritis, and in patients of any age in whom structural abnormalities are suspected. A plain abdominal roentgenogram may detect urolithiasis, a mass, or an abnormal gas pattern, all of which are suggestive of abscess. Previously, excretory urography or intravenous pyelography (IVP) was the most commonly used imaging technique. However, administration of the contrast material used in IVP may cause an allergic reaction or exacerbate renal insufficiency. Ultrasound imaging and computed tomographic (CT) scans are more sensitive than IVP for detection of renal pathology, and administration of contrast material is not necessary with ultrasonography. Compared with IVP, contrast-enhanced CT scans provide better parenchymal delineation but are less optimal to delineate the collecting system than is IVP. Ultrasonography is useful to detect urinary tract obstruction, and small calculi may be detected by spiral CT scans. Perinephric abscess, renal abscess, and emphysematous pyelonephritis may be diagnosed adequately by ultrasonography or CT scans. The detection of papillary necrosis requires contrast-enhanced urography (IVP) or CT scans.

Ultrasonography and voiding cystoureterography are recommended in patients

suspected of having reflux disease. Radionuclide-voiding cystography may also detect reflux disease.

## Differential Diagnosis

The acute cystitis-urethritis syndrome in women must be differentiated from herpes simplex infection, *C trachomatis* infection, and vaginitis. A pelvic examination should be performed to detect genital herpes simplex virus infection. *C trachomatis* infection has a more gradual onset of dysuria and should be suspected in sexually active women with a recent new sexual partner. Hematuria is usually absent in *Chlamydia* infection. A diagnosis of *Chlamydia* infection is confirmed by rapid diagnostic techniques using commercially available kits. Vaginitis is a common cause of dysuria, but patients usually complain of external dysuria, which begins shortly after the onset of micturition and results from urine contact with inflamed vaginal labia. Pyuria and hematuria are usually absent in vaginitis. The presence of gross or microhematuria may occur in association with genitourinary-tract neoplasms, urolithiasis, or structural abnormalities of the genitourinary tract system. Patients at opposite extremes of age groups may not present with symptoms that are typical of UTI. In children < 2 years of age, failure to thrive, vomiting, and fever may be the major manifestations. Elderly patients with pyelonephritis may present with fever, hypotension, and sepsis syndrome without symptoms of a urinary tract infection. Among elderly patients with gram-negative bacteremia without an obvious source, a UTI should be considered.

## Complications

Uncommon or rare complications of UTI include acute papillary necrosis, perinephric or intrarenal abscess, emphysematous pyelonephritis, or xanthogranulomatous pyelonephritis. When present, acute papillary necrosis is most common in diabetic dehydrated patients with pyelonephritis and is characterized by diminished renal function and sloughing of renal papilla. The most common predisposing factors for perinephric abscess are renal stones and diabetes mellitus, and perinephric abscess usually occurs as the result of obstruction or, less commonly, bacteremia. The infecting organisms for perinephric abscess are usually gram-negative bacilli or *S aureus*, if the cause is bacteremia. Polymicrobial infection is present in ~ 25% of cases of perinephric abscess. Intrarenal abscess usually occurs as the result of *S aureus* bacteremia. Perinephric or intrarenal abscess should be considered in patients with pyelonephritis who have been ill for = 2 weeks and in those who have a slow response or no response to effective antimicrobial therapy. Emphysematous pyelonephritis is a rare complication of pyelonephritis and most often occurs in elderly diabetics. This condition should be suspected in patients with rapidly progressive infections with sepsis syndrome that respond poorly to antimicrobial therapy. Xanthogranulomatous pyelonephritis is a rare form of chronic renal infection with massive enlargement of the kidney, in which the renal parenchyma is replaced by inflammatory granulomatous tissue, which is characterized by lipid-laden foamy macrophages. Renal calculus formation and obstruction are common. *P mirabilis* is occasionally recovered from urine culture.

## Antimicrobial Therapy

### A. Acute uncomplicated cystitis-urethritis in women.

**1. Single-dose therapy.** Single-dose antimicrobial therapy results in cure rates ranging from 65-100%, depending on the antimicrobial agent administered. High cure rates of 85-95% may be achieved after therapy with a fluoroquinolone, such as ciprofloxacin, ofloxacin, or levofloxacin, or with trimethoprim-sulfamethoxazole.  $\beta$ -Lactam therapy is less effective, possibly because of persistence of microorganisms in the periurethral and perirectal area or because of resistance of microorganisms to  $\beta$ -lactams. The advantages of single-dose therapy are high compliance and reduced adverse effects. The disadvantages include higher failure rates than longer courses of therapy, and the higher failure rates may be the result of undetected upper-tract infection that is inadequately treated with single-dose therapy. Patients who fail single-dose therapy with trimethoprim-sulfamethoxazole or a fluoroquinolone should be evaluated for possible upper-tract infection. Women with postcoital cystitis-urethritis are good candidates for single-dose therapy.

**2. Three-day therapy.** Numerous studies have demonstrated that 3 days of antimicrobial therapy are as effective as 7-10 days of therapy, and 3-day therapy should be considered as standard therapy. Trimethoprim-sulfamethoxazole or a fluoroquinolone should be considered as the agent of choice for 3-day therapy. With a susceptible microorganism, 3 days of  $\beta$ -lactam therapy results in cure rates similar to those after treatment with trimethoprim-sulfamethoxazole or a fluoroquinolone. However, therapy with ampicillin or amoxicillin may be less effective than a second- or third-generation oral cephalosporin because of the relatively high frequency of ampicillin-resistant *E coli* in community-acquired UTIs. Sexually active females with the gradual onset of symptoms or recent change in a sexual partner should be considered to have *C trachomatis* infection and should be treated as shown in [Box 16-2](#).

There are currently insufficient data to recommend shorter-course therapy (single-dose or 3-day treatment) in men or children with UTIs. These patients are at higher risk of structural abnormalities or upper tract infection, and therapy should be administered for 7-10 days. Follow-up urine cultures should be obtained 1-2 weeks after completion of treatment to detect relapses or persistence.

**B. Acute pyelonephritis.** Patients with severe infections, such as those with nausea, vomiting, and hypotension, should be hospitalized. Others with mild to moderate infection may be treated as outpatients, provided that they are compliant and are able to tolerate oral antimicrobial therapy. Antimicrobial therapy is initially empiric and should be modified appropriately based on the results of cultures and susceptibilities. Effective therapy results in defervescence of fever and other symptoms, usually within 48 h after onset of treatment. Failure to respond may be the result of resistant microorganisms or the presence of perinephric or intrarenal abscess or persistence of infection in polycystic renal disease. Antimicrobial therapy of pyelonephritis should be administered for 14 days. Patients with acute pyelonephritis should have an ultrasound examination to exclude obstruction or stones. A follow-up urine culture should be obtained 1-2 weeks after completion of therapy. In hospitalized patients, parenteral therapy may be changed to orally administered therapy when patients improve and are able to tolerate oral therapy.

**C. Asymptomatic bacteriuria.** Children should be treated with antimicrobial therapy as

described for those with symptomatic infection, as shown in [Box 16-2](#). Aside from pregnant women, adults, especially the elderly, do not benefit from antimicrobial therapy.

**D. Pregnancy.** The rationale for antimicrobial therapy in these patients is described above. The goal of treatment is to maintain sterile urine throughout pregnancy. The antimicrobial regimens are shown in [Box 16-2](#). Single-dose therapy has not been adequately studied in these patients. Three-day therapy may be as effective as seven-day treatment but there are relatively few published studies with three-day treatment of asymptomatic bacteriuria in pregnant women. Follow-up urine cultures should be obtained 1-2 weeks after completion of therapy and at monthly intervals throughout the duration of pregnancy. If bacteriuria recurs, the patient should be re-treated, and, if multiple relapses occur, suppressive therapy should be administered throughout gestation, and radiologic evaluation may be performed after delivery.

**E. Asymptomatic bacteriuria after urinary tract instrumentation.** The majority of patients with previously sterile urine who have persistent bacteriuria after instrumentation or removal of a urinary catheter should receive 3 days of antimicrobial therapy. The selection of therapy should be based on the results of culture and susceptibility tests.

**F. Relapsing UTI.** Relapse usually occurs within 1-2 weeks after completion of therapy and is most often associated with upper tract infection, structural abnormalities including stones, or chronic prostatitis. Bacteriologic eradication in patients with obstruction or calculi depends on surgical correction of obstruction or removal of stones. The treatment of relapsing chronic prostatitis is discussed below. Patients with upper tract infection who relapse after short-course therapy should be retreated for = 2 weeks. A 6-week course of therapy should be administered to those patients that relapse after a 2-week course. Some women will continue to experience relapse with no obvious cause or despite surgical correction of structural abnormalities. If relapse occurs after a 6-week course, in selected patients who have continuous symptoms of UTI, a treatment course of 6-12 months should be considered. Patients selected for long-term therapy include children, adults with continuous symptoms, or adults at high risk of progressive renal damage or those patients with obstructions that are not amenable to surgery. Asymptomatic adults with bacteriuria without obstruction should not receive long-term therapy.

**G. Reinfection.** Women with infrequent reinfection (= 2-3 times/year) should be treated with short-course antimicrobial therapy as if each UTI were a new, discrete episode. Single-dose self-administered therapy taken after sexual intercourse is usually effective to decrease the frequency of UTI related to sexual activity. In some women with frequent lower-tract reinfection, no precipitating event is apparent. In these patients with symptomatic, frequent reinfection, long-term antimicrobial therapy is warranted. If reinfection occurs during treatment, urine culture and sensitivity should be obtained, and the prophylactic regimen should be changed based on the results.

## **H. Prostatitis.**

**1. Acute prostatitis.** Antimicrobial therapy of acute prostatitis in young men (< 35 years

of age) should include agents that are effective against *N gonorrhoeae* and *C trachomatis* (Box 16-2). Patients older than 35 years usually have infection caused by members of the *Enterobacteriaceae*. Studies suggest that the relapse rate or development of chronic prostatitis may be higher in patients with acute prostatitis who are treated for < 4 weeks with antimicrobial therapy. Prostatic abscess usually requires drainage; cure with antimicrobial therapy alone is uncommon.

**2. Chronic prostatitis.** The selection of an antimicrobial agent should be based on culture and sensitivity results. Cure is difficult to achieve, and relapses are common. Therapy with trimethoprim-sulfamethoxazole or a fluoroquinolone results in higher drug concentrations in prostate tissue and superior cure rates compared with therapy with a  $\beta$ -lactam. The presence of prostatic calcification or stones is associated with a high failure rate. Chronic suppressive therapy, usually with trimethoprim-sulfamethoxazole or a fluoroquinolone or trimethoprim alone, may control symptoms of chronic bacterial prostatitis in patients who relapse after 1-3 months of antimicrobial therapy. Transurethral resection of the prostate, together with antimicrobial therapy, may be necessary to cure patients with chronic prostatitis and an enlarged prostate with or without calcifications, who remain symptomatic despite antimicrobial therapy.

**I. Perinephric or intrarenal abscess.** Patients with perinephric or intrarenal abscess usually require open drainage or ultrasound or CT-guided drainage. Patients with polycystic renal disease who fail to respond to antimicrobial therapy may require aspiration or surgical drainage of infected cysts. Patients with emphysematous pyelonephritis should undergo immediate nephrectomy because of the high mortality in patients treated with medical therapy alone. Patients with xanthogranulomatous pyelonephritis require nephrectomy.

## Prognosis

**A. Children.** Children without obstruction or vesicoureteral reflux have an excellent prognosis. Uncorrected obstruction with infection may result in severe progressive renal disease. Reflux, together with infection, is associated with development of progressive renal scarring and, if untreated, may progress to arterial hypertension and end-stage renal disease. Eradication of bacteriuria may reduce the severity of reflux. Mild to moderate reflux may disappear spontaneously in older children over time, probably as a result of maturation of the vesicoureteral junction. Surgery may be necessary to correct severe persistent reflux disease.

**B. Adults.** Prognosis of the large majority of adults with UTIs is excellent. Many women with UTIs had UTIs as children. A female who develops a UTI is more likely to develop subsequent infections than a woman who has had no prior UTI.

When associated with obstruction, infection may lead to progressive renal damage and failure. Recurrent infection in the absence of obstruction rarely, if ever, leads to progressive renal disease or arterial hypertension.

## Prevention

Postcoital lower UTIs in females may usually be prevented by administration of a single

dose of an antimicrobial agent after sexual intercourse (see above). Long-term prophylaxis should be considered for patients who have had frequent symptomatic relapses or recurrences of infection and are at risk of developing progressive renal damage, such as young children with vesicoureteral reflux or patients with obstruction or stones. For long-term prophylaxis, it is not usually necessary to administer the same dosage of an antimicrobial agent that has been used to treat symptomatic infection. For example, nightly administration of one single-strength trimethoprim-sulfamethoxazole or a lower dosage of a fluoroquinolone may suffice. Urine culture and antimicrobial sensitivity should be obtained periodically in patients who receive long-term prophylaxis, to monitor for development of resistance and persistence of bacteriuria. A change of antimicrobial therapy may be necessary in these patients.

## **NOSOCOMIALLY ACQUIRED URINARY TRACT INFECTIONS**

### **Essentials of Diagnosis**

- Majority asymptomatic.
- Fever, chills, possible suprapubic or flank pain.
- Positive urine or blood culture for gram-negative bacilli; number of bacteria usually = 100,000 colony forming units/mL of urine.

Urinary tract infection is the most common nosocomially acquired infection, accounting for = 40% of all nosocomial infections. Of nosocomial UTIs, = 80% are related to the use of a urethral catheter. The remaining cases are associated with other urinary tract instrumentations or surgery.

Catheter-associated UTI is one of the most common infections in acute care facilities and is the most common infection in chronic care settings. Before the development of closed catheter systems, the onset of bacteriuria in open draining systems occurred within 4 days after insertion of the catheter. With the closed-catheter system, the onset of bacteriuria is delayed to = 30 days after insertion. All patients with a chronic indwelling urinary catheter will eventually develop bacteriuria.

### **Epidemiology and Microbiology**

The duration of catheterization is the most important risk factor for the development of bacteriuria. The duration may be classified as short term (< 30 days) or long term (> 30 days).

Of patients with short-term catheterization, 15-30% will develop bacteriuria. *E coli* is the most common microorganism associated with short-term catheterization, accounting for ~ 25-30% of cases ([Box 16-3](#)). Other common microorganisms include *P aeruginosa*, *Klebsiella* spp., *Proteus* spp., and *S epidermidis*. Most cases of bacteriuria associated with short-term catheterization are caused by a single microorganism.

All patients with an indwelling urinary catheter for > 30 days will develop bacteriuria. New episodes of bacteriuria caused by different microorganisms occur commonly. In

addition, some microorganisms may persist for weeks, months, or years. Polymicrobial bacteriuria occurs in = 95% of patients with long-term catheterization. *Providencia stuartii* is one of the most common microorganisms that cause bacteriuria in patients with long-term catheterization and may persist for months and years.

## **Pathogenesis**

In patients with a urinary catheter, microorganisms may enter the bladder through at least three mechanisms: (1) At the time of catheter insertion, (2) through the lumen of the catheter, or (3) along the catheter-urethral interface.

The insertion of the urinary catheter through the urethra may transport microorganisms located within the periurethral area into the bladder. The insertion results in bacteriuria in from < 1% in young healthy individuals to > 20% in elderly or hospitalized patients. Microorganisms may enter the drainage bag, multiply, persist in the film of urine within the bag and tubing, ascend the lumen of the tubing, and enter the bladder. The closed drainage system reduces the risk of intraluminal entry of microorganisms into the bladder. The most likely mechanism for the entry of microorganisms into the bladder is along the catheter-ureteral interface. Microorganisms in the periurethral area enter the space between the catheter and the urethral mucosa and ascend into the bladder. This route probably accounts for 80% of episodes of bacteriuric females and 30% of those bacteriurias that occur in males.

Once bacteria enter the urinary bladder, they multiply and maintain themselves primarily through the production of a biofilm, which covers and secures bacteria on the mucosal or catheter surface where they are protected from natural host defenses or from the activity of antimicrobial agents. Microorganisms may ascend the ureters to the kidneys. The presence of chronic bacteriuria in association with an indwelling urinary catheter may result in the formation of urolithiasis or acute and chronic infection including pyelonephritis. Risk factors that predispose to bacteriuria in patients with indwelling urinary catheters include the duration of catheterization, diabetes mellitus, female sex, and errors in catheter care.

## **Clinical Findings**

**A. Signs and symptoms.** The majority of patients with short-term catheterization and bacteriuria are asymptomatic. However, 25-30% of these will develop signs of UTI with fever, suprapubic pain, or flank pain. Men are more likely to develop bacteriuria than women. Bacteremia usually caused by *E coli* occurs in < 5% of patients with short-term catheterization. Patients with long-term catheterization may develop symptoms of UTI similar to those of patients with short-term catheterization.

**B. Laboratory findings.** The diagnosis of bacteriuria is made by performing quantitative urine cultures on a specimen obtained by using aseptic techniques from the urinary bag. In most instances, quantitative culture yields > 100,000 colonies of bacteria/mL of urine.

## **Differential Diagnosis**

Among patients with indwelling urinary catheters who develop fever and signs of

infection, the urinary tract should be considered the most likely source of bacteremia. However, many patients with a chronic indwelling urinary catheter are at risk of bacteremia from other sources such as decubitus ulcer, aspiration pneumonia, intra-abdominal infections, and other conditions that are common in chronically ill, elderly patients.

## Complications

In addition, these patients may develop complications associated with catheter obstruction, stone formation, renal failure, or chronic pyelonephritis. Like patients with short-term catheterization, bacteremia may occur and is usually caused by *E coli* but also may be caused by *P stuartii* or other members of the *Enterobacteriaceae*.

Obstruction is the result of catheter plugging caused by a matrix composed of protein, bacteria, glycocalyx, and crystals. *P mirabilis* is the most common microorganism that causes catheter obstruction and stone formation in patients with long-term catheterization. Chronic pyelonephritis is related to the duration of catheterization. Chronic renal failure may occur, resulting from a combination of factors that includes chronic pyelonephritis, stone formation, and catheter obstruction.

## Therapy

The use of antimicrobial therapy may delay the onset but does not prevent bacteriuria in patients with an indwelling urinary catheter. Moreover, long-term administration of antimicrobial agents to these patients results in selection of resistant microorganisms in the urine. Asymptomatic bacteriuria in patients with an indwelling urinary catheter should not be treated with antimicrobial therapy. For most patients, if bacteriuria persists after removal of the catheter, short-term (3-day) antimicrobial therapy is recommended ([Box 16-2](#)). Patients who develop symptoms of infection that are associated with an indwelling urinary catheter should receive 7-10 days of antimicrobial therapy with specific activity in vitro against microorganisms recovered from blood or urine cultures.

Asymptomatic candiduria develops frequently in patients with long-term catheterization, especially among patients who have received antimicrobial therapy. Some patients may develop complications of candiduria, which include catheter obstruction, fungus ball formation, or invasion of the bladder wall or kidney parenchyma. In asymptomatic patients, removal of the catheter usually results in the disappearance of candiduria. For patients who develop complications, change of an obstructed urinary catheter, cystoscopic removal of a fungus ball, bladder irrigation with amphotericin B, or systemic therapy with orally or parenterally administered anti-*Candida* therapy may be necessary.

## Prognosis

The prognosis for bacteriuria in patients with short-term catheterization is excellent after removal of the catheter. The frequency of bacteremia originating from the urinary tract in patients with short-term catheterization is < 5%, and the mortality related to bacteremia from nosocomial bacteriuria in these patients is < 15%. Most deaths are related to severe underlying disease.

In patients with long-term urinary catheters, bacteriuria will persist for as long as the catheter is in place and may persist even after catheter removal, despite administration of antimicrobial therapy. The urinary tract is the source of the majority of febrile episodes of bacteremia in patients with long-term urinary catheters. The mortality during febrile periods that originate from a urinary source in patients with long-term catheters is 60-fold that of afebrile patients with chronic indwelling urinary catheters.

## **Prevention**

Prevention of bacteriuria may be considered as follows: avoidance of long-term urinary catheterization, prevention of bacteriuria once a urinary catheter is inserted, prevention of complications of bacteriuria, and prevention of patient-to-patient transmission.

**A. Avoidance of urinary catheterization.** Methods such as biofeedback, patient training for bladder-emptying techniques, and the use of special clothing, including adult diapers, may be effective in selected patients. Condom catheters have been used in men and probably reduce the risk of bacteriuria. Intermittent self or assisted catheterization delays the onset of bacteriuria and may reduce the frequency of bacteremia, febrile episodes, stone formation, and renal disease. Suprapubic catheterization may reduce the incidence of bacteriuria and ureteral strictures.

**B. Prevention of bacteriuria.** Once a urinary catheter is inserted, the major methods for prevention of bacteriuria are to maintain a closed catheter system and to remove the catheter as soon as possible. Irrigation of the catheter and bladder with antimicrobial agents has not been effective in preventing bacteriuria. The use of silver- or antibiotic-coated or -impregnated urinary catheters has been investigated. Conflicting results have been published, and more data are necessary to assess the efficacy of silver-coated urinary catheters in reducing the risk of bacteriuria. Antimicrobial agents should not be administered to patients with long-term catheterization, to prevent bacteriuria. Bacteriuria will occur despite antimicrobial therapy. Microorganisms will emerge that are resistant, and therapy is expensive. Methanamine is an antibacterial agent that forms formaldehyde in acidic urine and may be useful to reduce bacteriuria in patients with intermittent catheterization.

**C. Prevention of complications.** Blood and urine cultures should be obtained during febrile episodes, and antimicrobial therapy should be administered. Antimicrobial therapy should not be administered as prophylaxis for febrile episodes to patients with bacteriuria.

**D. Prevention of patient-to-patient transfer.** Nosocomial microorganisms reside on the skin and in the periurethral area of patients with indwelling urinary catheters. Patient-to-patient transmission may occur as the result of contamination of the hands of medical personnel who may then transmit these microorganisms to patients. Good hand-washing techniques and wound and skin precautions should be observed in patients with chronic urinary catheters. Education regarding good catheter hygiene and care of the closed catheter system is important for patients, family, and health care personnel. Outbreaks of multiresistant nosocomial catheter-associated urinary tract infections may occur. Hospital infection control should have adequate surveillance mechanisms in place and procedures to control and eradicate outbreaks, should they

occur.

BOX 16-1. Microbiology of Community-Acquired Urinary Tract Infection

---

**BOX 16-2. Empiric Antimicrobial Therapy of Urinary Tract Infections**

**Condition**

Women and girls,  $\geq 2$  years of age, with acute uncomplicated cystitis and/or urethritis

**First Choice**

- TMP/SMX, 1 double strength **OR** TMP, 8-12 mg/kg, plus SMX, 40-60 mg/kg twice daily for 3 d **OR**
- In patients 15 years of age or older, a fluoroquinolone<sup>1</sup> for 3 d

**Second Choice**

- Amoxicillin or amoxicillin/clavulanate, 500 mg or 45 mg/kg of amoxicillin three times daily for 3 d **OR**
- An oral cephalosporin<sup>1</sup> for 3 d **OR**
- TMP/SMX, 1 double-strength, single dose<sup>2</sup> **OR**
- A fluoroquinolone<sup>1</sup> single dose<sup>2</sup>

Women with risk factors for sexually transmitted diseases

- Doxycycline, 100 mg twice daily for 7 d

- Azithromycin, 1 g single dose

Adults not hospitalized with acute pyelonephritis

- Fluoroquinolone<sup>1</sup> orally for 14 d

- Amoxicillin/clavulanate, 500 mg orally **OR**

Children or hospitalized adults with acute pyelonephritis

- Ampicillin, 1 g IV<sup>3</sup> or 25-50 mg/kg every 4 h **OR**
- Ampicillin, 25-50 mg/kg every 6 h plus gentamicin or tobramycin, 5 mg/kg/d in divided or single daily dose for 14 d **OR**

- Second- or third-generation oral cephalosporin<sup>1</sup> for 14 d
- Ticarcillin/clavulanate, 3.1 g or 50-75 mg/kg of ticarcillin component every 6 h **OR**

- A third-generation cephalosporin<sup>1</sup> IV<sup>3</sup> for 14 d **OR**
- In patients 15 years of age or older, a fluoroquinolone<sup>1</sup> IV<sup>3</sup> or orally for 14 d

- Piperacillin/tazobactam, 3.375 g IV<sup>3</sup> every 6 h for 14 d or 80 mg/kg every 8 h or piperacillin component **OR**

Asymptomatic bacteriuria  
Children

- Treat with regimen for symptomatic cystitis-urethritis for 7 d

- Aztreonam, 1 g IV<sup>3</sup> every 8 h for 14 d or 30 mg/kg every 6-8 h

Pregnancy	<ul style="list-style-type: none"> <li>• Amoxicillin (dosage above) or oral cephalosporin,<sup>1</sup> or TMP/SMX (dosage above) or TMP, 100 mg orally twice daily, or nitrofurantoin, 100 mg orally twice daily for 7 days. Discontinue sulfa 2 wk before delivery. Avoid fluoroquinolone or tetracycline use.</li> </ul>	
Adults, elderly Caused by urinary tract instrumentation	<ul style="list-style-type: none"> <li>• No treatment necessary</li> <li>• Choice of therapy depends on results of culture and antimicrobial sensitivity. Treat for 3 d</li> </ul>	
Acute prostatitis Less than 35 years of age	<ul style="list-style-type: none"> <li>• Fluoroquinolone<sup>1</sup> for 7 d</li> </ul>	<ul style="list-style-type: none"> <li>• Ceftriaxone, 125 mg IM single dose, or other FDA-approved cephalosporin<sup>1</sup> plus either doxycycline, 100 mg orally twice daily for 7 d or azithromycin, 1 g orally as a single dose</li> </ul>
Older than 35 years of age	<ul style="list-style-type: none"> <li>• Fluoroquinolone<sup>1</sup> or TMP/SMX, 1 DS orally twice daily for 4 wks</li> </ul>	
Chronic prostatitis	<ul style="list-style-type: none"> <li>• Fluoroquinolone<sup>1</sup> or TMP/SMX, 1 DS twice daily orally for 1-3 mo</li> </ul>	
Urinary catheter associated	<ul style="list-style-type: none"> <li>• Aminoglycoside plus one of the following: a fluoroquinolone, a third-generation cephalosporin, piperacillin/tazobactam, or aztreonam for 7-14 d.<sup>4</sup> Dosages are as above.</li> </ul>	

<sup>1</sup>Dosage of fluoroquinolone or oral or parenteral cephalosporin depends upon specific drug selected for use.

<sup>2</sup>Single dose therapy not recommended for children 15 years of age or younger.

<sup>3</sup>Intravenous therapy may be changed to oral therapy with TMP/SMX or amoxicillin, amoxicillin/clavulanate, a cephalosporin, or a fluoroquinolone (see footnote 1) after initial satisfactory response and when culture results are available.

<sup>4</sup>Multiply resistant microorganisms are common; antimicrobial therapy may be adjusted based on results of susceptibility tests.

## **17 . Sepsis Syndrome — *Andrew D. Badley, MD & James M. Steckelberg, MD***

### **Essentials of Diagnosis**

- Sepsis should be suspected in patients who present with any combination of fevers, hypotension, altered mental status, or evidence of tissue hypoperfusion.
- The diagnosis requires Systemic Inflammatory Response Syndrome (SIRS), documented infection as the presumed cause of SIRS, and absence of alternative causes of SIRS.
- In a patient who is critically ill with SIRS, the etiology is often not immediately apparent; therefore a careful history and physical exam are required to determine the most likely specific cause.

### **General Considerations**

The Greek origins of the term sepsis refer to the process of putrefaction and decay. Historically, it has come to mean the presence of pathogenic microorganisms or their biologically active products in the host. It is the presence of biologically active products that causes the inflammatory response leading to such clinical sequelae as fever and hypotension. If the inflammatory response proceeds unchecked, it may ultimately lead to organ dysfunction, multiorgan failure, and death.

Recently, the term Systemic Inflammatory Response Syndrome (SIRS) has been introduced. This term refers to a specific host systemic response that may be elicited by a variety of clinical events, including infection, burns, pancreatitis, ischemia, trauma, hemorrhage, immune-mediated tissue injury, and exogenous stimuli. SIRS resulting from infection is called sepsis. Furthermore, sepsis that leads to altered tissue perfusion of vital organs (resulting in one or more of oliguria, hypoxemia, elevated lactate, or altered mentation) is called sepsis syndrome. Sepsis and sepsis syndrome are distinguished from infection, which is inflammation in response to invasion of a normally sterile site by microorganisms, and bacteremia, which is the presence of bacteria in the blood ([Figure 17-1](#)). When faced with a patient with SIRS, the objective is to define, if possible, its etiology, and, if SIRS is caused by infection, to administer appropriate antibiotics and supportive care guided by the patient's history and physical examination ([Table 17-1](#)).

**A. Epidemiology.** Data from the Centers for Disease Control indicate that the incidence of sepsis increased from 73.6 cases/100,000 person years in 1979 to 175.9 cases/100,000 person years in 1987, when sepsis became the 13th leading cause of death. Several factors may contribute to the increasing incidence of sepsis: (1) increased incidence and survival of persons predisposed to sepsis, such as persons infected with HIV, patients with cancer, the elderly, and those who have had organ transplants; (2) increased use of medical prostheses such as intravascular catheters and indwelling urinary catheters; and (3) widespread (and, at times, inappropriate) use

of antimicrobial agents that predispose toward the selection of virulent or multiply resistant pathogens.

**B. Pathogenesis.** The leading microbial cause of sepsis and septic shock is infections with gram-negative bacteria that initiate a cascade of events leading to SIRS. Bacteria may be in the bloodstream only transiently; therefore, sepsis and septic shock are not always associated with bacteremia. An integral component of the gram-negative-bacterial cell wall, lipopolysaccharide (LPS), is responsible for initiating a cascade that results in cytokine release and the early physiologic changes associated with septic shock ([Figure 17-2](#)). LPS within the circulatory system may form a complex with either bactericidal permeability-increasing protein or with LPS-binding protein. Complexes of bactericidal permeability-increasing protein-LPS are fated for destruction, whereas LPS-binding protein-LPS complexes bind with their receptor, CD14. Once bound by LPS-binding protein-LPS complex, CD14 initiates an intracytoplasmic signaling cascade that ultimately results in the translocation of nuclear factor kappa B (NF- $\kappa$ B) into the nucleus. NF- $\kappa$ B is a transcription factor that, once present in the nucleus, initiates the transcription of numerous cytokines including tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-1, IL-2, IL-6, IL-8, platelet activating factor, and interferon- $\gamma$ . These and other potential mediators including nitrous oxide, intracellular adhesion molecules, prostaglandins, and leukotrienes have been directly or indirectly implicated in the pathogenesis of septic shock ([Box 17-1](#)).

The sepsis syndrome may also occur after infections with gram-positive bacteria, viruses, protozoa, rickettsia, and helminths (none of which contain LPS). In these situations, alternate pathways of cytokine induction are invoked. Components of gram-positive bacteria including peptidoglycan and teichoic acids can directly activate the alternate pathway of the complement cascade. Once activated, the complement cascade induces lymphocyte proliferation and activation, as well as phagocyte activation, which generates the production of inflammatory cytokines. Gram-positive-bacterial components can also directly induce cytokine production; both peptidoglycan and lipoteichoic acid can induce IL-1 release from monocytes and macrophages, and lipoteichoic acid can additionally induce TNF- $\alpha$  and IL-6 release. Other bacterial proteins are also capable of causing cytokine production. Gram-positive enterotoxins and exotoxins can directly cause the release of IL-1, IL-6, and TNF- $\alpha$ . Furthermore, staphylococcal toxic shock syndrome toxin-1 is a more potent stimulus of IL-1 release than is LPS.

Regardless of the organism responsible for inducing sepsis, a common final pathway characterized by the release of proinflammatory mediators is activated, resulting in fever, hypotension, decreased organ perfusion, and other potential complications (see below).

## Clinical Findings

The clinical findings associated with sepsis syndrome may be related either to the pathophysiology of SIRS or to the infection that is the underlying cause of sepsis syndrome. The clinical findings associated with SIRS are similar regardless of the mechanism responsible for inducing the inflammatory cascade. Infections that are commonly associated with sepsis syndrome in a normal host include pneumonia,

meningitis, upper urinary tract infections, cellulitis, and intra-abdominal catastrophes (perforated viscus, diverticular abscess, etc). A careful history may identify an infection(s) for which a patient is at increased risk.

**A. Signs and Symptoms.** The signs and symptoms of sepsis syndrome are varied and may reflect in part the underlying infection that is the cause of the inflammatory response. A patient with sepsis may have few complaints or may complain of fevers, chills, pain, rash, or dyspnea. The focus of the physical examination should be to identify the source and severity of the underlying infection, as well as any associated complications. Essentials of the physical examination of a patient with suspected sepsis syndrome include the following:

- Vital signs should include temperature, respiratory rate, and blood pressure.
- Medical appliances such as intravenous lines and urinary catheters should be examined to determine whether these sites represent a potential portal of entry for infectious agents.
- The head and neck should be examined, looking for nuchal rigidity, conjunctival petechiae, and Roth spots.
- The oropharynx should be examined, looking for thrush (suggesting an underlying immunosuppressive state including chronic illness, HIV infection, malignancy, or chronic steroid use), quinsy, periodontal abscess, or evidence of herpes simplex infection.
- Examination of the skin may provide important diagnostic clues such as rashes of disseminated meningococcemia or ecthyma gangrenosum (seen with disseminated *Pseudomonas* infection) are important diagnostic clues. In addition, petechiae associated with disseminated intravascular coagulation may be present, as well as Janeway lesions and Osler's nodes. Last, signs of cellulitis or necrotizing fasciitis are an obvious clue to the cause of sepsis syndrome.
- The pulmonary system should be examined, focusing on signs of pneumonitis: impaired oxygenation, pulmonary consolidation, and empyema. Because patients with sepsis syndrome often develop adult respiratory distress syndrome (ARDS), it may be difficult to differentiate the pulmonary findings of pneumonia from those of ARDS.
- The cardiac examination will frequently be abnormal, owing to the compensatory changes associated with sepsis. Although uncommon, infective endocarditis may uncommonly lead to sepsis syndrome; therefore the finding of a new or changing murmur (especially a regurgitant one) is important. In addition, patients with sepsis syndrome will frequently be hypotensive; therefore a careful cardiac examination is needed to differentiate cardiogenic shock (with elevated jugular venous pressure, gallop rhythms, and evidence of right and/or left-sided congestive failure) from noncardiogenic shock caused by sepsis, which is initially a hyperdynamic, high-cardiac-output state.
- Examination of the abdomen focuses on tenderness, guarding, or absence of bowel sounds, suggestive of an intra-abdominal event such as perforation of a hollow viscus. In addition, it should be noted whether a patient has had a prior splenectomy, which is

associated with an increased risk for certain infections.

- Examination of kidneys seeks flank tenderness or increased size (by palpation, or by ballottement).
- Thorough pelvic and rectal examinations are necessary for all septic patients, to look for evidence of rectal or perirectal abscess, pelvic inflammatory disease, and prostatitis.

**B. Laboratory Findings.** Laboratory findings associated with sepsis syndrome may reflect decreased organ perfusion or may reflect the underlying infection. Frequently leukocytosis or leukopenia is present. In addition, anemia may be seen, which may be dilutional (after fluid resuscitation efforts) or associated with underlying chronic disease. Thrombocytopenia may accompany the development of disseminated intravascular coagulation, or reactive thrombocythemia may occur. Hypoxemia may be seen with pneumonitis or in response to the development of ARDS. If hypercarbia is seen in association with hypoxia, impending ventilatory failure may be present. Rising creatinine (with rising urea), elevations in lactose dehydrogenase (LDH), or rising transaminases are signs of decreased organ perfusion and are suggestive of sepsis syndrome.

For most patients with sepsis syndrome, initial laboratory screening should include the following: complete blood count, urinalysis, coagulation profile, glucose, blood urea nitrogen, creatinine, electrolytes, liver enzymes, bilirubin, lactose dehydrogenase, amylase, lipase, arterial blood gas, chest X-ray, and electrocardiogram. In addition, if meningitis is suspected, screening should also include cerebrospinal fluid testing for glucose, protein, cell count, culture, and rapid bacterial antigen testing. Microbiologic testing should be dictated by the clinical presentation, but in most patients, urine, sputum, and blood should be cultured for bacteria.

In selected patients, Swan Ganz catheters may be used to assess cardiac output, systemic vascular resistance, and pulmonary capillary wedge pressure. In early shock due to SIRS, cardiac output will be increased, systemic vascular resistance will be normal or low, pulmonary capillary wedge pressures will be normal or low, and venous oxygen saturation will be increased. These indices are of value in differentiating hypotension due to cardiogenic, hypovolemic, toxin mediated, or neurogenic causes, as well as assessing the adequacy of volume resuscitation.

**C. Imaging.** There are no imaging procedures that are specific for sepsis syndrome; however, carefully selected radiographic evaluations may aid in establishing the underlying infection. Every patient should have a chest X-ray performed, and, based on the clinical presentation, CT scanning or ultrasonography of the chest or abdomen may be appropriate.

## **Differential Diagnosis**

A patient with sepsis syndrome will have characteristic findings suggestive of SIRS; however, at the time of presentation, it may not be readily apparent that the etiology of SIRS is infection. Therefore all potential etiologies for SIRS must be considered in the differential diagnosis. The presence of burns, trauma, and some exogenous stimuli may be readily apparent, although at times it may be difficult to determine whether these

conditions are complicated by infection.

Clues to the potential presence of pancreatitis include an antecedent history of alcohol ingestion or of biliary colic. Not having such a history, however, does not exclude pancreatitis as a potential etiology of SIRS; therefore serum lipase and amylase determinations should be considered on all patients with SIRS. The diagnosis of ischemia (eg, ischemic bowel) as a potential precipitant of SIRS is often more difficult to establish, although signs and symptoms referable to the ischemic organ should provide clinical clues. In establishing the etiology of SIRS, the value of a careful history and physical exam cannot be overstated.

Virtually any focus of infection with virtually any organism can lead to the development of sepsis syndrome. Most commonly, the infectious agents responsible for causing sepsis syndrome in the community are bacteria, and the most common infections are community-acquired pneumonia, upper urinary tract infections, meningitis, and cellulitis. In hospitalized patients, line-associated bacteremia, aspiration pneumonia, ventilator-associated pneumonia, wound infections, and abscesses are typical causes of sepsis syndrome.

## **Complications**

The clinical findings related to sepsis syndrome are a reflection of the pervasive nature of the inflammatory mediators of sepsis. Virtually every organ system is affected in sepsis syndrome, although the degree of involvement of each organ varies widely between patients. Just as the effects of sepsis syndrome are present in virtually every organ system so are potential complications.

**A. Central Nervous System.** Toxic metabolic encephalopathy is associated with sepsis syndrome and is a consequence of several factors including cerebral hypoperfusion, medications, hypoxia, the biologically active products of the infective agent, and inflammatory mediators of sepsis. Encephalopathy may progress to coma, seizures, cerebral edema, and potentially death. In addition, in patients who are critically ill for prolonged periods, a distal sensory/motor polyneuropathy of unknown etiology, called critical illness polyneuropathy, may develop. Last, cerebral hemorrhage, or infarction may occur as a result of the coagulation abnormalities associated with sepsis syndrome.

**B. Pulmonary System.** The lungs may be affected in sepsis in several ways. They may be the primary site of infection giving rise to sepsis (ie, pneumonia) or may be subject to the forces of increased left-ventricular end diastolic pressure characteristic of a failing left ventricle. The development of hypoxia and hypocarbia may reflect the development of capillary leakage, leading to impaired gas exchange and consequent hyperventilation characteristic of ARDS. Abnormalities of oxygenation and ventilation can become refractory to mechanical ventilation and lead to death.

**C. Cardiovascular System.** The early cardiovascular response to the release of circulating inflammatory cytokines is characterized by normal or increased cardiac output with low systemic vascular resistance and a loss of vascular responsiveness to sympathetic agents (such as epinephrine). Later, myocardial dysfunction and a

decrease in the ejection fraction of the left ventricle may occur as a result of a putative myocardial depressant factor. The compensatory increase in heart rate is an attempt to maintain tissue perfusion by increasing cardiac output; failure to compensate appropriately may be indicative of a poor prognosis. Myocardial workload, in an attempt to compensate for the falling tissue perfusion, may increase markedly in sepsis syndrome; if the myocardium is unable to maintain adequate perfusion, cardiac ischemia may occur, leading to arrhythmias, myocardial infarctions, and death.

**D. Gastrointestinal System.** Normal gut motility and permeability may be altered in sepsis as a result of the effects of endotoxin and cytokines, resulting in the altered absorption of oral medications and bacterial overgrowth. Gastrointestinal complications of sepsis syndrome include bacterial overgrowth, which increases risk for developing nosocomial pneumonia, and functional obstructions such as toxic megacolon caused by impaired motility.

**E. Renal and Hepatic Systems.** The renal and hepatic systems commonly show evidence of dysfunction due to hypoperfusion and capillary leakage, although the use of medications including aminoglycosides, acetaminophen, and others may also contribute to organ injury. Elevations in levels of transaminases and hyperbilirubinemia are common and are associated with a poor prognosis. Rarely, liver injury may progress to ischemic hepatitis. Prerenal azotemia secondary to hypoperfusion is the most common form of renal dysfunction in sepsis syndrome, but other intrinsic renal disorders including acute glomerulonephritis and interstitial nephritis may occur.

**F. Hematologic System.** The hematologic system may be altered in sepsis syndrome, notably through the development of disseminated intravascular coagulation and impaired bone marrow synthesis of cellular precursors. Anemia, leukopenia, and thrombocytopenia may be due in part to failure of production of marrow precursors. Anemia may be corrected by transfusion, but leukopenia may impair host defenses, and thrombocytopenia may lead to bleeding, thereby aggravating hypotension, anemia, and tissue hypoperfusion.

**G. Musculoskeletal System.** Skeletal muscle dysfunction may be a consequence of the effects of endotoxin and hypoperfusion (also a consequence of the release of inflammatory mediators). Muscle injury may be reflected by rising creatinine kinase levels. Prolonged muscle dysfunction may lead to wasting and the development of critical illness myopathy.

**H. Endocrine System.** The physiologic stresses associated with sepsis may unmask occult endocrine deficiency states or, more rarely, may induce adrenal hemorrhage resulting in Addison's disease. The euthyroid sick syndrome is characterized by impaired conversion of T<sub>4</sub> to T<sub>3</sub> and by abnormal production of thyroid-binding globulin. This results in abnormal measurements of T<sub>4</sub> and T<sub>3</sub> with normal or decreased levels of thyroid-stimulating hormone.

## **Treatment**

The aims of treatment for patients with sepsis syndrome are threefold:

- Elimination of the infectious agent(s) responsible for inducing sepsis.
- Supportive care based in the intensive care unit aimed at normalizing oxygenation, ventilation, blood pressure, and tissue perfusion.
- Therapies intended to interrupt inflammatory mediators of sepsis.

**A. Elimination of Infectious Agent(s).** Eliminating infectious agents often consists of administering empiric antibiotics together with appropriate surgical drainage or debridement. The complete medical history and physical examination, in addition to the clinical scenario, are used to generate a microbiologic differential diagnosis and guide selection of empiric antibiotic therapy. Host factors that may predispose patients to certain infections are shown in [Box 17-2](#). In a critically ill patient with sepsis syndrome, several possible microbial etiologies commonly exist. Therefore broad-spectrum empiric antibiotic therapies are used until further microbiologic data are available, which might indicate that a more specific antimicrobial regimen is appropriate. Once available, culture data and sensitivity profiles should be used to narrow the spectrum of antibiotics (often to only one agent). The choice of initial antibiotics is based on the likelihood of specific microorganisms for the given clinical scenario ([Box 17-3](#)), and the choice of subsequent antibiotics is guided by the results of microbiology testing.

**B. Supportive Care.** Supportive care should be based in the intensive care unit and is aimed at normalizing oxygenation, ventilation, blood pressure, and tissue perfusion. The principal means of achieving this goal is aggressive fluid resuscitation, along with possible adjunctive therapy with pressors.

**C. Experimental Therapies.** Experimental therapies for sepsis are aimed at interrupting the inflammatory cascade that is common (SIRS caused by diverse stimuli). To date, no such therapies have become part of the standard practice of the medical management of the sepsis syndrome, but numerous strategies in various phases of development exist ([Box 17-4](#)).

Current knowledge concerning the pathogenesis of sepsis continues to increase. To date, > 30 mediators have been implicated; consequently, strategies aimed at blocking one mediator are not likely to be successful in reversing the process. Furthermore, clinical trials of sepsis therapies have enrolled patients with a variety of predisposing factors, in whom sepsis has been induced by a variety of agents. It is therefore possible that one therapy may be of benefit in a certain subgroup of patients (ie, cancer patients with pneumococcal sepsis), but this effect would not be detected in such trials. Future studies aimed at defined populations with similar etiologies for sepsis are underway.

## Prognosis

The proportion of patients with sepsis who develop septic shock varies between 20% and 40%. Despite increased understanding of its pathogenesis and advances in supportive care, the crude mortality rate of septic shock remains between 50% and 80%.

## Prevention & Control

Because sepsis syndrome is not one infection, there is no one thing that can be done to prevent its development. In general, early recognition of infection and appropriate therapy may help to prevent the development of the "sepsis cascade." For individuals in the community, appropriate vaccinations, including pneumococcal vaccination for patients with chronic obstructive pulmonary disease, may help to decrease the incidence of infections and perhaps of sepsis syndrome. For hospitalized patients, several measures may decrease the incidence of sepsis syndrome: (1) appropriate use of prophylactic perioperative antibiotics, (2) restriction of the use of medical appliances (such as intravenous lines) to only those patients with definite indications, and (3) strict adherence to infection control procedures (to decrease the rate of spread of infection among other patients), including adherence to hand washing policies by hospital staff. In addition, for patients who are at special risk for the development of infections, such as transplant recipients, compliance with prophylactic antibiotics (such as trimethoprim-sulfamethoxazole) is also effective in reducing the incidence of infections and therefore the incidence of sepsis syndrome.

Essentials of Diagnosis
-

**Table 17-1.** Clues to the diagnosis of sepsis.

**Epidemiology**

- Any patient may develop sepsis.
- Patients with impaired immune systems are at higher risk.
- Alterations in local defenses (such as breaks in the skin, burns) place patients at risk.

**Clinical**

- Signs and symptoms of infection
- Impaired hemodynamics and tissue perfusion consistent with the Systemic Inflammatory Response Syndrome (SIRS):
  - Hyperthermia (>38°C) or hypothermia (< 36°C)
  - Tachypnea (respiratory rate > 20 breaths/min)
  - Hypotension (systolic blood pressure < 90 mmHg, or drop of > 40 mmHg from baseline)

**Laboratory**

- Leukocytosis (> 12 × 10<sup>9</sup> cells/L) or leukopenia (< 4 × 10<sup>9</sup> cells/L)
- Left shift in leukocyte differential (> 10% band forms)
- Changes that reflect decreased tissue perfusion: elevated lactate dehydrogenase, evidence of organ hypoperfusion (elevated creatinine, rising transaminases, thrombocytopenia, hypoxemia)
- Changes associated with the site of underlying infection (decreased pO<sub>2</sub> in a patient with pneumonia, etc.)

## **18 . Fever of Unknown Origin — *Julie Brahmer, MD & Merle A. Sande, MD***

### **Essentials of Diagnosis**

- Fever is defined as a core body temperature above 38.3 °C.
- Objective documentation of a fever is important in determining whether a patient is actually febrile.
- A thorough history and physical examination are necessary in order to focus diagnostic studies.
- Routine tests include chest x-ray, blood culture, chemistries, and a complete blood count.
- Knowing the most common causes of a fever of unknown origin (FUO) in each special population helps focus the diagnostic strategy.

### **General Considerations**

Fever is defined as a core body temperature above the normal daily variation. Normal body temperature is 37-38 °C and varies by as much as 0.6 °C throughout the day. The core temperature, measured orally or rectally, is usually lowest in the morning and highest between 4:00 and 6:00 PM.

Several endogenous and exogenous pyrogens can cause fever. Exogenous pyrogens, such as toxins, products of microbes, and microbes themselves, cause release of endogenous pyrogens called cytokines, including interleukin-1, interferon, tumor necrosis factor, interleukin-6, and interleukin-11.

Most of these cytokines are produced by macrophages in the reaction to exogenous pyrogens. These cytokines cause the hypothalamus to increase prostaglandin synthesis, which is thought to cause an upward shift of the normal core temperature set point ([Figure 18-1](#)).

### **Definitions of FUO**

The classic definition of FUO is a fever of >3 weeks' duration that is >38.3 °C on several occasions, the cause of which is not discovered after 1 week of evaluation in a hospital. This definition was a functional one because it eliminated acute causes of fevers, including acute viral infections, and, in > 90% of cases, the cause of the fever could be found. However, under current insurance guidelines and with newer technology available, a 1-week hospital stay is neither feasible nor practical. Therefore an updated version of the classic FUO definition has been proposed that defines it as documented fevers > 38.3 °C for > 3 weeks' duration, when the source of the fever is not discovered during either 3 days of hospital investigation or 3 outpatient visits.

Additional definitions of FUO exist for different population subgroups, including HIV-positive patients, neutropenic patients ( $< 500$  polymorphoneutrophils/mm<sup>3</sup>), the elderly, hospitalized patients, and pediatric patients. These definitions help the clinician direct the investigation to discover the most likely cause of the fever.

FUO in HIV-infected patients is defined as a fever = 38.3°C for 4 weeks' duration in outpatients or  $> 3$  days in inpatients whose HIV infection has been previously documented. In neutropenic patients, FUO is defined as a fever = 38.3 °C for 3 days with negative cultures after 2 days. In the elderly, the definition of FUOs is similar to the classic definition, except that the patients are elderly. In hospitalized patients, nosocomial FUO is defined as a fever  $> 38.3$  °C lasting 3 days, which was not present or incubating on admission and produces negative cultures after 2 days. Definite criteria for FUOs in children have not been established, but, according to Gartner, the best definition is a fever occurring for = 8 days for which the history, physical examination, and laboratory data fail to reveal a cause ([Tables 18-1](#), [18-2](#), and [18-3](#)).

## Clinical Findings

To diagnose the cause of an FUO, the clinician should first document the presence of fever and its characteristics. Are there fevers, and how high do they get? Sometimes the presence of fever is only subjective (the patient feels warm but his or her temperature is normal). Although the fever pattern is rarely helpful in establishing a diagnosis, a history of periodic fever spikes suggests malaria, lymphoma, or cyclic neutropenia. Lymphoma (non-Hodgkin's and Hodgkin's) can present with the classic Pel-Ebstein fever, which is characterized by intermittent febrile periods lasting for days followed by days to weeks of afebrile periods. A reversal of the normal late-afternoon fever spike, that is, the presence of a morning fever spike, suggests tuberculosis, disseminated *Salmonella* infection, and polyarteritis nodosum. Two fever spikes may occur in a 24-h period with tuberculosis or malaria. Periodic fevers (those that last for days to weeks and then abate or occur at regular intervals) in children include cyclic neutropenia, familial Mediterranean fever, and a syndrome of fever, pharyngitis, and aphthous stomatitis.

The history and physical examination are extremely important for the diagnosis of an FUO because they enable the physician to focus the diagnostic studies. The history should include family history, ethnic background, travel history, and animal exposures. The history and physical examination should be repeated periodically if no cause of the FUO is discovered during the first evaluation. It is also important to discontinue as many medications (prescription and over-the-counter) as the patient can tolerate since drug fevers are common.

Laboratory tests and evaluation should be focused by the history and physical examination and should not be used randomly. Serial blood cultures (three blood cultures over a 48-h period) should be drawn to detect a bacterial, fungal, or mycobacterial infectious cause ([Table 18-3](#)). A history of exposures to animals might warrant specific serological studies, for example, brucellosis. A history of travel to endemic areas might dictate the need for a malaria smear. The Mantoux test with a purified protein derivative should be done in all patients, since tuberculosis is a common cause of FUOs even without a history of exposure.

However, if the clinical suspicion of tuberculosis is high (as for HIV-positive patients), a negative purified protein derivative does not rule out tuberculosis as a cause of FUO, and appropriate biopsies and cultures are indicated. A screening chest x-ray should be obtained to rule out lung diseases.

In general, noninvasive testing should be performed first. If the cause of an FUO is not discovered by these tests, then invasive testing may be necessary to establish a diagnosis. Invasive testing may include computed tomography scans, bone marrow biopsies, liver biopsies, and, rarely, abdominal laparotomy. Advanced scanning technology has significantly diminished the role for abdominal laparotomy.

## Differential Diagnosis

The differential diagnosis for FUO is broad. It is therefore best to categorize the potential causes into disease processes and then consider their likelihood within different subgroups of patients. The most common causes of classic FUOs (in nonhospitalized, ambulatory patients who do not fit into other subgroups) include infections, neoplasms, hypersensitivity, and autoimmune diseases ([Table 18-4](#)). In HIV-positive patients, the major causes of fever of unknown origin are infections such as tuberculosis, atypical mycobacterium such as *Mycobacterium avium* complex, and fungal infections. In contrast, the major causes of FUOs in elderly patients are malignancy and collagen vascular disorders, followed by occult infections.

In children, FUOs are rare. It is important to remember that normal mean temperatures increase with age until the child is 18 months old, after which they decrease. Therefore a temperature of 38.3 °C is normal in an 18-month-old child. Infectious diseases account for 45% of all FUOs in children, and half of these are respiratory tract infections. Of FUOs in children, ~ 13% are caused by connective tissue diseases, and ~ 6% are caused by neoplasia.

By knowing the frequency of the different diagnoses in each subgroup of patients, the clinician can narrow the search for the cause of the fever ([Table 18-5](#)). If these investigations are done properly, in > 90% of patients the causes of an FUO will be diagnosed.

**A. HIV-Positive Patients.** In HIV-positive patients with an FUO, other specialized testing should be performed. The differential diagnosis for HIV-related FUOs consists of mainly infectious causes such as tuberculosis, *Mycobacterium avium* complex, and disseminated fungal infections. Neoplasms such as lymphomas also cause FUOs in AIDS patients. Tuberculosis is a common cause, especially if the CD4 count is high. If the CD4 count is significantly decreased (< 100), atypical mycobacteria, mainly *Mycobacterium avium*, are the most common *Mycobacterium* species causing fever. Therefore work-ups of FUOs in AIDS patients should focus on those diagnoses.

Blood cultures should be done for bacteria, fungi, and mycobacteria. A serum cryptococcal antigen should also be ordered, because cryptococcal disease is also common in AIDS patients. Stool cultures should be obtained only if the patient has diarrhea. A chest x-ray should be obtained. A routine screening chest computed

tomography scan to look for adenopathy may be useful, since *M avium* complex can cause isolated hilar and mediastinal adenopathy not seen on chest x-rays. Bone marrow biopsy and liver biopsy should be considered early in the evaluation if the above tests are negative. Of HIV patients with FUOs, 86% will have a diagnosis established.

**B. Elderly Patients.** In elderly patients, the differential diagnosis of FUOs varies slightly from the classical differential. Neoplasms such as lymphoma or malignancies metastatic to the liver are the most common causes. Collagen vascular diseases, especially temporal arteritis, are also more frequent in the elderly. The classic presentation of jaw claudication and vision loss for giant cell arteritis may be absent in the elderly. Occult infections, especially abdominal infections or prostatitis in elderly males, can cause FUOs because the classical physical findings may be absent and the leukocyte count normal. Tuberculosis is also a significant cause of FUOs in the elderly. Other diseases such as sarcoidosis, lupus, Still's disease, and factitious fevers are more common in younger patients.

Because of the increased incidence of temporal arteritis, a temporal artery biopsy should be considered as a diagnostic test along with the other routine studies. Because of the increased incidence of occult abdominal abscesses, a computed tomography scan of the abdomen should be part of the evaluation. If, after a thorough investigation, no explanation for the fever is found, the patient may be monitored closely, weekly to biweekly, as an outpatient.

## Treatment

Empiric drug trials should be used with extreme caution and should not take the place of a thorough investigation for the cause of the FUO, especially if an infection is suspected. If malignancy is strongly suspected, a trial of naproxen can be tried. If investigations for an FUO in an HIV-positive patient are not successful in finding the cause, an empiric trial of antimycobacterial therapy may be useful. However, empiric treatment has not been evaluated scientifically. Neutropenic patients are the only group in which empiric broad-spectrum antibiotics should be started (see [Chapter 26](#)). Empiric therapy for neutropenic patients classically includes ceftazidime and an aminoglycoside; however, this may vary depending on gram-negative bacterial antibiotic susceptibilities in each hospital. Vancomycin can be added if a gram-positive infection is suspected or if the patient has persistent fevers. If fevers persist in this setting, antifungal agents should be added to the antibiotic regimen. Empiric antibiotic therapy should be started only after appropriate cultures have been done.

## **19 . Fever & Rash — *Peter K. Lindenauer, MD MSc, & Merle A. Sande, MD***

### **Essentials of Diagnosis**

- The combination of fever and rash is not a specific finding and can be seen in a variety of infectious and noninfectious disorders. Adverse reactions to drugs are the most common noninfectious cause of fever and rash.
- Because of the life-threatening nature of many of the illnesses causing fever and rash, a thorough, yet rapid, evaluation is required.
- Rule out treatable but immediately life-threatening causes of fever and rash early on.
- Diagnosis is best made by a thorough history and a proper classification of the rash. Laboratory testing is useful and specific for some diseases but of limited value for many others.
- An empiric approach to therapy is warranted when patients appear ill and a definitive diagnosis has not been made.
- Isolation is often warranted for patients with fever and rash when meningococemia or varicella is being considered, as these illnesses can be transmitted by respiratory droplets.

### **General Considerations**

The combination of fever and rash is a dramatic finding and can often reflect a life-threatening illness. Because of the variety of infectious and noninfectious disease processes that can present in this manner, an organized and thoughtful approach to patients with this syndrome is essential ([Table 19-1](#)).

More than for many other clinical problems, the history obtained from patients with fever and rash is critical in establishing an accurate diagnosis and embarking on effective treatment. Essential historical elements to review include the following: drug and dietary history, human and animal contacts (including a detailed sexual history), occupational exposures, travel, and immunizations. Reviewing the patient's prior medical history is vital as is a review of prior adverse drug reactions. Both the season and geographic location should be factored into the differential diagnosis. Special populations to consider include hospitalized patients as well as the immunosuppressed, especially those with HIV infection. Finally, a careful review of the time course and distribution of the rash can provide extremely valuable diagnostic clues.

### **PATIENT HISTORY**

#### **Drug Use**

Patients should be asked about all drug use: both prescription and over the counter, traditional and alternative, licit and illicit in the preceding weeks. Prescription drugs are common causes of fever and rash, and almost any drug may lead to this syndrome ([Figure 19-1](#)). Mechanisms underlying the development of adverse drug reactions can be either immunologically or nonimmunologically mediated, but in many instances the pathogenesis is not understood. Hospitalized patients who often begin treatment with multiple medications over a short time period are an extremely susceptible group. Because of the variety of mechanisms underlying the development of such adverse reactions, the cutaneous manifestations range from simple maculopapular to petechial or desquamating.

Frequently implicated medications include penicillins, sulfonamides, phenytoin, allopurinol, barbiturates, and occasionally nonsteroidal anti-inflammatory agents. Serum sickness is a multisystem illness that presents with fever, rash, arthritis, and glomerulonephritis and results from the deposition of circulating immune complexes throughout the body. It can be caused by exposure to sera but more commonly is induced by medications such as the ones listed above. Vasculitis syndromes can be caused by medications as well as by infections and malignancies. Photosensitivity is a property of certain drugs including tetracyclines, thiazide diuretics, and selected NSAIDs; as such, sun exposure should be reviewed. Because the preceding comments are, for the most part, equally applicable to over-the-counter as well as alternative medicines, use of both is important to document.

Illicit drug use, and injection drug use in particular, exposes the user to a range of bacterial and viral pathogens. Fever and rash in an injection drug user should raise the immediate possibility of infective endocarditis or acute hepatitis B infection. Moreover, because skin and soft tissue infections are common in this patient population, they are at higher risk of developing toxic shock and toxic streptococcal syndromes.

## **Diet**

Diet is occasionally found to be the cause of fever and rash. Food allergies to such substances as eggs, nuts, chocolate, and shellfish can cause both immediate, immunoglobulin E-mediated reactions and delayed hypersensitivity. The ingestion of undercooked pork or beef can result in trichinosis that may present with rash. Raw seafood and shellfish have been associated with vibrio vulnificus infections in patients with underlying liver disease. Typhoid fever is commonly associated with rash and is frequently seen in patients returning from the developing world where it is transmitted by the fecal oral route.

## **Contacts**

Contacts with sick individuals or with animals are important modes of transmission for many of the diseases that can cause fever and rash ([Box 19-1](#)). Viral illnesses are commonly transmitted this way, especially the classic childhood exanthems varicella zoster, rubella, measles, "fifth disease" (erythema infections resulting from parvovirus B-19), along with mononucleosis and cytomegalovirus. Bacterial infections, notably streptococcal and meningococcal, are usually associated with contact with an afflicted individual. Sexual contact is a mode of transmission of hepatitis B and is the source of

gonococcal, chlamydial, and syphilis infection. Acute HIV infection obtained sexually or through injection drug use often presents with fever, pharyngitis, and generalized rash.

### **Insect and Animal Exposure**

Insect and animal contacts are another important source of exposure to microbial pathogens that cause fever and rash in the setting of severe illness. Ticks are the vectors for Rocky Mountain Spotted Fever and Lyme disease; however, in only one-half of patients with Rocky Mountain Spotted Fever and one-third of patients with Lyme disease is a history of tick exposure obtainable. Capnocytophagia is an infection strongly associated with dog and cat bites in patients who are immunosuppressed, usually in the setting of splenectomy. Contact with livestock or contaminated water should raise the possibility of leptospirosis, whereas tularemia is seen in patients exposed to infected wild rabbits.

### **Travel**

Travel to endemic regions is usually described in cases of coccidioidomycosis and in viral hemorrhagic fever and scrub typhus. Malaria may present in travelers returning from an endemic area, and severe *Plasmodium falciparum* infections should be considered for those with petechial rashes accompanied by hemolysis, thrombocytopenia, and acute renal failure.

### **Occupational Exposure**

Occupational exposures should not be overlooked. Florists and gardeners are prone to sporotrichosis as a result of their extensive contact with soil and vegetation. Erysipelothrix, or fishmonger's cellulitis, is an unusual cause of fever and rash seen in patients with occupational or recreational fish contact.

### **Prior Medical History**

The prior medical history is the source of much valuable information when the clinician is confronted with a patient with fever and rash. Those with a history of valvular heart disease are at high risk for infective endocarditis. Immunosuppression from steroids, chemotherapy, or HIV is an important risk factor for the development of many of the infections previously discussed. Patients with a prior history of rheumatologic diseases or inflammatory bowel disease are often subject to flares that can include fever and rash as part of the presentation.

## **SEASON & GEOGRAPHIC SETTING**

Season and geographic setting are important factors influencing the diagnosis in patients with fever and rash. Rocky Mountain spotted fever is a disease of late spring to early fall, coinciding with increased exposure to the tick vectors *Dermacentor variabilis* or *Dermacentor andersoni*. Like Rocky Mountain spotted fever, Lyme disease occurs most commonly in the spring and summer months following contact with the infected tick nymph *Ixodes dammini* or *Ixodes pacificus*. Outbreaks of the exanthems caused by enteroviruses occur in warmer months, whereas streptococcal and meningococcal

disease occurs in late winter and early spring. Lyme disease cases cluster into three distinct geographic regions: the Northeast, the Upper Midwest, and the Far West. However, Rocky Mountain spotted fever has been reported in all states with the exception of Hawaii and Vermont, although its highest prevalence centers in the eastern and southern plains regions.

## **SPECIAL POPULATIONS**

### **HOSPITALIZED & IMMUNOSUPPRESSED PATIENTS**

Hospitalized patients are a special population and should be separately considered. As previously discussed, their high exposure to antibiotics and other new medications makes drug reaction a common cause of fever and rash. Neutropenic and immunosuppressed patients are at high risk of bacterial infection with *Pseudomonas aeruginosa*, *Clostridium* spp., and alpha hemolytic streptococci. Disseminated candidiasis, *Aspergillus*, and herpesvirus infections are common complications of neutropenia. Patients receiving broad-spectrum antibiotics or parenteral nutrition are at heightened risk of developing systemic candidiasis. Finally, indwelling catheters, shunts, prosthetic valves, and pacemakers place patients at risk of endovascular infections from recurrent transient bacteremic episodes.

### **HIV-INFECTED PATIENTS**

#### **Introduction**

Acute HIV infection may present with fever, rash, headache, pharyngitis, and aseptic meningitis. Dermatologic problems are common in this population and include eosinophilic folliculitis, papular dermatitis, and psoriasis. Pyoderma furunculosis and folliculitis can complicate HIV disease. Cutaneous manifestations of systemic infections may occur, and cutaneous infections may occur in severe forms. Varicella zoster and herpes simplex lesions are common and sometimes severe in HIV-infected patients. All disseminated fungal infections may involve the skin, and mycobacterial infection can present this way as well. Bacillary angiomatosis caused by *Bartonella* species is increasingly recognized as an important source of systemic illness (fever, hepatosplenomegaly, lymphadenopathy) accompanied by friable papules or nodules.

#### **Clinical Findings**

##### **A. Signs and Symptoms.**

**Appearance.** The appearance and distribution of the rash often provides valuable clues toward a diagnosis, and associated physical findings are characteristic of many of the entities described here.

The skin has a limited repertoire of responses to infections and immunologic challenges. Rashes can generally be divided into the following groups: (1) macular and maculopapular; (2) vesicular or bullous; and (3) pustular, petechial, or purpuric. Although this classification scheme can help limit the differential diagnosis, it must be understood that these distinctions are not absolute. Not only do many processes

present with a similar rash, but each disease or process can produce more than one type of rash (Table 19-2). Moreover, exanthems may change over the course of several hours or several days. Rocky Mountain spotted fever, which initially appears as an erythematous maculopapular eruption, often evolves into a petechial rash.

**1. Macular rashes.** A macular or maculopapular rash is the most common exanthem caused by the nonherpetic viruses such as enteroviruses (Figure 19-2), rubella, rubeola, and parvovirus B-19. Nevertheless, many serious infections can present this way including Rocky Mountain spotted fever, meningococemia, disseminated gonococcal infection, typhoid fever, and *Pseudomonas* sepsis. Lyme disease is associated with a characteristic rash termed erythema migrans, which is observed in > 60% of patients. Erythema migrans typically begins as a small red papule arising anywhere between 1 and 30 days after tick exposure and gradually expands to a ring of erythema with central clearing. Any site may be affected, but the axilla, groin, and thigh are most common. Some patients develop similar appearing secondary lesions at distant sites.

**2. Toxic shock syndrome** is characterized by a diffuse erythroderma (large macules) likened to a severe sunburn. The dermatologic findings are typically accompanied by fever, hypotension, and diffuse arthralgias and myalgias. Group A streptococci, which elaborate exotoxin, are capable of causing a similar syndrome, sometimes referred to as "toxic strep syndrome." While the skin is the portal of entry of most cases of toxic shock, in only a minority of cases can the actual source be identified. Although tampon use during menses was initially described in the majority of patients, this now accounts for less than half of the 300 or so annual reported cases. Whereas the skin infections resulting in toxic shock syndrome are often minor, those associated with toxic streptococcal infections are often severe. Myositis and necrotizing fasciitis are common sequelae of these infections, and this virulence is reflected in a case fatality rate for toxic streptococcal infections that is some fivefold higher than that seen in toxic shock. Secondary syphilis occurs some 6-8 weeks after healing of the chancre seen in primary syphilis, although some patients may progress to secondary syphilis while a chancre remains present. The lesions are erythematous and macular or maculopapular, are symmetrically distributed, and often involve the palms and soles (Figure 19-3). The rash is frequently accompanied by constitutional symptoms and lymphadenopathy. Drugs often produce maculopapular exanthems that are "cherry-red" in appearance. The "target lesions" of erythema multiforme and the "slapped cheeks" of parvovirus B-19 are both examples of maculopapular lesions distinctive enough to be almost pathognomonic.

**3. Vesicular rashes.** Vesicular lesions are caused by a number of viruses including varicella-zoster, herpes simplex, vaccinia, and the enteroviruses. The staphylococcal scalded skin syndrome is characterized by large bullae that rupture, leaving behind beefy red areas of denuded skin. *Pseudomonas* septicemia can be associated with vesicles that rapidly become hemorrhagic or with the centrally necrotic lesions of ecthyma gangrenosum. Stevens-Johnson syndrome causes vesicular lesions of both the skin and mucosa. Ulcerative colitis and Crohn's disease can cause vesicular lesions that progress to chronic ulceration and may have prominent mucosal involvement.

**4. Petechial, purpuric, or pustular rashes.** Petechial, purpuric, or pustular skin lesions often indicate life threatening illness. The identification of such a rash should call

immediate attention to the treatable bacterial or rickettsial infections that may be responsible for its appearance. Most prominent among these illnesses are meningococcemia, Rocky Mountain spotted fever ([Figure 19-4](#)), infective endocarditis, or sepsis with associated disseminated intravascular coagulation. Disseminated gonococcal infection produces a less severe illness often associated with migratory polyarthritides and tenosynovitis ([Figure 19-5](#)). Atypical measles can produce a petechial rash that may mimic that seen in Rocky Mountain spotted fever and is seen in that cohort of patients previously vaccinated with a killed measles vaccine. Occasionally, enteroviral infections can produce petechial lesions, and other viruses including dengue and Epstein-Barr virus may do so as well. Many noninfectious causes of fever and rash present with petechial lesions, the most important of which are systemic lupus erythematosus, Henoch-Schonlein purpura, thrombotic thrombocytopenic purpura, and many of the vasculitides.

**Distribution.** The distribution of the rash may also aid in diagnosis. A macular or petechial rash involving the palms or soles should suggest Rocky Mountain spotted fever, meningococcemia, infective endocarditis, *Mycoplasma* infection, scarlet fever, or bacteremia. The lesions of secondary syphilis, atypical measles, Kawasaki's disease, and many drug exanthems may present similarly. Maculopapular rashes caused by viruses usually spare the palms and soles, whereas these sites may be involved in vesicular exanthems caused by herpesvirus and certain coxsackie virus strains. Exanthems with a tendency to involve the extremities preferentially include gonococcemia, Henoch-Schonlein purpura, dermatomyositis, and sporotrichosis. The "rose spots" of typhoid fever and the maculopapular lesions of *Pseudomonas* sepsis are usually confined to the trunk. Scarlet fever begins on the face and neck and spreads to the trunk and extremities within 36 hours. Rubeola usually begins behind the ears and spreads throughout the body within the first day.

**B. Laboratory Findings.** As a general rule, diagnostic procedures that are likely to yield immediate results should be carried out on any lesion. Pustular, purpuric, or petechial lesions should be aspirated or scraped and the fluid obtained examined microscopically and cultured. Many patients with meningococcemia can be diagnosed by this simple procedure, which will demonstrate gram-negative biscuit-shaped cocci. Vesicular lesions should be unroofed, and the contents should be examined microscopically using a Wright or Giemsa stain to look for multinucleated giant cells or inclusion bodies characteristic of herpes virus infection (Tzanck test).

Needle aspiration can be used to diagnose group A streptococcal infections in patients with necrotizing fasciitis and should be considered as a means of diagnosing pseudomonas sepsis in immunosuppressed patients with maculopapular rashes. These techniques can provide immediate diagnosis long before a blood culture has had sufficient time to yield an organism. Punch biopsy can be used to identify fungal and mycobacterial disease involving the skin and is diagnostic of vasculitis and erythema multiforme. Immunofluorescent antibody staining is useful in skin biopsy specimens of patients with suspected Rocky Mountain spotted fever and is also used to diagnose systemic lupus erythematosus and pemphigus vulgaris.

In cases where genitourinary, articular, or neurologic symptoms coexist with rash, urethral and cervical swabbing and culturing is mandatory as is arthrocentesis and

examination of the cerebrospinal fluid. Blood cultures should be routinely performed in all patients since bacteremia is an especially common cause of fever and rash.

Serologic testing is limited in its usefulness in the acute setting but can be important for confirming a diagnosis and for disease reporting purposes. For example, serologic tests for Lyme disease, especially early in the course of disease, are hampered by an unacceptably high false negative rate and the diagnosis of Lyme disease is largely a clinical one. Polymerase chain reaction-based assays are emerging as an accurate method for diagnosing many of the diseases discussed in this chapter, but today, their limited availability and relatively high cost makes them a poor choice for the typical patient with fever and rash.

**C. Imaging.** A chest radiograph is a useful adjunct in the evaluation of patients with fever and rash since it can be used to detect pulmonary infiltrates or hilar adenopathy. Other imaging tests cannot be recommended on a routine basis.

### Differential Diagnosis

Because the differential diagnosis of fever and rash is so broad and because of the urgency involved in a small number of cases, it is useful to divide the disorders into the following categories: immediately life-threatening, treatable infectious, nontreatable infectious, and noninfectious causes ([Table 19-3](#)).

Associated physical findings are seen in many of the disorders that cause fever and rash, and their recognition is helpful in limiting one's differential diagnosis. Enanthems are mucous membrane eruptions, and many of the processes that involve the skin can involve the mucous membrane as well. Koplik's spots are diagnostic of rubeola and are found on the buccal mucosa opposite the second molar ([Figure 19-6](#)). They are blue-gray specks on a red base resembling a grain of sand. "Strawberry tongue" is characteristic of Kawasaki's disease, toxic shock syndrome, or scarlet fever. Palatal petechia is observed in 50% of patients with infectious mononucleosis and is also seen in infective endocarditis. Ulcerative mucosal lesions are observed in hand-foot and mouth disease, Behcet's syndrome, Reiter's syndrome, inflammatory bowel disease, and the Stevens-Johnson syndrome.

Meningitis and other neurologic changes may be observed in meningococcemia, Rocky Mountain spotted fever, staphylococcal bacteremia leptospirosis, Kawasaki's disease, toxic shock syndrome, Lyme disease, and as part of the aseptic meningitis seen in acute HIV and enteroviral infections. Lymphadenopathy is prominent in mononucleosis, syphilis, sarcoidosis, and drug hypersensitivity. Cervical adenopathy is seen in streptococcal pharyngitis in the setting of scarlet fever and with rubella. The finding of a heart murmur should raise the possibility of infective endocarditis even if findings such as Osler nodes, Janeway lesions, or splinter hemorrhages are absent. Fever and rash associated with pneumonia is seen in *Mycoplasma* infection, atypical measles, Rocky Mountain spotted fever, coccidioidomycosis, or sepsis associated with staphylococcal or pseudomonas pneumonia.

### Complications

Complications relate to the specific pathogen responsible for the syndrome of fever and rash, and no complications are common to the group. Patients with meningococemia are at risk for the development of the sepsis syndrome, disseminated intravascular coagulation, or death unless appropriate antibiotics are promptly begun. Rocky Mountain spotted fever is a multisystem disease that can cause encephalitis in approximately one quarter of cases. Infective endocarditis, if left untreated, rapidly progresses and is associated with valve destruction and incompetence as well as complications from septic emboli, such as stroke. Toxic shock syndrome is associated with profound hypotension, and it is this aspect of the illness that results in the vast majority of its complications. The complications from toxic epidermal necrolysis and staphylococcal scalded skin syndrome relate primarily to the degree of epidermal necrosis and include metabolic derangement and severe immunosuppression.

## Treatment

Treatment of fever and rash may be specific (as in the case of a recognized bacterial infection presenting in a classic fashion), empiric (as for the toxic appearing patient with petechial skin lesions), or supportive (as in most viral infections). A general approach to patients with fever and rash depending on whether the illness was nosocomially acquired or in a community is found in [Box 19-2](#). While this can provide a useful starting place, the clinician is strongly encouraged to tailor decisions regarding the need for, and type of, antibiotic therapy only after a careful review of the factors discussed earlier in this chapter.

## Prognosis

Mortality in patients with fever and rash is closely tied to the organism or process responsible for the syndrome and to the timeliness of recognizing and instituting appropriate therapy.

## Prevention and Control

Isolation is useful to reduce the risk of spread of meningococemia and varicella zoster. Care in the avoidance of tick exposure is the only method of preventing Rocky Mountain spotted fever and Lyme disease. The practice of safe sex can eliminate the possibility of obtaining syphilis or gonococcal infections.

    - Essentials of Diagnosis
-

### **Table 19-1. Diagnostic approach to fever and rash.**

- Obtain a thorough history, reviewing all drugs and medications used in the preceding weeks, travel, contacts with sick children and adults, exposure to pets, wild animals or insects, sexual history, prior immunizations, past medical history paying particular attention to rheumatic diseases, valvular heart disease or immunosuppression, and onset and distribution of the rash and associated symptoms.
- On physical examination, note the overall severity of the patient's illness, the form and distribution of the rash, and the presence of any associated physical findings.
- Rashes should be grouped as (a) macular and maculopapular, (b) vesicular and vesiculobullous, or (c) petechial, purpuric, and pustular. Each of these categories has a fairly unique differential diagnosis.
- Petechial, purpuric, and pustular lesions **that** can be aspirated should be gram stained and sent for culture. Vesicular and vesiculobullous lesions should be unroofed, scraped, and examined for the presence of multinucleated giant cells or inclusion bodies. Punch biopsy is a useful method for diagnosing both infectious and noninfectious disorders and should be considered whenever Rocky Mountain Spotted Fever is suspected or whenever a diagnosis is in doubt. Aerobic and anaerobic blood cultures **should be obtained for all patients.**
- **In the acute setting**, serologic studies are of limited usefulness for most of the disorders **that** cause fever and rash.
- Polymerase chain reaction-based assays are rapidly emerging as the diagnostic tests of choice for a number of infections **that** cause fever and rash, but their use is limited by availability.

**BOX 19-2.** Empiric Therapy of Fever and Rash<sup>1,2</sup>

	<b>Community Acquired</b>	<b>Hospital Acquired<sup>3</sup></b>
<b>First Choice</b>	Ceftriaxone 2 g IV every 24 h <b>PLUS</b> doxycycline <sup>4</sup> 100 mg IV every 12 h	Ceftazidime 2 g IV every 8 h <b>PLUS</b> APAG <b>PLUS</b> vancomycin 1 g IV every 12 h
<b>Second Choice</b>	Chloramphenicol 100 mg/kg/d IV divided every 6 h	Piperacillin <b>PLUS</b> APAG <b>PLUS</b> vancomycin 1 g IV every 12 h
<b>Penicillin Allergic</b>	Ciprofloxacin <sup>5</sup> 500 mg IV every 12 h <b>PLUS</b> doxycycline 100 mg IV every 12 h	Ciprofloxacin 500 mg IV every 12 h <b>PLUS</b> APAG <b>PLUS</b> vancomycin 1 g IV every 12 h

<sup>1</sup>Because of the diverse causes of fever and rash, it is of limited value to suggest empiric antibiotic therapy in a blanket way.

<sup>2</sup>In immunocompromised patients, *Varicella zoster* infections should be treated aggressively with intravenous acyclovir.

<sup>3</sup>Hospitalized patients and those with immunosuppression are at higher risk of developing pseudomonas sepsis syndromes and disseminated staphylococcal infections and should have antibiotic coverage extended with a third-generation cephalosporin with activity against *Pseudomonas* spp., or an extended-spectrum penicillin (piperacillin, ticarcillin) and an aminoglycoside, as well as vancomycin. However, antibiotics themselves may cause fever and rash, and discontinuation of drugs may be the treatment of choice. APAG, Antipseudomonal aminoglycoside. Dosing of gentamicin and tobramycin is 5 mg/kg every 24 h or 1.5 mg/kg every 12 h.

<sup>4</sup>Patients with a history compatible with Rocky Mountain spotted fever should be treated empirically with doxycycline because the laboratory diagnosis of this infection cannot be relied on.

<sup>5</sup>Ciprofloxacin should not be used in children.

## 20 . Infectious Diarrhea — *William P. Ciesla, Jr., MD, & Richard L. Guerrant, MD*

### Essentials of Diagnosis

- Key signs and symptoms include increased frequency of stools and/or the presence of unformed or watery stools, grossly bloody stool, tenesmus, abdominal cramping or pain, fever, nausea and vomiting, and volume depletion.
- Most enteric pathogens are acquired by the fecal-oral route with food or water. Other risk factors include antibiotic use, travel to the developing world, AIDS, and institutional care.
- Infectious diarrhea is classified as inflammatory or noninflammatory based on the underlying pathophysiology; cases are distinguished clinically by the history and the presence or absence of fecal leukocytes or lactoferrin.
- Once the stool has been examined for fecal leukocytes or lactoferrin, additional laboratory workup should be individualized for each patient based on the available data.
- In the United States, inflammatory infectious diarrhea is caused chiefly by *Shigella*, *Salmonella*, and *Campylobacter* spp.; noninflammatory diarrhea has numerous viral, bacterial, and protozoal causes.
- Grossly bloody diarrhea is often secondary to enterohemorrhagic *Escherichia coli* (EHEC).
- Antibiotic-associated diarrhea and colitis are often caused by *Clostridium difficile*.

### General Considerations

Diarrheal illnesses caused by bacterial, protozoal, or viral pathogens remain a major cause of morbidity and mortality throughout the world. In developing countries, poor sanitation and substandard living conditions create an environment in which diarrheal pathogens exact a terrible toll, especially among children. In the industrialized world, infectious diarrhea remains a common problem among all age groups. Moreover, epidemiologic events such as the AIDS epidemic, the globalization of the food supply, and emergence of new pathogens are increasingly factors in diarrheal illnesses. Chlorine-resistant *Cryptosporidium parvum* now threatens our drinking water, *Cyclospora cayetanensis* and EHEC menace our food supply, and toxigenic *C difficile* increasingly is a problem in hospitalized and institutionalized patients. Given the ubiquitous nature of infectious diarrhea, it is imperative that primary care physicians and infectious disease specialists have a firm understanding of the diagnosis and treatment of these diverse and potentially devastating illnesses.

**A. Epidemiology.** The magnitude of the morbidity and mortality related to infectious diarrhea is staggering. Overall, diarrheal illnesses are the second leading cause of

death after cardiovascular diseases and the leading cause of death among children. In the developing world, the diarrheal attack rate can be as high as 6-12 episodes per child per year and an estimated 3-4 million children below the age of 5 years will die each year as a result of complications related to diarrhea (> 9,000 deaths per day). These regions continue to experience pandemics secondary to diarrheal pathogens, as witnessed for example, by the extension of the seventh cholera pandemic to South America in the early 1990s. The impact of infectious diarrhea on health of those infected reaches far beyond the acute symptoms. Repeated or chronic diarrheal illnesses are increasingly recognized as major contributors to malnutrition worldwide, potentially leading to impaired intellectual development, growth retardation, and increased susceptibility to other infectious pathogens.

In industrialized countries, a century of achievements in public health and sanitation have markedly diminished the widespread carnage of diarrheal pathogens common in the developing world. Nevertheless, infectious diarrhea remains a significant problem, one that appears to be increasing with the emergence of new epidemiologic factors and pathogens. Every year in the United States, there are an estimated 25 million cases and 5,000-10,000 deaths caused by infectious diarrhea. As elsewhere in the world, children experience the highest incidence of diarrhea; between 2.0 and 3.2 illnesses per child per year (up to 5.0 illnesses per child per year for children in day care). However, adults and especially the elderly are not spared. The elderly population especially is at risk for the more serious sequelae of infectious diarrhea, and most of the mortality related to gastroenteritis in adults occurs in this group.

A number of different epidemiologic factors are important to consider when approaching a patient who may have diarrhea caused by an infectious agent. Contaminated food or water ingestion, recent travel, antibiotic use, HIV positivity or AIDS, and institutional or day care all are important clues to identify the patient who may be at increased risk for developing infectious diarrhea.

**Contaminated Food.** The acquisition of diarrheal pathogens through the food supply is a major problem both in the developing world and in the United States, where 400-600 documented food-borne outbreaks and millions of cases are estimated to occur each year. A number of foods and pathogens have been associated with food-borne diarrheal illnesses: raw or poorly cooked shellfish (*Vibrio parahaemolyticus*, Norwalk virus), chicken (*Campylobacter jejuni*; see [Chapter 57](#)), eggs (*Salmonella enteritidis*; see [Chapter 53](#)), chocolate milk (*Listeria monocytogenes*; see [Chapter 51](#)), reheated fried rice (*Bacillus cereus*; see [Chapter 51](#)), and undercooked beef, unpasteurized apple cider, lettuce, and alfalfa sprouts (EHEC; see [Chapter 53](#)). The mode of food contamination is varied; an infected food handler with poor hygiene, untreated human or animal waste used as fertilizer, unclean water used to wash or prepare food, and animal feces mixing with meat products during or after slaughter all have been implicated. In addition, evolving social and economic factors are emerging to further facilitate the spread of food-borne pathogens in the United States. First, over one-third of the produce now consumed in the United States is imported, often from developing regions with varied agricultural practices and abundant exotic pathogens. This threat manifested itself recently in several outbreaks associated with imported Guatemalan raspberries contaminated with the parasite *Cyclospora* sp. Second, an increasing proportion of meals are now prepared outside the home (eg, in restaurants), exposing large numbers

of people to common source outbreaks related to, for example, an infected food handler or contaminated foodstuffs. Finally, the intentional contamination of the food supply by diarrheal pathogens has emerged as a form of biological terrorism. One incident in the United States involved > 700 cases of *Salmonella* gastroenteritis related to the intentional contamination of restaurant salad bars with *Salmonella typhimurium*. This criminal act was committed by a religious commune in an apparent attempt to influence voter turnout for a local election.

**Contaminated Water.** Drinking water, often contaminated by human or animal fecal waste, is a common mode of acquisition of diarrheal pathogens in the developing world and when natural disasters disrupt the normal sanitation infrastructure in industrialized countries. In addition, many lakes, rivers, and streams contain myriad organisms such as *Giardia lamblia* and EHEC. Hikers and swimmers are at risk when they drink unfiltered water from these sources. In the past, municipal water supplies in the United States were generally considered free from diarrheal pathogens because of modern chlorination and filtering procedures. This notion was challenged in 1993 when a large water-borne outbreak of infectious diarrhea in Milwaukee was caused by the parasite *Cryptosporidium parvum*. This outbreak affected > 400,000 people despite the use of standard purification procedures; further outbreaks have occurred despite even more stringent filtration standards.

**HIV and AIDS.** HIV-positive and AIDS patients are at significant risk for diarrheal illnesses. More than 30 million patients are believed to be infected with HIV worldwide, and it has been estimated that 50-90% of these patients will develop a significant diarrheal illness at some point, especially as the CD4 count drops below 200. Depending on the pathogen involved, these patients can develop debilitating chronic diarrhea with few therapeutic options. Infectious agents and drug side effects are the two major causes of diarrhea in this population.

**Hospitalization or Institutional Care.** Hospitalization or institutional care is another important and often overlooked risk factor. In the United States, 1-2% of all hospitalized patients will develop an episode of nosocomial diarrhea, leading to volume and electrolyte losses as well as predisposing the patient to other nosocomial infections. Large populations of compromised patients, frequent antibiotic use, and *C difficile* spores in the hospital environment all contribute to the risk in this population. Children in day care are also at increased risk, given the poor personal hygiene and clustering of large numbers of children together in this setting. Outbreaks are often caused by organisms such as *Shigella* or *Giardia* spp. that require a small infectious dose and are readily spread from child to child by direct contact.

Antibiotic use places patients at risk for the development of antibiotic-associated diarrhea, especially in the hospital setting. The onset of diarrhea usually occurs while the antibiotic is being administered, but onset can be delayed for several weeks after the antibiotic has been stopped. Virtually all antibiotics have been implicated as a cause; clindamycin has the highest risk with 10-20% of patients who receive antibiotics developing antibiotic-associated diarrhea, but penicillins and cephalosporins are the most important culprits given their widespread use. *C difficile* infection accounts for ~20% of all antibiotic-associated diarrhea and virtually all cases of pseudomembranous colitis secondary to antibiotic use. The etiology of the remaining cases of

antibiotic-associated diarrhea remains unknown.

**Travel to Developing Countries.** Travel from an industrialized country to the developing world places large numbers of people at risk for the acquisition of infectious diarrhea. An estimated 8 million Americans travel to developing regions each year, and up to 50% will develop diarrhea during their stay. Although these illnesses are rarely life-threatening, they have a significant impact on the tourist industry and on business travelers. Traveler's diarrhea has also been a major problem in military deployments, leading to the incapacitation of large numbers of soldiers. Early in operation Desert Storm during the Gulf War in 1990, for example, the attack rate for infectious diarrhea among American soldiers in Saudi Arabia was as high as 10%/week.

## Clinical Findings

Documenting a careful and directed history is absolutely critical when approaching the patient who may have infectious diarrhea. Clues in the history are very helpful in assessing the severity of the patient's illness, narrowing the differential diagnosis of potential pathogens, and choosing an appropriate therapeutic course.

**A. Signs and Symptoms.** Diarrhea is defined as  $> 250$  g of stool per 24 h, but such a measurement is rarely made clinically. A more practical definition is an increase in stools to = 2-3 liquid stools per day, an increased frequency of stools compared with the patient's normal pattern or the presence of liquid stools. In infants, the number of diaper changes may help discern if a diarrheal illness is present.

In general, two different clinical syndromes are described in patients with infectious diarrhea, each with its own set of causative organisms. Noninflammatory diarrhea occurs with pathogens that act primarily in the small intestine to induce fluid secretion by various mechanisms and produce minimal, if any, intestinal inflammation. These patients usually present with voluminous watery diarrhea, nausea and vomiting, abdominal cramps, and minimal or low-grade fevers. The second syndrome, inflammatory diarrhea, is typically seen with pathogens that induce inflammation in the colon via invasion or cytotoxins. These patients present with fever, diarrhea with smaller volumes of stool (often  $< 1$  L), blood or mucus in the stool (dysentery), tenesmus, and lower quadrant cramping. A history of grossly bloody stools should suggest EHEC infection, now the major infectious cause of bloody diarrhea in the United States. The duration of the diarrhea should be determined, because this information is also helpful in narrowing the differential.

Whether inflammatory or noninflammatory, diarrhea may be acute (lasting  $< 2$  weeks) or persistent (lasting  $> 2$  weeks); some refer to diarrhea lasting  $> 1$  month as "chronic." Acute diarrhea is usually caused by infectious agents (viruses and bacteria), the ingestion of preformed bacterial toxins, or drugs. Persistent diarrhea is more often caused by parasitic pathogens or noninfectious causes.

The hydration status of the patient should be assessed by asking about orthostatic symptoms (dizziness or lightheadedness upon standing), decreased urine output, increased thirst, and the ability of the patient to take oral fluids. For viral infections and certain types of bacterial food poisoning, prominent nausea and vomiting may be a clue

to the diagnosis. High-grade fever is more common with pathogens that invade or disrupt the colonic epithelium, leading to intestinal inflammation. Mild abdominal cramping or pain is often present. More severe abdominal pain, localized to the right lower quadrant and mimicking acute appendicitis, can be seen with *Yersinia enterocolitica* and *C jejuni* infections.

The patient should be asked about similar illnesses in family members or close contacts, suggesting a common source outbreak related to a specific pathogen. The clinician must also be aware of any potential outbreaks that may be occurring in the community and always be alert to potential clustering of similar cases, which may point to an unrecognized outbreak. A careful history of recent food ingestion, including any deviations from the normal diet, should be obtained. HIV risk factors or a history of HIV positivity or AIDS is important, as is a sexual history for anal intercourse-related sexually transmitted diseases (STDs) (proctitis caused by gonorrhea, syphilis, herpes, or *Chlamydia* infection).

The key to examining the patient with diarrhea is to assess the hydration status and determine if there has been significant volume loss. Supine and standing blood pressure and pulse rates should be determined to assess for orthostatic hypotension. Supine hypotension and resting tachycardia can indicate life-threatening hypovolemia and the need for aggressive fluid resuscitation. The mucous membranes should be assessed for moisture and the skin for tenting. In infants, lethargy, dry mucous membranes, flat fontanelles, sunken eyes, poor capillary refill, and poor skin turgor may all be clues of significant hypovolemia.

The abdominal exam usually is unrevealing in most cases of infectious diarrhea. There may be diffuse, mild tenderness and hyperactive bowel sounds, but usually no rebound or guarding. However, severe cases of *C difficile* may result in peritoneal signs and *Y enterocolitica* and *C jejuni* can mimic an acute appendicitis as mentioned. A rectal examination and stool guaiac test should be performed to look for occult blood. A fresh stool sample should be obtained in a specimen cup for gross examination to give an objective assessment of the patient's complaints. The appearance of the stool—watery, mucoid, or grossly bloody—can be very helpful in narrowing the differential diagnosis and focusing the laboratory examination.

**B. Laboratory Findings.** The lab evaluation of suspected infectious diarrhea should begin with testing of the stool for the presence of fecal leukocytes. The stool normally does not contain fecal leukocytes, and if present, they are considered a marker for colonic inflammation secondary to both infectious and noninfectious causes. This test can be performed easily at the bedside using a stool smear stained with methylene blue or it can be done by the microbiology lab in most hospitals. Because the neutrophils will degenerate with time, the sample should be examined as soon as possible. In most series, the sensitivity of the fecal leukocyte test for various inflammatory pathogens (*Salmonella*, *Shigella*, and *Campylobacter* spp.) detected by stool culture varies from 45% to 95% depending on the pathogen (most sensitive for *Shigella* spp.).

Another, more stable marker for the presence of intestinal inflammation is lactoferrin. Lactoferrin is an iron-binding glycoprotein released from neutrophil secondary granules; its presence in stool is indicative of colon inflammation. False positives are known to

occur in breast-fed infants, so fecal lactoferrin should be used with caution in this population. In one study, fecal lactoferrin, detected using a commercially available latex agglutination assay, was 83-93% sensitive and 61-100% specific for patients with *Salmonella*, *Campylobacter*, or *Shigella* spp. detected by stool culture. Lactoferrin tests have the advantage of being sensitive in cases in which the pathogen can lyse the fecal leukocytes as a result of cytotoxic toxins (*C difficile*), via adherence mechanisms (*Entamoeba histolytica*) or if the stool sample is not examined immediately.

Testing for fecal leukocytes or lactoferrin is advocated as a way to help identify infections by diarrheal pathogens that result in intestinal inflammation, because the patients may benefit from antimicrobial therapy and tend to have more severe sequelae. The clinical presentation can provide clues to identify these patients, but there can be considerable overlap in symptoms between the inflammatory and noninflammatory syndromes. The presence of fecal leukocytes or lactoferrin provides information in addition to the history to decide whether a stool culture and antibiotic therapy are indicated. The limitations of using fecal leukocyte or lactoferrin testing for this purpose are obvious from looking at their respective sensitivities and specificities. However, as long as the clinician recognizes these limitations and interprets the results in the context of the clinical setting, fecal leukocyte or lactoferrin tests should remain important tools in approaching the patient with infectious diarrhea.

Stool cultures should be considered for all patients suspected of having inflammatory diarrhea based on the clinical and epidemiologic history, a positive fecal leukocyte or lactoferrin test, or both. In the United States, the most common infectious causes of inflammatory enteritis are *C jejuni*, *Salmonella* spp., and *Shigella* spp. Most laboratories will automatically culture for these organisms if stool is sent for routine bacterial culture. Stool culture for other bacterial pathogens often will require special media or handling. In these cases, communication with the microbiology laboratory about the clinically suspected pathogens is very helpful to ensure that the specimens are cultured properly. Patients with grossly bloody diarrhea or a suggestive epidemiologic history should have their stool cultured for EHEC O157:H7. However, an increasing portion of EHEC infections are now caused by non-O157 serotypes (= 50%), so if EHEC is suspected, non-O157 serotypes must be considered. A commercially available enzyme immunoassay can now identify the presence of Shiga bacillus toxin in *E coli* isolates or in the stool. It is sensitive, specific, and often will remain positive after the stool culture becomes negative.

For hospitalized patients, the use of routine bacterial stool cultures and parasite examinations should be governed by the "3-day rule" for bacterial cultures and the "4-day rule" for parasite exams recently advocated by the College of American Pathologists. These rules are based on several studies showing that the yield of such tests is extremely low in patients who develop diarrhea after being hospitalized for > 3-4 days and such tests are not cost effective. The pathogens that are detected by these tests are uncommonly acquired in the hospital setting in the United States. However, the application of these rules should be flexible and allow for those cases where, after careful clinical consideration, potential pathogens likely to be detected by these tests are still in the differential irrespective of the length of hospitalization.

If the diarrhea persists for > 7 days or if the history raises the possibility of a parasitic

infection, then the stool should be examined by the appropriate studies. Helpful tests include the classic ova and parasite exam, the funnel gauze test for *Strongyloides* spp., direct fluorescence staining for *Giardia* and *Cryptosporidium* spp., modified acid fast stain of the stool for *Cryptosporidium* or *Cyclospora* spp., or trichrome staining for microsporidia. The ova and parasite (O+P) exam involves concentrating the stool specimen and then preparing a smear to look for parasite cysts or trophozoites and intestinal helminths. Among the diarrheal pathogens that can be detected by the O+P smear are *E histolytica* and *G lamblia*. Unfortunately, the O+P exam can have a low yield, so consideration should be given to using one of the pathogen-specific tests noted above.

A history of recent antibiotic use or hospitalization in a patient with diarrhea should raise the concern of *C difficile*, and the stool should be tested for the presence of *C difficile* toxins. The gold standard assay is the stool-cytotoxin test, looking at the ability of toxin B to induce cytopathic effects in cultured cells. It is 94-100% sensitive and 99% specific. Several new immunoassays are now available that are cheaper and faster than the stool-cytotoxin assay, but also less sensitive and specific. Several stool samples should be tested over sequential days before completely excluding *C difficile* infection.

In addition to stool studies, patients with severe diarrhea, fever, abdominal pain, or volume loss should have serum chemistries, including sodium, potassium, chloride, blood urea nitrogen, and creatinine, and have a complete blood count checked.

**C. Imaging.** Radiographic studies are usually not helpful or indicated in the evaluation of infectious diarrhea except in specific cases. Severe *C difficile* colitis may lead to toxic megacolon and the associated risks of intestinal perforation. Patients with *C difficile* colitis who exhibit severe abdominal pain, peritoneal signs, and a decreasing output of diarrhea should be monitored for this potentially devastating complication with serial abdominal x-rays.

Direct imaging such as sigmoidoscopy, colonoscopy, or esophagogastroduodenoscopy can play a role in cases of chronic diarrhea in which the diagnosis remains unclear despite use of appropriate studies. Esophagogastroduodenoscopy with duodenal aspiration or biopsy can be used to detect *G lamblia*. Sigmoidoscopy or colonoscopy may show mucosal changes like erythema, ulcers, or pseudomembrane formation (*C difficile*). Biopsy may reveal adherent bacteria (enteroaggregative *E coli*), viral inclusions (cytomegalovirus colitis) or pathology consistent with noninfectious diseases.

## Differential Diagnosis

The most important question in managing the patient with suspected infectious diarrhea is to decide who will benefit from a directed laboratory evaluation and specific antimicrobial therapy. For most cases of noninflammatory diarrhea, the illness will be self-limited and require only supportive care. In these cases, extensive laboratory evaluation will be of no benefit except from an epidemiologic standpoint and will waste considerable health care resources. As a general rule, patients with a duration of illness longer than 2 days, high fever, systemic toxicity, bloody stools, fecal leukocytes or lactoferrin, severe volume depletion or abdominal pain, and those who are immunocompromised (ie, with immunosuppressive chemotherapy after organ transplant

or with AIDS) should have a more extensive evaluation initiated at presentation. Other patients can be followed for resolution of their illness and evaluated only if one of the above criteria develops or as part of a public health investigation.

[Figure 20-1](#) outlines a general approach to the patient with infectious diarrhea, using the history and the presence or absence of fecal leukocytes or lactoferrin to classify the diarrhea as noninflammatory or inflammatory. Unfortunately, there are no prospective studies that validate this algorithm by showing a decrease in morbidity or mortality. However, keeping in mind the limitations of fecal leukocytes or lactoferrin as previously discussed, it is useful to begin to formulate the differential diagnosis and to guide therapy. [Box 20-1](#) lists the common pathogens causing inflammatory and noninflammatory diarrhea, bloody diarrhea, and diarrhea in AIDS patients and in travelers to developing countries. In the following section, we discuss some of the more common pathogens, briefly outlining general epidemiologic, clinical, and diagnostic information that will be useful in narrowing the differential diagnosis. The reader is referred to the specific chapters elsewhere in this book for more detailed and complete information about the potential pathogens. Finally, in considering the differential diagnosis in a patient with diarrhea, the clinician must always remember noninfectious causes and obtain a careful history of medication use, enteral feedings, and symptoms suggestive of inflammatory bowel disease, endocrinopathies, ischemic colitis, or malabsorption.

#### **A. Inflammatory Diarrhea [positive fecal white blood cells and or fever].**

**Bacterial Species.** *C jejuni* ([Chapter 57](#)) is probably the major cause of community-acquired inflammatory enteritis in the United States, causing an estimated 2 million cases each year. The organism is transmitted via poorly cooked chicken and contaminated milk or water or on unwashed cooking utensils. The infection usually results in an acute enteritis with watery or bloody stools, fever, and abdominal pain that usually resolves within 1 week. The diagnosis is made by isolating the organism by stool culture.

*Salmonella* ([Chapter 53](#)) gastroenteritis is another major cause of inflammatory diarrhea acquired via contaminated food, milk, or water. Within 48 h of ingestion, most patients will develop fever, watery diarrhea, and abdominal cramping that resolves within 10 days. The stool contains moderate numbers of fecal leukocytes, and the diagnosis is made by stool culture. *S enteritidis* (associated with undercooked eggs) and *S typhimurium* are the most common *Salmonella* isolates implicated in the United States. A small percentage of patients with enteric fever syndromes from *Salmonella typhi* or *Salmonella paratyphi*, characterized by fever and abdominal pain, may present with constipation, diarrhea, or both, early in the course. Bacteremia and subsequent metastatic foci of infection are serious complications that can occur with *Salmonella* gastroenteritis and enteric fever.

*Shigella* ([Chapter 53](#)) species should be suspected in patients who present with acute diarrhea combined with fever and blood or mucus in the stool. As compared with *Salmonella* or *Campylobacter* spp., transmission occurs more often via direct patient-to-patient spread. In the United States, *Shigella* infection affects mainly children and is especially important in the day care setting. *Shigella sonnei* accounts for 60-80%

of cases in the United States and less commonly causes bloody stools. *Shigella flexneri* is most common in the developing world and is more frequently associated with grossly bloody stools. Other pathogenic species include *Shigella dysenteriae* and *Shigella boydii*. Patients usually complain of fever and watery diarrhea early in the course. Later, the stool volume may decrease and tenesmus with bloody stools (40% of cases) may develop. The duration usually is = 5 days, but occasionally can last weeks. The stool classically has sheets of fecal leukocytes, and the diagnosis is confirmed by stool culture.

Several *E coli* species ([Chapter 53](#)) can lead to diarrhea. EHEC are Shiga toxin-producing *E coli* that are an emerging diarrheal pathogen. The intestines of cattle appear to be the major reservoir of the organism. Infection is associated with the ingestion of contaminated meats, vegetables, and water. The meat, especially ground beef, is contaminated by feces with slaughter. Vegetables and water are contaminated by cattle waste used as fertilizer or present in runoff. After an incubation period of 3-4 days, patients develop cramping, abdominal pain, and diarrhea. The stool may then become bloody over several days. Interestingly, EHEC infection may have no associated fever or fecal leukocytes or lactoferrin. Thus, acute bloody diarrhea with no fecal leukocytes or fever should not exclude the consideration of EHEC, which is now the major infectious cause of grossly bloody diarrhea in the United States. Of those infected, = 6% may develop hemolytic uremic syndrome (HUS) 2-14 days after disease onset. The diagnosis is confirmed by isolating *E coli* O157:H7 by culture or via the demonstration of Shiga toxin from *E coli* isolates or in the stool (non-O157 serotypes). Enteroinvasive *E coli* strains cause diarrhea via invasion and induction of an inflammatory reaction in the intestine. Enteroinvasive *E coli* strains cause a disease similar to that caused by *Shigella* spp. and are rare in the United States. Enteroaggregative *E coli* is a recently described pathogen that can cause a persistent, mildly inflammatory diarrhea and malnutrition among people in the developing world and in patients with AIDS in the United States.

*C difficile* ([Chapter 53](#)) is a major cause of antibiotic-associated and nosocomial diarrhea. The disease normally occurs in the hospital setting, but community-acquired cases are being increasingly recognized. The organism overgrows the colon when the normal flora is altered by antibiotics, certain chemotherapeutic agents, or after abdominal surgery. Two protein toxins, toxins A and B, are released into the colon and lead to the development of diarrhea. The disease ranges from asymptomatic carriage to mild diarrhea to more severe forms of colitis with or without pseudomembrane formation. Pseudomembranes are mucosal plaques comprised of neutrophils and cellular debris, reflecting the inflammatory nature of the toxins. The most severe forms can lead to toxic megacolon and colonic perforation. The diagnosis is made by detecting the toxins in the stool via the methods discussed previously.

*V parahaemolyticus* and other *Vibrio* species ([Chapter 57](#)) are the major causes of seafood-related diarrhea in the United States, Japan, and the developing world. In the United States, the disease is most common along the Atlantic and Gulf coasts. The consumption of improperly cooked crab and shrimp meat and exposure to contaminated seawater (including the use of seawater to clean cooking utensils on cruise ships) are the main vehicles for disease transmission. In the United States, acute self-limited outbreaks are the rule, with explosive watery diarrhea and cramping abdominal pain

developing within 24 h after exposure and lasting for up to several days. The organism will not grow on routine stool cultures; the diagnosis requires that the organism be isolated on thiosulfate citrate bile salts sucrose agar.

**Parasites.** *E histolytica* ([Chapter 81](#)) is a major protozoan cause of invasive diarrhea, especially in the developing world. It is typically found in lower socioeconomic areas with poor sanitation, in institutionalized patients, and in immigrants from endemic areas. The intestinal disease caused by *E histolytica* includes asymptomatic infection, noninvasive diarrhea, acute rectocolitis (dysentery), and fulminant colitis with the risk of toxic megacolon and colonic perforation. Amebic colitis is usually associated with heme-positive stools, but fecal leukocytes can be absent owing to the ability of the pathogen to lyse human polymorphonuclear neutrophil leukocytes. Male patients are at greater risk for developing amebic liver abscesses. The diagnosis is made by identifying the parasite in the stool, by commercially available antigen detection assays, or by serology.

**Viruses.** Cytomegalovirus ([Chapter 33](#)) is an important cause of inflammatory diarrhea in compromised patients, especially those with AIDS. AIDS patients with cytomegalovirus enteritis present with watery diarrhea and can develop hematochezia and fever. On endoscopy, the mucosa may show plaque-like pseudomembranes, erosions, or ulcers, and biopsy should reveal the characteristic intranuclear inclusions.

## **B. Noninflammatory Diarrhea (Watery Diarrhea with No Fecal Leukocytes).**

**Bacteria.** Enterotoxigenic *E coli* strains ([Chapter 53](#)) producing heat-labile enterotoxin (LT) or heat-stable enterotoxin (ST) toxins are a major cause of diarrhea in the developing world and among travelers. Transmission occurs via contaminated food or water. After an incubation period of 1-2 days, the patient develops watery diarrhea (3-10 unformed stools per day) and cramps. The symptoms usually resolve over several days or < 1-2 days if treated early with effective antimicrobial agents. An unfortunate minority will have disease that lasts longer than 1 week. Fever and bloody stools are uncommon.

*Vibrio cholerae* ([Chapter 57](#)) is a well characterized diarrheal pathogen that has caused seven major pandemics since the 1800s. The seventh pandemic spread to Latin America in the early 1990s, and cases have been imported into the United States. The organism is ingested with contaminated food or water, and the infection that results ranges from asymptomatic to the full-blown cholera syndrome with voluminous watery diarrhea. Severe cases can rapidly progress to hypovolemic shock and death in < 12 h. Fever or abdominal pain is usually absent. The stool is often described as similar to rice water in appearance and is rarely bloody. Diagnosis is made clinically and confirmed by culturing the organism from the stool.

*Mycobacterium avium* complex ([Chapter 62](#)) is a common cause of diarrhea in patients with advanced HIV infection. Disseminated *M avium* complex presents with fever, sweats, weight loss, and, in 40% of cases, watery diarrhea. Diagnosis is made by isolating *M avium* complex from the stool and blood.

**Protozoa.** *G lamblia* ([Chapter 84](#)) causes prolonged diarrhea in both immunocompetent and compromised patients. The incubation period is 1-2 weeks after exposure to

contaminated water or direct contact with an infected patient. The infection may be asymptomatic or loose, and foul-smelling stools can develop, often associated with cramping, flatulence, nausea, and cramps. The symptoms may persist for weeks to months if untreated. The diagnosis is confirmed by identifying the trophozoites or cysts in the stool or duodenal aspirates or by detecting *Giardia* antigens in the stool via a commercially available enzyme-linked immunosorbent assay.

*Cryptosporidium parvum* ([Chapter 83](#)) is another highly infectious protozoa that is endemic throughout much of the world, including the United States. The organism is spread via contaminated water and direct patient contact. After an incubation period of 1 week, immunocompetent hosts develop diarrhea, cramps, and weight loss lasting for days to weeks before resolving. Low-grade fever occurs in 50% of infected individuals. In AIDS patients, the organism can cause a severe chronic diarrhea and biliary tract infections. The diagnosis is made by identifying the cysts by a modified acid-fast stain of the stool (often missed on routine O+P) or via a commercially available fluorescence antibody stain.

*Cyclospora cayetanensis* ([Chapter 83](#)) is an emerging protozoal cause of diarrhea associated with contaminated drinking water or foods (raspberries and lettuce). Unlike *Cryptosporidium* spp., the life cycle of *C. cayetanensis* requires a maturation phase outside the host and is thus less likely to be spread directly by person to person contact. In immunocompetent patients, after an incubation period of 1 week, a self-limited illness with watery diarrhea, cramps, and prominent fatigue ensues. It is a rare cause of diarrhea in AIDS patients in the United States, likely owing to the widespread use of trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis in these patients. It is, however, a common cause of diarrhea in this population elsewhere in the world. The diagnosis is made by identification of the organism on a modified acid-fast stain of the stool (not identified on routine O+P) or by detecting the oocysts in the stool by fluorescence microscopy (the autofluorescent oocysts without special staining).

*Isospora belli* ([Chapter 83](#)) is endemic in tropical countries, and infection is associated with travel or residence in these regions. Like *C. cayetanensis*, it causes self-limited infections in normal hosts and chronic diarrhea in AIDS patients except in the United States, where it is uncommon probably owing to TMP-SMX use. It is diagnosed by modified acid-fast staining of stool to detect the cysts.

Microsporidia infections ([Chapter 83](#)) caused by *Enterocytozoon bieneusi* and *Septata intestinalis* are endemic in the United States and worldwide. Infection is commonly encountered in patients with advanced AIDS and causes a prolonged watery diarrhea with frequent relapses. The cysts are not identified by acid-fast stains, but rather require a modified trichrome stain of the stool or small-bowel biopsy.

**Viral.** Rotaviruses ([Chapter 37](#)) are a major cause of gastroenteritis worldwide and are estimated to be responsible for 10-20% of all diarrhea-related deaths. In the United States, millions of infections occur annually leading to > 100,000 pediatric admissions and 200 deaths. The peak incidence of disease is in the 6- to 24-month-old age group, and virtually all children have been infected by age 3. Adults remain susceptible to infection, but tend to have milder symptoms. Spread of the virus appears to be by the fecal-oral route and, for unknown reasons, the infection occurs mainly in the winter

months. The disease is characterized by mild fever, watery diarrhea, nausea, and vomiting over 2-5 days. Immunodeficient children and adults are predisposed to developing chronic rotavirus infections with diarrhea that can last for months. The diagnosis is confirmed by rotavirus antigen enzyme-linked immunosorbent assay of the stool or by a less sensitive, more rapid latex agglutination test.

Caliciviruses ([Chapter 38](#)), including Norwalk or Norwalk-like viruses, are very common causes of viral gastroenteritis that are spread via the fecal-oral route. Outbreaks have occurred in relation to the consumption of contaminated water, food, or shellfish. Most outbreaks are characterized by an incubation period of 1-2 days, a duration of illness of 1-3 days, prominent vomiting, and a negative stool workup. Watery diarrhea with 4-8 stools/24 h is common, and low-grade fever occurs in 50% of cases. The secondary attack rate in affected households can be very high. Diagnosis is based on clinical features and a lack of identifiable pathogens on laboratory workup. Serologies can be helpful to confirm the diagnosis retrospectively.

## Complications

Volume depletion and electrolyte abnormalities remain the most serious sequelae of diarrheal illnesses worldwide. It is especially a problem in the very young and the elderly, owing to a lack of ready access to fluids for rehydration or to underlying diseases that may limit the ability of elderly people to cope with the volume changes. In some diseases, such as cholera, the volume loss may be massive, and the patient can progress to hypovolemic shock within 24 h. Electrolyte losses in the stool are also common with diarrhea, potentially leading to hypokalemia and metabolic acidosis. Profound hypoglycemia, leading to lethargy, coma, and seizures, can occur rarely with severe cholera, especially in children.

Malnutrition is being increasingly recognized as a major complication of repeated or chronic diarrheal illnesses in the developing world. There is growing evidence that children with such infections exhibit growth retardation and possibly cognitive dysfunction compared with matched controls. If future studies confirm this relationship, then malnutrition may well emerge as the most devastating long-term sequela of infectious diarrhea.

Nosocomial infections are increased in hospitalized patients with preceding or ongoing episodes of nosocomial diarrhea. In one study, patients with nosocomial diarrhea had a 10-fold higher risk of nosocomial urinary tract infections as compared with matched controls without diarrhea.

Hemolytic uremic syndrome (HUS) is another complication of enteric pathogens, most notably EHEC. Patients with HUS typically present with renal failure, microangiopathic hemolytic anemia, and thrombocytopenia 2-14 days after the onset of the diarrhea. In prior outbreaks, 6% of infected patients with *E coli* O157:H7 developed HUS, 50% of whom required dialysis and had mortality as high as 1.2% (> 250 deaths per year in the United States). The risk of developing HUS after EHEC infection appears to be increased with the use of antimotility drugs, and these agents are contraindicated in suspected cases. Antimicrobial therapy may increase the risk of HUS as well, but this remains controversial.

Guillain-Barre syndrome, an acute demyelinating polyneuropathy, is another potential complication of enteric infections, especially after *C jejuni* infection. Of patients with Guillain-Barre, 20-40% had a documented *C jejuni* infection in the prior several weeks. Patients usually present with ascending motor weakness and may require mechanical ventilation for respiratory muscle involvement. The mechanism of how this infection may trigger this immune-mediated syndrome remains unknown.

Postinfectious arthritis has been described several weeks after an invasive diarrheal illness with *Campylobacter*, *Shigella*, *Salmonella*, or *Yersinia* spp., especially in patients with a human leukocyte antigen-B27 phenotype.

## Treatment

As with the diagnostic approach, optimal therapy for a given diarrheal illness should be guided by a number of different factors. The age and health of the patient; volume status; ability to take oral fluids; presence of fever, blood, leukocytes, or lactoferrin in the stool; and suspected pathogen all need to be considered. For example, an adult in the United States with < 1 day of noninflammatory diarrhea can be treated with oral fluids and monitored. A child with voluminous diarrhea in a cholera-endemic region and significant volume loss will require more aggressive fluid resuscitation and antimicrobial therapy. Finally, a child with bloody diarrhea after consumption of an undercooked hamburger will require the consideration of different sequelae and treatment concerns than those in the first two cases. Given the huge range of presentations, sequelae, and therapies available with the various diarrheal pathogens, it is important to emphasize that therapy must be tailored to each patient based on the available clinical and laboratory data.

**A. Volume and Electrolyte Replacement.** The most important aspect to current diarrheal therapy is to maintain adequate hydration and electrolyte balance during the acute episode. This usually can be accomplished safely with oral rehydration therapy, which should be used in all patients except those unable to take oral glucose-electrolyte solutions or who have massive diarrhea that may require aggressive intravenous hydration to treat life-threatening hypovolemia. Ideally, oral rehydration solutions should contain 3.5 g of sodium chloride, 2.5 g of sodium bicarbonate, 1.5 g of potassium chloride, and 20 g of glucose per liter of water, alternated with free water ad libitum. Such solutions are commercially available in packets that are easily prepared by mixing with water. If commercial preparations are not available, a substitute oral rehydration solution can be made by adding 1/2 teaspoon table salt, 1/2 teaspoon baking soda, and 2-4 tablespoons of sugar per liter of clean water. Two bananas or 1 cup of orange juice is used to provide potassium. Instead of glucose, 40-60 g of cereal flour (rice) can be added to a liter of water and boiled with the other ingredients. Patients should drink as much fluid as their thirst dictates. If intravenous therapy is needed, a normotonic fluid such as normal saline or lactated Ringer's solution should be given with potassium supplementation as guided by the serum chemistries. The volume status should be monitored closely by observing the vital signs, respiratory status, and urine output, and the infusion rate adjusted as needed. The patient should be switched to oral rehydration solution as soon as feasible.

**B. Antimicrobial Agents.** In certain bacterial and protozoal infections, antimicrobial agents decrease symptom duration and fecal shedding, especially if started early in the disease. However, they have potential adverse effects, including increased cost, risk of inducing or selecting for resistant organisms, antibiotic-associated diarrhea, increased *Candida* infections, and a possible increased risk of HUS with EHEC infections. The challenge for clinicians is to decide which patients with diarrhea will benefit from starting antimicrobial therapy before the results of stool studies are available.

Antibacterial therapy should be considered in all patients with diarrhea in whom certain pathogens are suspected, because antibiotics in these cases can decrease the duration of symptoms and prevent serious sequelae. Which organisms should be covered in an individual patient will depend on the available clinical and epidemiologic data. In general, patients with suspected *Shigella*, *Campylobacter*, or severe *C difficile* infection, traveler's diarrhea, or *V cholerae* infection should be started on empiric therapy once the diagnosis is entertained, because the antimicrobial agents will influence the course of the illness. For *Shigella* and *Campylobacter* spp., antimicrobial therapy has been shown to decrease the duration of the diarrhea. Fecal excretion of these organisms is also decreased with antibiotic therapy and in settings where the potential for spread is present; for example, day care is another indication for therapy.

For nontyphoidal *Salmonella* gastroenteritis, antibiotic therapy may decrease the duration of illness, but paradoxically may prolong fecal excretion of the organism or predispose to systemic invasion. Antimicrobial therapy for *Salmonella* gastroenteritis should be considered for those patients who may be at increased risk for bacteremic dissemination, including the very young, the elderly, or immunocompromised patients, and for those with an enteric fever syndrome. Otherwise, nontyphoidal *Salmonella* gastroenteritis is generally self-limited and antimicrobial agents are best avoided. As mentioned, antibiotic therapy is not currently recommended for suspected or confirmed EHEC infections, especially in children. To date, studies are contradictory on whether the incidence of HUS is decreased or increased in patients who had received antibiotics, and further studies are needed to clarify this issue.

*C difficile* infections should be treated initially by stopping the antimicrobial therapy. If the symptoms persist or if the patient is severely ill and has underlying medical conditions, then specific therapy should be started. Although antibiotic therapy is generally not indicated in noninflammatory diarrhea, antimicrobial agents can shorten the duration of the symptoms and attenuate the volume loss in patients with cholera or traveler's diarrhea. [Boxes 20-2](#) and [20-3](#) list the suggested therapies (for adults and children) that should be started once the respective pathogens are suspected.

The issue of antimicrobial resistance must be considered when choosing antibiotic therapy for enteric pathogens. For example, *Shigella* and *Salmonella* spp. are increasingly resistant to ampicillin and TMP-SMX, whereas *Campylobacter* resistance to fluoroquinolones is emerging (especially in Thailand). Stool cultures are therefore not only valuable to confirm suspected bacterial pathogens, but also to supply susceptibility patterns for a given isolate. Knowledge of the local resistance patterns, adequate culture specimens before antibiotic use, and monitoring of the patient's clinical response are all required to ensure that the correct antimicrobial therapy has been given.

Specific antiparasitic therapy is currently available for patients with confirmed or suspected *G lamblia*, *E histolytica*, *I belli*, and *C cayentanensis* infections. No specific therapy has proven consistently effective against *Cryptosporidium* spp. in AIDS patients; paromomycin has had limited success. In general, resistance has not been a problem with the protozoal pathogens, but relapses can occur with pathogens like *Giardia* spp.

Traveler's diarrhea, most commonly caused by enterotoxigenic *E coli*, can be reduced from a duration of 3-5 days to 2 days or less with effective antimicrobial therapy. TMP-SMX and ciprofloxacin hydrochloride are the two most commonly used antibiotics, but resistance to TMP-SMX is now fairly widespread. As with other forms of diarrhea, oral rehydration is critical and should be initiated as soon as the illness begins regardless of the use of antimicrobial agents. Antimotility agents can be used once effective antimicrobial agents have been initiated, especially in patients with dysentery symptoms or bloody stools.

**C. Antimotility Agents.** These agents, such as the opiates loperamide hydrochloride or diphenoxylate, can help make the patient more comfortable, especially for cases of noninflammatory diarrhea. Antimotility agents can also be helpful in patients with dysentery symptoms or inflammatory diarrhea when these agents are administered after the appropriate antimicrobial agents have been started. Such agents are contraindicated in suspected EHEC infections, because they have been associated with an increased incidence of HUS in children, and in inflammatory diarrhea if specific antimicrobial therapy has not been started.

## Prognosis

With adequate volume replacement, good supportive care, and antimicrobial therapy if indicated, the prognosis of infectious diarrhea is excellent with minimal morbidity and mortality. As with many illnesses, the morbidity and mortality are concentrated in the very young and the elderly. In the United States, the mortality now associated with infectious diarrhea is significantly < 1.0%. There are exceptions such as EHEC infections, which had an associated mortality of 1.2% in most studies related to the development of hemolytic uremic syndrome. Oral rehydration therapy and improvements in sanitation have begun to have an impact on mortality in the developing world. Nevertheless, considerable work remains to reduce the levels of mortality in these regions to that of the developed world. The biggest improvements likely will come with changes in economic and social conditions rather than from any further improvements in medical therapy.

## Prevention & Control

Because most diarrheal pathogens are spread via the fecal-oral route, their acquisition can be prevented by maintaining good personal hygiene. This includes frequent handwashing after toilet use and especially during food preparation. The value of good hygiene by food handlers and cooks to avoid the spread of food-borne pathogens can not be overstated. Diapers of children with diarrhea should be disposed of as soon as possible with minimal contamination of the living environment. Human sewage should be removed from living areas, and farm animals should be kept separate from human dwellings. Nosocomial diarrhea can be reduced by using antibiotics judiciously, by

avoiding broad-spectrum antibiotics if possible, and by careful handwashing, which may potentially reduce the spread of *C difficile* spores within the hospital environment.

Because food and water are common vectors for pathogens, these areas should be given special attention. Drinking water, water used to clean food, or water that is used in cooking should be filtered and chlorinated. If there is any concern about water safety or if unpurified water is taken from lakes or rivers, then it should be boiled for several minutes before consumption. When swimming in lakes or rivers, people should take care not to ingest the water. Sea water is often contaminated with *Vibrio* species, and caution should be exercised when using this water for cooking or washing or when swimming.

All fruits and vegetables should be washed thoroughly with clean (boiled, filtered, or treated) water before consumption, especially given the quantity of produce now imported into the United States. Untreated human or animal waste should not be used to fertilize fruits and vegetables. All meats and seafood should be cooked adequately. Chicken and ground beef should be cooked until the red or pink is gone. Only pasteurized dairy products and juices should be consumed. A recent outbreak of EHEC was associated with drinking unpasteurized apple cider made with apples contaminated, after falling to the ground, by cattle feces.

The prevention of traveler's diarrhea begins with the avoidance of potentially contaminated food or water and with the maintenance of good personal hygiene. All drinking water should be boiled, or carbonated beverages should be consumed. Ice cubes should be avoided, unless made with boiled water. Food should be well cooked, and unpeeled fruits and food from salad bars and street vendors should be avoided. These measures can reduce, but not eliminate, the risk of acquiring traveler's diarrhea and are difficult to strictly adhere to. Bismuth subsalicylate tablets taken 4 times a day for up to 3 weeks and antibiotic prophylaxis with fluoroquinolones are effective in preventing many cases of traveler's diarrhea. However, given the cost, the risk of contributing to resistance, drug side effects, and the fact that a short course of antimicrobial agents can significantly ameliorate traveler's diarrhea if it occurs, such prophylaxis is not currently recommended by most experts.

Vaccines are a promising area for the prevention of infectious diarrhea, but the effectiveness and scope of the currently available vaccines are limited. At present, vaccines are available for *V cholerae*, typhoid fever, and rotavirus. The current parenteral cholera vaccine is not very effective and not recommended for use. Newer oral cholera vaccines based on the toxin B-subunit or inactivated whole cells are more effective, and the immunity is of longer duration. However, neither is currently licensed in the United States. The older parenteral typhoid vaccine was only 70% effective and had frequent side effects. A newer parenteral vaccine based on the capsular polysaccharide Vi-antigen is now available in the United States. It is also 70% protective, but requires only 1 dose and has fewer side effects. An oral, live-attenuated typhoid vaccine is available, requiring 1 capsule every other day for 4 doses and having an efficacy similar to that of the other two vaccines. The recently approved oral rotavirus vaccine covers serotypes 1-4 and is given to infants at 2, 4, and 6 months of age. In several international trials, the vaccine decreased the incidence of gastroenteritis by 50%, severe disease by 75%, and hospitalization for dehydration by almost 100%.

Fever was the most common side effect, especially in the first week after the administration, but overall the vaccine was very safe. More recent data, however, have shown an increased risk of intussusception in infants vaccinated in the prior 1-2 weeks. Vaccination in infants is no longer recommended.

## 21 . Hepatobiliary Infections — *Paul B. Eckburg, MD & Jose G. Montoya, MD*

### Essentials of Diagnosis

- History of household or sexual contact with individuals with hepatitis, travel or residence in endemic areas, human immunodeficiency virus (HIV) risk factors or established acquired immunodeficiency syndrome (AIDS), blood transfusion, needle stick injury, hepatotoxic medication or alcohol use, intravenous (IV) drug use, biliary colic or known gallstones, recurrent cholangitis, or liver transplant.
- Fever, nausea, vomiting, aversion to smoking, tender hepatomegaly, or right-upper-quadrant pain.
- Hepatocellular damage (elevated aminotransferases) or cholestasis (elevated bilirubin and alkaline phosphatase) on hepatic biochemical testing.
- Positive serologies for hepatitis viruses or *Entamoeba histolytica*, or positive blood culture for enteric bacteria.
- Inflamed gallbladder, dilated intra- or extrahepatic ducts, or intrahepatic lesion on hepatobiliary imaging.
- Liver biopsy histopathology with nonspecific hepatocellular necrosis or granulomas.

### General Considerations

A large number of infectious organisms can cause liver or biliary tract abnormalities, either by direct invasion or by the effects of systemic infection and sepsis ([Table 21-1](#)). There is a wide range of clinical presentations in hepatobiliary infections, depending on the specific organism, the host response, and the immune status of the host. Clinical syndromes may feature abnormal hepatic biochemical tests, focal hepatic lesions, granulomatous disease, or obstructive jaundice. A thorough history, physical exam, and biochemical liver test panel are usually sufficient for making a diagnosis of the type of hepatobiliary disease in = 80% of cases. However, symptoms, signs, and liver test abnormalities are often not specific enough to make an accurate diagnosis without the aid of cultures or serologies, hepatobiliary imaging, or liver biopsy.

**A. History and physical exam.** The history should elicit a detailed sexual, occupational-exposure, IV drug use, and blood transfusion record (eg, assess HIV and hepatitis risk factors), as well as travel to endemic areas, alcohol use, current medications, diet (eg, risk of hepatitis A), and history of cholelithiasis. Symptoms are often nonspecific (eg, prodromal fatigue and malaise in acute hepatitis) and rarely helpful in establishing the cause of hepatobiliary disease. Some clinical syndromes may be asymptomatic (eg, chronic hepatitis B), whereas others may have a fulminant course (eg, acute hepatitis B).

The clinical exam is also nonspecific, with fever, hepatomegaly, and right-upper-quadrant abdominal pain and tenderness being common in a variety of hepatobiliary infections. The abdominal exam may be unremarkable, as in some cases of chronic hepatitis and granulomatous hepatitis. Clues to the diagnosis can be obtained by finding extrahepatic manifestations of disease. For example, urticaria may be seen in early hepatitis B, and porphyria cutanea tarda may be associated with hepatitis C. Autoimmune phenomena such as thyroiditis and inflammatory bowel disease (IBS) may be seen with autoimmune hepatitis or sclerosing cholangitis. Glomerulonephritis may be seen in either hepatitis B or C infection.

## **B. Diagnostic methods for evaluation of hepatobiliary infection.**

**1. Laboratory studies.** Abnormal hepatic biochemical tests may be the first evidence of liver disease. Elevated serum aminotransferase levels are sensitive indicators of hepatocellular injury. Alanine aminotransferase is located in the hepatocyte cytosol and is more specific for liver disease. Aspartate aminotransferase is located in both the cytosol and mitochondria and is also found in other organs such as the brain, kidneys, blood cells, and skeletal muscle. The degree of aminotransferase elevation does not seem to correlate with the severity of liver injury and is of little prognostic value. However, the magnitude of the elevation may help in differentiating the cause of liver injury. For example, markedly elevated levels are seen in ischemic injury, damage from toxins (eg, acetaminophen), viral hepatitis, and occasionally acute common bile duct obstruction.

Elevated alkaline phosphatase level is helpful in diagnosing biliary tract disease in the context of other abnormal hepatic tests, but it is not helpful in differentiating the site of damage within the biliary system. For example, elevated alkaline phosphatase is common in obstruction or disease of the extrahepatic biliary tree (eg, acute cholangitis caused by choledocholithiasis), the main hepatic ducts (eg, in sclerosing cholangitis), interlobular ducts (eg, granulomatous hepatitis), and canalicular membranes (eg, with rifampin therapy). Serum  $\gamma$ -glutamyl transpeptidase can be used to confirm a hepatic origin of an elevated alkaline phosphatase, but it otherwise lacks specificity for hepatic dysfunction.

Hyperbilirubinemia is of little prognostic value in acute biliary obstruction, but its level can be correlated with mortality in chronic liver diseases. High levels of total bilirubin can be seen in acute cholangitis, sclerosing cholangitis, and certain systemic infections involving the liver, such as septic shock and leptospirosis. Most other hepatic infections are associated with only mild elevations in bilirubin (< 5 mg/dL). Almost all infections of the hepatobiliary system feature > 50% direct bilirubin as part of the total bilirubin level.

## **2. Imaging.** See [Table 21-2](#).

**a. Ultrasonography.** Ultrasonography is the preferred method for diagnostic imaging of the right upper quadrant when gallbladder disease is suspected. It is relatively inexpensive, noninvasive, and may be performed at the patient's bedside. Gallstones, gallbladder wall thickening, and localized tenderness over the gallbladder (sonographic Murphy's sign) correlate highly with the presence of acute cholecystitis. Cystic duct calculi may be more difficult to visualize, and the overlying duodenum may prevent

visualization of choledocholithiasis (75% sensitivity vs 95% sensitivity in detecting cholelithiasis).

**b. Abdominal computed tomography (CT).** Abdominal CT is less reliable than ultrasound in detecting gallbladder wall abnormalities or gallstones, and it has sensitivity similar to that of ultrasound in detecting choledocholithiasis (75%). However, CT is the preferred test in detecting other causes of posthepatic biliary obstruction, because it has better visualization of the retroperitoneum and lymph nodes and can simultaneously visualize the liver, biliary tree, and pancreas. CT is also the test of choice in evaluating for liver abscesses, and it can identify air and calcifications within intrahepatic lesions (eg, echinococcal cysts).

**c. Direct cholangiography.** Direct cholangiography, with injection of contrast into the biliary tree, is used when there is strong suspicion of choledocholithiasis (eg, in acute cholangitis). This can be performed by either percutaneous transhepatic cholangiography (PTC) or by endoscopic retrograde cholangiopancreatography (ERCP). It is superior to both ultrasonography and CT in detecting common bile duct stones, and offers the potential for therapeutic intervention in removing the stones. ERCP has the advantage over PTC in being able to perform a papillotomy or placing a common bile duct stent if needed for stone extraction.

**d. Hepatobiliary scintigraphy.** Hepatobiliary scintigraphy (eg, dimethyl iminodiacetic acid scan) uses a radiolabel such as  $^{99m}\text{Tc}$  to visualize the path of biliary excretion. This test may be used to evaluate for cystic duct obstruction (eg, in acute cholecystitis) if ultrasonography is negative.

**e. Magnetic resonance cholangiography.** Magnetic resonance cholangiography is emerging as an alternative to ERCP for imaging the biliary tree. The test is noninvasive and does not require contrast material. However, if choledocholithiasis is detected, the stone cannot be removed during the procedure as with ERCP.

**3. Liver biopsy.** Percutaneous liver biopsy is indicated when imaging studies reveal a space-occupying lesion and an infectious or neoplastic etiology is suspected but not yet established. It is also useful in staging disease and determining the severity of hepatocellular damage in chronic viral hepatitis (often used to assess the need for and predict response to antiviral therapy). Liver biopsy can be used to diagnose infiltrative processes such as granulomatous hepatitis (eg, in patients with fever of unknown origin). In patients with a focal hepatic lesion, liver biopsy should be performed under ultrasound or CT guidance.

## INFECTIONS OF THE LIVER

### ACUTE VIRAL HEPATITIS

#### Essentials of Diagnosis

- Prodrome of malaise, nausea, vomiting, and low-grade fever.

- Possible tender hepatomegaly, jaundice, dark urine, and acholic stools.
- Marked elevation in aminotransferase levels.
- Presence of serum antigen or antibody to a specific hepatitis virus.

## General Considerations

Acute viral hepatitis is caused by five agents, the hepatitis A, B, C, D, and E viruses. Acute viral hepatitis may also be part of other systemic viral illnesses, such as infectious mononucleosis and cytomegalovirus (CMV) infection. Several recently discovered viruses (hepatitis F, GB-C, and G viruses) are currently being further characterized. In the United States, ~ 40% of cases of acute viral hepatitis are caused by hepatitis B virus (HBV), 30% by hepatitis A virus (HAV), 20% by hepatitis C virus (HCV), 2% by hepatitis D virus (HDV), and 1% by hepatitis E virus (HEV) (the remaining cases are of unclear etiology). All five viruses can cause acute hepatitis, which is clinically similar to other causes of hepatitis, eg, drug-induced or ischemic hepatitis, and can only be distinguished by specific viral serologies. Only HBV, HCV, and HDV can cause chronic infection. Each of these viruses is discussed briefly; for details on the hepatitis viruses, see [Chapter 39](#).

HAV is a single-stranded RNA-containing picornavirus that causes sporadic outbreaks and epidemics of acute hepatitis. It does not cause chronic hepatitis. Its major route of transmission is fecal-oral spread, which is enhanced by crowding and poor hygiene. Common-source outbreaks may involve contaminated water and food (eg, shellfish). Household contacts are at highest risk for infection (~ 25% of cases), followed by participants in daycare centers (15% of cases), travelers to endemic areas (5%), homosexual men (4%), and IV drug users (2%). Transfusion-associated HAV is extremely rare. Viremia occurs during the incubation period (2-6 weeks), and fecal excretion of HAV may occur for = 2 weeks before clinical illness. Replication and shedding of the virus therefore may occur although the subject is asymptomatic, which suggests that this process is noncytopathic to the liver. Liver injury is mediated by the host immune response, primarily involving cytotoxic T cells and natural killer cells.

HBV is a hepadnavirus that has a partially double-stranded DNA genome, an inner core protein (hepatitis B core antigen), and outer surface antigen [hepatitis B surface antigen (HB<sub>s</sub>Ag)]. It infects > 400 million people worldwide, although it is more prevalent in Southeast Asia, China, and Africa. In the United States, most HBV infection results from sexual exposure (= 60%), IV drug use (10-15%), and rarely occupational exposure; = 30% have an unknown source of infection. In endemic countries, maternal-neonatal vertical transmission and horizontal spread among children is quite common. Like HAV, HBV does not kill hepatocytes. Liver injury occurs from the host's immune attack against the virus, including a specific cytotoxic T cell response against hepatitis B core antigen (presented on the surface of infected hepatocytes). The immature immune systems of neonates are unable to clear the virus, and > 90% of infected neonates become chronic asymptomatic carriers. Only 1-5% of immunocompetent adults remain chronically infected, however acute infection may feature severe hepatocellular injury and symptomatic illness. Fulminant hepatitis occurs in < 1% of cases.

HDV (or delta agent) is a blood-borne defective RNA virus that causes hepatitis only in association with HBV. Like HBV, prevalence rates vary from region to region, although it is endemic in the Mediterranean, Russia, Middle East, and the Amazon basin of South America. Percutaneous spread is the major route of transmission. The pathogenesis of HDV infection is not fully understood. Both acute HDV coinfection with HBV and HDV superinfection in HB<sub>s</sub>Ag carriers have been well-described. In superinfection, acute disease is more severe, and chronic hepatitis with rapid progression to cirrhosis is more common.

HCV is a single-stranded RNA virus related to the flaviviruses. It is the most common cause of post-transfusion hepatitis worldwide. Six genotypes have been identified to date, each with varying disease severity and treatment response. The most common genotypes in the United States and Europe are 1a and 1b; the latter is associated with more advanced disease and suboptimal treatment response. Prevalences of HCV seropositivity are 1-2% in the United States and 4-6% in parts of Africa and the Middle East. HCV is primarily transmitted in contaminated blood and less effectively through other body fluids. Risk factors for infection include IV drug use (= 50% of cases), hemodialysis, tattooing, and blood and IV immunoglobulin (Ig) transfusion. Perinatal and sexual transmissions are relatively rare. The exact mechanism of hepatic injury remains undefined, but cytotoxic T cells directed against viral epitopes are likely involved. High rates of viral mutations into quasi-species allow the virus to evade immune surveillance, leading to chronic infection in > 80% of cases.

HEV is a caliciviruslike RNA virus involved in waterborne outbreaks of acute hepatitis. Like HAV, it causes a self-limited hepatitis spread via the fecal-oral route and does not result in a chronic carrier state. HEV causes epidemic and endemic disease in India, Southeast Asia, parts of Africa, and Mexico, and it should be suspected in travelers to these areas with acute hepatitis. Pathogenesis of liver damage by HEV is poorly understood, but may involve both direct viral and immune-mediated effects.

## Clinical Findings

**A. Signs and symptoms.** The clinical presentation is variable, from asymptomatic (eg, majority of acute hepatitis C) to fulminant (eg, acute hepatitis E in pregnancy). The five types of viral hepatitis cannot be distinguished based on clinical findings alone ([Table 21-3](#)). During the incubation period, patients may have malaise, myalgias, arthralgias, anorexia, nausea, vomiting, and aversion to smoking. Low-grade fevers and abdominal pain may be experienced during this prodrome phase. An icteric phase that features jaundice and transient worsening of prodromal symptoms may follow, with subsequent gradual improvement during convalescence. On examination, tender hepatomegaly may be present in over half of cases; however splenomegaly is uncommon. Immune complexes may develop in acute hepatitis B, leading to a preicteric serum sickness-like syndrome with glomerulonephritis, polyarthritis, urticaria, and systemic vasculitis in < 10% of cases. Extrahepatic syndromes have also been associated with acute hepatitis C, including cryoglobulinemia, membranoproliferative glomerulonephritis, porphyria cutanea tarda, and Mooren corneal ulcers.

**B. Laboratory findings.** Aminotransferase levels are typically > 300 U/L and often > 1000-2000 U/L. Elevated aminotransferases may be discovered on routine testing in

asymptomatic patients. Moderately elevated bilirubin and alkaline phosphatase levels occur during the icteric phase and may persist after normalization of the aminotransferases. Leukocytosis is uncommon; however, a relative leukopenia may be seen. Urinalysis may reveal a mild proteinuria and bilirubinuria during the icteric phase.

Serology for the specific viral antibodies and antigens is key to making the correct diagnosis (see [Chapter 39](#)). In acute hepatitis A, HAV IgM is the most important diagnostic test. This antibody appears early in the disease, peaks within the first week of illness, and disappears in 3-6 months (HAV IgG may persist for years).

In hepatitis B, HB<sub>s</sub>Ag is the first serum marker to appear. It is detectable before evidence of abnormal biochemical tests and persists throughout acute (and chronic) hepatitis. Hepatitis B surface antibody rises after the clearance of HB<sub>s</sub>Ag, leaving a window of seronegativity to the surface protein (between the disappearance of HB<sub>s</sub>Ag and the appearance of hepatitis B surface antibody). The appearance of hepatitis B surface antibody signals noninfectivity and protection from recurrence and is the only positive marker in those vaccinated for HBV. Hepatitis B core antibody may be used to diagnose HBV infection because IgM rises shortly after the appearance of HB<sub>s</sub>Ag and will be present before hepatitis B surface antibody appears. Hepatitis B core IgG rises later and persists whether recovery or chronic hepatitis B develops; it is not a protective antibody. Of note, hepatitis B core antigen does not appear in the serum. HB<sub>e</sub>Ag and HBV DNA are more specific markers for infectivity and ongoing replication, and they appear only in HB<sub>s</sub>Ag-positive sera. HBV polymerase chain reaction is now available and has been used to assess the response of chronic hepatitis to antiviral therapy; however, its role has not been fully established. Coinfection with HDV is suggested by a positive HDV antibody or HDV RNA.

In hepatitis C, HCV antibody can be detected by enzyme-linked immunosorbent assay; however, this test has suboptimal sensitivity and 50% specificity. If a false-negative or -positive test is suspected, recombinant immunoblot assay for HCV antibody may be used to confirm the diagnosis. Serum HCV RNA can be detected by polymerase chain reaction; a positive result indicates infectivity. Polymerase chain reaction should be used only if recombinant immunoblot assay for antibodies is indeterminate or when assessing response to antiviral treatment. Similarly, HEV antibody and RNA are present in acute hepatitis E.

## Differential Diagnosis

Acute hepatitis may be clinically similar in such systemic infections as infectious mononucleosis, CMV, herpes simplex virus, leptospirosis, secondary syphilis, brucellosis, and Q fever. Right-upper-quadrant pain, jaundice, and markedly elevated transaminases may also occur in drug-induced hepatotoxicity or ischemic liver damage (eg, "shock liver" in sepsis). Fever, jaundice, and abnormal hepatic biochemical tests may be seen in autoimmune hepatitis and cholangitis. The prodromal phase of acute viral hepatitis is nonspecific and may resemble influenza virus infection.

## Treatment

Only supportive and symptomatic treatment is available. No specific antiviral agents have been shown to be useful in this syndrome, and there is no benefit of corticosteroid therapy. Patients should avoid hepatotoxic medications, alcohol, and narcotic agents. Those with fulminant hepatitis should be hospitalized for intensive monitoring and correction of coagulopathy. Limited studies in the treatment of acute hepatitis C with interferon- $\alpha$  (IFN- $\alpha$ ) suggest a reduction in the risk of chronic hepatitis; however, this should be considered experimental at this time. This approach is impractical for HBV because > 95% of infected adults have self-limited hepatitis.

## **Prevention**

Hand washing, needle precautions, and protected intercourse are important in preventing disease. Continued screening of blood donors and blood products may further reduce the frequency of blood-borne infections. Vaccines and immune globulin are available for the prevention and postexposure prophylaxis of HAV and HBV infection. HAV vaccination is recommended for those planning travel to endemic areas, and is available as Havrix (1.0 mL intramuscularly) or Vaqta (0.5 mL intramuscularly). HAV Ig is indicated for all close contacts (ie, household contacts) of known HAV-infected individuals, given as a 0.02 mL/kg intramuscular injection within the incubation period. HBV vaccine (Recombivax-HB or Engerix-B) is now universally recommended for all infants and high-risk adults, and is given in a series of three injections, at 0, 1, and 6 months. HDV is also best prevented by this vaccine. Postexposure prophylaxis with HBV Ig should be administered as early as possible after sexual, mucous membrane, or perinatal exposure (0.06 mL/kg intramuscularly), followed by the vaccination series. There is no effective vaccine for HCV.

## **Prognosis**

Patients with acute viral hepatitis usually recover within 3-16 weeks of clinical illness. It is not uncommon for abnormal hepatic biochemical tests to persist longer. Overall mortality is < 1%. HAV and HEV do not have chronic carrier states, although HAV infection may persist up to 1 year with the potential for relapses before complete recovery. HEV infection during pregnancy is associated with a higher mortality. HBV infection is associated with a higher mortality if there is an associated HDV infection, and superinfection of HDV invariably leads to chronic infection. Chronic hepatitis B occurs in = 90% of infected infants and 1-5% of adults. Chronic HCV infection occurs in 80% of all cases, with = 30% progressing to cirrhosis.

## **CHRONIC VIRAL HEPATITIS**

### **Essentials of Diagnosis**

- Possible malaise, fatigue, weakness, and elevated aminotransferase levels.
- Persistent serum HB<sub>s</sub>Ag or HCV antibodies for = 6 months.
- Liver biopsy histopathology with characteristic hepatocellular necrosis and fibrosis.

### **General Considerations**

Chronic viral hepatitis is currently the leading indication for liver transplantation and is the main cause of cirrhosis and hepatocellular carcinoma in the world. It is defined as persistently elevated aminotransferase levels with characteristic histopathologic changes for  $\geq 6$  months duration. Of the hepatitis viruses, only HBV, HCV, and HDV can cause chronic hepatitis.

Chronic hepatitis B features persistent HB<sub>s</sub>Ag for  $> 6$  months. It affects  $> 400$  million people worldwide. The disease is highly endemic in Southeast Asia, the Pacific islands, Africa, and the Middle East, and  $\approx 15\%$  of these populations are chronically infected. Of infected neonates,  $\approx 90\%$  later develop chronic hepatitis B, in contrast to 1-5% of adults. The pathogenesis underlying the rates of chronic infection in different age groups is largely unknown. However, in children it likely involves immune tolerance, in allowing viral replication to proceed without a destructive cytotoxic T-cell response. The natural history of disease is variable. Some patients spontaneously enter a phase of immune clearance, with a decrease of HB<sub>e</sub>Ag and HBV DNA and appearance of HB<sub>e</sub>Ab. The course may fluctuate with recurrent flares or sustained remission.

Unlike HBV, HCV infection does not involve integration into the host genome (there is no DNA intermediate in its life cycle). Persistence of the virus results from a high mutation rate during replication, with production of quasispecies and avoidance of the host immune response. Of acute HCV cases, 80% develop chronic disease.

## Clinical Findings

**A. Signs and symptoms.** The different forms of chronic hepatitis cannot be distinguished by clinical presentation. Patients may be asymptomatic with incidental abnormal hepatic serum tests, or they may present with end-stage liver disease with cirrhosis and portal hypertension. Malaise and weakness are common symptoms.

**B. Laboratory findings.** Hepatic biochemical tests usually reveal mildly elevated aminotransferases (2- to 20-fold), hyperbilirubinemia, elevated prothrombin time, and hypoalbuminemia. Chronic hepatitis B is distinguished by persistent serum HB<sub>s</sub>Ag, HB<sub>e</sub>Ag, and HBV DNA levels ([Table 21-4](#)), in conjunction with characteristic histopathologic findings on liver biopsy. Remission or response to treatment may be suggested by loss of HB<sub>e</sub>Ag and DNA levels despite persistent HB<sub>s</sub>Ag. Chronic HCV is diagnosed by persistent HCV antibodies and positive serum HCV RNA with concurrent histopathologic changes on biopsy. Of note, false-positive HCV antibodies can occur in autoimmune hepatitis, which can clinically present like chronic hepatitis C.

**C. Biopsy.** Liver biopsy is used to assess disease activity and is recommended before institution of treatment to determine disease severity and predict response to treatment. Histopathology of chronic hepatitis features nonspecific diffuse inflammation (T-cell infiltration) and hepatocyte necrosis. Chronic hepatitis C may be associated with periportal lymphoid aggregates, steatosis, and bile duct damage.

## Treatment

Despite similarities in clinical and histopathologic characteristics, chronic viral hepatitis caused by HBV or HCV responds differently to therapy. IFN- $\alpha$  is the only effective treatment for both hepatitis C and B.

IFN- $\alpha$  induces the clearance of HBV by enhancing the host immune response. Of chronic hepatitis B cases, ~ 33% enter remission (negative HB<sub>e</sub>Ag) after a 4- to 6-month course of IFN. This therapy is indicated only when the patient has persistent elevations in aminotransferases, HB<sub>e</sub>Ag, and HBV DNA. Patients with normal aminotransferase levels respond poorly to IFN therapy (eg, Asian patients who acquired the disease in childhood). Liver biopsy is recommended before treatment to assess severity of fibrosis and cellular injury. IFN- $\alpha$  is administered over a 4- to 6-month course ([Box 21-1](#)). Patients with concomitant chronic HDV require higher and longer doses of IFN (9 million units thrice weekly for 12 months), which leads to a sustained response in only 15-25% of cases. In addition to IFN- $\alpha$ , long-term suppressive therapy with nucleoside analogs (eg, lamivudine) may prove to be beneficial in achieving sustained inhibition of HBV replication. Lamivudine is approved for treatment of chronic HBV with evidence of active replication (administered 100 mg orally daily for 1 year). However, long-term treatment may lead to the emergence of resistant mutant virus.

IFN- $\alpha$  is also recommended for patients with chronic HCV ([Box 21-1](#)). Therapy lasting 6 months may lead to remission of disease in 50% but a sustained response in only 10-25%. Long-term response is unlikely if HCV RNA is still detectable after 3 months of therapy. Ribavirin may prove to have long-term benefit when used initially in combination with IFN. Early studies showed that higher rates of remission are possible when ribavirin is used in combination with IFN- $\alpha$ . This has been confirmed in a recent double-blind, placebo-controlled trial from Sweden, showing that more patients have a sustained virologic response at 1 year after 24 weeks of therapy with combination IFN and ribavirin than IFN therapy alone. Combination of IFN and ribavirin is the therapy of choice for chronic HCV. A sustained virologic response rate of 40% is seen in patients treated with this combination for 48 weeks. This response rate is higher in patients with non-1 genotype or a low HCV viral load.

## **Prognosis**

The exact frequency of progression of chronic hepatitis B to cirrhosis is unknown, but likely occurs in 10-50% of cases. HB<sub>s</sub>Ag carriers have a 200-fold-higher relative risk of developing hepatocellular carcinoma than noncarriers. Chronic hepatitis C progresses to cirrhosis in 20-30% of cases, and the risk of developing hepatocellular carcinoma is higher than in HBV infection, occurring a mean of 30 years after initial HCV infection. Chronic hepatitis C has a better long-term response to IFN if HCV genotype 2 or 3 is present. In contrast, < 10% of HCV genotype 1 cases (80% of cases in the United States) respond to IFN.

## **GRANULOMATOUS HEPATITIS**

### **Essentials of Diagnosis**

- Fever and nonspecific liver test abnormalities.

- Constitutional symptoms or asymptomatic.
- Characteristic granulomas on liver biopsy histopathology.

## General Considerations

Granulomas develop in the liver when the reticuloendothelial system is exposed to certain foreign antigens. They usually reflect a systemic disease process, whether being infectious or noninfectious in etiology. Granulomas are nodular infiltrates of epithelioid cells, which are transformed macrophages. The stimuli for such a transformation may include undegraded foreign matter (eg, mycobacterial products) or inflammatory mediators released by sensitized T cells. Triggered macrophages release interleukin-1 and other pyrogens that account for the fevers seen in this disease.

Infectious diseases are the most common cause of granulomatous hepatitis ([Table 21-5](#)), of which tuberculosis is the most common. The diagnosis of tuberculous granulomas is difficult, because *Mycobacterium tuberculosis* can cause either noncaseating or caseating hepatic granulomas, and the organism is demonstrated on staining or culture in < 50% of cases. Fungi are another common cause, with histoplasmosis being the most common fungal etiology of granulomatous hepatitis in the United States.

## Clinical Findings

Fever is common, and granulomatous hepatitis may present as a fever of unknown origin. Clinical presentation varies from nonspecific hepatic biochemical abnormalities in asymptomatic individuals to vague abdominal pain, weight loss, and night sweats. Laboratory abnormalities are also nonspecific, however elevated alkaline phosphatase levels are common, and aminotransferase and erythrocyte sedimentation rate levels are variably elevated. Liver biopsy is essential for diagnosis to demonstrate the characteristic granulomas. This must be supplemented with specific stains (eg, acid-fast stains and silver staining), cultures (eg, for bacteria, fungi, and mycobacteria), and serum serologies (eg, for viral causes and Q fever) to diagnose the specific cause. Imaging is not helpful in the workup of granulomatous hepatitis.

## Differential Diagnosis

This syndrome may be indistinguishable from hepatic granulomas caused by noninfectious diseases. Sarcoidosis and hypersensitivity drug reactions (eg, allopurinol, sulfonamides, and quinidine) are the most common, followed by chronic granulomatous disease of childhood, Hodgkin's disease, and other lymphomas. Of note, the cause remains unknown in = 50% of cases in some series.

## Treatment

Treatment of infectious causes of granulomatous hepatitis is directed toward the specific cause. Granulomas seem to resolve as the systemic infection clears. Corticosteroids have been shown to be efficacious in some cases of idiopathic granulomatous hepatitis.

However, some experts recommend an empiric trial of two-drug antituberculous therapy before steroid administration, given the frequency of false-negative cultures for tuberculosis and the potential for disseminated tuberculosis with steroid therapy. Treatment response should be monitored by clinical parameters and repeat biopsy at 6-12 months.

## HEPATIC ABSCESS

### 1. PYOGENIC LIVER ABSCESS

#### Essentials of Diagnosis

- Right upper quadrant abdominal pain.
- Fever, chills, and leukocytosis.
- Tender hepatomegaly.
- Intrahepatic lesion on hepatic imaging.
- Possible indolent course, with malaise and poorly localized abdominal pain.

#### General Considerations

Despite frequent exposure of the liver to bacteria in both the portal and systemic circulatory systems, the development of pyogenic liver abscesses is rather rare. The extensive network of reticuloendothelial cells in the hepatic sinusoids is highly protective. Hepatic abscess formation can occur when this defense system is overwhelmed, by bacterial invasion from either the biliary tree (eg, acute cholangitis), the portal vein (pyelephlebitis), the hepatic artery, direct trauma, or adjacent bacterial infection. The incidence of pyogenic liver abscess is ~ 15 cases/100,000 hospital admissions, and over one-third of such cases are secondary to direct extension from a biliary tract infection. Bacteria less commonly invade the liver from the portal system (eg, with appendicitis or IBS), systemic circulation (eg, *Staphylococcus aureus* abscesses in children), or penetrating trauma (eg, complication of ventriculoperitoneal shunt placement). Over half of liver abscesses are polymicrobial ([Box 21-2](#)), but a single organism may be involved in abscesses from a systemic source (eg, *Candida* spp. in neutropenic hosts). Either hepatic lobe may be involved; however, the right lobe is more commonly involved given its size and propensity to receive most portal blood flow. Abscesses may be single or multiple, ranging from widely scattered microabscesses (eg, in *S aureus* sepsis) to single large polymicrobial abscesses. Of pyogenic liver abscesses, ~ 15% have no known cause and are classified as cryptogenic.

#### Clinical Findings

**A. Signs and symptoms.** The patient may present with high fever, rigors, and severe right-sided abdominal pain. A more acute and severe clinical picture (with fever, jaundice, abdominal pain, and shock) may be seen with multiple abscesses, usually associated with acute cholangitis. However, up to half of cases may have chronic

symptoms of malaise, fatigue, weight loss, and poorly localized pain that worsens with movement. If the abscess is adjacent to the liver capsule, referred right shoulder pain may occur, which may worsen with coughing. Breath sounds may be reduced over the right lung base secondary to an associated pleural effusion. Physical exam often reveals tender hepatomegaly, which is often accentuated by percussion over the surface of the liver.

**B. Laboratory findings.** Hepatic biochemical abnormalities are nonspecific, including a slightly elevated total bilirubin, elevated aminotransferases (two- to threefold), and hypoalbuminemia. Alkaline phosphatase and  $\gamma$ -glutamyl transferase levels may be elevated up to fivefold of normal values, especially when associated with biliary tract obstruction. Leukocytosis with a left shift is common, and anemia is often noted. Blood cultures may be positive in = 50% of cases.

**C. Imaging.** Abdominal CT with contrast is the procedure of choice. It allows for the precise localization and visualization of small abscesses (< 1 cm); detects gas within abscesses in = 30% of cases (which suggests that gas-producing bacteria are present); distinguishes tumors, cysts, and hematomas; defines other intraabdominal abnormalities; and allows for CT-guided aspiration of the abscess if indicated. Abscesses appear as well-defined hypodense lesions that enhance on CT with contrast; rim enhancement is relatively uncommon. Right-upper-quadrant ultrasonography is a rapid alternative and has 70-90% sensitivity for differentiating cystic vs solid intrahepatic lesions. As seen sonographically, an abscess may be a hypodense or hyperdense ill-defined lesion. Note that both imaging tests may be negative in identifying intrahepatic abscesses in the neutropenic host (eg, hepatic candidiasis).

## Differential Diagnosis

The major diagnostic challenge is to distinguish pyogenic from amebic abscess, because treatment differs depending on the etiology. Amebic abscess may be suggested by a hepatic abscess in an immigrant or traveler from an endemic area, a young or previously healthy adult, or a positive enzyme-linked immunosorbent assay for *E histolytica*. Pyogenic abscess is suggested by a positive blood culture and the presence of associated biliary tract infection, underlying liver disease, or IBS. Tender hepatomegaly and liver lesions on imaging may also be seen with liver cysts, metastatic carcinoma, lymphoma, and infarction.

## Treatment

Drainage of the abscess and IV administration of antibiotics are the mainstays of treatment. Drainage is often done via percutaneous catheter drainage or percutaneous needle aspiration, usually under CT or ultrasound guidance. Recently, percutaneous needle aspiration has been deemed as safe and effective as continuous catheter drainage; however, repeated aspirations may be necessary in = 30%. Percutaneous drainage may not be necessary in cases with relatively small abscesses (< 5-cm diameter), and successful treatment may be achieved with antibiotics alone, depending on the clinical stability of the patient. Open abdominal surgery is reserved for cases that fail to respond to percutaneous drainage.

Initial antibiotic regimens should include metronidazole until amebic abscess is ruled out by serologies ([Box 21-3](#)). The antibiotics should cover the most common bacterial pathogens, including gram-negative bacilli and anaerobes. Ampicillin, an aminoglycoside, and metronidazole have been effective, although an increase in the incidence of ampicillin-resistant *Enterobacteriaceae* has been noted, and aminoglycoside nephrotoxicity is a serious limitation of this regimen. An alternative regimen is a third-generation cephalosporin plus metronidazole (or clindamycin if amebic abscess has been ruled out) or a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combination plus metronidazole. In patients with a history of recent exposure to third-generation cephalosporins and prolonged hospitalization, certain gram-negative bacilli (ie, *Serratia* spp., *Pseudomonas* spp., indole-positive *Proteus* spp., *Citrobacter* spp., *Enterobacter* spp., and *Acinetobacter* spp.) may have developed resistance to all cephalosporins and  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combinations. Pending susceptibility studies, alternative regimens for these patients include a carbapenem, or a fourth-generation cephalosporin or ciprofloxacin plus clindamycin or metronidazole. (Fluoroquinolones are the antibiotics of choice in patients allergic to penicillin, and a combination of ciprofloxacin plus either clindamycin or metronidazole is a reliable alternative.) Antibiotics should be continued for a minimum of 6 weeks, usually to 12 weeks (2-3 weeks IV, followed by oral regimen). Some authors recommend treatment for = 6 months if the abscess is streptococcal.

## Prognosis

Despite aggressive treatment, the mortality ranges from 10-25%. An increase in mortality is noted in patients with multiple abscesses, increased age, and associated comorbid conditions. Morbidity and mortality may be caused by formation of portal or splenic thromboses, pleural or pericardial effusions, rupture into the pericardium, fistula formation, empyema, or sepsis.

## 2. AMEBIC ABSCESS

### Essentials of Diagnosis

- Fever and right-upper-quadrant abdominal pain.
- Cystic lesion on abdominal imaging.
- Positive serology for antibody to *Entamoeba histolytica*.

### General Considerations

*E histolytica* is endemic worldwide, with an estimated 10% of the world's population being infected. It is more prevalent in India, Africa, the Far East, and Central and South America, especially in areas with poor hygiene. Amebic liver abscess is the most common extraintestinal complication of amebiasis (occurring in 8.5% of cases). Hepatic infection occurs when trophozoites in the colon ascend in the portal system and invade the parenchyma. Subsequent ischemia and lysis of neutrophils with release of toxic products contribute to parenchymal destruction. Trophozoites advance away from the necrosis and are located in the outer edge of the abscess. The term abscess is actually

a misnomer because the central necrosis contains proteinaceous material without neutrophils.

## Clinical Findings

**A. Signs and symptoms.** Amebic abscesses may be difficult to distinguish from pyogenic abscesses. Patients with an amebic abscess are usually more acutely ill, with fever and abdominal pain for < 10-days duration. An indolent course is uncommon. Patients are also younger, usually from high-prevalence areas, or are recent travelers. If the pericardium is involved, the patient may present with chest pain or congestive heart failure, and a pericardial friction rub may be present. Dyspnea, cough, and pleuritic chest pain may be present when rupture into the pleural space occurs. Diarrhea is relatively uncommon, occurring in < 30% (despite the colon being the organism's point of entry). Jaundice and tender hepatomegaly are uncommon.

**B. Laboratory findings.** Aminotransferase levels are variable; however, alkaline phosphatase is usually elevated and albumin decreased. Leukocytosis without eosinophilia is common. The erythrocyte sedimentation rate may be elevated, and anemia may be present. Serum antibodies to amoebae via enzyme-linked immunosorbent assay or indirect hemagglutination assay are present in > 90% of cases. However, serology may be negative in acute disease (but positive on repeated testing in 7-10 days) and may be positive if the patient had amebiasis in the past (as the antibody levels may persist for years after acute infection).

**C. Imaging.** Both CT and ultrasonography are sensitive imaging studies for diagnosis of amebic abscess, but it is difficult to distinguish amebic abscesses from pyogenic abscesses or complex cysts. On sonography, the abscess usually appears as a round hypoechoic lesion near the liver capsule, with a paucity of significant wall echoes. CT with contrast may demonstrate a well-defined low attenuation lesion with a thick enhancing wall and surrounding zone of edema. Either CT or ultrasonography allows for percutaneous aspiration if pyogenic abscess needs to be ruled out. Of note, viable trophozoites are seen only in the periphery of the abscess. Fluid from the center of the abscess yields no organisms and varies in appearance, from yellow to reddish-brown ("anchovy paste").

## Treatment

Because amebicidal therapy is highly effective, percutaneous aspiration is not necessary. Catheter drainage should be considered only when amebic serologies are negative, bacterial superinfection of an amebic abscess is suspected, or a left-hepatic-lobe abscess threatens rupture into the pericardium. Metronidazole is the drug of choice ([Box 21-4](#)). This must be followed by a luminal agent, as *E histolytica* is present in the colon previous to hepatic invasion. Luminal agents include diloxanide furoate, paromomycin, or diiodohydroxyquin. Symptoms usually respond in 3 days. If no improvement occurs after 3 days of treatment, consider percutaneous aspiration of the abscess to rule out a bacterial process.

## Prognosis

Mortality caused by uncomplicated amebic abscess is < 1%. Mortality is higher if the abscess ruptures into the peritoneum, pleural space, or pericardium. Cure of the amebic abscess apparently results in immunity, because recurrence in patients with positive amebic antibodies is extremely rare.

## LIVER INFECTIONS IN PATIENTS WITH HIV

### General Considerations

The majority of patients with AIDS have abnormalities on hepatic biochemical tests at some point in their illness. Opportunistic infections and neoplasms affect the liver in = 80% of patients with AIDS in autopsy studies. The types of hepatic disease in HIV infection vary ([Table 21-6](#)). Acute hepatocellular damage is usually caused by viruses (eg, the hepatitis viruses, CMV, Epstein-Barr virus, herpes simplex virus, and HIV itself) or hepatotoxic drugs (eg, azidothymidine, dideoxyinosine, isoniazid, rifampin, ritonavir, or trimethoprim-sulfamethoxazole). The most common viral cause of hepatitis in HIV is HBV, and 20% of persons who are HIV-positive become chronic carriers (in contrast to 5% of HIV-negative adults). Granulomatous hepatitis is one of the most common presentations of hepatic infection in HIV patients, usually secondary to mycobacterial disease (eg, *Mycobacterium avium* complex), fungi (eg, disseminated histoplasmosis), or protozoa (eg, *Pneumocystis carinii* infection in patients receiving aerosolized pentamidine prophylaxis). Mass lesions are most commonly neoplastic. Vascular lesions may be caused by peliosis hepatis (*Bartonella henselae* infection) or Kaposi's sarcoma.

### Clinical Findings

Liver disease in HIV patients has an extremely variable presentation depending on the cause. Patients may be asymptomatic or have a fever of unknown origin (eg, in granulomatous hepatitis). Fever and right-upper-quadrant abdominal pain are common in acute viral hepatitis from any cause. Liver infection may be heralded as weight loss and hepatomegaly (eg, in peliosis hepatis). Jaundice is relatively uncommon and, when present, is usually caused by drug-induced hepatotoxicity (eg, with isonicotinic acid hydrazide or trimethoprim-sulfamethoxazole). Extrahepatic findings on exam may give clues to the diagnosis, eg, the presence of concomitant cutaneous lesions (in Kaposi's sarcoma or bartonellosis) or pulmonary tuberculosis. Hepatic biochemical tests are almost always abnormal, however, in nonspecific patterns. CD4 cell counts may aid in the differential diagnosis. For example, tuberculosis, Kaposi's sarcoma, and acute viral hepatitis are possible at any time in the course of disease, even with a normal CD4 count. Patients with  $CD4 < 100/mm^3$  are more susceptible to such infections as *M avium* complex and CMV.

### Diagnostic Approach

A detailed history and physical are imperative and should focus on previous opportunistic infections, hepatotoxic medications, alcohol use, and recent travel. Hepatic biochemical testing is usually not helpful in diagnosis. Evidence for hepatocellular damage warrants further serologic testing, such as hepatitis viral serologies, and a trial of cessation of potentially toxic medications. If workup remains negative, consider liver

biopsy. If a cholestatic pattern predominates on biochemical testing, imaging can be used to search for focal lesions or dilated biliary ducts. Consider ERCP in patients who present with fevers, jaundice, and abdominal pain or who have dilated biliary ducts on imaging, for potential biliary drainage, cultures, and biopsy specimens for further testing. Patients with HIV usually have histopathologic abnormalities on liver biopsy. About one-third of biopsy specimens yield nonspecific findings, however liver biopsy remains the most specific diagnostic tool for effective diagnosis of liver infection in HIV.

## **INFECTIONS OF THE BILIARY TRACT**

### **ACUTE CALCULOUS CHOLECYSTITIS**

#### **Essentials of Diagnosis**

- Severe abdominal pain and tenderness localized to the right upper quadrant.
- Nausea and vomiting.
- Fever and leukocytosis.

#### **General Considerations**

Acute calculous cholecystitis, associated with cholelithiasis, accounts for > 90% of cases of cholecystitis. This severe inflammation of the gallbladder wall results from stasis of bile secondary to an obstructed gallbladder infundibulum or cystic duct by a stone. Obstructed bile and the associated increase in pressure lead to damage of the gallbladder mucosa and the release of inflammatory mediators. Bacteria may be present in the inflamed gallbladder in up to half of cases, but they likely play a secondary role in the inflammatory process. Distention and edema of the gallbladder wall may lead to ischemia, with resulting gangrene, empyema, or perforation. Cholecystitis in children usually results from pigment stones that develop in hemolytic disease.

#### **Clinical Findings**

**A. Signs and symptoms.** Patients may have had previous episodes of biliary colic associated with cholelithiasis, but acute cholecystitis is heralded by severe and sustained pain that is more localized to the right upper quadrant. Children may have periumbilical, back, or poorly localized abdominal pain. Nausea, emesis, and fever are common. On exam, right-upper-quadrant tenderness is invariably present and may be associated with guarding and rebound caused by peritoneal irritation. Murphy's sign may be present, characterized by sudden cessation of inspiration secondary to severe tenderness during right upper quadrant palpation. Approximately 20% of cases have jaundice, and 20% have a palpable mass in the right upper quadrant secondary to irritated omentum overlying the inflamed gallbladder.

**B. Laboratory findings.** The leukocyte count is usually high, with an associated bandemia. The total bilirubin may be elevated; however, the level rarely rises above 4 mg/dL. Mild elevations in alkaline phosphatase and aminotransferase levels are also present.

**C. Imaging.** Abdominal ultrasound is the test of choice. It has 88-94% sensitivity and 78-80% specificity for detecting acute cholecystitis, suggested by a thickened gallbladder wall (> 5 mm), positive sonographic Murphy's sign, and the presence of pericholic fluid. Hepatobiliary imaging with  $^{99m}\text{Tc}$  (eg, dimethyl iminodiacetic acid scan) may be useful in detecting an obstructed cystic duct, which is often the precipitating event in acute cholecystitis. The test is reliable when the total bilirubin is < 5 mg/dL, and is 98% sensitive and 81% specific for acute cholecystitis. However, biliary scintigraphy is more time consuming, involves injection of radiopharmaceuticals, and does not allow for imaging of the gall bladder and surrounding structures. Plain films of the abdomen may show radiopaque gallstones (= 15% of cases); however, they are not helpful in the diagnosis of acute cholecystitis.

### Differential Diagnosis

Fever, nausea, vomiting, and right-upper-quadrant abdominal pain may be present in a number of other disorders, such as acute hepatitis, liver abscess, acute pancreatitis, perforated peptic ulcer, right-lower-lobe pneumonia with associated pleurisy, and appendicitis (especially in pregnancy). Definite localization of tenderness over a palpable gallbladder with radiation of pain to the right scapular area strongly supports the diagnosis of acute cholecystitis.

### Complications

Perforation of the gallbladder may occur, especially if gangrene develops from progressive ischemia and gas-forming bacteria, including *Escherichia coli* in diabetic patients and *Clostridium perfringens* in emphysematous cholecystitis. This syndrome is more common in males and diabetics, and ~ 30% of cases are associated with acalculous cholecystitis. Empyema may result from bacterial invasion of the gallbladder wall, usually involving enteric gram-negative bacilli and anaerobes. Treatment is essentially the same as for acute cholecystitis; however, urgent surgical treatment is usually indicated in patients with empyema. Repeated episodes of acute calculous cholecystitis or chronic irritation of the gall bladder wall by stones may lead to chronic cholecystitis. Cholangitis and pancreatitis are potential complications if gallstones migrate and obstruct the common bile duct or pancreatic duct.

### Treatment

In most cases, acute calculous cholecystitis will subside with conservative therapy alone. Bowel rest should be instituted and IV fluids administered. Antibiotics are most likely required in such clinical settings as sepsis, empyema, emphysematous cholecystitis, and cholangitis. In these patients, antibiotic options include a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor, a carbapenem, ciprofloxacin plus metronidazole or clindamycin, or trovafloxacin. Ampicillin should be used with caution, given recent emergence of ampicillin-resistant *E coli* in community-acquired infections with this organism. If urgent cholecystectomy is considered, prophylactic antibiotics may be administered perioperatively; regimens include a second-generation cephalosporin with moderate anaerobic activity, such as cefoxitin or cefotetan.

Laparoscopic cholecystectomy is now considered the procedure of choice for removal of the gallbladder. Cholecystectomy is mandatory if there is evidence of emphysematous cholecystitis or perforation.

## **ACUTE ACALCULOUS CHOLECYSTITIS**

### **General Considerations**

Acute acalculous cholecystitis is infection of the gallbladder in the absence of gallstones. It is less common than gallstone-associated disease (2-12% of cases of acute cholecystitis); however it is much more serious. Gangrene of the gallbladder is 30-fold more common than in calculous cholecystitis, and perforation is ~ 5-fold more common, which leads to a higher mortality (= 67% mortality, in contrast to 3%). Patients with this syndrome are usually elderly or seriously ill and include patients with severe burns and trauma, patients who are recuperating from major surgery, or those receiving intensive care and parenteral nutrition. Comorbid conditions with higher risk of developing acalculous cholecystitis include cardiovascular disease, diabetes mellitus, systemic arteritis (eg, polyarteritis nodosa), and immunocompromise (eg, AIDS). The pathophysiology is poorly understood, but may be associated with bile stasis and gallbladder dysfunction. Bile stasis and paucity of gallbladder contractions may occur in critically ill patients and patients who receive parenteral nutrition. The retained bile may lead to gallbladder wall inflammation and ischemia, with subsequent microbial invasion of the gallbladder mucosa. In immunocompetent patients, the most common offending microorganisms include gram-negative bacilli and anaerobes. In immunocompromised patients including patients with AIDS (particularly in those who have not yet received benefit from highly active antiretroviral therapy), organisms include CMV, *Cryptosporidium* spp., microsporidia, *Isospora* spp., *Salmonella* spp., and *Campylobacter* spp.

### **Clinical Findings**

**A. Signs and symptoms.** Acute acalculous cholecystitis is often clinically indistinguishable from calculous cholecystitis, with fever, right upper abdominal pain and tenderness, nausea, vomiting, and anorexia. This syndrome is extremely difficult to diagnose, because many patients are critically ill with vague, generalized complaints or are unable to provide a history given sedation or mechanical ventilation in an intensive care unit.

**B. Laboratory findings.** Leukocytosis, hyperbilirubinemia, and mild elevations in aminotransferase levels are common.

**C. Imaging.** As in acute calculous cholecystitis, abdominal ultrasound often reveals a thickened gallbladder wall, distention, subserosal edema, and pericholic fluid. The sensitivity and specificity of abdominal CT may approach 100% in detecting this disease.

### **Treatment**

Removal of the infected gallbladder and administration of antibiotics are imperative. IV

fluids and antibiotics should be started promptly. Antibiotics should cover gram-negative bacilli and anaerobes (see treatment of acute cholangitis).

## **ACUTE CHOLANGITIS**

### **Essentials of Diagnosis**

- Fever, jaundice, and leukocytosis.
- Severe right-upper-quadrant abdominal pain.
- Nausea and vomiting.
- Possible progression to hypothermia, hypotension, and altered mental status.

### **General Considerations**

First described by Charcot in 1877, acute cholangitis is acute biliary infection superimposed on an obstructed biliary tree. Bile is normally sterile, because of constant bile flow into the duodenum and the presence of secretory IgA in the biliary tract. However, in the presence of obstruction, bile under pressure may be infected by ascending bacteria in the common bile duct from the gut or from the portal or systemic circulation ([Box 21-5](#)). Obstruction of the common bile duct is primarily from stones (= 80% of cases), which usually arise from the gallbladder but may spontaneously form in the bile duct (eg, postcholecystectomy). Obstruction may also be secondary to carcinoma of the common bile duct or adjacent pancreas, biliary stricture, or sclerosing cholangitis. In children, acute cholangitis occurs in the presence of ductal abnormalities or immunocompromise. It is most often a complication of the Kasai procedure for biliary atresia, which establishes biliary drainage via a Roux-en-Y connection to the porta hepatis. Cholangitis results from the removal of the protective sphincter of Oddi during the procedure and ascension of bacteria from the jejunal limb.

This syndrome may range from an acute ascending cholangitis, associated with incomplete common bile duct obstruction and ascending bacteria from the duodenum, to acute obstructive suppurative cholangitis, which features complete bile duct obstruction, pus in the biliary tree, and potential for progression to sepsis and intrahepatic abscess formation.

### **Clinical Findings BR>**

**A. Signs and symptoms.** A previous history of biliary colic with jaundice may be present. The classic triad of fever, jaundice, and right-upper-quadrant pain, known as Charcot's triad, is present in only 20-70% of cases. Patients with acute obstructive suppurative cholangitis may present with septic shock, including altered mental status and hypotension (which, along with the classic triad, make up Reynolds pentad). Children infrequently present in septic shock, and fever may be their only symptom. Hepatomegaly is variably palpable in association with biliary obstruction; however, right-upper-quadrant and epigastric pain is usually present on exam.

**B. Laboratory findings.** Most patients have elevated leukocyte counts,

hyperbilirubinemia, and elevated alkaline phosphatase levels. Serum aminotransferase levels are often elevated, although to a lesser degree (only severalfold). Up to one-third of cases have elevated serum amylase caused by concomitant obstruction of the pancreatic duct; 10% of cases have clinical evidence of gallstone pancreatitis.

**C. Imaging.** Both abdominal ultrasonography and CT may demonstrate dilated biliary ducts, but CT scan is more effective in demonstrating both the cause (70% vs 38%) and the level (88% vs 60%) of the obstruction. Cholangiography via PTC or ERCP provides the most accurate means of determining the cause and location of the obstruction. If choledocholithiasis is suspected, ERCP is the procedure of choice because it allows for papillotomy or papillary dilation with stone extraction or stent placement.

### Differential Diagnosis

Fever, jaundice, right-upper-quadrant pain, and abnormal liver tests can also be seen in acute viral hepatitis (often with higher aminotransferase levels and lower total bilirubin), acute common bile duct obstruction, sepsis-associated cholestasis, liver abscess (jaundice less common), and sclerosis cholangitis (fever is uncommon). Biliary tract imaging or liver biopsy may be required to distinguish between an obstructive process and hepatocellular damage.

### Complications

Prolonged, untreated obstructive jaundice may lead to hepatocellular damage and possible cirrhosis. Hypoprothrombinemia may predispose the patient to excessive bleeding. In contrast to hypoprothrombinemia in hepatocellular disease, prolonged prothrombin times associated with obstructive jaundice may be corrected with daily intake of vitamin K.

### Treatment

Antibiotics and biliary drainage are the mainstays of treatment, because acute cholangitis is invariably fatal without urgent decompression of the biliary tree. Before drainage, IV fluid resuscitation and IV vitamin K (if elevated prothrombin time) should be administered. The empiric antibiotic regimen of choice should have broad-spectrum coverage of enteric gram-negative bacilli, however it is controversial whether gram-positive cocci and anaerobes should be covered in the empiric regimen ([Box 21-6](#)). No studies have shown a particular antibiotic regimen superior over others. Combinations of antibiotics include a 7- to 10-day course of a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor, an amino penicillin with an aminoglycoside and metronidazole, a second-generation cephalosporin with antianaerobic activity, a third-generation cephalosporin plus metronidazole or clindamycin, or a ureidopenicillin plus either metronidazole or clindamycin. Ciprofloxacin plus metronidazole, or clindamycin, or imipenem, appear to be promising alternatives. Aminoglycosides must be used with caution (especially after the fifth day of use), given their potential for nephrotoxicity. Ampicillin should be used with caution given the recent emergence of ampicillin-resistant *E coli* in community acquired infections caused by this organism. Prolonged therapy with ceftriaxone should be avoided given its propensity to form biliary sludge.

Of cases of acute cholangitis, = 75% initially respond to IV fluids and antibiotics, allowing for a small delay in biliary drainage. However, biliary decompression with drainage of the obstructed biliary tree is crucial in the management of this syndrome in severely ill patients. Classically, common bile duct exploration and placement of a T-tube were the procedures of choice. Now drainage can be accomplished with either PTC or ERCP during the diagnostic workup of these patients. They are both associated with less morbidity (34% vs 66%) and mortality (10% vs 33%) than open abdominal surgery, although PTC is associated with significant bleeding in the context of liver dysfunction. ERCP is usually more appropriate, as it allows for stone extraction or placement of a biliary stent during the procedure. After decompression of the biliary tree, antibiotics should be continued until there is full resolution of symptoms or for 7-10 days of therapy. Longer courses are advocated for refractory or recurrent disease. In children with post-Kasai procedure cholangitis, many support the use of long-term prophylaxis with trimethoprim-sulfamethoxazole (20 mg/kg/d of trimethoprim).

## Prognosis

With appropriate treatment, mortality from acute cholangitis is < 10%. Mortality rates are higher in those with acute obstructive suppurative cholangitis, sepsis, and severe underlying disease. Clinical factors associated with poorer prognosis include old age, female sex, evidence of acute renal failure, concomitant liver abscess or cirrhosis, and malignant biliary tract obstruction. Acidosis (pH < 7.4), hyperbilirubinemia (total bilirubin > 90 mmol/L), hypoalbuminemia (albumin < 30 g/L), and thrombocytopenia (platelet count < 150) also predicted poorer outcome.

In children, the incidence of cholangitis after the Kasai procedure is highest in the first postoperative year (43-78%). This incidence is significantly lower if an intussusception valve is designed at the site of the jejunostomy. Each episode of postoperative cholangitis carries a 1% mortality rate in these patients.

## RECURRENT PYOGENIC CHOLANGITIS

Also known as oriental cholangiohepatitis, recurrent pyogenic cholangitis is characterized by recurrent attacks of suppurative cholangitis. It is endemic in Southeast Asia and may be seen in Asian immigrants. The bile duct infections are caused by gram-negative bacilli and less commonly anaerobes ([Box 21-5](#)) via transient portal bacteremia, in the context of bile stasis and ductal epithelium damage. The recurrent infections lead to the formation of large, muddy-brown pigment stones within the ducts. The initial damage to bile duct epithelium may be secondary to parasitic infection (eg, *Clonorchis sinensis*, *Opisthorchis* spp., or *Ascaris lumbricoides*) or a low-protein diet (leading to pigment stone formation), both common in Southeast Asia. The biliary damage is usually localized to the left hepatic lobe.

This syndrome peaks in 30- to 40-year-olds. Patients may have a history of recurrent attacks of acute cholangitis. Clinically, recurrent pyogenic cholangitis is indistinguishable from acute cholangitis. Abdominal CT is the imaging test of choice, which identifies the characteristic dilated central intrahepatic ducts that taper peripherally, often localized to the left hepatic lobe. As in acute cholangitis, ERCP can be used to visualize the biliary

tree and allow for drainage. Treatment includes prompt administration of broad-spectrum antibiotics and IV fluids. Drainage may be needed in the 15% of cases that fail antibiotic therapy. Removal of pigment stones and relieving biliary strictures may help prevent future attacks.

## **SCLEROSING CHOLANGITIS**

Primary sclerosing cholangitis is a cholestatic disease of unknown etiology, featuring chronic inflammation and scarring of the intra- and extrahepatic bile ducts. Although the cause is unknown, recurrent damage of the bile ducts has been a proposed mechanism, possibly from chronic portal bacteremia (eg, in IBS), toxins from enteric flora, chronic viral infections, or ischemic damage. It is more common in men aged 20-40 years and often occurs in patients with IBS. Cholangiography reveals a characteristic beaded appearance to the biliary tree, secondary to focal areas of ductal dilatation proximal to strictures. There is no effective treatment to date. Survival is improved with liver transplantation.

In contrast, secondary sclerosing cholangitis occurs as a known complication of obstructive cholangitis (eg, choledocholithiasis), toxic damage to the biliary tract (eg, intraductal formaldehyde during echinococcal cyst extirpation), ischemia (eg, vasculitis), or a neoplastic process (eg, cholangiocarcinoma). Obstructive cholangitis may be seen with a number of different infections, including *A lumbricoides*, recurrent pyogenic cholangitis, or *Cryptococcus neoformans*. Clinical presentation is similar to that of primary sclerosing cholangitis, including jaundice, pruritus, and right-upper-quadrant abdominal pain. Fever and weight loss are less common. A history of recurrent bouts of ascending cholangitis may be elicited. Cholangiography often shows focal strictures and dilated ducts, in contrast to the more uniform involvement of the biliary tree in primary sclerosing cholangitis. Treatment of recurrent episodes of cholangitis is similar to that of acute cholangitis, namely IV fluids, antibiotics directed against the specific pathogen, and biliary drainage. Pruritus is treated symptomatically, usually with topical emollients, antihistamines, or cholestyramine. Focal biliary strictures can be treated with endoscopic dilation or stent placement.

## **AIDS-RELATED CHOLANGITIS**

AIDS-related cholangitis is a form of secondary cholangitis caused by opportunistic infections in late-stage AIDS. It was first discovered to be caused by *Cryptosporidium* spp. and CMV in the mid 1980s, and later found to be also associated with microsporidia, *Isospora* spp., *M avium* complex, and human herpes virus 8. Portal tract invasion by these pathogens leads to bile duct injury and ischemia, with subsequent scarring of the biliary tract. Such organisms may also contribute to sphincter of Oddi dysfunction and development of papillary stenosis, which is seen in = 70% of cases.

Clinically, patients present with right-upper-quadrant pain and fever; however, jaundice is distinctly less common than in acute cholangitis (10% of cases). Nausea, vomiting, weight loss, and diarrhea are common. Patients typically have elevated alkaline phosphatase, mildly elevated aminotransferases, and CD4 cell count < 100/mm<sup>3</sup>. Stool cultures may be positive for *Cryptosporidium*, and bile culture obtained during ERCP may grow microsporidia. Definitive diagnosis is via biopsy of the involved tissue. ERCP

is the procedure of choice for cholangiography, biopsies, and possible sphincterotomy if papillary stenosis is present.

There is no effective treatment for this condition. The course of cholangitis is not significantly influenced by therapy directed at specific pathogens, including ganciclovir, foscarnet, paromomycin, or azithromycin. Pain management is imperative, and ursodeoxycholic acid may improve pain and cholestasis in some patients. Prognosis is poor with a median survival of 7 months after diagnosis. Death is usually secondary to another opportunistic process in late-stage AIDS.

### GYNECOLOGIC INFECTIONS

#### VULVOVAGINITIS

##### Essentials of Diagnosis

- Risk factors: use of antibiotics, elevated levels of estrogen, sexually active lifestyle, history of sexually transmitted diseases.
- Vulvar irritation, dysuria, vaginal discharge with or without odor, labial erythema.
- Change in vaginal pH.
- Microscopic examination of vaginal secretions may show characteristic yeast forms, clue cells, or trichomonads.

##### General Considerations

Vulvovaginitis is an extremely common syndrome; one study found that vulvovaginitis was diagnosed in more than 25% of the women attending sexually transmitted diseases clinics. It is estimated that 75% of all women experience at least one episode of vulvovaginal candidiasis in their lifetime. The organisms that cause vulvovaginitis cause very similar symptoms, so that a specific diagnosis cannot be made on symptoms alone ([Table 22-1](#)).

The most common infectious agents that cause vulvovaginitis are *Candida albicans* and other *Candida* species, *Trichomonas vaginalis* (which is discussed in [Chapter 15](#)), and agents involved in bacterial vaginosis (BV) ([Box 22-1](#)). Other etiologic agents include *Staphylococcus aureus*, herpes simplex virus (HSV), and papillomavirus. Much rarer agents, seen mainly in immunocompromised patients, include *M tuberculosis*, *Salmonellae*, *Enterobacteriaceae*, actinomycetes, and schistosomes. Noninfectious vaginitis can be caused by a foreign body, a genital neoplasm, estrogen deficiency in postmenopausal women leading to atrophic vaginitis, chemical vaginitis, and allergic reactions. Lichen planus can cause desquamative vaginitis, and fixed-drug eruptions can cause lesions in the genital area. This section will focus on candidal vaginitis, trichomonal vaginitis, and BV.

Vulvovaginal candidiasis accounts for approximately one-third of all cases of vulvovaginitis. *Candida albicans* probably accounts for 80-90% of cases of vulvovaginal candidiasis. *Candida tropicalis* accounts for 5% and is associated with a higher rate of recurrence after treatment. *Torulopsis glabrata* accounts for 10%, and this type of vulvovaginal candidiasis may be more difficult to eradicate with standard therapies. The relative incidence of vaginitis caused by fungi other than *C albicans* appears to be

increasing in some populations, which is attributed in part to the common use of topical antifungal agents in short courses. Factors favoring overgrowth of yeasts include the use of antibiotics, presence of high estrogen levels as in pregnancy and during oral-contraceptive use, wearing of tight clothing, and impairment of cell-mediated immunity or phagocytic cell function (as often occurs in women with AIDS or during post-transplant or post-chemotherapy periods).

BV is a polymicrobial infection associated with *Gardnerella vaginalis*, a gram-variable pleomorphic rod. This condition is more frequent in sexually active women and in populations with a higher prevalence of sexually transmitted diseases. The pathophysiology of BV is unclear, but a loss of the normal predominance of *Lactobacillus* species and increases in vaginal pH and numbers of anaerobic and aerobic bacteria are suspected. The characteristic fishy odor of BV may be caused by increased numbers of such anaerobes as *Bacteroides*, *Prevotella*, *Peptostreptococcus*, and *Mobiluncus* species and genital mycoplasmas. There is evidence to support the idea that BV is a sexually transmitted disease, in that *G vaginalis* can be isolated from the urethras of more than 80% of the male sexual partners of women with BV. However, *G vaginalis* can also be isolated from prepubescent girls who are not sexually active and from sexually inactive women. BV can be seen in women or girls who have never been sexually active, and the disease can recur even without sexual reexposure. BV tends to occur in women older than those who are at risk for gonorrhea and chlamydia. Women who are diagnosed as having BV should be screened for other sexually transmitted diseases, but it is not currently recommended that their sexual partners be routinely treated as well.

### **Clinical Findings (see [Table 22-1](#), "Typical Features of Common Vaginitides")**

**A. Signs and Symptoms.** Perivaginal pruritis is frequent with all three types of common infectious vaginitides, ie, candidal, trichomonal, and bacterial agents. Dysuria may be present. In candidal vulvovaginitis, there is often little or no vaginal discharge, but if present, it is usually thick and curdy. The labia may be pale or erythematous; there may also be small satellite papules or papulopustules at the margin of the erythematous area. Trichomonal vaginitis is also associated with vaginal irritation and sometimes dysuria and labial erythema. There may be a frothy greenish discharge. BV can present in the same manner but with a characteristically strong odor to the vaginal discharge, which is also usually gray-white in color. Physical examination may reveal very few abnormal findings, as there is rarely uterine or adnexal tenderness.

**B. Laboratory Findings.** The vaginal pH in candidal vaginitis is normal (4.5), whereas in trichomonal vaginitis and BV it is usually elevated. Adding 10% potassium hydroxide to vaginal discharge fails to elicit a fishy odor in candidiasis, whereas trichomonal vaginitis and BV have characteristically fishy odors (positive "whiff" test). Yeast forms may be visible under microscopy on a KOH preparation, although they are not visible in 30-50% of women who have candidal vulvovaginitis. With trichomonal vaginitis, microscopy should reveal trichomonads in 70% of cases. Epithelial cells appear normal, and there may be an increased number of polymorphonuclear cells. On wet mount examination of vaginal discharge in BV, clue cells, which are vaginal epithelial cells studded with tiny coccobacilli, can be seen. Culturing for *G vaginalis* can be performed, but the appearance of clue cells on the wet mount appears to be the most specific

criterion for the diagnosis of BV.

## Differential Diagnosis

As discussed above, other types of vaginal infections and processes can mimic vulvovaginitis caused by *Candida*, *Trichomonas*, and *Gardnerella* species.

## Complications

Trichomonal infection can be complicated by vaginitis emphysematosa, in which gas-filled pockets of tissue fill the vaginal wall. This condition will resolve upon treatment of the trichomonal infection. Women with trichomonal vaginitis are more likely to have vaginal-cuff cellulitis after hysterectomy and, if they are pregnant, are more likely to have premature or prolonged rupture of membranes, premature labor, low-birth-weight babies, and postabortion infection. Women with BV are at increased risk for salpingitis, vaginal-cuff and wound infections after surgery, postpartum fever, chorioamnionitis, premature labor, and premature delivery. The treatment of both candidal and trichomonal vaginitis may be complicated by frequent recurrences.

## Treatment

Vulvovaginal candidiasis is usually treated with topical antifungal agents ([Box 22-2](#)). There are a wide variety of treatments, all of which appear to be equally effective. Commercially available preparations, usually imidazoles or triazoles, are safe in pregnancy and tolerated well by patients. Treatment with an imidazole for 7 days yields a cure rate of approximately 80-94%. Shorter (3-day) regimens have approximately the same cure rate with improved patient compliance. Single-dose regimens do not appear to be as effective as the 3- or 7-day treatments. Pregnant women may require longer treatment. Oral therapy with fluconazole, ketoconazole, and itraconazole is available as well, but the potential toxicities are greater, and most patients do not require systemic therapy. Recurrent infection can be a problem with vulvovaginal candidiasis and probably results from endogenous relapse caused by small numbers of yeasts that have survived treatment. The rate of recurrence may be decreased by administering short courses of topical or oral antifungal agents during days 5-11 of the menstrual cycle, switching to a lower-estrogen-dose formulation of an oral contraceptive, and treating the male partner if he has candidal balanitis.

Trichomonal vaginitis should be treated with metronidazole (see [Chapter 15](#) for more detailed discussion). The sexual partner should be treated simultaneously. Metronidazole is contraindicated in early pregnancy and in lactating women.

BV can be treated with metronidazole. Clindamycin and oral cephalosporins are also acceptable therapy. Vaginal regimens are also available, and cure rates are reported to be similar to those achieved with oral metronidazole.

## Prognosis

Topical treatment of candidal vulvovaginitis has a cure rate range of 80-94%. However, 3-6 weeks after completion of treatment, *Candida* can be cultured from quite a few

women (9-33%) who have undergone this treatment. Subspeciation of *Candida* suggests that approximately 40% of these women are infected with new strains of *Candida* species. Our current understanding of the mechanism of recurrence is extremely limited. Therapy to decrease the number of recurrences is aimed at eliminating or minimizing the aforementioned risk factors.

In *Trichomonas vaginalis* infection, a single dose of metronidazole reportedly provides a cure rate of 90%. For BV, cure rates associated with treatment with metronidazole are reported to be 80-90%.

## CERVICITIS

### Essentials of Diagnosis

- Risk factors: young (under age 24), unmarried, sexually active women; lower socioeconomic status, a new sexual partner within the past 2 months, a history of gonococcal infection, and a history of *T vaginalis* infection; women who use an intrauterine device (IUD) are prone to infection with actinomycetes.
- Erythema around the cervical os, mucopurulent cervical discharge, fever, chills, and uterine tenderness may be present, or patients may be asymptomatic.
- Ten to thirty polymorphonuclear leukocytes per oil immersion field on Gram stain of cervical discharge.
- Ligase chain reaction (LCR) and polymerase chain reaction (PCR) tests for rapid diagnosis of cervicitis caused by *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.

### General Considerations

Cervicitis is also covered in [Chapter 15](#). The most common causes of cervicitis are *N gonorrhoeae* and *C trachomatis* ([Box 22-3](#)). Populations at higher risk for cervicitis include young (under age 24), unmarried, sexually active women of lower socioeconomic status. Their risk increases if they have had a new sexual partner in the past 2 months, a history of gonorrhea, or a history of infection with *T vaginalis*. Asymptomatic or latent infection appears to be common with both organisms, leading to such complications as salpingitis, tubo-ovarian abscess, pelvic inflammatory disease (PID), and potential infertility. Concomitant infection with more than one organism can occur.

Rates of chlamydial infection have been estimated to be 5-30% (of women attending prenatal clinics). Pregnant women need prompt treatment because chlamydial infection can be transmitted to the infant; also, chlamydial genital infection has been associated with complications during labor such as an increased risk of premature rupture of membranes, preterm labor, and infants who are small for their gestational age.

Rates of asymptomatic infection with *N gonorrhoeae* have been estimated to be approximately 5% in women attending family planning clinics. Reported rates of infection during pregnancy are 2-7.3%. Asymptomatic infection at nongenital sites is

important with *N gonorrhoeae*, because up to 40% of infected women have positive rectal cultures, and 22% have positive pharyngeal cultures. As with chlamydial infection, infection with *N gonorrhoeae* can be complicated by salpingitis, tubo-ovarian abscess, and PID. Disseminated gonococemia can occur. In pregnancy, gonococcal infection has been associated with a higher rate of maternal and fetal morbidity.

Other causes of cervicitis include HSV, human papillomavirus, and other agents.

## Clinical Findings

**A. Signs and Symptoms.** The diagnosis of cervicitis is suggested by the presence of a mucopurulent cervical discharge. Fever and pelvic pain may occur, particularly when the infectious process is complicated by salpingitis. On physical examination, erythema around the cervical os may be present; the os may also be raised and very friable. The clinical presentation cannot reliably distinguish among etiologic agents of cervicitis.

**B. Laboratory Findings.** Gram stain of cervical discharge may show numerous (10-30) polymorphonuclear leukocytes per oil immersion field. The presence of gram-negative diplococci on the Gram stain confirms the diagnosis of *N gonorrhoeae*, but their absence does not rule out the possibility. Chlamydial infection is suggested by the presence of intracytoplasmic inclusions on Giemsa stain of cervical discharge. Fluorescent antibody staining and enzyme-linked immunosorbent assays (ELISA) to identify chlamydial antigens are also available, but positive results need to be confirmed by culture. LCR or PCR tests of cervical discharge or LCR tests of urine can help make a rapid diagnosis of chlamydia or gonorrhea infection. For both chlamydia and gonorrhea, culturing is also useful.

## Differential Diagnosis

A diagnosis such as vaginitis is suggested by the vaginal discharge. Vaginal candidiasis, however, results in a typical whitish, curdy discharge; bacterial vaginosis (BV) and trichomonas vaginosis can result in a foul-smelling discharge, without the striking number of white cells found in cervicitis caused by chlamydial or gonorrheal infection.

## Complications

Cervicitis caused by chlamydia or gonorrhea infection will progress to PID in 10-40% of women with cervicitis. Other complications include Fitz-Hugh-Curtis syndrome, or perihepatitis, which is characterized by fever and right upper quadrant pain. Chlamydial cervicitis in a pregnant woman can result in postpartum endometritis or, if she undergoes an abortion, postabortion infection. Premature rupture of membranes, preterm labor, and small-for-gestational-age infants can result from untreated chlamydial infection in pregnant women. Infection acquired by the infant during delivery leads to such complications as pneumonia in 40-50%, as well as nasopharyngeal infection and ophthalmia neonatorum.

Gonococcal infection can be complicated by bacteremia, leading to polyarthrititis; endocarditis, myopericarditis, meningitis, and hepatitis can also occur. Infection in

pregnant women has been associated with a higher incidence of prematurity, prolonged rupture of membranes, maternal peripartum fever, chorioamnionitis, and intrauterine growth retardation. In the newborn, gonococcal infection acquired at birth can result in pneumonia, nasopharyngeal infections, and ophthalmia neonatorum. Ophthalmia neonatorum prophylaxis consists of the instillation of 1% silver nitrate or erythromycin ointment in each eye.

## Treatment

Penicillinase-producing *N gonorrhoeae* species are becoming more prevalent, making penicillin an ineffective choice for empiric therapy of cervicitis. Current recommendations are in [Box 22-4](#). The recommendations recognize that simultaneous infection with *C trachomatis* and *N gonorrhoeae* is common, so that both organisms should be treated. Pregnant women should not receive tetracyclines. In addition, the newer macrolides have not been approved for use in pregnant women.

## Prognosis

As stated previously, 10-40% of cervicitis cases caused by gonococcal or chlamydial infection in women will progress to PID, with the potential for infertility.

## Prevention & Control

Both *C. trachomatis* and *N. gonorrhoeae* are reportable diseases. All sexual partners of the patient should be notified and treated promptly. The effects of untreated cervicitis in pregnant women and neonates can be minimized by the screening and prompt treatment of high-risk pregnant women when they are seen for prenatal care. Administration of erythromycin ointment or silver nitrate drops to neonates is an important step in prophylaxis against ophthalmia neonatorum.

## PELVIC INFLAMMATORY DISEASE

### Essentials of Diagnosis

- Risk factors: young sexually active women with multiple sexual partners, frequent sexual intercourse, and new sexual partners within the previous 30 days.
- Signs: a pelvic mass may be discovered by examination or ultrasonography.
- CDC minimum criteria: lower abdominal tenderness, cervical motion tenderness, and adnexal tenderness. Women who present with these symptoms should be treated empirically for PID in the absence of other diagnoses to explain their signs and symptoms.
- CDC routine criteria: temperature of greater than 38.3 °C, abnormal cervical or vaginal discharge, elevated erythrocyte sedimentation rate or C-reactive protein, and laboratory documentation of chlamydial or gonorrheal infection. The presence of these findings provides further support for the diagnosis of PID.

- CDC elaborate criteria: histopathologic evidence of endometritis on biopsy, tubo-ovarian abscess on sonography or other radiologic tests, and laproscopic abnormalities consistent with PID. The presence of these findings provides the strongest support for the diagnosis of PID.

## General Considerations

The vague term "pelvic inflammatory disease" is used to refer to acute, subacute, chronic, or recurrent infection caused by the ascent of cervical microorganisms to the endometrium, fallopian tubes, and other pelvic structures ([Box 22-5](#)). Therefore, salpingitis, tubo-ovarian abscess, pelvic peritonitis, and endometritis will be included in the term pelvic inflammatory disease or PID.

Women at risk for PID are those who have untreated cervicitis due to *N gonorrhoeae* or *C trachomatis*. It is estimated that 10-40% of women with these infections do not receive adequate treatment and, in these women, symptomatic PID subsequently develops. *N gonorrhoeae* accounts for 40-60% of women with acute salpingitis, whereas *C trachomatis* accounts for 20-25%. Other risk factors for PID include sexual activity among teenagers, a new partner in the previous 30 days, frequent intercourse, bacterial vaginosis, frequent douching, and tobacco and substance abuse. Use of an IUD slightly increases the risk of PID—it is thought that this increased risk is due to introduction of organisms into the upper reproductive tract at the time of insertion.

PID is an ascending, polymicrobial infection. Organisms most frequently implicated in PID are *N gonorrhoeae*, *C trachomatis*, and genital *Mycoplasma* spp. Anaerobes such as *Peptococcus*, *Peptostreptococcus*, and *Bacteroides* are often involved. *E coli*, *Gardnerella vaginalis*, *H influenzae*, and group B streptococcus are the most frequent aerobes involved.

## Clinical Findings

**A. Signs and Symptoms.** Lower abdominal, adnexal, and cervical motion tenderness are present in most patients with PID. (These are the CDC's minimum criteria for the diagnosis of PID.) The pain and tenderness are often associated with the onset of menses and may radiate to the back and down both lower extremities. A temperature of greater than 38.3 °C and abnormal cervical or vaginal discharge provide further support for the diagnosis (see CDC routine criteria listed under "Essentials for Diagnosis" above).

**B. Laboratory Findings.** Findings on laboratory studies, unfortunately, can be within normal limits. Abnormalities such as a leukocytosis, elevated sedimentation rate, or C-reactive protein can support the diagnosis, but their absence or presence does not confirm the diagnosis. Gram stain of cervical secretions may reveal the presence of gram-negative diplococci, suggesting *N gonorrhoeae* as the causative organism. Culdocentesis may also be performed, and the fluid obtained should be examined for white cells; the presence of numerous white cells suggests PID, but appendicitis can also present in the same manner.

**C. Imaging.** Ultrasonography of the pelvis may reveal an inflammatory mass consistent

with tubo-ovarian abscess. Laparoscopy remains the most accurate method for diagnosing PID and should be performed in cases in which the diagnosis remains uncertain. Hyperemia of the tubal surface, edema of the tubal walls, and an exudate on the tubal surface are consistent with PID. Cultures can be obtained at the time of laproscopic examination and may help guide therapy.

## Differential Diagnosis

Appendicitis can present in a fashion similar to PID. A good history and physical examination may help differentiate between the two, although the diagnosis may not be established with certainty until the appendix is visualized at surgery. Ectopic pregnancy is suspected based on an elevated  $\beta$ -hcG level and ultrasound. Ultrasound may also be helpful in excluding entities such as ovarian cysts or ovarian torsion. Endometriosis can mimic chronic PID in that patients may present with complaints of chronic abdominal pain. However, they may also complain of irregular or heavy menstrual bleeding, which is more typical of endometriosis than of PID.

Nongynecologic problems such as irritable bowel syndrome or gastroenteritis should be suspected in patients who present with diarrhea and other bowel complaints. History and physical examination will also help differentiate cholecystitis from PID. Nephrolithiasis and pyelonephritis can also be differentiated from PID by location of abdominal pain, history, and urinalysis.

## Complications

At least 25% of women with PID have serious sequelae, such as infertility, ectopic pregnancy, and chronic pelvic pain. Acute complications include pelvic peritonitis if there is rupture of an abscess or extension of the infectious process into the peritoneal space. Pelvic cellulitis with thrombophlebitis may result. Abscess, bacteremia, and septic shock may develop.

## Treatment

Treatment should begin with empiric antibiotics as soon as the diagnosis is suspected. The CDC has published recommendations for the treatment of PID ([Box 22-6](#)). PID may be treated on an outpatient basis, with oral antibiotics. Ambulatory patients should, however, be reevaluated within 72 hours of beginning treatment. Under certain circumstances, hospitalization is recommended. The patient should be hospitalized when the diagnosis is uncertain and a surgical emergency such as acute appendicitis cannot be excluded; a pelvic or tubo-ovarian abscess is suspected; the patient is pregnant, an adolescent, or noncompliant; or the patient has failed or not tolerated outpatient therapy.

Regimen A (see [Box 22-6](#)) provides recommendations for treating gonorrhea and chlamydia. Regimen B provides recommendations for treating gonorrhea and chlamydia, as well as anaerobes. All sexual partners should be notified, treated empirically for chlamydia and gonorrhea, and tested for other sexually transmitted diseases.

In the case of a tubo-ovarian abscess, the patient should be hospitalized and begun on broad-spectrum antibiotics that provide anaerobic coverage. Surgical intervention is indicated when there is failure to defervesce within 72 hours or when there is an increase in the size of the abscess. Most tubo-ovarian abscesses 4-6 cm in diameter resolve in response to medical therapy alone, but only 40% of abscesses larger than 10 cm respond to medical therapy alone.

## Prognosis

A recent meta-analysis of 34 treatment regimens from 1966 to 1992 found cure rates to be above 90% for the commonly used treatment regimens, which form the basis for the current CDC treatment guidelines.

The incidence of infertility after the first bout of PID is approximately 12%. This rises to 25-35% after the second episode, and to 50-75% after three or more episodes. The risk of ectopic pregnancy increases to sevenfold that of a woman who has never had PID. Infertility rates are higher after tubo-ovarian abscess, with only 7-14% of women able to conceive.

## Prevention & Control

Prevention consists of treating women and their sexual partners for cervicitis and aggressively screening women at high risk.

# INFECTIONS AFTER GYNECOLOGIC SURGERY

## Essentials of Diagnosis

- Risk factors: more common in women who are premenopausal, undergoing abdominal versus vaginal hysterectomy, or of lower socioeconomic status and in women who undergo surgeries of longer duration or have bacterial vaginosis (BV) at the time of surgery.
- Lower abdominal and pelvic pain and fever lasting from 2 days to several weeks after operation.
- Variable tenderness on abdominal and pelvic examinations; palpable abdominal mass may be present with pelvic abscess.
- Leukocytosis and elevated sedimentation rate; blood cultures and cultures of purulent cervical or wound drainage may be helpful.
- Computed tomography and ultrasonography can help confirm the presence of an abscess.

## General Considerations

The usual pathogens in gynecologic, postoperative infections are endogenous pelvic flora ([Box 22-7](#)). These are *Lactobacillus* spp., streptococci, *Gardnerella vaginalis*,

*Enterobacteriaceae*, and anaerobes. Although *Fusobacterium* spp. and *B fragilis* are not usually present in the vaginal flora, they are often found in pelvic infections postoperatively. Factors such as hospitalization can cause a dramatic shift in the vaginal flora and predispose a patient to a postoperative pelvic infection. Use of spermicidal vaginal preparations, use of the female condom, douching, and the phase of the menstrual cycle can also affect the vaginal flora. Risk factors for the development of a postoperative infection include abdominal (versus vaginal) hysterectomy, lower socioeconomic status, premenopausal status, duration of surgery, and BV.

## Clinical Findings

**Pelvic Cellulitis.** Pelvic cellulitis is the most common infection after hysterectomy. Patients present on the second or third postoperative day with lower abdominal and pelvic pain, usually more severe on one side. The temperature is usually above 38.5 °C. On abdominal and pelvic examination there is tenderness over the parametrial area. Cultures may be obtained from the vaginal cuff, although some believe that such cultures can be misleading because of contamination by vaginal flora.

**Cuff Cellulitis and Abscess.** Cuff cellulitis after hysterectomy usually manifests within 10 days of discharge from the hospital, with central lower abdominal and pelvic pain, vaginal discharge, and low-grade fever. Examination of the abdomen reveals slight suprapubic tenderness, and pelvic examination reveals no masses and only vaginal surgical margin tenderness. An inflammatory reaction at the surgical margin of the vaginal cuff is normal and does not require treatment.

Cuff abscess occurs when a well-localized collection develops above the vaginal cuff. These patients usually present on the second or third postoperative day with fever and a sense of fullness in the lower abdomen. Purulent material obtained from the surgical margin should be cultured aerobically and anaerobically.

**Pelvic Abscess.** Patients with pelvic abscesses are usually premenopausal women. They may present weeks after the original procedure. Typically patients may have received a course of antibiotics in the hospital for presumed pelvic cellulitis, but they relapse after discharge. Patients present with high spiking fevers, especially in the late afternoon or early evening, and may complain of pelvic or lower abdominal pain. There may be notable leukocytosis and considerable elevation in the erythrocyte sedimentation rate. Ultrasonography or computed tomography can confirm the presence of an abscess.

## Treatment

Patients with pelvic cellulitis can be treated with single-agent antibiotic therapy. Cefotetan, cefoxitin, ampicillin/sulbactam, and ticarcillin/clavulanic acid are all reasonable choices ([Box 22-8](#)). In patients with  $\beta$ -lactam allergies, clindamycin and gentamicin can be used. Therapy should be continued until the patient is afebrile for at least 24 hours, and administration of oral antibiotics after parenteral treatment is generally thought to be unnecessary.

Patients with cuff cellulitis can be treated with oral antibiotics, such as amoxicillin,

clavulanic acid, or both, as outpatients, as long as they monitor their temperature at home and are reevaluated within 72 hours ([Box 22-8](#)). For cuff abscess, parenteral antibiotic therapy is needed and should be continued until the patient has been afebrile for at least 24 hours ([Box 22-8](#)).

Treatment of pelvic abscesses requires parenteral antibiotic therapy ([Box 22-8](#)). Surgical drainage is not always necessary, because antibiotic therapy alone may be successful. Clindamycin and gentamicin are often used, because *B fragilis* and other gram-negative anaerobes are often isolated from pelvic abscesses. Parenteral antibiotics should be administered until the patient has been afebrile for 48-72 hours. Other parameters to monitor are the white blood cell count, amount of drainage, and abdominal pain and tenderness. Often recommended is treatment with oral antibiotics for 7 days after completion of a course of parenteral antibiotics. The patient should be reevaluated in 2 weeks to ensure that reaccumulation of the fluid has not occurred. Surgical drainage is necessary in patients who fail to respond to antibiotic therapy alone. Catheter drainage of the abscess should continue until the drainage ceases. Laparotomy is required in patients for whom all of the above measures fail.

## **Prevention & Control**

The risk of these gynecologic postoperative infections can be reduced by treatment of BV in women who will be undergoing gynecologic procedures. Minimizing operative time and using the vaginal approach to hysterectomy can also help prevent these infections.

# **INTRAPARTUM & POSTPARTUM INFECTIONS**

## **INTRODUCTION**

This section discusses major infections that occur during the intrapartum period (chorioamnionitis) and the postpartum period (postpartum endometritis, puerperal ovarian vein thrombophlebitis, and episiotomy infection), as well as during or after abortion.

## **CHORIOAMNIONITIS**

### **Essentials of Diagnosis**

- Risk factors: preterm labor, prolonged rupture of membranes, multiple vaginal examinations, and preexisting bacterial vaginosis (BV); also, a hematogenous spread of organisms due to a bacteremic episode can occur.
- Gram stain and culturing of amniotic fluid may be useful.
- Characteristic leukocyte esterase and glucose concentrations in amniotic fluid.
- Fever, tachycardia, and uterine tenderness in pregnant women.
- Fetal tachycardia and heart rate abnormalities; evidence of fetal distress.

## General Considerations

Chorioamnionitis refers to infection of the uterus and its structures during pregnancy. This syndrome is also referred to as intra-amniotic infection syndrome or IAIS. This infection is more common in women with preterm labor, occurring in up to 25% of such women; in women at term, the incidence is only 1 to 2%. It tends to occur in a setting of prolonged rupture of membranes or after multiple vaginal examinations, which allow the ascent of the causative organisms into the uterus and its contents ([Box 22-9](#)). Preexisting bacterial vaginosis is also a predisposing factor. Some cases are caused by the hematogenous spread of organisms into the uterus during a bacteremic episode. Organisms that have been cultured from amniotic fluid include vaginal flora such as *Gardnerella vaginalis*, *Mycoplasma hominis*, streptococci, and anaerobes. Gram-negative rods, especially *E coli*, and enterococci, are also commonly isolated. Infections with group B streptococci or *E coli* are particularly associated with the complication of bacteremia and are the most frequent isolates in neonates born to mothers with chorioamnionitis.

## Clinical Findings

**A. Signs and Symptoms.** The diagnosis of chorioamnionitis is made on clinical grounds. Asymptomatic cases make the diagnosis more difficult; 5-10% of women with preterm labor and intact membranes have symptomatic infection, whereas another 10% have subclinical infection. In patients with preterm premature rupture of membranes, up to 25% may have subclinical infection. Signs and symptoms usually seen in women with chorioamnionitis include fever, tachycardia, and uterine tenderness. The fetus may show signs of distress, including tachycardia and decreased variability in heart rate. Amniotic fluid is rarely foul smelling or purulent. Term pregnant women may experience dysfunctional labor, requiring induction or cesarean delivery for arrested progress of labor.

**B. Laboratory Findings.** Amniotic fluid can be aspirated and analyzed to support the clinical diagnosis of chorioamnionitis. A Gram stain and culture of the fluid may be helpful. Increased leukocyte esterase activity and glucose concentration (< 10-15 mg%) may also be diagnostic.

## Complications

One complication of chorioamnionitis is dysfunctional labor, necessitating induction or cesarean delivery. Approximately three-quarters of women with chorioamnionitis require augmentation of labor with oxytocin. Cesarean delivery is required in approximately 40%. Left untreated, chorioamnionitis can result in bacteremia in the mother and pneumonia and bacteremia in the neonate.

## Treatment

Antibiotics should be administered as soon as the diagnosis is made ([Box 22-10](#)). Prompt delivery, usually within 12 hours, is an essential part of treatment.

## Prognosis

No maternal deaths from chorioamnionitis were reported in states in which such statistics were tracked from the 1980s to early 1992. However, postpartum infection in the mother is very common. Perinatal mortality is increased, with premature infants at higher risk than term infants.

## Prevention & Control

Chorioamnionitis can be prevented or its incidence decreased by the treatment of bacterial vaginosis in pregnant women. Minimizing vaginal examinations and manipulations, especially in women with preterm labor or prolonged rupture of membranes will also decrease the risk.

## POSTPARTUM ENDOMETRITIS

### Essentials of Diagnosis

- Risk factors: lower socioeconomic status, cesarean delivery, prolonged rupture of membranes and duration of labor, preexisting bacterial vaginosis (multiple vaginal examinations and use of internal fetal monitors).
- Fever on first or second postpartum day; lower abdominal pain and uterine tenderness.
- Leukocytosis and bacteremia possible.

### General Considerations

Postpartum infection of the uterus is more common after cesarean delivery, with an incidence ranging from less than 10% on private services to 50% in indigent patients in large teaching hospitals. In comparison, the incidence of endometritis is only 0.9-3.9% after vaginal delivery. Other risk factors for postcesarean endometritis include longer duration of labor or of ruptured membranes, bacterial vaginosis, multiple vaginal examinations, and use of an internal fetal monitor.

Endometritis is a polymicrobial infection. Group B streptococci, *Gardnerella vaginalis*, *E coli*, anaerobes, and enterococci are common culprits ([Box 22-11](#)). Endometritis after vaginal delivery typically occurs 2 days to 6 weeks after delivery and has been associated with *Chlamydia trachomatis*. Group A  $\beta$ -hemolytic streptococci can cause endometritis as well, sometimes in association with toxic shock. Nosocomial transmission and outbreaks occur and require special isolation procedures. *Ureaplasma urealyticum* and *Mycoplasma hominis* have also been isolated from the endometrium and blood of affected patients.

### Clinical Findings

**A. Signs and Symptoms.** Generally fever develops on the first or second postpartum day. Lower abdominal pain is also usually present. On pelvic examination there may be uterine tenderness.

**B. Laboratory Findings.** Leukocytosis is usually present. Transvaginal uterine cultures can be obtained, but results are often difficult to interpret because of the presence of contaminants. Blood cultures will yield growth in 10-20% of patients.

### **Differential Diagnosis**

Other conditions such as puerperal ovarian vein thrombophlebitis (see next section), wound infection, or pelvic infection should be considered. Puerperal ovarian thrombophlebitis is rare but is usually associated with postcesarean endometritis. Half to two-thirds of patients will have a characteristic palpable abdominal mass. Wound infections or other pelvic infections should be considered when the patient fails to respond to antimicrobial therapy appropriate for the treatment of postpartum endometritis. Noninfectious causes of postpartum fever, such as breast engorgement and drug fever, should also be considered.

### **Complications**

Bacteremia can occur with postpartum endometritis and does occur in 10-20% of patients. However, it does not correlate with severity of illness or with prolonged recovery.

### **Treatment**

Mild to moderately severe postpartum endometritis is treated with an extended-spectrum penicillin (ticarcillin/clavulanic acid or ampicillin/sulbactam) or second-generation cephalosporin (cefotetan or cefoxitin) ([Box 22-12](#)). Severe postpartum endometritis can be treated with clindamycin and gentamicin, especially after cesarean delivery. Therapy should be continued until the patient is afebrile for 24 hours, is free of abdominal pain, and no longer has a leukocytosis. There is no need to continue oral antibiotics after the patient is discharged from the hospital. However, women known to have chlamydial endometritis should receive oral erythromycin or doxycycline for a full course even when they have responded well to parenteral therapy as above.

Several possibilities should be considered when a patient fails to respond to antimicrobial therapy. First, the diagnosis should be questioned and other diagnoses should be considered. Second, the treatment regimen may not cover drug-resistant pathogens. Multi-drug-resistant anaerobes are emerging and do account for some treatment failures. Third, an undrained abscess may be present. Finally, enterococcal species superinfection may exist. Enterococcal superinfection should be considered when enterococci are isolated in pure culture or in heavy growth from an endometrial specimen. In the past, ampicillin plus gentamicin were effective for enterococcal infection. However, the prevalence of  $\beta$ -lactam resistance, high-level aminoglycoside resistance, and, more recently, even vancomycin resistance complicates empiric treatment of enterococcal infection. Depending on the incidence of multiple-drug-resistant enterococci at a given locale, vancomycin plus gentamicin may be the best choice for suspected enterococcal infection until susceptibility test results are available. In cases in which the isolate is also resistant to vancomycin, infectious

disease experts should be consulted. Cephalosporins have no role in the treatment of enterococcal infection but may be needed to treat other suspected pathogens.

## Prognosis

The prognosis is usually good, because intravenous antibiotic therapy is quite effective.

## Prevention & Control

Prophylactic antibiotics should be administered to any patient who is undergoing a cesarean section after labor or rupture of membranes, regardless of duration. Cefazolin, 1-2 g IV after the umbilical cord is clamped, with a second dose given 4 hours later in high-risk patients, is adequate prophylaxis. Alternatively, metronidazole or clindamycin and gentamicin can be given to patients with a  $\beta$ -lactam allergy. Even with prophylactic antibiotics, postpartum endometritis will develop in 15% of women.

## PUERPERAL OVARIAN VEIN THROMBOPHLEBITIS (POVT)

### Essentials of Diagnosis

- Acute onset of fever, chills, and lower abdominal pain.
- Sausage-shaped or ropelike abdominal mass on physical examination.
- Computed tomography (CT), Doppler ultrasonography, and magnetic resonance imaging (MRI) can help confirm the diagnosis.

### General Considerations

Puerperal ovarian vein thrombophlebitis (POVT) occurs in the postpartum period and is a result of thrombosis of the ovarian veins ([Box 22-11](#)). It is usually associated with postcesarean endometritis, but it can occur in the absence of endometritis. Its incidence is 1 per 2000 deliveries or 1-2 per 100 patients with postpartum infection. In many patients, POVT is diagnosed after failure to respond to a therapeutic trial of antibiotics for presumed postpartum endometritis.

### Clinical Findings

**A. Signs and Symptoms.** The onset of symptoms usually occurs 2-4 days postpartum and is usually acute. Patients experience pain in the lower abdomen, often on the right side. Fever and chills also occur. The degree of tachycardia that occurs is often disproportionate to the degree of temperature elevation. An abdominal mass can be palpated in half to two-thirds of patients and is sausage shaped or ropelike. The mass usually extends from the right uterine cornua to the upper abdomen. Signs of respiratory distress may be present if pulmonary embolization has occurred.

**B. Laboratory Findings.** Laboratory studies are not helpful in diagnosis. Leukocytosis may be present, and coagulation studies are sometimes abnormal. Results of blood cultures are usually sterile.

**C. Imaging.** Computed tomography, duplex Doppler ultrasonography, and magnetic resonance imaging can be used to confirm the diagnosis.

### **Differential Diagnosis**

Puerperal ovarian vein thrombophlebitis must be differentiated from postpartum endometritis. Indeed, many women with POVT are first diagnosed with postpartum endometritis. When appropriate therapy fails, the correct diagnosis of POVT often is made. Other diagnoses to be considered include postpartum episiotomy infection (see next section), PID, pelvic abscess, or other nongynecological sources of fever.

### **Complications**

The complication of pulmonary embolization should always be considered, especially if tachypnea, hypoxia, chest pain, or other signs of respiratory distress develop.

### **Treatment**

Continuous intravenous anticoagulation with heparin is important. The optimal duration of anticoagulation is not known, but many clinicians treat for 7-10 days (if pulmonary embolization has not occurred). Administration of broad-spectrum antibiotics against common pelvic pathogens is also helpful ([Box 22-12](#)).

### **Prognosis, Prevention, & Control**

The prognosis with POVT is good when pulmonary embolization has not occurred. Early mobilization after delivery and prophylactic anticoagulation for high-risk patients can help reduce the risk of POVT.

## **EPISIOTOMY INFECTIONS**

### **Essentials of Diagnosis**

- Edema and erythema along the site of episiotomy.
- More serious infections involving deeper layers of tissue may not manifest with edema and erythema of the overlying skin.
- Local pain; if there is more serious infection, fever and chills along with other systemic complaints.

### **General Considerations**

Infections of episiotomies are rare, with an incidence of 0.1%. There is a higher risk of infection, up to 1-2%, with episiotomies that involve third- or fourth-degree extensions. A classification scheme for episiotomy-related infections separates such infections based on their depth of infection. A simple episiotomy infection is a localized infection that involves only the skin and superficial fascia along the incision. Edema and erythema

may be present along the incision site. Causative organisms include streptococci, staphylococci, *Enterobacteriaceae*, and anaerobes ([Box 22-11](#)). A superficial fascia infection without necrosis can present without very striking clinical signs or symptoms except that the skin is edematous and erythematous along the incision. Superficial fascia infection with necrosis (or necrotizing fasciitis) involves infection of the superficial fascia that spreads into the fascial clefts overlying the deep fascia. The skin overlying the wound may not appear erythematous or edematous, but the patient will have considerable systemic manifestations of infection. Skin involvement occurs after vessels supplying the overlying skin are thrombosed. Myonecrosis is extremely rare and refers to infection beneath the deep fascia, involving muscle. *Clostridium perfringens* is the usual etiologic agent. Myonecrosis can occur as a complication of an inadequately treated or untreated necrotizing fasciitis. It can also occur in the subgluteal muscles surrounding the hip joint or psoas muscle after introduction of organisms by a paracervical or pudendal needle.

## Clinical Findings

**A. Signs and Symptoms.** As noted previously, the patient will usually have localized edema and erythema along the incision site if the infection is a simple infection. When necrotizing fasciitis occurs, the skin may not appear erythematous or edematous at all. However, the patient may experience extreme systemic manifestations such as high fever and chills. Pain is often more severe than clinical signs of infection. Definitive diagnosis of necrotizing fasciitis is made at surgery when the surgeon finds extensive undermining of surrounding tissues and lack of resistance in the superficial fascial plane to probing with a blunt instrument. Necrotizing fasciitis is a medical emergency and requires immediate surgical intervention.

**B. Laboratory Findings.** Laboratory findings will vary with the extent of infection; a patient with a simple episiotomy infection may have very few laboratory abnormalities, whereas a patient with myonecrosis can present with severe hypotensive shock.

**C. Imaging.** Imaging is not necessary except in unusual cases. The diagnosis is made by inspection of the episiotomy site in cases of simple and superficial infections and by surgical exploration in more serious infections.

## Complications

Sepsis as well as pelvic abscess and extensive necrosis of pelvic structures may occur if early infections are not diagnosed and treated promptly.

## Treatment

Simple infections may be treated with an oral antibiotic such as amoxicillin/clavulanic acid. Optimal therapy for more serious infections involves both systemic antibiotics and surgical debridement ([Box 22-12](#)).

## Prognosis

For simple episiotomy infections, the prognosis is quite good, with few complications

seen. More serious infection such as myonecrosis can have a graver prognosis.

## SEPTIC ABORTION

### Essentials of Diagnosis

- Occurs in the presence of retained products of conception or operative trauma; more likely when pregnancy is advanced, technical difficulties during the procedure occur, and a sexually transmitted pathogen is present.
- Fever, chills, abdominal pain, or vaginal bleeding within 4 days of abortion.
- Tachycardia, tachypnea, or abdominal tenderness on physical examination. The patient may be in frank hypotensive shock.
- Sanguinopurulent discharge and uterine tenderness on pelvic examination.
- Leukocytosis, anemia, or positive cervical or blood cultures.
- Pelvic ultrasound can confirm the presence of retained products of conception.

### General Considerations

Postabortion infection can occur in the presence of retained products of conception or operative trauma. It is an ascending process, and risk factors include more advanced pregnancies, technical difficulties, and the presence of a sexually transmitted pathogen. The most common causative organisms are endogenous pelvic flora ([Box 22-13](#)). However, *Clostridium perfringens* can be the causative agent of postabortion infection and can cause a characteristic presentation of massive intravascular hemolysis.

### Clinical Findings

**A. Signs and Symptoms.** Patients commonly present within 4 days of the procedure with fever, chills, abdominal pain, and vaginal bleeding. Often there has been passage of placental tissue.

Patients with mild infection or simple endometritis may appear mildly ill with low-grade fever and mild uterine tenderness. Patients with more serious infection will present with severe systemic manifestations, sometimes in hypotensive shock.

On physical examination, there will be elevated temperature, tachycardia, tachypnea, and uterine tenderness. Sanguinopurulent discharge may be evident on pelvic examination. The patient with bacteremia and resultant hypotensive shock may be agitated and disoriented. The patient with *C perfringens* infection may display jaundice, mahogany-colored urine, and striking anemia caused by intravascular hemolysis.

**B. Laboratory Findings.** A complete blood count will reveal leukocytosis and sometimes hemolytic anemia, which is severe with *C perfringens*. Gram stain and culturing of cervical material may reveal the causative organism. Blood cultures should

be obtained and may reveal the causative organism in the patient with bacteremia.

**C. Imaging.** Pelvic ultrasound can be performed to confirm the presence of retained products of conception.

### **Differential Diagnosis**

Other diagnoses to be considered in this setting include appendicitis, pyelonephritis, pelvic abscess, and noninfectious causes of fever.

### **Complications**

Postabortion infection can progress to bacteremia and frank shock. Perforation of the uterus may occur both during abortion and during curettage. Pelvic or adnexal abscesses may result from untreated infection. Necrotizing myometritis with *Clostridium* spp. can also occur.

### **Treatment**

Simple postabortion endometritis requires only oral doxycycline ([Box 22-14](#)). More serious infections require curettage and parenteral antibiotic therapy. Laparoscopy or laporotomy and hysterectomy may be necessary when the condition fails to respond to curettage and appropriate antibiotics.

### **Prognosis**

The prognosis is generally good for simple postabortion endometritis. Patients in whom therapy fails have a high risk of infertility owing to the necessity of hysterectomy, whereas patients with *C perfringens* infection may have a grave prognosis.

### **Prevention & Control**

Screening for sexually transmitted diseases before abortion may decrease the risk of acquiring this infection. Performing abortion procedures in medical facilities with proper infection control has resulted in a dramatic decline in the number of these infections in the past decade.

## **INFECTIONS OF SPECIAL CONCERN DURING PREGNANCY**

### **GROUP B STREPTOCOCCUS (GBS)**

#### **Essentials of Diagnosis**

- High fever after delivery or uterine and adnexal tenderness.
- Early neonatal infection presents as fever, lethargy, respiratory distress, jaundice, and hypotension. Late-onset neonatal infection presents as meningitis and, less commonly, as bacteremia.

- Isolation of group B streptococcus (GBS) from neonatal or maternal blood cultures or a history of maternal colonization with GBS.

## **General Considerations**

GBS is estimated to cause approximately 15,000 infant and 48,000 maternal infections in the United States each year. GBS causes postpartum endometritis in the mother and early-onset disease (bacteremia) or late-onset disease (meningitis) in the neonate. It is also the cause of intrapartum chorioamnionitis, urinary tract infections, and postpartum wound infections. GBS can be part of the normal fecal and vaginal flora, and asymptomatic carriage rates vary from 5-40%, depending on the culture technique used and the population studied.

Risk factors for carriage of GBS include use of an intrauterine device and age younger than 20 years. Although vaginal colonization can be transient, approximately one-third of pregnant women are colonized throughout their pregnancy. Transmission to the neonate is estimated to occur 60% of the time when the mother is colonized. Early-onset disease is probably acquired by the neonate in utero or as the neonate passes through an infected birth canal. The number of cases of early-onset disease is estimated to be 1.3-3.7/1000 live births. Early-onset disease tends to occur in premature and low-birth-weight babies in the first 6-12 hours of life. Additional risk factors for early-onset disease include premature rupture of membranes, multiple births, maternal chorioamnionitis, maternal GBS bacteremia, and low levels of maternal type-specific capsular antibodies. The overall mortality is now approximately 15%.

Late-onset disease occurs in 0.5-1.8/1000 live births, and the mortality is approximately 10%. It usually presents 1 or more weeks after birth. The mode of transmission is by contact with hospital nursery personnel. Typically the maternal history and the birth are not complicated, and most affected infants are full term.

## **Clinical Findings**

The neonate will display nonspecific signs such as fever, lethargy, respiratory distress, jaundice, and hypotension. There may be seizure activity if the onset is late. Isolation of the organism from blood or other sites (cervical cultures) is diagnostic. A history of maternal colonization may be obtained.

## **Treatment**

Treatment of GBS infection in the mother and neonate includes empiric broad-spectrum antibiotics until culture results are known. Penicillin is the antibiotic of choice, once cultures are confirmed.

## **Prevention & Control**

Several groups have shown that treatment of GBS in the mother with intrapartum antibiotics helps reduce the incidence of neonatal GBS disease by about 33-50%. Several groups have published guidelines for prophylaxis ([Box 22-15](#)). The American Academy of Pediatrics in 1992 recommended universal screening of all women for GBS

by obtaining cultures from the distal vagina and anorectum at 26-28 weeks' gestation. Intrapartum prophylaxis should then be given to GBS carriers who are at risk for neonatal sepsis. Risk factors include preterm labor, preterm premature rupture of membranes, multiple gestation, intrapartum fever, and real or anticipated membrane rupture for a period of 18 or more hours.

The American College of Obstetricians and Gynecologists (ACOG) 1992 guidelines did not advocate routine screening but rather the administration of intrapartum antibiotics (penicillin G, ampicillin, or erythromycin) based on the presence of certain risk factors: preterm labor, preterm premature rupture of membranes, prolonged membrane rupture, a sibling affected by GBS disease, and intrapartum maternal fever. Currently, ACOG advocates following their 1992 guidelines or obtaining routine cultures in women beginning at 32 weeks' gestation and treating with penicillin G those women with positive cultures at the time of labor.

The CDC advocates either the 1992 ACOG guidelines or screening all women at 35-37 weeks' gestation and administering intrapartum penicillin G for all culture-positive women. Several studies have shown, however, that despite the many guidelines, there is significant variability in screening and treatment among practitioners.

## **TERATOGENIC INFECTIONS & OTHER INFECTIONS OF CONCERN IN PREGNANCY**

### **INTRODUCTION**

Certain infections, whether primarily acquired or reactivated during pregnancy, are of special concern. These infections are important either because of their teratogenic effects or the morbidity and mortality with which they are associated in neonates. The teratogenic infections covered in this section are syphilis, toxoplasmosis, cytomegalovirus, rubella, and varicella. Measles, mumps, and parvovirus are discussed as well, as they can cause significant morbidity in the neonate. Herpesvirus and papillomavirus are also discussed, as they can be very common problems during pregnancy. [Tables 22-2](#) and [22-3](#) describe these infections and summarize their treatment, prevention, and control during pregnancy and afterward.

### **SYPHILIS IN PREGNANCY**

#### **Essentials of Diagnosis**

- Presentation similar to nonpregnant women.
- Late abortion after fourth month of pregnancy, stillbirth, or congenital syphilis in the neonate.

#### **General Considerations**

Congenital syphilis has become more of a problem in recent years, owing to the dramatic increase in the number of cases of syphilis. Pregnancy in a woman with syphilis may have any of the following outcomes: late abortion after the fourth month of

pregnancy, stillbirth, a congenitally infected infant, or a healthy uninfected infant. There is no difference in presentation or diagnosis of syphilis in pregnant women. Any suspicious lesion in a pregnant woman should be examined, and serologic testing over a 6-8 week period should be performed. A positive nontreponemal (rapid plasma reagin [RPR] or Venereal Disease Research Laboratory [VDRL]) test result should be followed up with a fluorescent treponemal antibody absorption (FTA-ABS) test for confirmation. A nonreactive or borderline FTA-ABS test result in light of a positive nontreponemal test result should prompt a search for the cause of a biologic false-positive test, such as malaria, leishmaniasis, hepatitis, leprosy, antiphospholipid syndrome, or lupus anticoagulant.

If the mother has primary or secondary syphilis, it is very likely that the infant will be infected, as the spirochetemia that accompanies primary or secondary syphilis is usually quite intense. If the mother has early latent syphilis, there is an 80% chance of fetal infection. Once spirochetes enter the fetal circulation, dissemination to the tissues rapidly follows. The most severe cases of fetal infection follow maternal infection early in pregnancy, and fetal death may occur if the burden of spirochetemia is high. If spirochetemia occurs later in pregnancy, the child may be stillborn or die of congenital syphilis in the neonatal period. When intrauterine infection occurs relatively late in pregnancy, the child may be born with mild or no symptoms of infection. Signs and symptoms of infection may develop 2-4 weeks after birth. Occasionally congenital infection does not become apparent until several months have passed. It is also possible for the infant to acquire infection upon passage through the birth canal, by contact with a syphilitic lesion. Infants who acquire infection in this manner often have a presentation similar to sexually acquired syphilis.

## Clinical Findings

**A. Signs and Symptoms.** Pregnancy does not affect the presentation of syphilis. Please see [Chapters 15](#) and [65](#) for a more detailed discussion of syphilis.

**B. Laboratory Findings.** Darkfield examination of a chancre may show *T pallidum*. Nontreponemal serology, VDRL or RPR, will be positive. Such tests should be followed up with an FTA-ABS for confirmation. If the findings on FTA-ABS are negative, the clinician should search for a cause of a biologic false-positive treponemal test. Polymerase chain reaction (PCR) on amniotic fluid has been shown to be very sensitive and specific. Spirochetes may be recoverable from fetal blood or from amniotic fluid. Maternal immunoglobulin G (IgG) that has crossed the placenta will cause positive results on nontreponemal and treponemal tests of cord and fetal blood. Serial quantitative serologic testing of the infant may show a rising titer—this is consistent with congenital infection.

## Differential Diagnosis

Cutaneous lesions in the newborn are not always caused by syphilis. Erythroblastosis fetalis, congenital toxoplasmosis, rubella, and cytomegalovirus (CMV) infection can also cause cutaneous lesions and fetal abnormalities.

## Treatment

The treatment of a pregnant woman with syphilis is the same as that in the general population. Some clinicians recommend that penicillin-allergic pregnant patients be desensitized to penicillin, as penicillin is thought to be the only antibiotic that reliably treats the fetus as well as the mother. Some practitioners recommend a second dose of benzathine penicillin G 1 week after the initial dose, especially in the third trimester. After treatment, the woman should be monitored with quantitative serologic titers and re-treated if there is a fourfold or higher increase in the titer.

The neonate should receive aqueous crystalline penicillin G (100,000-150,000 U/kg/d in 3 divided doses) for 14 days or aqueous procaine penicillin G intramuscularly (IM) for 14 days.

### **Prognosis, Prevention, & Control**

In a series of 403 pregnancies in women with positive serology for syphilis, 18% resulted in congenital syphilis (half of the babies were stillborn neonates). Of the mothers who gave birth to babies with congenital syphilis, 81% had not received any treatment for syphilis. Prevention of congenital syphilis requires prompt treatment of mothers who have syphilis as well as aggressive screening for syphilis in high-risk populations.

## **TOXOPLASMOSIS IN PREGNANCY**

### **Essentials of Diagnosis**

- Maternal infection as mild or subclinical flulike illness; sometimes cervical lymphadenopathy, fatigue, malaise, or atypical lymphocytosis.
- Infants can be asymptomatic or have chorioretinitis, blindness, deafness, seizures, microcephaly, hydrocephalus, fever, jaundice, hepatosplenomegaly, pneumonitis, or coagulopathy.
- Serologic diagnosis of mother and newborn; fetal ultrasound can be performed after maternal infection is confirmed. PCR testing on amniotic fluid can also be performed.

### **General Considerations**

Toxoplasmosis is caused by the intracellular parasite *Toxoplasma gondii*. The prevalence of disease varies by geographic location. Congenital infection is relatively uncommon in the United States, where screening is not routinely done, but is very common in France, where universal screening is mandatory. Please see [Chapter 81](#) for more discussion of toxoplasmosis in the general population.

In pregnancy, infection is often subclinical or mild and self-limited. A mononucleosis-like syndrome can occur, with fatigue, malaise, cervical lymphadenopathy, and atypical lymphocytosis. Pregnancy does not appear to predispose to more severe illness, but there may be an increased incidence of pregnancy-related complications in women who acquire primary infection while pregnant. The overall risk of fetal infection is 40%, and

the later in pregnancy the woman acquires infection, the higher the risk of transmission to the fetus. The earlier in pregnancy the woman acquires infection, however, the higher the risk of severe manifestations of infection in the fetus. Transmission rates have been reported as 17% in the first trimester and 65% in the third trimester.

## **Clinical Findings**

**A. Signs and Symptoms.** As stated, maternal infection may be very mild. In the infected infant, however, disease can be severe. There may be chorioretinitis, blindness, deafness, seizures, microcephaly, hydrocephalus, fever, jaundice, hepatosplenomegaly, pneumonitis, and coagulopathy. In many asymptomatic infants, chorioretinitis can develop, which may lead to blindness in adolescence or adulthood.

**B. Laboratory Findings and Imaging.** Diagnosis depends on serology, both in the mother and infant. The mother's IgG and IgM titers should be measured. If titers are elevated and consistent with maternal infection, fetal ultrasound should be performed, looking for intracerebral calcifications, microcephaly, aqueductal stenosis, and hydrocephalus. After birth, infants suspected of having congenital toxoplasmosis should have serial serologies. The presence of IgM antibody indicates acute infection, whereas declining IgG titers in the absence of IgM antibodies indicate passive transfer of maternal antibodies. PCR tests on amniotic fluid appear to be as accurate as conventional diagnostic tests.

## **Differential Diagnosis**

Congenital toxoplasmosis should be differentiated from congenital syphilis, erythroblastosis fetalis, congenital rubella, and cytomegalovirus infection (CMV).

## **Treatment**

Many practitioners consider documentation of first-trimester fetal infection a reason for termination of pregnancy. Maternal infection between conception and the 24th week of gestation may also justify termination of the pregnancy.

When maternal infection is confirmed, treatment with spiramycin (1.5 g twice a day orally) should be started and continued throughout the pregnancy. Such treatment has been reported to reduce the incidence of fetal infection by 60%. Toxicity is minimal, and although generally available in Europe, spiramycin can be obtained in the United States only by application to the U.S. Food and Drug Administration (FDA). Pyrimethamine and sulfadiazine also can reduce the rate of transmission to the fetus and prevent progressive fetopathy but are associated with more toxicity. Folinic acid, 6 mg orally 3 times a week, should be given with this regimen. Because of the potential for teratogenicity, some clinicians recommend that pyrimethamine be begun only after the 14th week of gestation.

In the neonate, treatment of overt toxoplasmosis involves 6 months of therapy with pyrimethamine plus sulfadiazine and folinic acid and an additional 6 months of alternating monthly therapy with spiramycin. Healthy infants suspected of having congenital infection can be treated with pyrimethamine and sulfadiazine for 21 days

followed by spiramycin until a definitive diagnosis is established.

## **Prognosis**

The prognosis is good for the mother; 15% of infants born to infected mothers will be severely affected.

## **Prevention & Control**

Prevention of toxoplasmosis can be achieved by thoroughly cooking meat, thoroughly washing fruits and vegetables, and avoiding contact with cat litter and soil or other materials contaminated with cat feces.

## **CYTOMEGALOVIRUS IN PREGNANCY**

### **Essentials of Diagnosis**

- The mother may be asymptomatic or have a mononucleosis-like illness.
- The infant may demonstrate cytomegalic inclusion disease, characterized by hepatosplenomegaly, jaundice, thrombocytopenia, chorioretinitis, cerebral calcifications, and microcephaly. Interstitial pneumonitis may develop.
- Maternal infection may be suggested by characteristic atypical lymphocytes and abnormal hepatic transaminases; the diagnosis can be made by isolation of cytomegalovirus (CMV) in urine or peripheral blood leukocytes, by serology, or by PCR on blood.
- Neonatal infection may be diagnosed by demonstration of CMV in urine; PCR testing of amniotic fluid is not yet standardized.

### **General Considerations**

CMV is thought to be the most common congenital infection in humans. Rates of seropositivity in the adult population range from 35% to close to 100%, depending on the population studied. Approximately 1% of all live-birth infants in the United States are infected by CMV. 90% of infants with infection will be asymptomatic at birth, but manifestations of infection such as sensorineural hearing loss, chorioretinitis, mental retardation, and neurologic deficits will develop later in 10-20% of infants. More severe symptoms will occur in infants who are symptomatic at birth.

CMV differs from other causes of congenital infection in that mothers with both primary infection and a history of infection can transmit the virus to the fetus. Children born to mothers with a history of infection prior to conception are less likely to be symptomatic at birth, and the presence of maternal antibody may help prevent the serious sequelae of congenital infection. Transmission occurs by the passage of virus across the placenta or by ascending infection from the cervix. It can also occur during the neonate's passage through the birth canal, but this will not cause congenital infection.

## Clinical Findings

**A. Signs and Symptoms.** Maternal infection may be asymptomatic, subclinical, or similar to mononucleosis. Congenital infection can be asymptomatic initially, although in 10-20% of asymptomatic infants neurologic deficits such as sensorineural hearing loss will develop later, usually within the first 2 years of life. Symptomatic cytomegalic inclusion disease develops in 6-19% of infants infected in utero. This is characterized by hepatosplenomegaly, jaundice, thrombocytopenia, chorioretinitis, cerebral calcifications, and microcephaly. Interstitial pneumonitis may also develop. The mortality rate of infants who are symptomatic at birth is approximately 29%. Perinatal infection can occur, in which the neonate acquires the virus from the mother who is seropositive, during passage through the birth canal. Most infections occurring in this manner are subclinical, although there have been some cases of interstitial pneumonitis developing in these infants, especially in premature infants.

**B. Laboratory Findings.** The mother may demonstrate seroconversion on serologic testing. Hepatic transaminase levels may be abnormal, and atypical leukocytes may be present. Virus can be isolated from the urine and peripheral blood leukocytes, but urine positivity may persist for months to years and does not establish acute infection. CMV-specific immunoglobulin M (IgM) can be detected in cord blood in approximately 60% of infected infants, but false-positive reactions also occur. Polymerase chain reaction (PCR) testing may be used to detect virus in amniotic fluid, but the technique has not yet been standardized.

## Treatment

There is no approved treatment available for congenital infection. Viruria can be suppressed with adenine arabinoside, but rebounds as soon as therapy is stopped. Ganciclovir therapy is being studied in research protocols.

## Prognosis

As stated earlier, neurologic deficits will develop in 10-20% of asymptomatic infants within the first 2 years of life. Of infants infected in utero, cytomegalic inclusion disease will develop in between 6% and 19%, with a mortality rate approaching 30%.

## Prevention & Control

Prevention is difficult owing to the number of subclinical infections. There are experimental live attenuated vaccines under investigation in immunocompromised adults. Routine screening of pregnant women is not recommended at this time.

## RUBELLA IN PREGNANCY

### Essentials of Diagnosis

- Mild maculopapular rash, generalized lymphadenopathy, and transient arthritis in mothers.

- Cataracts, heart abnormalities, deafness, microcephaly, mental retardation, hepatosplenomegaly, hemolytic anemia, pneumonia, and striate radiolucencies in the bones. Extensive permanent sequelae in infants.
- Serologic diagnosis in mother and infant; virus isolation can be accomplished, but may take several weeks.

## General Considerations

There are a notable number of women of child-bearing age who are susceptible to rubella, and thus their infants are at risk for congenital rubella, a disease with many serious and permanent sequelae. Rubella in pregnant women is similar to that in nonpregnant women; the likelihood of subclinical infection is similar as well. Spontaneous abortion occurs in 4-9% and stillbirths in 2-3% of pregnancies complicated by rubella infection.

The sequelae of fetal infection are thought to be caused by the effect of rubella virus on fetal cells, that is, prevention of cells from multiplying properly, resulting in fewer cells and smaller organs.

Transmission of infection is greatest in the first trimester, with rates up to 80% for the first 12 weeks of pregnancy, 54% during the 13th and 14th weeks, and 25% during the second trimester. Fetal infection occurs with both symptomatic and asymptomatic maternal infection, although the risk of fetal anomalies is greatest when infection occurs during the first trimester.

## Clinical Findings

**A. Signs and Symptoms.** As already stated, maternal infection is characterized by a mild maculopapular rash, generalized lymphadenopathy, and transient arthritis. Maternal infection may also be subclinical.

Congenital rubella infection is characterized by hepatosplenomegaly, jaundice, hemolytic anemia, pneumonia, and striated radiolucencies in the bones. More permanent sequelae include microcephaly, sensorineural hearing loss, congenital heart abnormalities such as patent ductus arteriosus, cataracts, glaucoma, microphthalmia, and mental retardation. Delayed manifestations include endocrinopathies, such as vascular abnormalities as arteriosclerosis and hypertension, and panencephalitis.

**B. Laboratory Findings.** Viral isolation may take up to 6 weeks, so serologies are often relied upon to make the diagnosis. Neutralization and hemagglutination (HI) antibodies appear soon after onset of the rash and persist indefinitely. Seroconversion of the HI antibodies is diagnostic. Complement fixation (CF) antibodies appear several days after onset of the rash and disappear after 10-20 years in 50% of individuals. CF antibody titers may be helpful in individuals in whom the HI antibody titer remains stable. A rubella immunoglobulin M (IgM) assay may also help to define recent infection. In infants, diagnosis is made by isolation of the virus from various body fluids (positive in approximately 90% of infected infants) or by serology. Persistence of immunoglobulin G (IgG) antibody over time supports the diagnosis of congenital rubella, as titers of

passively transmitted maternal antibody begin to disappear after about 1 month.

### **Treatment**

There is no treatment for infected infants or mothers, other than supportive care.

### **Prognosis**

The overall mortality for infants is 5-35%.

### **Prevention & Control**

Currently a live attenuated vaccine is available, which induces immunity in approximately 95% of recipients. Although the risk of transmission of vaccine virus to the fetus is small, vaccination is contraindicated in known pregnancy. If a woman receives vaccine and then discovers that she is pregnant, she should be counseled with respect to the risks of vaccine to the fetus, and termination of the pregnancy may be considered.

All unvaccinated women of childbearing age should have their rubella antibody titers evaluated, because clinical history of previous rubella infection is unreliable. If a woman is seronegative and not pregnant, she should receive the vaccine.

## **VARICELLA INFECTION DURING PREGNANCY**

### **Essentials of Diagnosis**

- Typical vesicular rash in the mother.
- Infants may have characteristic vesicular rash, disseminated disease, or congenital anomalies or might be asymptomatic at birth but have an episode of zoster many years later.
- Maternal varicella infection diagnosed clinically by examination of direct fluorescent antibody (DFA) preparations of infected cells from lesions or by serology.
- Neonatal infection diagnosed serologically.

### **General Considerations**

The incidence of varicella infection as a complication in pregnancy is estimated to be about 0.01-0.7 cases/1000 pregnancies. Varicella infection in adults is more severe than in children. Pregnant women may have a more severe form of the disease than nonpregnant women, with a 41% mortality among infected women in the former group. Varicella-zoster virus (VZV) infection can have several effects on a pregnant woman and her fetus. Intrauterine infection with VZV can occur, rarely leading to congenital anomalies. Postnatal disease can also occur in newborns, ranging from a benign course characterized by typical lesions to a fatal disseminated form of disease. Zoster can also appear in the infant or child years after birth, even when the newborn subject was

asymptomatic at birth. Such congenital anomalies as hypoplastic limbs and cutaneous scarring seen with VZV are thought to be caused by viral damage to developing tissues in a dermatomal distribution.

## **Clinical Findings**

**A. Signs and Symptoms.** Maternal disease is relatively easy to diagnose, as the mother will have the characteristic rash. Maternal infection at any stage of pregnancy can result in fetal growth retardation, aplasia of a single limb, cutaneous lesions, neurologic damage such as hearing loss, psychomotor retardation, microphthalmia, chorioretinitis, and cataracts. Neonatal disease ranges from benign cutaneous rash to disseminated disease with pneumonitis.

**B. Laboratory Findings.** Maternal infection can be diagnosed clinically, with confirmation by immunofluorescence of scrapings from a lesion. Seroconversion is also diagnostic. In the newborn, immunofluorescence or culturing of a lesion provides the diagnosis, as does persistence of antibody long after maternal antibodies are expected to disappear.

## **Prognosis**

Although the actual rate of fetal transmission is unknown, 5-7% of pregnancies complicated by VZV infection in the first trimester result in a newborn with congenital malformations. In pregnancies complicated by infection within 3 weeks of delivery, 17-24% of babies are infected at birth or shortly thereafter. Infants born to mothers with current varicella infection are at greatest risk of the development of disseminated disease, which is associated with a mortality rate of 30%.

## **Treatment & Prevention**

Pregnant, nonimmune women who have been exposed to the virus can be given varicella immune globulin within 96 hours of the exposure. However, there is no evidence that this practice will prevent viremia and, thus, fetal infection. Acyclovir should be given to the infected mother. Infants should receive varicella immune globulin if the mother develops disease 5 days before delivery or 2 days after delivery. Infants with disseminated disease should receive antiviral therapy.

## **HERPES SIMPLEX VIRUS INFECTIONS IN PREGNANCY**

### **Essentials of Diagnosis**

- Characteristic lesions in mothers.
- Vesicular rash, keratoconjunctivitis, encephalitis, and disseminated disease in neonates.
- History of herpes infection in mothers or their partners and positive results on viral cultures, immunofluorescence, or polymerase chain reaction (PCR) tests of cerebrospinal fluid (CSF).

## General Considerations

Neonatal herpes simplex virus (HSV) infection is estimated to occur in 2-7 infants/10,000 live births. Most cases are acquired during labor and delivery and are caused by HSV-2. Risk factors for neonatal HSV infection include active genital lesions at delivery, primary infection (greater risk than with recurrence), a history of genital herpes in mothers or their partners, delivery through an infected birth canal, delivery by cesarean section 6 or more hours after rupture of membranes, and instrument-assisted delivery. Premature infants are more likely than term infants to be infected. It is estimated that 0.1-0.39% of all pregnant women shed HSV at delivery. Cultures of the mother's genital tract collected days or weeks before delivery do not predict an infant's chances of exposure at the time of delivery.

## Clinical Findings

**A. Signs and Symptoms.** The mother may have active genital lesions or be asymptomatic. Of infants affected by HSV infection, 40% have mothers do not recall a history of HSV infection. An infant will commonly show signs of infection at 1-3 weeks of age. HSV infection can result in skin disease with the characteristic vesicular lesions, keratoconjunctivitis and chorioretinitis, encephalitis, and disseminated disease.

**B. Laboratory Findings.** Most useful for diagnosis is isolation of the virus from skin lesions from the mother or infant. Immunofluorescent smears of cells from lesions are more rapid than culturing. DFA preparations of infected cells from lesions may provide a diagnosis relatively quickly. Serology is generally not useful, as it is often difficult to differentiate acute from past infection with the virus as well as whether the infection is due to HSV-1 or -2. Polymerase chain reaction (PCR) tests on cervical fluid may be more sensitive in detecting asymptomatic viral shedding in women.

## Treatment & Prevention

The mother may be treated with oral acyclovir if she has active lesions. The neonate needs treatment with acyclovir intravenously. Predicting shedding of virus at the time of delivery is difficult. The American College of Obstetricians and Gynecologists (ACOG) recommends that cultures be taken to confirm the diagnosis of HSV when a pregnant woman has typical lesions. If there are no visible lesions at the time of delivery, vaginal delivery is acceptable. Weekly surveillance cultures of a woman with a history of HSV are not necessary. Amniocentesis in an attempt to confirm fetal infection is not recommended. Cesarean delivery should be performed when there are active lesions near the time of labor, when membranes are ruptured for less than 6 hours, or when there are prodromal symptoms of a recurrence.

## Prognosis

It has been estimated that for a woman experiencing a primary episode of genital herpes at the time of delivery, there is a 50% risk of her neonate acquiring neonatal herpes, whereas for a woman who has a recurrence of genital herpes at the time of delivery, the risk is 3%.

## HUMAN PAPILLOMAVIRUS IN PREGNANCY

### Essentials of Diagnosis

- Condylomata acuminata in mothers.
- Laryngeal papillomas in children born to infected mothers.
- Polymerase chain reaction (PCR) analysis of lesions in mother and child to make rapid diagnosis.

### General Considerations

Human papillomavirus (HPV) is the causative agent of genital warts, or condylomata acuminata. Various subtypes are more likely to cause malignant transformation of cervical cells, leading to cervical intraepithelial neoplasia and cervical cancer. In children, the virus can cause laryngeal papillomas, with exposure to the virus presumably occurring during passage through the birth canal. However, the virus can be transmitted to the child even when the mother has subclinical infection and no apparent lesions; as well, infants delivered by cesarean section have virus DNA in their nasopharynx, suggesting that there may be transplacental transmission of virus. The number of children who are born to infected mothers and later develop laryngeal papillomas is not known.

### Clinical Findings

**A. Signs and Symptoms.** Infection in the pregnant woman may be notable for the great increase in size and number of genital lesions. The lesions may grow so large that vaginal delivery is impossible, necessitating cesarean delivery. The infant may be asymptomatic at birth, but laryngeal papillomas may develop within the first 2-5 years of life. These papillomas are located on the vocal cords and epiglottis but can involve the whole larynx and tracheobronchial tree.

**B. Laboratory Findings.** In the mother, cervical scrapings, biopsies of lesions, or scrapings from the lesions will display typical HPV-induced histologic or cytologic changes. PCR can detect viral DNA rapidly. Biopsies or scrapings from the child's lesions can also be tested by PCR.

### Treatment

Lesions are treated if they cause discomfort or when it is anticipated that they will interfere with delivery. Trichloroacetic acid (50% or 80%) in 70% ethanol applied to the lesions three times a week or once a week is inexpensive and safe for the mother and fetus. Cryotherapy and laser ablation are also safe and well-tolerated in pregnant women. Podophyllin, 5-fluorouracil cream, and interferon therapy should not be administered to pregnant women.

Currently, the American College of Obstetricians and Gynecologists does not

recommend routine cesarean delivery in women who have HPV infection.

### **Prognosis, Prevention, & Control**

In the mother, genital warts usually diminish in size after delivery. In the child, surgery may be required to remove laryngeal papillomas. One study found that 32% of children born to mothers with genital papillomavirus had positive oral scrapings for papillomavirus DNA. Prevention consists of screening high-risk women aggressively for HPV.

### **MEASLES, MUMPS, & PARVOVIRUS INFECTION IN PREGNANCY**

Measles infection complicates 6-40/100,000 pregnancies. There appears to be an increased risk of stillbirth, abortion, prematurity, and low birth weight in infants born to mothers who had infection while pregnant. There is no recognizable pattern of congenital anomalies with measles infection. Pregnant, nonimmune women who are exposed to the virus should be given immune serum globulin (0.25 mg/kg) within 6 days of the exposure. Such prophylaxis may modify maternal infection, but effects on fetal infection are unknown. Vaccination against measles is contraindicated within 3 months of conception because of the possibility of transmitting vaccine virus to the fetus.

Mumps infection occurs less frequently than measles during pregnancy, with an incidence of 0.8-10 cases/100,000 pregnancies. Mumps in pregnant women is similar to mumps in nonpregnant women. Transplacental infection does occur, but it is very rare. Virus has been isolated from breast milk, so transmission of virus from lactating women to their infants is possible. Virus can also be isolated from placental and fetal tissues, and there is a possible association between mumps during pregnancy and fetal endocardial fibroelastosis. Perinatal mumps can occur as well and may be complicated by pneumonia. Maternal infection may increase the risk of fetal loss. There is no effective treatment for an infected mother or child, other than supportive care. Prevention is best accomplished by ensuring that all women of childbearing age have been vaccinated against mumps.

Parvovirus (see [Chapter 42](#)) causes erythema infectiosum in childhood and aplastic crises in patients with hemolytic anemia. It is an uncommon infection during pregnancy (< 1% of all pregnancies), and an uncommon cause of stillbirths in women who have been exposed to the virus. Fetal hydrops and fetal death have been linked to some cases of parvovirus B19 infection during pregnancy. A large prospective study found that 17% of pregnant women who became immunoglobulin M (IgM)-positive in the first trimester suffered fetal losses, whereas 6% of women who became IgM-positive during the third trimester suffered fetal losses. If a pregnant woman has an illness compatible with parvovirus B19 infection, parvovirus antigen or DNA may be detectable in serum as may specific IgM antibodies. The fetus should be monitored by ultrasonography and maternal serum alpha-fetoprotein (AFP) levels. Elevated AFP levels have been detected 6 weeks before fetal death and 4 weeks before anomalies are noted on ultrasonography.

***Candida* spp.**

- First Choice**
- Fluconazole, 150 mg orally x 1
  - Miconazole, 1200 mg supp x 1; 200 mg supp qhs x 3 days; or 2% cream qhs x 7 days
  - Clotrimazole, 500 mg supp x 1; 200 mg supp qhs x 3 days; 100 mg supp qhs x 7 days; 1% cream qhs x 7 days
  - Butoconazole, 2% cream qhs x 3 days
  - Terconazole, 0.4% cream qhs x 7 days

- Second Choice**
- Nystatin, 100,000 U supp qhs x 14 days
  - Ketoconazole, 200 mg orally twice a day x 3-5 days
  - Itraconazole, 200 mg orally twice a day x 1 day or 200 mg orally daily x 3 days
  - Fluconazole, 100 mg orally daily x 1-3 days

- Pregnancy**
- Any topical treatment listed above

***Trichomonas* spp.**

- Metronidazole, 2.0 g orally x 1

- Metronidazole, 500 mg orally bid x 7 days

- Clotrimazole, 100 mg supp qhs x 14 days
- Metronidazole, 2.0 g orally x 1 (only in 2nd or 3rd trimester)

## Section III. Special Patient Populations

### 23 . Patients With Aids — *Dani-Margot Zavasky, MD, Julie L. Gerberding, MD, MPH & Merle A. Sande, MD,*

#### Essentials of Diagnosis

- Predisposing factors include sexual activity with an infected person, injection drug use, blood product transfusion, especially between 1978 and 1985, perinatal exposure to an infected mother, and percutaneous occupational exposure.
- Key signs and symptoms include systemic illness with fevers, night sweats, weight loss, diarrhea, lymphadenopathy, depressed immunity as evidenced by opportunistic infections, and unusual malignancies such as Kaposi's sarcoma and lymphomas.
- Laboratory findings of antibody to human immunodeficiency virus (HIV)-1, 23-1 confirmed with Western blot, viral genome by polymerase chain reaction or branched DNA assay, HIV p24 antigen, and lymphopenia, especially depressed CD4 cell count. (See [tables 23-1, 23-2](#))

#### General Considerations

When the first clusters of cases of *Pneumocystis carinii* pneumonia and Kaposi's sarcoma were identified in 1981, it was not known that this was just a prologue to one of the most significant pandemics in the history of mankind and that, < 20 years later, 50 million people would be affected. Our knowledge of the disease started with the dramatic growth in the number of cases of unusual opportunistic infections in patients without prior inherited immunodeficiency disorders. Acquired immunodeficiency syndrome (AIDS) entered the medical and colloquial vocabulary. Not until 1983 was the offending agent identified as a virus. Known initially as lymphadenopathy-associated virus, then human T-cell lymphotropic virus type III, and AIDS-associated retrovirus, the microorganism acquired its current name, human immunodeficiency virus (HIV), in 1986. See [Chapter 40](#) for a discussion of the virology of HIV and other retroviruses.

**A. Epidemiology.** Retrospective examination of sera collected for studies of the genetics of hematologic diseases indicate that HIV was already present in sub-Saharan Africa in the 1950s and in the United States by the late 1970s. In 1985, a related but distinct virus, HIV-2, was also found to be endemic in parts of West Africa and to cause AIDS. To date, this virus has been relatively restricted geographically, although it has been imported into the Western Hemisphere.

AIDS has been now reported in more than 150 countries. The United Nations estimates that as of December 2000, 58 million people have been infected with HIV. 22 million people have already died, of which 3 million died in 2000. As we are entering the third decade of AIDS history, the epidemic continues to spread rapidly through several continents. A total of 16,000 persons are infected per day worldwide, including 1600

children < 15 years of age. Women constitute over 40% of the adult cases. About 7000 people die from complications of HIV infection every day. Most infected persons live in either sub-Saharan Africa (> 70%) or South/Southeast Asia (> 20%).

In recent years, the epidemic has been particularly explosive in South/Southeast Asia and Central and Eastern Europe. The predominant mode of transmission appears to be heterosexual contact in Asia and injection drug use in Europe. Increasing syphilis incidence in Central/Eastern Europe signifies an increase in sexually transmitted diseases (STDs) of all kinds, including HIV, in this part of the world. There were 700,000 HIV infected patients by the end of 2000 compared with just 420,000 at the end of 1999.

In the United States, 920,000 AIDS cases and 460,000 deaths from AIDS were reported through December 2000. The total number of infected individuals in the United States probably exceeds 1 million; 45,000 of which became infected in 2000. The epidemiology of HIV infection is changing in the United States as the pandemic evolves. In 1992, 50% of all cases occurred in gay men and 25% in intravenous drug users, whereas 15% were derived from heterosexual contacts. Currently, the greatest increase in viral spread is occurring in the heterosexual population, similar to that observed in sub-Saharan Africa. The trends also confirm increase of infection in blacks and Hispanics, with blacks constituting ~ 41% of all adult cases. Also, women now account for 23% of all adult cases in the United States. The epidemic appears to affect predominantly women of color, particularly black women of African descent living in the southeastern part of the United States, in small rural communities (as opposed to the large cities, where HIV transmission in this same population occurred in the 1980s). Cases of AIDS in Hispanic women of Puerto Rican ancestry also predominate in the Northeast, especially in the states of Connecticut, New York, and New Jersey. However, in the Southwest and the West, Hispanic women of mostly Mexican and Central American descent have the same infection rate as white women. The facilitators of transmission in this heterosexual population again appear to be multiple sexual partners and the exchange of sex for money and drugs, especially crack cocaine.

In 1997, HIV/AIDS dropped from the first to the second leading cause of death in young adults in the United States. In 2000 it wasn't even one of the top 10 causes of death in young adults. The death rate in black men is fourfold that in white men and is also higher in black women than white men. Improved medical management of HIV disease resulted in an overall 23% decrease in AIDS deaths, especially among homosexual men, beginning in 1996. Also, between 1992 and 1995, perinatal AIDS cases decreased by 27% as a result of the widespread use of maternal and infant antiretroviral prophylaxis with zidovudine (AZT).

**B. Pathogenesis.** HIV is transmitted between humans in at least three ways: sexually, perinatally, and by exposure to contaminated body fluids, especially blood. The virus has been demonstrated in particularly high titers in semen and cervical secretions, and a majority of infections result from sexual contact. Infection is facilitated by breaks in epithelial surfaces, which provide direct access to the underlying tissues or bloodstream. The relative fragility of the rectal mucosa together with a large number of sexual contacts probably contributed to the predominance of the disease among male homosexuals in the initial stages of the epidemic. Heterosexual transmission accounts for an increasing proportion of new cases in the western world but has always been the

dominant mode of transmission in the developing countries. Sexual transmission appears to be more efficient from men to women. The risk of perinatal transmission from an infected mother to her child has been estimated at 20-30%.

Testing of donor blood and the use of recombinant or specially treated coagulation factors have now virtually eliminated blood products transfusion as a source of infection in developed countries. Transmission of infection by blood is now largely associated with the sharing of needles and syringes by injection drug users. In some areas of the world, the seroprevalence of HIV infection among injection drug users has been as high as 70%. Transmission of infection to health care workers is rare but occurs after 0.3% of exposures to blood during needle punctures.

Transmission of HIV does not occur through a casual (nonsexual) contact with infected individuals or through insect vectors. The virus has been detected in saliva, tears, urine, and breast milk, but with the exception of breast milk, these fluids are not sources of infection.

## **PREDICTORS OF DISEASE PROGRESSION**

### **Introduction**

The course of HIV disease is dictated by the severity of the individual's immune deficiency and the resulting complications. The recent impact of highly active antiretroviral therapy (HAART) on the slowing progression of HIV infection has been dramatic; however, therapy is complicated and expensive, thus not available to the vast majority of patients worldwide that would benefit.

The determinants of progression of the HIV disease have been under intense scrutiny by the research community. Results of prior studies emphasized the role of high viral load, presence of particularly virulent strains (eg, those that produce syncytium formation in culture) and low T-lymphocyte function as predictors of rapid disease progression. Recently, several coreceptors for HIV have been identified. The two most important of these are CCR5 and CXCR4. Individuals homozygous for a deletion in the CCR5 gene are resistant to infection regardless of multiple exposures to the virus. Some infected persons who are heterozygous for this deletion have been noted to have a prolonged AIDS-free survival. In current clinical practice, however, two main markers are used to monitor disease progression and to evaluate the need for and response to treatment: CD4 lymphocyte count and viral load.

### **CD4 Lymphocyte Count (Immunologic Monitor)**

CD4 lymphocytes are the major cellular target for HIV. Both absolute CD4 counts and the rate of decline have prognostic predictive value and are used to determine the need for antiretroviral therapy and for opportunistic infection prophylaxis. CD4 counts do not accurately indicate viral load per se, but they predict the short-term risks for progression to AIDS-related illness.

### **Quantitative HIV RNA (See [table 23-2](#)) (Virologic Monitor)**

The quantitative titer of circulating HIV RNA (viral load) is the single best predictor of long-term progression and response to treatment. Viral load is used to assess the steady-state concentration of HIV, the response to treatment, and, most likely, tissue HIV RNA production.

Two main methods are generally used to measure viral load: reverse transcriptase-polymerase chain reaction (RT-PCR) and branched-chain DNA (bDNA) amplification. (See [table 23-2](#)) By 2001, three commercial assays based on these methods or modifications of these methods were used to measure viral load: Amplicor HIV Monitor (RT-PCR, lower limit of detection = 400 viral copies/mL), Quantiplex HIV assay (bDNA, lower limit of detection = 500 copies/mL), and Nuclisens (lower limit of detection = 40 copies/mL). Assays with even more sensitivity such as Amplicor Ultrasensitive (lower limit of detection = 20 copies/mL) and Quantiplex HIV 3.0 (lower limit of detection = 50 copies/mL) are currently undergoing clinical evaluation. To optimize interpretation, two measurements of viral load should be obtained on two separate occasions in the same laboratory using the same assay. When possible, viral load testing should be delayed until 4 weeks after intercurrent infections are treated, acute illnesses have resolved, and following an immunization.

Current guidelines for viral load testing suggest that the pretreatment measurement be obtained to evaluate the patient's prognosis and that tests be repeated every 3-4 months until treatment is started. Once treatment is initiated, a measurement should be obtained 4-8 weeks later to determine whether the expected initial therapeutic response (0.5-0.75 log reduction in titer) has been achieved. Another measurement should be made 3-4 months later to determine whether HIV replication is fully suppressed (below the level of detection). If not, then adherence should be assessed and treatment modifications considered. Once the patient is on a stable antiviral regimen, viral load tests should be obtained every 3-4 months to monitor ongoing virologic response.

## CLINICAL SYNDROMES

### INTRODUCTION

HIV infection can produce a huge array of clinical syndromes. In general, these syndromes correlate with the duration of illness and severity of immunosuppression. The major clinical syndromes and their treatment are described in [Box 23-1](#). The following sections describe the most common symptoms associated with HIV infection at various stages of infection.

#### 1. CONSTITUTIONAL SYMPTOMS

Fever (with or without night sweats) is common in patients infected with HIV, especially in the setting of advanced disease. The absolute CD4 cell count can help to guide the evaluation and differential diagnosis.

**A. Early Disease (CD4 > 500).** Etiology similar to that in immunocompetent patients except for more common bacterial pneumonia and tuberculosis. Acute HIV infection is also associated with fever.

**B. Midstage Disease (CD4 200-500).** Particular attention should be given to the possibility of disseminated tuberculosis. In sexually active adults, STDs and anorectal infections often go unrecognized as sources of fever.

**C. Late Disease (CD4 75-200).** When fever accompanies an accelerated catabolic state with weight loss and anorexia, the presence of an opportunistic infection or malignancy (mainly lymphoma), signifying the onset of AIDS should be suspected. Systemic symptoms with fever also predominate over pulmonary complaints in early PCP. Common etiologies of fever at this stage of HIV disease are also disseminated tuberculosis, nontyphoid *Salmonella* bacteremia, bartonellosis, and fungal diseases including histoplasmosis, coccidioidomycosis, and cryptococcosis.

**D. Advanced Disease (CD4 < 75).** Even though diseases as outlined in late-stage disease can also occur at this stage, disseminated mycobacterium avium complex and systemic cytomegalovirus (CMV) infections are common.

## 2. CENTRAL NERVOUS SYSTEM (CNS)

### Altered Mental Status

Changes in mentation involve cognitive dysfunction, decreased level of consciousness, and delirium and psychosis. Altered mental status can be caused by both infectious and noninfectious disorders. Differential diagnosis, again, is influenced by the known degree of immunosuppression, that is, the stage of HIV disease. Most infections occur in patients with CD4 counts < 200.

The mainstay of evaluation includes history (especially of substance abuse), neurological examination, neuroimaging (computer tomography or MRI), cerebrospinal fluid examination, and thorough review of medications. Altered mental status at any CD4 count can be caused by bacterial meningitis, neurosyphilis, as well as by noninfectious etiologies such as metabolic disorders, seizures, or trauma. Recreational drug use and prescription medication toxicity are other possibilities.

**A. Late Disease (CD4 75-200).** At this stage of the HIV disease, patients can be afflicted with cryptococcal meningitis, herpes virus family (CMV, HSV, and VZV) encephalitis, and *Toxoplasma* encephalitis. Patients are also vulnerable to HIV-associated dementia (AIDS dementia complex) and primary CNS lymphoma, which can be the result of Epstein-Barr virus-associated transformation of infected cells.

**B. Advanced Disease (CD4 < 75).** Disorders typical for late disease as well as progressive multifocal leukoencephalopathy are caused by a human polyomavirus known as JC virus. Primary CNS lymphoma and advanced AIDS dementia complex are more common at this stage.

### Headache

Headache may pose a challenging diagnostic dilemma. Besides a vast array of opportunistic CNS infections and malignancies, it can result from muscle tension, or a systemic illness without a direct affliction of intracranial structures. Headache can be

induced by a medication frequently used for treatment of HIV disease, for example, AZT, or by migraine not related to HIV infection. At any stage of the HIV disease, patients are more susceptible to bacterial meningitis or sinusitis as well as to neurosyphilis. Other opportunistic infections tend to occur at specific levels of immunosuppression.

**A. Early Disease (CD4 > 500).** Aseptic meningitis probably caused by HIV itself can accompany acute seroconversion in the early stage of HIV disease.

**B. Midstage Disease (CD4 200-500).** Aseptic meningitis syndrome is even more common than in earlier stages and can assume a form of chronic meningitis.

**C. Late Disease (CD4 75-200).** Many disorders mentioned above that can alter mental status also cause headache. These include cryptococcal meningitis and *Toxoplasma* encephalitis.

**D. Advanced Disease (CD4 < 75).** Both progressive multifocal leukoencephalopathy and primary CNS lymphoma are more frequent.

### 3. GASTROINTESTINAL SYMPTOMS

#### Dysphagia

Swallowing difficulty (dysphagia) is frequently accompanied by pain (odynophagia). Patients complain about the sensation of food sticking. Appropriate diagnosis and treatment are important not only to alleviate the discomfort but also to prevent weight loss and malnutrition. At any stage of HIV disease, patients can develop reflux esophagitis. However, esophageal complaints and disorders are more typical for late to advanced disease.

**A. Midstage Disease (CD4 200-500).** Early thrush (oral mucosal candidiasis) can occur with some esophageal discomfort. In that setting, PCP prophylaxis is indicated irrespective of the CD4 count.

**B. Late Disease (CD4 75-200).** Most common cause is *Candida* esophageal mucosal infection with frequent concomitant oral lesions. HSV type 1 or 2 can induce mucosal ulceration.

**C. Advanced Disease (CD4 < 75).** Same as late disease, but CMV and aphthous ulcers are more frequently encountered.

#### Diarrhea

Diarrhea is a commonly encountered clinical problem in HIV-infected patients and may be caused by HIV itself. Symptoms range from frequent loose stools to fulminant diarrhea, producing profound weight loss, malabsorption, and intravascular fluid depletion. A thorough evaluation is warranted because virtually any gastrointestinal pathogen may be found.

Both small bowel and colon can be affected, causing enteritis or colitis, respectively. Symptoms of enteritis include profuse, watery diarrhea often with symptoms of bloating, nausea, and periumbilical cramping. Volume depletion and malabsorption may be marked. Colitis presents with fever, lower abdominal pain, tenesmus, and passage of frequent, small volume stools with mucus and sometimes blood. Characteristics of symptoms can guide the choice of initial diagnostic procedure but are unreliable to predict the most likely pathogen. CD4 cell count can, again, be useful in outlining differential diagnosis.

At any CD4 cell count, the following agents should be considered: *Clostridium difficile*; *Salmonella*, *Campylobacter*, *Shigella*, and *Cyclospora* spp.; *Entamoeba histolytica*; *Giardia lamblia*; *Isospora belli*; enteroviruses; and *Strongyloides stercoralis*. Most of the antiretroviral drugs also cause diarrhea.

**A. Late Disease (CD4 75-200).** *Cryptosporidium parvum* and *Microsporidium* spp. should also be considered in addition to those listed above.

**B. Advanced Disease (CD4 < 75).** *Mycobacterium avium* complex and CMV should be included in the differential diagnosis.

#### 4. RESPIRATORY SYMPTOMS (DYSPNEA/COUGH)

The differential diagnosis of lower respiratory symptoms is extensive and largely depends on the stage of HIV disease with consideration to current PCP prophylaxis, history of travel, or area of residence. Tuberculosis can occur with various clinical signs, depending on the degree of immunosuppression and should be considered in every HIV patient regardless of CD4 count. Appropriate isolation precautions should be undertaken according to clinical suspicion. Irrespective of CD4 counts, typical bacterial causes of pneumonia should also be considered, especially *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Legionella pneumophila*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*.

**A. Late Disease (CD4 75-200).** PCP should always be considered, particularly in the setting of a lack of appropriate prophylaxis. Fungal pneumonias with *Coccidioides immitis*, *Cryptococcus neoformans*, or *Histoplasma capsulatum* are also possible. Kaposi's sarcoma is also known to cause pulmonary lesions, especially with worsening immunodeficiency.

**B. Advanced Disease (CD4 < 75).** Besides the above etiologies, *Pseudomonas aeruginosa* and *Aspergillus* species can be encountered, especially with neutropenia or repeated hospital exposure. Non-Hodgkin's lymphoma can also affect lungs. Isolation of CMV and *Mycobacterium avium* complex is common, but they rarely cause symptomatic pulmonary disease.

#### 5. CUTANEOUS LESIONS

##### Introduction

Various dermatologic diseases are extremely common in HIV infection, affecting ~90%

of patients. Some of the conditions occur in immunocompetent individuals but are more severe and resistant to therapy in HIV-infected persons. Other skin conditions are unique to HIV disease and tend to follow the degree of immunosuppression. Patients with HIV disease tend also to have a preponderance for drug sensitivity reactions compared with an HIV-negative population.

**A. Early Disease (CD4 > 500).** Primary HIV infection may be associated with rash. Lesions associated with STDs (eg, genital HSV or genital warts) can be seen. Staphylococcal folliculitis, impetigo, ecthyma, hidradenitis, and cellulitis are the most common bacterial skin infections. Kaposi's sarcoma lesions can also occur at this stage.

**B. Midstage Disease (CD4 200-500).** Mucocutaneous candidiasis, oral hairy leukoplakia, herpes zoster, psoriasis, seborrheic dermatitis, and atopic dermatitis become evident.

**C. Late Disease (CD4 75-200).** Skin infections occurring earlier in the HIV course become more chronic (HSV, for instance) and refractory to therapy. Opportunistic fungal infections (eg, cryptococcosis or histoplasmosis) can present as skin lesions. Eosinophilic folliculitis associated with pruritus tends to affect patients with worsening immunosuppression.

**D. Advanced Disease (CD4 < 75).** Very unusual skin lesions can occur that warrant biopsy to establish a diagnosis. Bacillary angiomatosis and *Molluscum contagiosum* can develop, signifying a profound immunosuppression.

## Treatment

In the past 2 years, tremendous progress has been made in treatment of HIV infection. New combination treatment regimens can suppress virus replication below the level of detection in many individuals. However, cure is still not possible.

Antiretroviral treatment guidelines are undergoing rapid evolution, but some consensus about general principles has been achieved. First, the major goal of treatment is to suppress viremia and prevent immunosuppression. To reduce the risk that drug-resistant isolates will emerge, therapy should be implemented only when the patient is ready to adhere to a treatment regimen. Treatment is recommended for all patients with symptomatic HIV infection (eg, AIDS, thrush, and fever of unknown origin). For asymptomatic patients, the decision is more complex. Potential benefits of starting therapy in these patients include the following:

- Earlier control of HIV replication.
- Decreased opportunity for mutations to occur.
- Decreased total body viral burden.
- Prevention of immunosuppression.
- Delay in progression to AIDS.

However, these potential benefits must be weighted against treatment risks:

- Reduced quality of life due to drug toxicity and the inconvenience of treatment.
- Earlier development of drug resistance.
- Limitations in future drug options.
- Unknown long-term treatment toxicity.

Most experts believe that treatment should be offered to asymptomatic patients when immunosuppression has developed (ie, CD4 < 350) or when viral load is high (ie, > 30,000 copies/mL with bDNA assay or 55,000 copies/mL with RT-PCR), especially if the patient desires treatment and is likely to adhere to it. (See [table 23-3](#))

Monotherapy is no longer recommended for HIV treatment. A combination of three antiviral drugs, to fully suppress plasma HIV below the level of detection, is now recommended. Antiviral drugs are grouped into three categories: (See [table 23-4](#))

- Nucleoside reverse transcriptase inhibitors (NRTI): nucleoside analogs that inhibit HIV reverse transcriptase (RT), interfering with formation of DNA.
- Nonnucleoside reverse transcriptase inhibitors (NNRTI): inhibit RT by a different mechanism than NRTI.
- Protease inhibitors (PI): prevent cleavage of viral proteins precursors interfering in viral maturation and assembly.

[Table 23-4](#) lists the drugs that were approved for HIV treatment by 1998. Adherence, side effects, and drug-drug interaction should be considered when choosing a regimen. All medications are started at the same time at the full dose (although dose escalations are needed for ritonavir, nevirapine, and ritonavir in combination with saquinavir).

Numerous clinical trials confirmed that antiretroviral combination therapy results in greater reductions of viral RNA copies, less frequent emergence of resistance, and a more sustained therapeutic response. Available data and clinical experience support using a combination of two NRTIs along with a PI as the most potent combination available (HAART). However, the choice of drugs has to be individualized based not only on the patient's virologic and immunologic response but also on the patient's tolerance of side effects, ease of use, potential drug-drug interactions, and cost. With growing numbers of new antiretrovirals, the recommendations about the best combination therapy continue to be modified. Alternatives to the two NRTI-one PI combination are indicated in [Table 23-5](#).

For suggestions when initial treatment fails, See [Table 23-6](#). Responses to failure.

Medical care should focus on providing comfort, preventing the opportunistic infections, and managing the new complexities of antiretroviral therapy. In the terminal stage of

HIV disease, treatment of the virus itself along with opportunistic infections and especially the malignancies is often palliative and should be instituted after careful consideration of the potential complications of therapy. A thorough discussion of these facts with the patients will facilitate realistic treatment expectations. The use of life-support measures, including cardiopulmonary resuscitation and mechanical ventilation, should also be addressed as early as possible. The survival rate for AIDS patients with respiratory failure has actually improved in the past few years, and intensive care is certainly not contraindicated. However, the expected benefit from aggressive measures must be balanced against the overall quality of life in the face of progressive disease.

## **Prognosis**

Throughout the course of HIV disease, there is an active viral replication and concomitant stimulation and destruction of the immune system, even during the clinically asymptomatic period. The rate of progression of the infection that eventually culminates in complete destruction of the CD4 lymphocytes is determined by a balance between the pathogen virulence factors and the host genetic make-up and immune defenses against HIV.

## **Prevention & Control**

Vaccine against HIV is not yet available, and prevention of infection relies on controlling transmission of the virus. Control encompasses both prevention counseling and postexposure prophylaxis.

Assessment of risk factors as well as specific risk reduction information should be a part of routine primary care and a component of evaluation at the specific HIV testing centers and STD clinics. A supportive, nonjudgmental atmosphere, along with repeated, specific information targeting specific identified risk factors, is most effective.

Injection drug users should be encouraged to join a drug rehabilitation program and offered evaluation for entry into methadone maintenance programs if available in the community. Short of discontinuation of drug injection, some behavioral modifications can reduce the risk of a potential HIV transmission; for example, using sterile equipment or cleaning drug paraphernalia, especially needles and syringes, with water and then bleach (for at least 30 seconds). Some communities also offer needle/syringe exchange programs. Eliminating needle sharing or reducing the number of sharing partners could further reduce the risk of transmission.

Promotion of safer sexual practices should be an essential part of prevention counseling. Such practices focus on implementation of consistent condom use and the reduction of the number of partners. Screening and treatment of STDs further contribute to reducing the risk of sexual transmission of HIV.

Counseling should also incorporate issues of contraception and a possibility of virus transmission from an infected mother to her baby. All pregnant HIV-infected individuals should receive antiviral treatment to prevent viral transmission to the baby. Even though only AZT monotherapy was studied and proved to reduce the risk of HIV transmission to

the neonate, a single drug antiviral regimen is no longer acceptable for treatment of the mother. Thus combination therapy should be used. Mothers should also be counseled about the potential risk of HIV transmission via breast milk, and alternative infant feeding should be initiated.

Prevention of occupational exposures should involve education and reinforcement of universal precautions and implementation of devices and safe disposal of contaminated materials that would minimize a possibility of exposure to infected body fluids. Postexposure prophylaxis with antiviral medications after an occupational high-risk exposure to contaminated body fluids has become widely accepted, and specific treatment protocols have been implemented by various health-care institutions. In general, postexposure prophylaxis should be initiated as soon as possible after a known or a potential exposure and should consist of a combination either of zidovudine and lamivudine or stavudine and didanosine. With either regimen, consideration should be given to the addition of a protease inhibitor (nelfinavir or indinavir) if exposure is especially risky (large volume/high titer) or if the source patient has a high viral load (> 50,000 copies/mL), has advanced AIDS, or has been previously treated with one or both nucleoside analogues in the recommended two-drug regimens. Triple therapy is the regimen preferred by most health-care providers.

Experience with occupational postexposure prophylaxis has led recently to considerations for expansion of prophylactic treatment of individuals with recent sexual exposure to HIV. The current proposed regimen is the same as for occupational exposure. Postexposure prophylaxis should only constitute a backup for failure of primary prevention measures. Counseling and implementation of risk reduction programs should always be the mainstay of prevention of HIV transmission.

**Table 23-1.** Laboratory tests commonly used in the diagnosis of infection with HIV-1.

<b>Test</b>	<b>Primary Purpose(s)</b>
<b>HIV-1 antibody tests</b>	
<b>A. Detection of antibody in serum or plasma</b>	
<b>1. Enzyme-linked Immunosorbent Assay (ELISA) followed by Western blot</b> for confirmation. Current ELISA assay detects antibodies to both HIV-1 and HIV-2.	For all high-risk groups ( <i>Table 1</i> ); antibody becomes positive approx. 3 wks. post-disease acquisition in majority; 6 mos. after infection, 95% pts antibody-positive.
<b>Western blot:</b> 1. No antibodies (bands) detected = <b>negative</b> 2. Antibody (bands) to Gp41 and Gp 120/160 or either of latter plus p24 = <b>positive</b> 3. Any other pattern of positive = <b>indeterminate</b> . Proceed to plasma viral load testing.	
<b>2. Rapid detection method:</b> Examples: Single use diagnostic system (SUDS)	Results available in 30 minutes or less When quick answer needed, e.g., test blood of source pt in occupational exposure. Pts who may not comply with return visit: ER, STD clinics
<b>3. Home test kits</b> , e.g., Home Access Express. <b>NOTE: Other kits sold on internet unreliable.</b>	Encourage individuals at risk to determine their antibody status. Convenient. Anonymity maintained.
<b>B. Detection of HIV-1 antibody in other body fluids</b>	
<b>1. Antibody in oral mucosal transudate</b> (OraSure)	Major advantage is avoidance of need for a needlestick. Easy to use; collected by health care worker
<b>2. Antibody in urine</b> (Sentinel or Calypte): HIV-1 Urine ELISA	Rapid—results in 2.5 hrs. Like rapid tests, could be used on source blood if occupational exposure or in ERs, STD clinics

**Table 23-3.** Timing of antiretroviral treatment.

**When should antiretroviral treatment be started? The most important factor in answering this question is to determine if the patient is ready to comply with the difficult regimens** since lack of compliance guarantees failure of the treatment and facilitates the emergence of resistant subpopulations of virus, making it more difficult to treat the patient later. It also creates the potential for spread of resistant viruses to others. Studies indicate that about 1/3 of patients are totally adherent, 1/3 partially adherent, 1/3 almost totally nonadherent to prescribed treatment. Two important factors affect adherence: (1) the number of pills and (2) ease of administration of the regimen (qd better than bid, which is better than tid). Mixing medications with different frequency and food restrictions makes total adherence nearly impossible. In one study of 88 pts, virologic failure occurred in 22% of pts who were adherent for >95% doses and in 61% of those with 80% to 94.5% adherence. Every effort should be made to come to an agreement or contract with the patients as to what he/she is capable of or willing to comply with prior to initiating treatment. Frequent follow-up with advice and encouragement to the patient is important to help maintain compliance and to detect noncompliance. In 2001, a shift to a more conservative (later initiation) of treatment was supported, based on saving drugs as long as possible from developing resistance and on minimizing long-term drug toxicity without sacrificing efficacy.

An exception to late therapy is the acute retroviral (HIV) syndrome: Most authorities would treat immediately with HAART in an attempt to rapidly control viral proliferation, establish a lower viral set-point and preserve the immunologic response (virus-specific cytotoxic T-cells and CD4 helper cells) against HIV.

**Ranges of CD4 Cell Count and Viral Load Levels for Therapy Initiation**

CD4 + Cells, x10 <sup>6</sup> /L	Plasma HIV RNA Level, copies/mL		
	<5,000	5,000-30,000 βDNA (55,000 PCR)	>30,000 βDNA (>55,000 PCR)
<350	Consider therapy	Recommend therapy	Recommend therapy
>350	Defer therapy	Defer therapy	Recommend therapy

*Note:* Therapy is recommended in symptomatic patients.

**Table 23-6.** Responses to failure of treatment.

**What is the appropriate treatment when the antiretroviral regimen fails? Failure may be due to many different reasons, and it is important to identify the cause. Most treatment failures are due to a patient's lack of compliance** with the complicated triple-drug therapies. Patients may not recognize that they are being noncompliant or may be too embarrassed to admit it. The following actions and/or recommendations should be considered in the event of failure of the treatment:

- When the increase in viral RNA is likely due to a patient's **noncompliance** to treatment, **one may initially reinstitute the original regimen**, especially if the patient stopped all drugs at once (it has been shown that after a year on treatment, when drugs are stopped simultaneously, the viral isolates will still be sensitive to all three drugs, and patients will again respond to reinitiation of the original treatment).
- When the increase in viral RNA is likely due to the patient's **erratic compliance** with the treatment, or **if the patient was compliant and still showed a rise in viral RNA**, the virus may well be resistant to all drugs. **In that event, a change in treatment is warranted, and, if possible, all drugs should be changed.**
- When treatment failure cannot be shown to be due to either noncompliance or erratic compliance, **drug malabsorption** or a **drug-drug interaction**, both of which can decrease the effective plasma drug concentrations, should be considered. The use of plasma drug levels in cases where the cause of failure is not apparent may also be of value.
- **Tests for detection of mutations that confer resistance (genotyping) and phenotypic tests for detection of resistance to antiretroviral drugs are now commercially available and are recommended for supporting the above clinical decisions regarding which drugs should be used next.**

**BOX 23-1. Clinical Syndromes, Opportunistic Infections, and Neoplasms Caused by HIV**

<b>Syndrome &amp; Cause</b>	<b>Clinical Presentation</b>	<b>Laboratory Correlates</b>
Early Disease (CD4 > 500) Acute Retroviral Syndrome (HIV)	<ul style="list-style-type: none"> <li>• Fever</li> <li>• Adenopathy</li> <li>• Pharyngitis</li> <li>• Rash</li> <li>• Myalgia/arthralgia</li> <li>• Diarrhea</li> <li>• Headache</li> <li>• Nausea/emesis</li> <li>• Hepatosplenomegaly</li> <li>• Neuropathy</li> <li>• Encephalopathy</li> </ul>	<ul style="list-style-type: none"> <li>• Thrombocytopenia</li> <li>• Lymphopenia, then atypical lymphocytosis</li> <li>• Transaminitis</li> <li>• High-level HIV viremia</li> </ul>
Aseptic meningitis (HIV)	<ul style="list-style-type: none"> <li>• Headache</li> <li>• Photophobia</li> <li>• Fever</li> </ul>	<ul style="list-style-type: none"> <li>• CSF: lymphocytic pleocytosis, modest increase in protein</li> </ul>
Immune Thrombocytopenic Purpura (ITP)	<ul style="list-style-type: none"> <li>• Easy bruising</li> <li>• Epistaxis</li> <li>• Splenomegaly</li> </ul>	<ul style="list-style-type: none"> <li>• Thrombocytopenia; no clonal production defect on bone marrow aspiration</li> <li>• IVIG, Danazol, alpha-interferon, splenectomy</li> </ul>
Midstage Disease (CD4 200-500) Mycobacterium tuberculosis (TB)	Classic reactivation pulmonary disease with higher CD4 counts; cough, fever, weight loss, upper lobes infiltrate, pulmonary cavities. Atypical presentation with lower CD4 with hilar adenopathy, diffuse pulmonary infiltrates without cavitation, pleural effusions, or extrapulmonary disease (blood, lymph nodes, CNS, genitourinary tract, pleura).	CXR; sputum: AFB smear; bronchoscopy if sputum is negative; blood cultures for AFB positive; pleural or lymph node biopsies
Kaposi's Sarcoma (HHV-8)	<ul style="list-style-type: none"> <li>• Mucocutaneous palpable, firm, nontender nodules or ecchymosis-like lesions; violaceous, brown or black.</li> <li>• Oral lesions common.</li> <li>• Visceral disease: GI with bleeding, perforation, and obstruction; pulmonary with dyspnea cough, bronchospasm.</li> <li>• Lesions may become painful.</li> <li>• Edema formation.</li> </ul>	Biopsy recommended; virus visualized during bronchoscopy and endoscopy.

Pneumococcal Disease  
(*Streptococcus pneumoniae*)

- Sinusitis or pneumonia with productive cough, fever, pleuritic chest pain; evidence of consolidation or effusion on physical exam.
- Meningitis bacteremia common.

CXR with lobar; positive s  
BAL; positive blood culture  
or CSF.

Thrush (oral Candidiasis)

- Pseudomembranous form with white plaques that can be wiped off leaving erythematous or bleeding base.
- Erythematous form with smooth, red patches.

KOH prep of the scraping

## 24 . Infections in Transplant Recipients — *Robin Patel, MD*

### Essentials of Diagnosis

- Signs and symptoms include fever, chills, pulmonary infiltrates, skin rash, allograft dysfunction in transplant recipients.
- Distinguishing features include the following:
  1. Type of transplant [liver, lung, heart, pancreas, kidney, small bowel, peripheral blood stem cell (PBSC), bone marrow].
  2. Immunosuppression history (type, dose, duration).
  3. Cytomegalovirus (CMV) serology of donor and recipient (pretransplant).
  4. History of infectious diseases.
  5. Exposures (travel, tuberculosis, animals, occupation, etc).

### General Considerations

Solid-organ, PBSC and bone marrow transplantation have become therapeutic options for many human diseases. PBSC, bone marrow, liver, kidney, heart, and lung transplantation have become standard therapy for selected end-stage diseases. Pancreas (including islet cell) and small bowel transplantation are also being evaluated in this regard. PBSC involves using stem cells mobilized by the administration of recombinant human granulocyte macrophage colony-stimulating factor. There are several types of PBSC or bone marrow transplants:

- Allogeneic transplantation involves transplantation from a human leukocyte antigen identical or non-identical relative or an unrelated donor who is fully or partially matched for human leukocyte antigens.
- Syngeneic transplantation involves transplantation from an identical twin who is completely identical for all genetic loci.
- Autologous transplantation involves harvesting PBSC or bone marrow from a patient, treating the same patient with high doses of intensive chemotherapy and subsequently reconstituting the same patient with his/her own PBSC or bone marrow.

Infection remains a major complication of all types of transplantation. The optimal approach to infection in transplant recipients is prevention; failing this, its prompt and aggressive diagnosis and therapy are essential. The sources of infectious agents post-transplantation include endogenous organisms, the transplant allograft itself, and the environment. An important principle to consider when evaluating transplant recipients for infection is that the usual inflammatory response to an infectious organism

may be attenuated as a result of immunosuppressive therapy and therefore that the signs and symptoms of infections may be blunted and diagnostic techniques may be compromised. Because of this, aggressive and often invasive investigations of seemingly minor findings may be warranted.

## **Pretransplantation Infectious Diseases Evaluation**

Before transplantation, all potential candidates should be evaluated for active infection that may require therapy or preclude transplantation, risk factors for infection, including latent infections that might be reactivated post-transplantation, and the use of immunosuppressive agents. A complete history should be obtained, focusing on any history of infection and any unusual exposures ([Table 24-1](#)). A complete physical examination should also be performed. [Table 24-1](#) outlines infectious disease tests that should be performed pretransplantation.

Further investigations are pursued depending on elicited risks. For example, serologic testing for *Coccidioides immitis* may be performed on a patient with a history of travel to or residence in the southwestern United States or Mexico. Patients who have traveled to or resided in an area where *Strongyloides stercoralis* is endemic should be examined for evidence of infection with this parasite. Lung transplant candidates should be evaluated for colonization of the respiratory tract with such agents as *Aspergillus* spp.

## **Timing of Post-Transplantation Infection**

**A. Solid-Organ Transplantation.** There are three time frames, influenced by surgical factors, the level of immunosuppression, and environmental exposures, during which infections of specific types most frequently occur after solid-organ transplantation ([Box 24-1](#)). These include the first month; the second through the sixth months; and the late post-transplant period (beyond 6 mo).

Most infections during the first month post-transplantation are related to surgical complications and are similar to infections occurring in general surgical patients. These include bacterial and candidal wound infections, pneumonia, urinary tract infections, line sepsis, and infections of biliary, chest, and other drainage catheters. In general, any episode of unexplained fever or bacteremia occurring in the early post-transplantation period should be suspected as being caused by technical or anatomical problems related to the allograft. In the first month post-transplantation, renal and pancreas transplant recipients are at risk for perigraft abscesses, infected or uninfected hematomas, lymphoceles, and urinary leaks. Liver transplant recipients are at risk for portal vein thrombosis, hepatic vein occlusion, hepatic artery thrombosis, biliary stricture formation and leaks, infected and uninfected hematomas and hepatic and perihepatic abscesses. Heart transplant recipients are at risk for mediastinitis and infection at the aortic suture line, with resultant mycotic aneurysm, and lung transplant recipients at risk for disruption of the bronchial anastomosis and pneumonia. The only common viral infection seen during the first month post-transplantation is reactivated herpes simplex virus (HSV) infection in individuals seropositive for this virus pretransplantation. The prophylactic use of acyclovir during this period, however, has significantly reduced the incidence of reactivated HSV infection.

The period from the second to sixth month postsolid-organ transplantation is the time during which infections "classically" associated with solid-organ transplantation manifest. Opportunistic pathogens such as CMV, *Pneumocystis carinii*, *Aspergillus* spp., *Nocardia* spp., *Toxoplasma gondii*, and *Listeria monocytogenes* manifest during this period. In addition, during the early and middle periods, reactivation disease syndromes are occasionally encountered because of organisms present in the recipient pretransplantation. The introduction of high-dose immunosuppression may result in clinical illness owing to reactivation of *Mycobacterium tuberculosis*, an occult focus of bacterial infection, viral hepatitis, *Histoplasma capsulatum*, or *C. immitis*. Chronic or latent infection of the donor that involves the allograft, such as HIV, hepatitis B virus (HBV), hepatitis C virus (HCV), or fungal or mycobacterial infection, may be transmitted to the immunosuppressed recipient and become clinically apparent during the early and middle periods.

From 6 months post-transplant onward, most solid-organ transplant recipients do relatively well, suffering from the same infections seen in the general community. These include influenza virus infection, urinary tract infection, and pneumococcal pneumonia. The only opportunistic viral infection commonly seen during this period is reactivated varicella zoster virus (VZV) infection manifesting as shingles. Rarely, CMV retinitis occurs.

Two situations, however, predispose patients to other infections in this late post-transplant period. First, patients who have had frequent episodes of acute rejection requiring augmented immunosuppressive therapy or those with chronic rejection who are maintained at a high baseline level of immunosuppression remain at increased risk for the opportunistic agents more classically seen in the second to the sixth months post-transplant (CMV, *P. carinii*, *L. monocytogenes*, *T. gondii*, *Aspergillus* spp., and *Nocardia* spp.). Second, patients with chronic infections such as HIV, HBV, and HCV infections, may suffer from morbidity associated with these agents.

**B. PBSC and Bone Marrow Transplantation.** There are three time frames within which the majority of infections develop after PBSC and bone marrow transplantation ([Box 24-1](#)). These include the first month after transplant (before engraftment); the second through the third month after transplant (engraftment); and the late post-transplant period, 3 months or later after transplant. During the first month after transplantation, before engraftment, granulocytopenia and damaged mucosal surfaces caused by pretransplant chemotherapy and radiotherapy are the predominant defects in host defenses. At this time, patients are most susceptible to infections caused by gram-negative and gram-positive aerobic bacteria and fungi. Reactivated HSV infections in patients previously seropositive for HSV are also common, similar to the situation in solid-organ transplant patients. And, similar to the situation in solid-organ transplant patients, the prophylactic use of acyclovir during this period has significantly reduced the incidence of reactivated HSV infection.

During the second to third month after PBSC and bone marrow transplant when engraftment has occurred, patients have profound impairment of both cellular and humoral immunity. These abnormalities are more severe and persist longer in patients with acute graft-versus-host disease (which is the major risk factor for infection during the second to third month after transplantation). Autologous and syngeneic transplant

recipients who are not usually at risk for graft-versus-host disease experience significantly fewer and less severe infections after engraftment than allogeneic transplant recipients. Interstitial pneumonia related to CMV and pulmonary aspergillosis are the major infectious complications seen in patients with graft-versus-host disease, especially when high doses of immunosuppressive therapy are given for treatment. Gram-positive bacterial infections related to indwelling intravenous catheters, gram-negative bacteremia in patients with graft-versus-host disease of the gastrointestinal tract, pulmonary infection caused by adenovirus, respiratory syncytial virus, or parainfluenza virus, hemorrhagic cystitis caused by BK virus or adenovirus, as well as viral gastroenteritis, may be seen during this time period.

The period from 3 months onward after PBSC and bone marrow transplantation is characterized by gradual recovery over several months of both cellular and humoral immunity. The process of donor-derived immune reconstitution is generally complete by 1-2 years after transplantation. Except for reactivation of VZV infections (shingles) and infections of the respiratory tract caused by *Streptococcus pneumoniae* and *Haemophilus influenzae* or common respiratory viruses, PBSC and bone marrow transplant recipients without graft-versus-host disease experience relatively few late infections. Immune recovery, however, is seriously delayed by chronic graft-versus-host disease, which causes persistent and profound defects in both cellular and humoral immune responses. Decreased secretory IgG production, impaired splenic function, inadequate opsonizing antibody, and the bronchopulmonary sicca syndrome characteristic of chronic graft-versus-host disease contribute to respiratory tract infections. Late onset interstitial pneumonia that is caused by CMV or *P. carinii* may occur in patients with ongoing graft-versus-host disease. The destructive effects of chronic graft-versus-host disease on mucocutaneous surfaces also provide a source for infection by staphylococci and other bacteria.

## **BACTERIAL INFECTIONS**

### **COMMON BACTERIAL INFECTIONS**

#### **Introduction**

Clinical findings and treatment of common bacterial infections in transplant recipients are discussed in the relevant syndrome and organism chapters (see chapter cross references below).

**A. Liver Transplant Recipients.** Bacterial infections of the liver, biliary tract, peritoneal cavity, bloodstream, and surgical wound are the most commonly seen bacterial infections in liver transplant recipients (see [Chapter 21](#)). Most such infections occur within the first month (or two) after transplantation. Many of these infections are related to technical problems with the liver graft such as bile leaks or biliary obstruction. Bacterial liver abscesses are sometimes associated with biliary strictures but more often are related to ischemia of the allograft from thrombosis of the hepatic artery. Computed tomography, ultrasonography, cholangiography, and/or angiography are required to evaluate anatomic abnormalities. The flora of these infections typically involves enterococci, anaerobes, gram-negative enteric rods, and staphylococci. Risk factors for bacterial infections in liver transplant recipients include CMV infection, acute rejection,

prolonged hospitalization, increased operative transfusion requirements, prolonged duration of surgery, rejection, reoperation, retransplantation, and elevated bilirubin or creatinine levels. In liver transplant recipients, the presence of a Roux-en-Y choledochojejunostomy increases the risk of sepsis overall, infectious complications related to liver biopsy, and enterococcal and *Pseudomonas* bacteremia by facilitating reflux of enteric organisms into the biliary system and hence into the hepatic allograft.

## Prevention

Selective bowel decontamination reduces gram-negative infections in liver transplant recipients.

**B. Lung Transplant Recipients.** The most common type of bacterial infection in the lung transplant recipient is pulmonary (see [Chapters 9 and 10](#)). This is a result of denervation of the lungs and airways abolishing the cough reflex distal to the tracheal or bronchial anastomosis, impaired mucociliary clearance, and airway inflammation secondary to rejection. The anastomosis is particularly vulnerable to local pathogen colonization as suture material present may initiate a local immune response. Lung transplant recipients are also at risk for mediastinitis because of leaks from the airway anastomosis. Risk factors for bacterial pneumonia after single lung transplantation include underlying primary or secondary pulmonary hypertension in the presence of airway complications of stenosis or dehiscence.

## Prevention

The incidence of bacterial pneumonia in lung transplant recipients may be dramatically reduced by the use of antimicrobial agents tailored to the results of cultures and stains for bacteria and fungi from the airways of the donor and recipient at the time of transplantation.

**C. Heart Transplant Recipients.** Pulmonary infections are the predominant bacterial infections seen in heart transplant recipients (see [Chapter 11](#)). Other types of bacterial infections seen in heart transplant recipients include wound infections (of which midline sternotomy infection can be particularly devastating); bacteremia, which most commonly results from vascular catheter infection; and urinary tract infection (see [Chapter 16](#)).

**D. Renal Transplant Recipients.** Renal transplant recipients are at risk for urinary tract infections (see [Chapter 16](#)). Multiple factors, including renal insufficiency, nutritional inadequacies, decreased amounts of urine flowing across the uroepithelium, opportunities for sepsis from dialysis accesses, underlying diabetes mellitus, and/or polycystic kidney disease, contribute to this increased incidence. Patients who receive a simultaneous pancreas transplant with bladder drainage have the added risk of enzymatic digestion of the protective glycosaminoglycan layer overlying the uroepithelium. In addition, the change in urinary pH caused by urinary, pancreatic, and endocrine secretions and underlying glycosuria favor bacterial urinary tract infection in combined kidney and pancreas transplant recipients. Pathogens causing urinary tract infections in renal transplant recipients include enterococci, staphylococci, and *Pseudomonas aeruginosa*, in addition to the usual enteric gram-negative bacteria. Wound infections may also be seen.

## Prevention

Prophylaxis with trimethoprim-sulfamethoxazole reduces the incidence of bacterial infection of the urinary tract and bacteremia after renal transplantation. However, controversy exists regarding the exact dosing, timing, and duration of trimethoprim-sulfamethoxazole for urinary tract infection prophylaxis in renal transplant recipients.

**E. Pancreas and Small Bowel Transplant Recipients.** The most common bacterial infections in pancreas transplant recipients are wound and intra-abdominal infections (see [Chapters 12](#) and [13](#)). Human small bowel transplant recipients are likewise at risk for intra-abdominal and wound infections.

**F. PBSC and Bone Marrow Transplant Recipients.** Since the early 1980s, the bacterial causes of infection in patients undergoing PBSC and bone marrow transplantation during the initial 3 mo after transplant have changed from predominantly gram-negative bacillary organisms to mostly gram-positive organisms. The extensive use of indwelling central intravenous catheters, more severe cases of oral mucositis from chemotherapeutic agents, the administration of oral quinolones for prophylaxis, and the empiric treatment of febrile episodes with antibiotics directed primarily against gram-negative bacilli have likely contributed to this rise in gram-positive bacterial infections. Coagulase-negative staphylococci, viridans streptococci, *Staphylococcus aureus*, and *Corynebacterium* spp. are the most common gram-positive bacterial pathogens seen in this group of patients.

An increased risk of both colonization and bacteremia caused by viridans streptococci has been associated with quinolone prophylaxis in PBSC and bone marrow transplant recipients. Septic shock and the adult respiratory distress syndrome are occasionally seen in association with viridans streptococcal bacteremia. Despite the apparent decline in gram-negative bacterial infections, the possibility of infection caused by *Escherichia coli* and other *Enterobacteriaceae*, as well as *P aeruginosa* and other nonfermenting gram-negative bacilli, must still be considered when decisions about empiric antibiotic therapy are being made.

Bacteremia and soft tissue infections are the most common presentations of bacterial infections during the initial months after PBSC and bone marrow transplant (see [Chapter 13](#)). Exit site infections of intravenous catheters, infections involving the perirectal area, and oral mucositis are common local types of bacterial infection. Bacterial infections of the respiratory tract may occur at anytime, including 4 or more months after transplantation. At this later time period, encapsulated bacteria (eg, *S pneumoniae* and *H influenzae*) are frequent pathogens that may cause pneumonia, bronchitis, sinusitis, and, less commonly, meningitis.

## Prevention

Bacterial infections in PBSC and bone marrow transplant patients with graft-versus-host disease after engraftment may be prevented by prophylaxis with trimethoprim-sulfamethoxazole. Oral chemoprophylaxis with quinolones in granulocytic

patients is widely used. Oral quinolones are well tolerated and eliminate most gram-negative bacterial infections. The use of quinolones for prophylaxis is, however, controversial.

## **LEGIONELLA SPECIES**

### **General Considerations**

*Legionella* infection can occur in any type of transplant recipient, can be nosocomial or community acquired, and can be seen at any time post-transplant. *Legionella pneumophila* is the most common species involved but *Legionella micdadei*, *Legionella bozemanii*, *Legionella dumoffii*, and other *Legionella* spp., may be pathogens in transplant recipients. More details are found in [Chapter 58](#).

### **Clinical Findings**

**A. Signs and Symptoms.** *Legionella* infection typically causes pneumonia with symptoms of fever, chills, headache, diarrhea, chest pain, malaise, dyspnea, and cough.

**B. Laboratory Findings.** Prompt request for diagnostic tests for *Legionella* spp. including direct fluorescent antibody testing and culture of sputum or bronchoalveolar lavage specimens as well as urinary antigen testing in any patient with suspected legionellosis is recommended. Serologic testing is of limited usefulness because of the need to obtain acute and convalescent phase titers and because seroconversion is not specific for *Legionella* infection. Furthermore, the humoral response may be compromised in transplant recipients. Molecular diagnostic assays are under development.

**C. Imaging.** Pulmonary infiltrates are typically seen on chest X-ray.

### **Treatment**

Treatment is classically with a quinolone or macrolide with or without rifampin ([Box 24-2](#)). If legionellar pneumonia is nosocomial, a search should be made for sources of legionella in the environment, especially in the hot water supply and ventilation systems.

## **NOCARDIA SPECIES**

### **General Considerations**

Nocardial infections have been reported to occur in all types of transplant recipients. Nocardial infection is most commonly caused by *Nocardia asteroides*, but other species of *Nocardia* may also cause infections in transplant recipients. More details are found in [Chapter 63](#).

### **Clinical Findings**

**A. Signs and Symptoms.** The most common presentation is pulmonary and includes

fever and cough. Central nervous system and cutaneous infections may be present.

**B. Laboratory Findings.** Gram and modified acid fast stains and cultures of sputum or bronchoalveolar lavage fluid are useful in the diagnosis of pulmonary nocardial infection. All transplant patients with nocardiosis should be evaluated for central nervous system disease.

**C. Imaging.** Pulmonary infiltrates, pleural effusions, cavitating lesions, or nodules may be visualized on chest x-ray. Nocardial brain abscess, inflamed meninges, and ventriculitis may also be seen.

## Treatment

Sulfonamides, either alone or in combination with trimethoprim, are the treatment of choice for nocardiosis ([Box 24-2](#)). Alternatives include minocycline, chloramphenicol, erythromycin, amikacin, ampicillin, amoxicillin-clavulanate, ciprofloxacin, imipenem, meropenem, ceftriaxone, cefuroxime, and cefotaxime, but antibiotic susceptibility testing should be performed because resistance may be present. Antimicrobial therapy should be continued for a prolonged period after cure because of the tendency for relapse, although the optimal duration of therapy is unknown.

## Prevention

Trimethoprim-sulfamethoxazole used for *P. carinii* prophylaxis may prevent nocardiosis ([Box 24-3](#)).

## **SALMONELLA SPP.**

There is an increased incidence of salmonellal infection in renal transplant recipients. The most common presentation is a febrile illness with bacteremia. *Salmonella* infections are discussed further in [Chapter 53](#).

## **LISTERIA MONOCYTOGENES**

### General Considerations

Transplant recipients are at greatest risk for infection caused by *L. monocytogenes* during the first 2-3 mo after transplant, but listerial infection may occur at any time after transplant. Listeriosis occurs in all types of transplant patients and may be transmitted via contaminated food. It is most commonly seen from the months of July through October. More details are found in [Chapter 51](#).

### Clinical Findings

**A. Signs and Symptoms.** Two-thirds of infected transplant patients have infections involving the central nervous system including meningitis, meningoencephalitis, and encephalitis, and one-third have primary bacteremia. Patients with meningitis present with headache, fever, signs of meningeal irritation, depressed level of consciousness, seizures, and/or focal neurological defects. The portal of entry for *L. monocytogenes* is

the gastrointestinal tract, and patients may report cramps and diarrhea as the initial manifestations of their infection.

**B. Laboratory Findings.** In patients with central nervous system infection, cerebrospinal fluid examination often, but not always, reveals a predominance of polymorphonuclear leukocytes, a low concentration of glucose, and a negative Gram stain. Importantly, *L. monocytogenes* may be confused with diphtheroids in Gram-stained smears of pus or sputum.

### Treatment

Intravenous ampicillin and gentamicin are recommended for treatment ([Box 24-2](#)). Trimethoprim-sulfamethoxazole is also effective.

### Prevention

Trimethoprim-sulfamethoxazole, used for *P. carinii* prophylaxis, may additionally prevent listeriosis ([Box 24-3](#)).

## VIRAL INFECTIONS

### CYTOMEGALOVIRUS

#### General Considerations

CMV is extensively discussed in [Chapter 33](#). CMV infection occurs in the majority of solid-organ and allogeneic PBSC and bone marrow transplant recipients, primarily in the first 3 mo post-transplant. CMV infection also occurs in 40-45% of recipients of syngeneic or autologous PBSC and bone marrow transplant recipients, but symptomatic infections are infrequent in these groups. CMV may be transmitted to transplant recipients via infected donor material or transfused cellular products.

Three major patterns of CMV transmission are observed in transplant recipients.

**Primary infection** develops when a CMV seronegative individual receives cells latently infected with the virus from a seropositive donor followed by viral reactivation.

**Secondary** infection or reactivation infection develops when endogenous latent virus is reactivated in a CMV seropositive individual post-transplantation. **Superinfection** or **reinfection** occurs when a seropositive recipient receives latently infected cells from a seropositive donor and the virus that reactivates post-transplantation is of donor origin.

After primary infection with CMV, long-term cellular and humoral immunity usually develop, but CMV remains latent or persistent within the host. Viral persistence is controlled in the immunocompetent host by an intact cellular immune system. Immunosuppression administered after transplantation may lead to uncontrolled viral replication and consequently symptomatic CMV infection. A solid-organ transplant recipient without prior immunity to CMV pretransplantation who receives an organ containing latent or persistent virus (primary infection) is at higher risk of uncontrolled viral replication than a patient who has prior immunity to CMV pretransplantation

(secondary infection or reinfection). In PBSC and bone marrow transplant recipients the CMV seropositive recipient with a CMV seronegative donor is at higher risk of uncontrolled viral replication than patients in other serologic groups. Likewise, the higher the degree of immunosuppression, the higher the risk of uncontrolled viral replication. In solid-organ transplant recipients, the use of antilymphocyte preparations (eg. OKT3 monoclonal antibodies) and fulminant hepatitis at the time of transplantation (in liver transplant recipients) are risk factors for symptomatic CMV infection. Graft-versus-host disease is a risk factor for CMV infection in PBSC and bone marrow transplant recipients.

In the immunosuppressed transplant recipient, CMV has four major effects:

1. It causes infectious diseases syndromes (see below).
2. It has been implicated in causing increased immunosuppression, which may explain the frequent association of CMV with other opportunistic infections such as fungal and *Pneumocystis* infections.
3. It has been associated with allograft rejection in the form of early onset allograft rejection in renal transplant recipients and chronic allograft rejection (allograft atherosclerosis) in cardiac transplant recipients (in some, but not all, studies) as well as possibly the vanishing bile duct syndrome in liver transplant recipients (controversial).
4. It has been implicated in exerting a negative effect on survival after solid-organ transplantation.

CMV infection therefore has a potential impact on both patient and graft outcome.

## **Clinical Findings**

**A. Signs and Symptoms.** CMV infection exhibits a wide range of clinical manifestations from asymptomatic infection to severe lethal CMV disease. Most cases of CMV disease after transplantation are of mild to moderate severity and are rarely fatal in the current decade. Manifestations of mild to moderate disease include fever and malaise without additional signs or symptoms. Myalgias, arthralgias, and, at times, arthritis may occur.

Organ involvement by CMV correlates with the organ transplanted as follows: Hepatitis occurs most frequently in liver transplant recipients; pancreatitis occurs most frequently in pancreas transplant recipients; and pneumonitis occurs most frequently in lung, heart and lung, and PBSC and bone marrow transplant recipients. Gastroenteritis is also frequently seen in PBSC and bone marrow transplant recipients. In addition, myocarditis, although rare, typically presents in heart transplant recipients. Other sites of involvement of CMV include the gallbladder, pancreas, epididymis, biliary tract, retina, skin, endometrium, and central nervous system. CMV retinitis is distinctive in that it usually presents > 6 mo post-solid-organ transplantation.

**B. Laboratory Findings.** CMV may be associated with leukopenia or thrombocytopenia. The diagnosis of CMV infection in tissue has traditionally been based on the recognition of cytomegalic inclusion bodies. CMV may also be detected in tissue

specimens by immunohistochemistry or DNA hybridization techniques. Tube cell culture and shell vial culture techniques can be used to detect replicating CMV in body fluids and tissue with the former having the disadvantage of taking 7-14 days of incubation for CMV to exhibit cytopathic effect. The rapid shell vial culture technique, however, can detect the presence of CMV after 16 hours of incubation. Importantly, akin to bacterial blood cultures, multiple viral blood cultures may be necessary to detect CMV by the shell vial assay. Detection of CMV antigenemia in blood leukocytes of transplant recipients is at least as sensitive as and more rapid than the shell vial technique and provides an earlier marker of CMV infection.

Molecular techniques can detect CMV DNA in peripheral blood leukocytes, whole blood, serum, plasma, and other clinical specimens and can detect CMV RNA in peripheral blood leukocytes and whole blood.

The serologic diagnosis of CMV infection is suboptimal compared to the above techniques; many patients with positive CMV cultures do not show concomitant evidence of seroconversion. Serologic testing, however, is recommended for the pretransplantation evaluation of the CMV serostatus of transplant donors and recipients.

## Treatment

Effective currently available antiviral agents for the treatment of CMV include ganciclovir, foscarnet, cidofovir, and intravenous immune globulin ([Box 24-2](#)). In solid-organ transplant recipients, intravenous ganciclovir is the mainstay of therapy. Ganciclovir alone is generally of little benefit for treatment of either CMV pneumonia or gastroenteritis in PBSC and bone marrow transplant recipients, although the combination of intravenous ganciclovir plus intravenous immune globulin appears to have some efficacy. The absorption of ganciclovir after oral administration is low, and its use cannot be recommended for the treatment of CMV infection and disease after transplantation.

Side effects of ganciclovir include leukopenia, thrombocytopenia, anemia, nausea, infusion site reactions, diarrhea, renal toxicity, seizures, mental status changes, fever, rash, and abnormal liver function tests. Hematologic and renal function should be monitored while patients are receiving ganciclovir. Renal toxicity may occur when ganciclovir is used in conjunction with other nephrotoxic agents such as amphotericin B, azathioprine, aminoglycosides, and cyclosporine.

The possibility of viral resistance should be considered in patients with poor clinical response or persistent viral excretion during ganciclovir therapy. Mutations in viral thymidine kinase and/or DNA polymerase genes mediate resistance.

## Prevention

**A. Selection of Organs from CMV Seronegative Donors for CMV Seronegative Recipients.** Knowledge of the CMV serostatus of the donor and recipient pretransplant will predict which patients will develop CMV disease. Although the solid-organ transplant patient at highest risk for development of CMV infection is the seronegative recipient of a seropositive allograft, protective matching of seronegative donors and recipients is not

currently advocated ([Box 24-3](#)).

**B. Use of CMV Seronegative, Filtered, or Leukocyte-Poor Blood Products.** The use of CMV seronegative, filtered, or leukocyte poor blood products reduces CMV transmission, and these should be used at least in seronegative recipients.

**C. Active Immunization with a Vaccine.** In theory, one of the simplest interventions for the prevention of CMV disease after transplantation would be immunization of seronegative recipients with a vaccine given once in anticipation of future viral challenge. A live attenuated CMV vaccine, which uses the Towne strain of virus, is both safe and immunogenic; however, there is no significant decrease in the incidence of CMV disease in renal transplant recipients receiving this vaccine. New interest in developing a vaccine subunit product has emerged over the last few years. A subunit vaccine containing recombinant glycoprotein B, which is being developed by several biotechnology companies, is undergoing clinical trials.

**D. Passive Immunization with Immune Globulins.** Immune globulin preparations (including unscreened or unselected and hyperimmune globulin preparations) have been studied as agents for CMV prophylaxis. In solid-organ transplant recipients, intravenous immune globulins have been shown to be effective in preventing CMV disease in renal and non-high-risk (CMV-seropositive donor/CMV-seronegative recipient) liver transplant recipients. It appears that, at least in solid-organ transplant recipients, hyperimmune globulin is more effective in this role than standard immune globulin. Notably, immune globulin prophylaxis typically costs several thousand dollars per patient.

**E. Prophylaxis with Antiviral Agents.** Oral acyclovir has little role in preventing CMV after transplantation with the exception of possible efficacy in renal transplant recipients. Oral valganciclovir has been shown to be effective in preventing CMV infection and disease in renal transplant recipients. Prophylactic intravenous ganciclovir can prevent CMV disease in PBSC and bone marrow transplant recipients but is associated with neutropenia.

On the basis of published randomized trials, a 2-week course of intravenous ganciclovir may be considered for CMV prophylaxis in certain solid-organ transplant recipients; a 4-week course is recommended for CMV seropositive recipients of heart allografts. Intravenous ganciclovir alone is not effective, however, in solid-organ transplant populations at highest risk for CMV disease, including lung transplant recipients and donor CMV seropositive recipients CMV seronegative individuals, unless it is administered for a prolonged period (90 days). The studies to date have used intravenous ganciclovir, which is not ideal because of the ongoing need for intravenous access and the costs engendered. In this regard, oral ganciclovir has been shown as effective in preventing CMV infection and disease in liver and kidney transplant recipients and has been widely adapted for CMV prophylaxis, replacing intravenous ganciclovir in most instances.

Limitations associated with oral ganciclovir use include the need to take multiple tablets each day, cost, potential emergence of ganciclovir-resistant CMV strains, and the emergence of late onset CMV disease (following discontinuation of prophylaxis). New

agents, such as valganciclovir as well as other promising compounds that are being developed, may provide improved CMV prophylaxis for solid-organ and PBSC and bone marrow transplant recipients.

#### **F. Adoptive Transfer of CMV Specific T-Cell Clones Generated from the Donor.**

The development of CMV specific cytotoxic T-lymphocyte responses enhances survival from serious CMV infections. Thus, adoptive transfer of CMV specific T-cell clones generated from the PBSC or bone marrow donor is being studied as an approach to restoring immunity to CMV in the PBSC or marrow recipient.

**G. Preemptive Therapy.** Preemptive therapy of CMV involves the administration of antiviral agents to a subgroup of patients before the appearance of disease. This is dependent on a laboratory marker or patient characteristic that identifies a subgroup of individuals at high risk of disease at a time when antimicrobial intervention would be maximally effective in aborting the disease process. Compared with a prophylactic approach of administering antiviral agents to all patients, only patients at risk of developing symptomatic CMV infection receive specific antiviral therapy. Therefore fewer patients receive an antiviral agent and probably for a shorter period, leading to advantages in terms of cost, emergence of resistant viral strains, and medication side effects.

Candidate laboratory tests for this therapeutic mode include molecular and antigenemia tests. Many transplantation programs are using molecular or antigenemia tests to monitor their transplant recipients after transplantation and intervening with preemptive therapy based on a positive result.

Identifying patient characteristics that place the transplant recipient at risk for CMV infection is another facet of preemptive therapy. Such risk factors include the use of OKT3 monoclonal antibodies in solid-organ transplant recipients and the presence of fulminant hepatitis at the time of transplantation in liver transplant recipients. Many transplantation programs are intervening with preemptive ganciclovir when antilymphocyte therapy is used in solid-organ transplant recipients. A similar approach based on other risk factors requires further study but may also be beneficial.

## **HERPES SIMPLEX VIRUS**

### **General Considerations**

Herpes simplex virus most commonly causes reactivation infection but may cause primary infection transmitted by person to person contact or via the transplant donor. Herpes simplex virus antibodies are found in three-quarters of adult transplant recipients. After primary infection, the virus remains latent in sensory nerve ganglia. Herpes simplex virus infection occurs in all types of transplant recipients. More information is found in [Chapter 33](#).

### **Clinical Findings**

**A. Signs and Symptoms.** Herpes simplex virus reactivation results in oral or genital mucocutaneous lesions usually during the first month after transplant. Herpes simplex

virus occasionally causes pneumonitis, tracheobronchitis, esophagitis, hepatitis, or disseminated infection.

Most orolabial infections are mild, although severe ulceration and discomfort, which may be complicated by bacterial superinfection or esophageal involvement, are noted in some patients. Anogenital infection usually presents as large areas of ulceration and may or may not have the typical vesicular appearance of HSV infection in the nonimmunocompromised host.

Herpes simplex virus can cause pneumonia and may be associated with a high mortality rate. This usually occurs as a secondary pneumonia in intubated patients with severe pneumonia caused by other agents. The virus is reactivated in the oropharynx. The mucosa is traumatized by the endotracheal tube, and the virus is presumably spread via the endotracheal tube to the lower respiratory tract. Certain caveats must be noted. Herpes simplex virus isolated from sputum or other respiratory secretions does not definitively imply HSV pneumonitis. Also, even if HSV is believed to be causing pneumonitis, another pathogen should be sought as HSV is often a secondary pathogen.

Herpes simplex virus esophagitis causes dysphagia and mimics candidal esophagitis. Esophagitis may complicate orolabial infection, particularly if the mucosa has been traumatized by endotracheal intubation or nasogastric tubes. Herpes simplex virus is also a cause of diffuse or focal hepatitis in solid-organ transplant recipients, usually during the first 2 months after transplantation. Diffuse or focal hepatitis secondary to herpes simplex virus is characterized by a rapidly progressive course accompanied by hypotension, disseminated intravascular coagulation, metabolic acidosis, gastrointestinal bleeding, and associated bacteremia. Disseminated HSV disease may rarely occur. Uncommonly, disseminated cutaneous infection with HSV may occur at sites of previous skin injury such as burns or eczema (eczema herpeticum).

**B. Laboratory Findings.** The diagnosis is made by performing a direct immunofluorescence test, Tzanck test, molecular diagnostic assay or culture of tissue and body fluids or both. Typing of isolates may be performed by a variety of techniques. Serologic techniques are helpful in the determination of the pretransplantation serologic status of transplant recipients.

## **Treatment**

Treatment of HSV infection is with acyclovir ([Box 24-2](#)). Side effects of acyclovir include local inflammation or phlebitis after intravenous infusion, renal toxicity caused by precipitation and crystallization of the drug in the renal tubules, confusion, delirium, lethargy, tremors, seizures, nausea, light-headedness, diaphoresis, and rash. Mucocutaneous infection in transplant recipients should be treated with oral acyclovir if the infection has a benign course or with intravenous acyclovir in more serious cases. Disseminated or deep HSV infection should always be treated with intravenous acyclovir.

Newer agents, such as famciclovir and valacyclovir, may be used instead of acyclovir. Although more toxic than acyclovir, ganciclovir and foscarnet are also effective against

HSV. A concern with respect to chronic acyclovir use is the development of acyclovir resistant mutants of HSV. Acyclovir resistance may arise from mutations in the genes for thymidine kinase or DNA polymerase. Acyclovir resistance has been associated with progressive and severe disease in immunocompromised patients, particularly in those with HIV, and it is possible that resistance will become a problem for transplant recipients in years ahead.

## Prevention

Low-dose acyclovir prevents HSV stomatitis in transplant recipients ([Box 24-3](#)).

## VARICELLA ZOSTER VIRUS

### General Considerations

Varicella zoster virus causes two distinct clinical diseases after transplant. Ninety percent of adult transplant recipients are VZV seropositive pretransplant; VZV reactivation in this group will cause herpes zoster (shingles). The remaining 10% are VZV seronegative and thus are at risk for primary infection. More information is found in [Chapter 33](#).

### Clinical Findings

**A. Signs and Symptoms.** Localized dermatomal reactivation results in herpes zoster and may involve two or more adjoining dermatomes. There may be a few sites of cutaneous dissemination at distant sites. Additionally, a syndrome of unilateral pain without skin eruption associated with rises in specific antibody to VZV has been described in transplant patients. Primary VZV infection occurs after exposure of a VZV seronegative transplant recipient to VZV. The virus is transmitted by contact with an infected individual (usually via the respiratory route). This can occur at any time after transplantation and, although rare, can cause a life-threatening disseminated infection characterized by hemorrhagic pneumonia, skin lesions, encephalitis, pancreatitis, disseminated intravascular coagulation, and hepatitis. Primary VZV can also cause a chickenpox syndrome or hepatitis alone.

**B. Laboratory Findings.** Unilateral vesicular lesions in a dermatomal pattern are usually sufficiently characteristic of herpes zoster to enable a clinical diagnosis; however, culture of VZV on susceptible cell lines, demonstration of multinucleated giant cells on Tzanck smear, and/or direct immunofluorescence or identification of VZV using molecular techniques is recommended for confirmation. These techniques can also be used for diagnosis of primary infection.

### Treatment

For localized dermatomal zoster, the recommended treatment is intravenous acyclovir ([Box 24-2](#)). Oral famciclovir, valacyclovir, or acyclovir may be used as an alternative. For primary VZV infection, treatment consists of intravenous acyclovir in addition to varicella zoster immune globulin.

## Prevention

Because of the high mortality rate associated with primary VZV infection in transplant recipients, all candidates should be screened for antibody to VZV pretransplantation (see [Box 24-3](#)). Seronegative individuals should be urged to report promptly all exposures to VZV and varicella zoster immune globulin should be administered within 96 hours of exposure. Intravenous acyclovir should be administered within 24 hours of eruption of a skin rash if one occurs. Unfortunately, progression to severe disease and death can still occur. The use of low-dose acyclovir as HSV prophylaxis probably prevents VZV reactivation and possibly primary infection, although this has not been formally studied. Despite concerns regarding the use of live vaccines in transplant recipients, a recent study has demonstrated the safety of the VZV vaccine in pediatric renal transplant recipients. This vaccine should preferably be administered several months prior to solid-organ transplant, should reduce morbidity in seronegative solid-organ transplant recipients, and should provide considerable cost savings.

It is important to keep in mind that although most infections in transplant recipients are not communicable to health care workers, contact with a patient who has VZV infection, be it shingles or chickenpox, is a risk for all seronegative contacts including healthy staff working in transplant centers.

## EPSTEIN BARR VIRUS

### General Considerations

Epstein Barr virus (EBV) infection in transplant recipients may be associated with post-transplantation lymphoproliferative disease (PTLD), which is a significant cause of morbidity and mortality ([Table 24-2](#)). Post-transplantation lymphoproliferative disease occurs in solid-organ transplant recipients as well as in PBSC and bone marrow transplant recipients. The term PTLD acknowledges the fact that these lesions are heterogeneous and may not meet the diagnostic criteria for lymphoma. The spectrum of PTLD ranges from polyclonal to monoclonal. Monoclonal lesions may or may not contain detectable chromosomal abnormalities. PTLD is often multicentric and may involve the central nervous system, eyes, gastrointestinal tract, liver, spleen, lymph nodes, lungs, allograft, oropharynx, and other organs.

The pathogenesis of PTLD involves EBV replication often stimulated by antilymphocyte therapy, followed by cyclosporin-induced inhibition of virus specific cytotoxic T lymphocytes that normally control the expression of EBV infected, transformed B cells. Risk factors for PTLD include EBV seronegativity pretransplantation, antilymphocyte therapy for rejection or graft-versus-host disease, and CMV seromismatch. Increased levels of circulating EBV-infected lymphocytes and decreased EBV nuclear antigen antibody responses have been associated with the development of PTLD in solid-organ transplant recipients in some, but not all, studies. More information is provided in [Chapter 33](#).

### Clinical Findings

Epstein Barr virus infection (without PTLD) may manifest as malaise, fever, headache,

and sore throat. Clinical presentations of PTLD are varied and include a mononucleosis-like syndrome with fever, adenopathy, tonsillitis, and sore throat, fever, abdominal pain, anorexia, jaundice, bowel perforation, gastrointestinal bleeding, renal dysfunction, hepatic allograft dysfunction, pneumothorax, pulmonary infiltrates, and weight loss.

## Treatment

Treatment of EBV-related PTLD is outlined in [Table 24-2](#). High-level EBV oropharyngeal shedding found in primary infection is inhibited by acyclovir and ganciclovir, suggesting that antiviral therapy may be useful early when levels of viral replication are low. Unfortunately, once PTLD is established, treatment has been disappointing with the exception of drastically reducing the level of immunosuppression, which appears to have a beneficial effect in localized or polyclonal as well as multifocal or monoclonal PTLD. Disease localized to the transplanted organ or lymph nodes can be reversed with reduced immunosuppression and antiviral therapy; extranodal, multifocal, and brain disease typically require chemotherapy, radiation therapy, or both and are associated with a high mortality rate.

## OTHER VIRUSES

### General Considerations

Other viruses occasionally cause infection in transplant recipients. Adenovirus ([Chapter 32](#)), parainfluenza virus ([Chapter 30](#)), respiratory syncytial virus ([Chapter 31](#)), and influenza virus ([Chapter 29](#)) may cause upper respiratory tract infections and pneumonia (see also [Chapter 9](#)). Sporadic outbreaks of gastroenteritis caused by coxsackievirus ([Chapter 27](#)) or rotavirus occur ([Chapter 37](#)). BK virus ([Chapter 45](#)) and adenovirus viruria ([Chapter 32](#)) have been associated with hemorrhagic cystitis. BK virus has been associated with allograft nephropathy in renal transplant recipients. Both HBV and HCV may cause liver dysfunction after transplantation ([Chapter 39](#)). Transplant recipients are also at risk for human papilloma virus-associated malignancies ([Chapter 45](#)).

## FUNGAL INFECTIONS

### *PNEUMOCYSTIS CARINII*

#### General Considerations

*P carinii* pneumonia has been virtually eliminated in transplant recipients by the use of prophylactic trimethoprim-sulfamethoxazole. Clusters of cases of *P carinii* pneumonia have been reported, and a question of person-to-person transmission has been raised. More details are found in [Chapter 79](#).

#### Clinical Findings

**A. Signs and Symptoms.** *P carinii* pneumonia typically presents with fever, dyspnea, nonproductive cough, and hypoxemia out of proportion to the physical and radiographic

findings present. There is an increased incidence of pneumothorax.

**B. Laboratory Findings.** The diagnosis is made by examining bronchoalveolar lavage fluid or lung biopsy specimens by one of several techniques including calcefluor white, methenamine silver, and Wright Geimsa staining as well as monoclonal antibody or molecular techniques. In the case of lung biopsy specimens, histopathologic examination is also helpful.

**C. Imaging.** Typical radiographic findings include diffuse interstitial or interstitial and alveolar infiltrates, but atypical findings may be noted.

## Treatment

*P carinii* pneumonia is treated with high doses of trimethoprim-sulfamethoxazole or intravenous pentamidine ([Box 24-2](#)). The former regimen is preferable.

## Prevention

Trimethoprim-sulfamethoxazole provides excellent prophylaxis for *P carinii* pneumonia and should be given to all transplant recipients following transplantation ([Box 24-3](#)). Prolonged prophylaxis is indicated for heart-lung and lung transplant recipients and for patients with ongoing risk factors for *P carinii* pneumonia such as multiple episodes of rejection, ongoing graft-versus-host disease, treatment with antilymphocyte therapy, or persistent allograft dysfunction. Importantly, prophylaxis should be reinstated if it has been discontinued, in patients receiving augmented immunosuppression. Alternatives to trimethoprim-sulfamethoxazole for prophylaxis include intravenous or aerosolized pentamidine, dapsone, and atovaquone. For single lung allograft recipients who cannot tolerate trimethoprim-sulfamethoxazole, there is some controversy about the use of aerosolized pentamidine that may be inadequately delivered to the remaining diseased and therefore poorly ventilated lung.

## CANDIDA SPECIES

### General Considerations

Among the *Candida* species, *C albicans* is most frequently implicated in causing infections in transplant recipients, however, *C krusei*, *C glabrata*, *C zeylanoides*, and *C tropicalis* have also been reported as pathogens and may infect any type of transplant recipient. More details are found in [Chapter 73](#).

### Clinical Findings

**A. Signs and Symptoms.** Most fungal infections caused by *Candida* spp. occur in the first 2 months after transplantation. Localized infection of the oral cavity, gastrointestinal tract, or skin may occur. Serious candidal infections after transplant can present in myriad ways including intra-abdominal abscesses (most commonly in patients having undergone abdominal surgery such as liver and pancreas transplantation), hepatosplenic candidiasis (in PBSC and bone marrow transplant recipients), pulmonary infection, urinary tract infections (including cystitis, pyelonephritis, ureteral obstruction,

and parenchymal fungal balls), esophagitis, arthritis, endocarditis, aortitis, brain abscess, and mediastinitis. Catheter-related sepsis from infection by *Candida* spp. (and rarely other fungi) is a common presentation of fungal infection in transplant recipients and, as in other populations, is associated with prolonged hospitalization, especially in intensive care units, with central venous catheters in place.

**B. Laboratory Findings.** The diagnosis of candidal infections in transplant recipients is made by obtaining fungal stains and cultures of appropriate specimens. Fine needle aspiration cytology may be useful in the diagnosis of the hepatosplenic candidiasis syndrome in PBSC and bone marrow transplant recipients as well as fungal pyelonephritis in renal transplant recipients.

## Treatment

Agents used for the treatment of serious candidal infections in transplant recipients include amphotericin B, fluconazole, ketoconazole, itraconazole and caspofungin ([Box 24-2](#)). The choice of the agent depends on the clinical presentation and typical fungal susceptibility pattern of the organism. Importantly, azole antifungal drugs may increase blood levels of cyclosporin.

## Prevention

The use of a selective bowel decontamination regimen may reduce the incidence of candidal infections in liver transplant recipients. Fluconazole has been shown to prevent both deep and superficial candidal infections, excluding those caused by *C. krusei*, in liver and PBSC and bone marrow transplant recipients ([Box 24-3](#)).

## **CRYPTOCOCCUS NEOFORMANS**

### General Considerations

Infections caused by *C. neoformans* can occur at any time after transplantation in any type of transplant recipient. More details are found in [Chapter 74](#).

### Clinical Findings

**A. Signs and Symptoms.** Cryptococcal infection may present with a subacute or occasionally more acute meningitis, pneumonia, pleural infection, cutaneous lesions, fever alone, and rarely other unusual forms of infection such as retinitis, arthritis, pyelonephritis, or fever of unknown origin (see [Chapter 18](#)). Cutaneous involvement has been described. In men, foci of cryptococcal infection within the prostate gland may be a source of hematogenous dissemination.

**B. Laboratory Findings.** The cryptococcal antigen test, performed on serum and cerebrospinal fluid (and occasionally pleural fluid), provides a sensitive and rapid means of diagnosis. In *neoformans* meningitis, cerebrospinal fluid may show a lymphocytic pleocytosis, hypoglycorrhachia, and an elevated protein level. Culture and fungal stains (including calcofluor white, India ink, and methenamine silver stains) are helpful in the diagnosis. The cryptococcal antigen test may also be used to monitor response to

therapy. Importantly, cryptococcuria, when demonstrated, is almost always indicative of systemic infection; *C neoformans* is rarely a contaminant or nonpathogenic colonizer of the urinary tract. A cerebrospinal fluid examination should be performed in any transplant recipient with unexplained fever as well as in any such patient with *C neoformans* isolated from any site.

## MYCELIAL FUNGI

### General Considerations

The *Aspergillus* spp. most frequently implicated in causing disease in transplant recipients include *A fumigatus*, *A flavus*, *A niger*, and *A terreus*. In addition, an expanding list of unusual organisms including *Pseudalleschia boydii*, *Scopulariopsis brumptii*, *Trichosporon beigelii*, *Fusarium* spp., zygomycetes, and others, have been reported as causes of serious fungal infections in transplant recipients. Most fungal infections caused by *Aspergillus* spp. occur in the first 3 months after solid-organ transplantation and are associated with a high mortality rate. In PBSC and bone marrow transplant recipients, the onset of aspergillal infections is bimodal, peaking 16 and 96 days after transplant. The portal of entry of *Aspergillus* spp. is usually the respiratory tract (lungs and sinuses). Rarely, dissemination from a primary skin lesion or contiguous spread from a previously sustained skin lesion to bone may occur. *Aspergillus* spp. may also invade the gastrointestinal tract or rarely gain entry through an intravenous catheter. More details are found in [Chapters 75](#) and [77](#).

Zygomycetes, including *Rhizopus* spp., *Mucor* spp., *Absidia* spp., and *Cunninghamella bertholletiae* have been reported as pathogens in transplant recipients. Underlying metabolic disturbances resulting in an acidotic state such as that associated with diabetic ketoacidosis or that found in pancreatic transplant recipients with a bicarbonate leak and deferoxamine therapy are risk factors for zygomycosis. Zygomycetes are associated with rhinocerebral, pulmonary, gastrointestinal, cutaneous, and disseminated infections.

Endemic dimorphic fungal infections with geographically restricted endemic mycoses (*H capsulatum*, *C immitis*, *B dermatitidis*, and *Paracoccidioides brasiliensis*) can occur at any time after transplantation. In many cases, and especially with histoplasmosis, disseminated infection is seen. For more details, see [Chapter 70](#).

### Clinical Findings

**A. Signs and Symptoms.** In patients with aspergillosis, pulmonary symptoms including nonproductive cough, pleuritic chest pain, dyspnea, and low-grade fever predominate. From the lungs, *Aspergillus* spp. may disseminate to almost any organ including the brain, liver, spleen, kidneys, heart, pericardium, blood vessels, thyroid, gastrointestinal tract, bones, and joints. Clinical manifestations of central nervous system aspergillosis include alteration of mental status, diffuse central nervous system depression, seizures, evolving cerebrovascular accidents, and headache. *Aspergillus* spp. may cause peritonitis in renal transplant recipients on continuous ambulatory peritoneal dialysis and may cause intra-abdominal abscesses in liver transplant recipients.

**B. Laboratory Findings.** One should consider all pulmonary infections in transplant recipients to be possibly caused by mycelial fungi. Positive cultures for *Aspergillus* spp. in transplant recipients should never be ignored even though the isolation of *Aspergillus* spp. from respiratory and wound specimens does not always imply disease because this fungus may be a colonizer or a laboratory contaminant. Repeated isolation of *Aspergillus* spp. from sputum is suggestive of invasive disease, and the combination of positive sputum cultures and cavitary lung disease is highly suggestive of invasive disease. Conversely, sputum cultures are not always positive for *Aspergillus* spp. in patients with invasive aspergillosis. Bronchoalveolar lavage may be more helpful in this regard. The diagnosis of extrapulmonary infection is more difficult. Any suspicious lesion (eg, skeletal or cutaneous) should be biopsied.

**C. Imaging.** Chest radiographic findings in cases of pulmonary aspergillosis include nodular opacities, interstitial infiltrates, cavitary lung disease, or a pulmonary embolus type pattern; the chest x-ray may also be normal. For more details see [Chapter 70](#).

## Treatment

Treatment of deep fungal infections in transplant recipients does not differ significantly from that in other types of immunocompromised hosts ([Box 24-2](#)). Immunosuppression should be reduced as tolerated. Surgical extirpation or debridement should be performed for diagnostic and therapeutic purposes, if appropriate. Intravenous amphotericin B has been the mainstay of treatment for deep fungal infections in transplant recipients. The combination of cyclosporin and amphotericin B has been associated with renal failure. Some organisms (eg *P boydii*) are resistant to amphotericin B, emphasizing the need for identification of all fungal isolates in transplant recipients. Lipid formulations of amphotericin B have fewer side effects, especially including nephrotoxicity, than the standard preparation, but are more costly. Because of the high frequency of toxicity seen with amphotericin B, the use of azole antifungal agents for treating select fungal infections in transplant recipients is attractive. This is discussed further in chapters dealing with specific fungal organisms.

## Prevention

Laminar air flow isolation in PBSC and bone marrow transplant units prevents aspergillal infections. Intravenous amphotericin B should be given to PBSC and bone marrow transplant recipients with a well-documented history of invasive aspergillosis pretransplant.

# MYCOBACTERIAL INFECTIONS

## *MYCOBACTERIUM TUBERCULOSIS*

### General Considerations

All types of transplant recipients are at increased risk for both primary and reactivation *M tuberculosis* infection and disseminated disease is more commonly seen in transplant recipients than in nonimmunocompromised populations. For more information, see [Chapter 61](#).

## Clinical Findings

**A. Signs and Symptoms.** Presentations of *M tuberculosis* infection after transplantation include typical cavitary pulmonary disease as well as non-cavitary pulmonary, intestinal, skeletal, cutaneous, disseminated, and central nervous system disease. *M tuberculosis* infection in transplant recipients is usually accompanied by pyrexia. *M tuberculosis* is highly contagious, and all patients with pulmonary tuberculosis should be promptly isolated.

**B. Laboratory Findings and Imaging.** The diagnosis of tuberculosis differs little in the transplant population compared to other populations.

## Treatment

See [Chapter 61](#).

## Prevention

A detailed history of tuberculosis exposure should be obtained on all transplant candidates and a tuberculin test should be performed on all solid-organ transplant candidates and on PBSC and bone marrow transplant candidates with a history of tuberculosis exposure. Isoniazid prophylaxis is recommended for patients with positive tuberculin tests or other risk factors for tuberculosis. If possible isoniazid prophylaxis should be administered for nine months pretransplantation. If this is not feasible, isoniazid can be given following transplantation. In addition, tuberculin test positive transplant recipients who have not previously received treatment or prophylaxis might benefit from isoniazid prophylaxis when they receive antilymphocyte preparations.

## NONTUBERCULOUS MYCOBACTERIA

### General Considerations

Nontuberculous mycobacteria reported as pathogens in transplant recipients include *M kansasii*, *M avium-intracellulare*, *M fortuitum*, *M xenopi*, *M haemophilum*, *M marinum*, *M chelonai*, *M abscessus*, *M gastri*, *M scrofulaceum*, *M szulgai*, and *M thermoresistibile*, among others. These infections are rare, generally occur late in the post-transplant period and are most commonly chronic, manifesting as cutaneous lesions of the extremities, tenosynovitis, and/or joint infection. Less frequently, allograft, pulmonary, or intestinal involvement may occur. For more details, see [Chapter 62](#).

## PARASITIC INFECTIONS

### INTRODUCTION

Parasitic infections in transplant recipients are generally not associated with distinctive presentations with the exception of *Trypanosoma cruzi*, *Toxoplasma gondii*, and *S stercoralis*.

## **TRYPANOSOMA CRUZI**

### **General Considerations**

In patients with *T cruzi*-associated cardiomyopathy undergoing heart transplantation, a new acute phase of Chagas' disease may develop. This is characterized by fever, cutaneous lesions (with or without parasites), and myocarditis (with or without parasites) and is responsive to specific drug therapy. Parasites have been demonstrated in the transplanted hearts of such patients, (see also [Chapter 85](#)).

## **TOXOPLASMA GONDII**

### **General Considerations**

Toxoplasmosis after transplantation is usually the result of reactivation of latent donor-derived disease in *T gondii* seronegative heart transplant recipients. This typically occurs in the seropositive donor heart because of a predilection of the parasite to invade muscle tissues. Rarely, *T gondii* infection may be seen in other types of transplant recipients. Most cases occur within 2 months post-transplantation although cases have been reported between 1 day and 7 years after transplantation. For more details, see [Chapter 81](#).

### **Clinical Findings**

**A. Signs and Symptoms.** Clinical presentations include meningoencephalitis, brain abscess, pneumonia, myocarditis, pericarditis, hepatitis, and choreoretinitis.

**B. Laboratory Findings.** The diagnosis is made with certainty only by histopathologic demonstration of trophozoites with surrounding inflammation in tissue. Biopsy specimens may be stained with Wright-Geimsa or periodic acid-Schiff stains or with specific antibodies. Pulmonary organisms may be detected in bronchoalveolar lavage samples; the diagnosis of cardiac disease typically requires multiple cardiac biopsy specimens. Serologic testing is not very useful; however, a positive IgM titer or a fourfold rise in IgG titer supports the diagnosis of toxoplasmosis. Elevations of antibody levels in cerebrospinal fluid or vitreous fluid relative to those in peripheral blood are also indicative of infection in these sites. Antigen detection and molecular techniques are being developed and may be useful.

### **Treatment**

Toxoplasmosis is treated with pyrimethamine with folinic acid and either sulfadiazine or clindamycin ([Box 24-2](#)).

### **Prevention**

Toxoplasmosis is generally prevented by the same doses of trimethoprim-sulfamethoxazole used for *P carinii* prophylaxis ([Box 24-3](#)). An alternative is pyrimethamine.

## **STRONGYLOIDES STERCORALIS**

### **General Considerations**

*S stercoralis* is the one helminth that deserves special mention as concerns transplant recipients (see also [Chapter 86](#)).

### **Clinical Findings**

**A. Signs and Symptoms.** There have been reports of hyperinfection syndromes with *S stercoralis* after transplantation. This may result in gastrointestinal and pulmonary symptoms including tachypnea, dyspnea, cough, and hemoptysis. Enterocolitis and widespread dissemination of larvae to extraintestinal organs (eg heart, lung, central nervous system, and skin) may occur and larvae may entrain gram-negative bacilli resulting in gram-negative bacteremia and occasionally meningitis.

**B. Laboratory Findings.** The diagnosis may be made by examining stool specimens for rhabditiform larvae; several stool specimens should be examined since the yield of a single stool examination is only ~27%. Other means of diagnosis include duodenal aspirate, urine, ascitic fluid, wound and sputum examination, jejunal biopsy, culture, and serologic testing. Eosinophilia may be present.

**C. Imaging.** Alveolar or interstitial infiltrates may be seen on chest x-ray.

### **Treatment**

Thiabendazole or ivermectin is used to treat strongyloidiasis ([Box 24-2](#)).

### **Prevention**

As noted in the discussion on the pretransplantation evaluation, patients who have traveled to or resided in an area of endemic infection should be examined for evidence of infection with this parasite pretransplantation.

### **Differential Diagnosis in Transplant Recipients**

The main differential diagnosis of infections in transplant recipients is rejection. Drug toxicity must also be considered.

### **Prevention of Infections in Transplant Recipients**

**A. Vaccinations.** Vaccinations as outlined in [Box 24-3](#) should be administered prior to solid-organ transplantation. Live vaccines should generally be avoided. However, for the nonimmune solid-organ transplant candidate with a high likelihood of exposure to measles, consideration may be given to the administration of the measles vaccine prior to transplant (studies are required to document the safety of this approach). Similarly, the MMR vaccine is recommended ([Box 24-3](#)) following PBSC and bone marrow transplantation. A recent study has demonstrated the safety of the varicella vaccine in pediatric renal transplant recipients and consideration may be given to immunization of

solid-organ transplant candidates with no history of chickenpox. Immunization with live vaccines (eg measles vaccine, varicella vaccine), if performed, should be done as early as possible prior to solid-organ transplantation. All solid-organ transplant recipients should receive influenza vaccinations yearly and pneumococcal vaccine should be administered every 5-6 years, although the immune response to these vaccines may be impaired in transplant recipients.

For PBSC and bone marrow transplant recipients, vaccinations are administered following transplantation ([Box 24-3](#)).

**B. Avoidance of Epidemiologic Exposures Post-transplantation.** After transplantation, patients should be again counseled regarding measures aimed at reducing infections. Patients who are not immune to VZV should be counseled to avoid exposure to persons with chickenpox or shingles. If such an exposure does occur, a physician should be contacted immediately. All fresh fruits and vegetables should be washed. All meat and seafood should be cooked thoroughly. The source of the patient's drinking water should be reviewed. Patients with cats should avoid changing litter boxes if possible. (If changing the litter box is unavoidable, gloves should be worn and the litter box should be changed daily.) Gloves should be worn to clean fish aquaria. A mask should be worn when cleaning bird cages (if this activity is unavoidable). Patients should avoid contact with people who have colds, influenza, tuberculosis, and other contagious infections. Towels should not be shared with others unless they are washed between uses. Any plans for travel outside the United States, Canada, or western Europe should be discussed with the patient's physician before departure. All persons living in the same quarters as the patient should receive a yearly influenza vaccine, and inactivated (rather than oral) polio vaccine should be administered to those requiring polio vaccination.

**C. Donor-Related Transmission of Infectious Agents.** All potential organ and PBSC and bone marrow donors should be evaluated for any latent or active infection. Serologic studies of the donors should include tests for HIV-1, HIV-2, HBV, HCV, syphilis, CMV, and in many cases, *T gondii* and EBV.

Essentials of Diagnosis
-

**Table 24-1.** Clues to the diagnosis of infections in transplant recipients.

### **History**

- Immunosuppressive therapy: type and duration (current or past)

- Antibiotic allergies

- Past medical history: infectious diseases

Oral: dental caries, sinusitis, pharyngitis, herpes

Respiratory: pneumonia, tuberculosis

Cardiovascular: valvular heart disease, heart murmur (need for endocarditis prophylaxis)

Gastrointestinal: diverticulitis, diarrheal disease, hepatitis A, B, and C, intestinal parasitic infection

Genitourinary: urinary tract infections, prostatitis, vaginitis, genital herpes, genital warts, syphilis, gonorrhea, pelvic inflammatory disease, chlamydial infection

Cutaneous: skin and nail infections, varicella zoster virus infection

Osteoarticular: osteomyelitis; prosthetic joint(s)

Childhood illnesses: chickenpox, measles, rubella

Other: mononucleosis

- Vaccinations

### **Exposure History**

- Travel history: prior residence, travel, or both associated with the geographically restricted endemic mycoses, and/or parasitic disease, especially *Strongyloides stercoralis*, malaria, etc.

- Tuberculosis: exposure, prior tuberculous skin testing, chest x-ray abnormality

- Risk factors for bloodborne pathogen infection [including human immunodeficiency virus (HIV)]

- Animal and pet exposure (including vaccination status of pets)

- *Brucella* exposure

- Occupational exposure: farming, animal husbandry, gardening

- Drinking water source

- Exposure to young children

- Dietary habits: consumption of raw meat and seafood and unpasteurized milk products

### **Complete Review of Systems**

### **Complete Physical Examination**

## Laboratory Testing

- Pretransplantation:

Tuberculin skin test

Chest and sinus x-ray

Urinalysis and urine culture for bacteria

Serologic tests: cytomegalovirus, varicella zoster virus, Epstein-Barr virus, herpes simplex virus,\* *Toxoplasma gondii*,\*\* syphilis, hepatitis A virus, hepatitis B virus, hepatitis C virus, HIV, (*coccidioides immitis* if history of exposure present—see text)

- Post-transplantation:

Cultures and stains for bacteria, viruses, fungi, mycobacteria, etc, as indicated

Serologic testing as indicated

\*\*Heart transplant candidate

\*Optional

**Prophylactic Measures**

Pretransplant infectious disease evaluation

See Table 24-1

Vaccinations (administered following PBSC and bone marrow transplantations)

- Tetanus-diphtheria (12, 14 and 24 months post-transplant)
- Influenza (annual, lifelong, before transplant and 6-12 months post-transplant)
- Pneumococcus (23-valent, 12 and 24 months post-transplant)
- Hepatitis B (12, 14 and 24 months post-transplant)
- *Haemophilus influenzae* type B (12, 14 and 24 months post-transplant)
- Polio (inactivated) (12, 14 and 24 months post-transplant)
- MMR (live-attenuated, =24 months post-transplant and 2nd dose 6-12 months post-transplant)

Vaccinations (administered prior to solid-organ transplantation)

- Varicella zoster virus for non-immunocompetent organ transplant candidates (see Table 24-1 for cautions)
- Tetanus-diphtheria (booster, on schedule series as appropriate)
- Pneumococcus (23-valent)
- Hepatitis A virus (series, if non-immunocompetent)
- Hepatitis B virus (series, if non-immunocompetent)
- Influenza (annual, lifelong)

Cytomegalovirus prophylaxis

- Ganciclovir (1 g orally 3 times daily or 5 mg/kg IV daily to twice daily)
- Valacyclovir (2 g orally 4 times daily)
- Immune globulin (various regimens)
- Acyclovir (800 mg orally 4-5 times daily or 5 mg/kg IV 3 times daily)
- Protective matching
- CMV seronegative, filtered, or irradiated blood products

Herpes simplex virus stomatitis prophylaxis

- Acyclovir (200 mg orally 3 times daily or 5 mg/kg IV 2 times daily)
- Valacyclovir (500 mg orally daily)

Varicella zoster virus prophylaxis

- Immune globulin and/or acyclovir if exposed to varicella
- Vaccination (see above)

	<i>Pneumocystis carinii</i> prophylaxis	<ul style="list-style-type: none"> <li>• Trimethoprim-sulfamethoxazole (one 800 mg/160 mg double strength tablet daily or 1 double strength tablet every day or 1 double strength tablet twice daily on 2 days of the week)</li> <li>• Pentamidine (300 mg nebulized daily)</li> <li>• Atovaquone (1500 mg orally daily)</li> <li>• Dapsone (50 mg orally twice daily)</li> </ul>
	<i>Toxoplasma gondii</i> prophylaxis	<ul style="list-style-type: none"> <li>• Trimethoprim-sulfamethoxazole (same as for <i>P carinii</i> dosages)</li> <li>• Pyrimethamine (25 mg orally daily)</li> <li>• Quinolone (various regimens)</li> </ul>
	Bacterial infection prophylaxis (PBSC and bone marrow transplant recipients)	
	Fungal infection prophylaxis (PBSC and bone marrow and select solid organ transplant recipients)	<ul style="list-style-type: none"> <li>• Fluconazole (400 mg orally or 150 mg IV daily)</li> </ul>
	<i>Mycobacterium tuberculosis</i> infection prophylaxis	<ul style="list-style-type: none"> <li>• Isoniazid (300 mg orally daily)</li> </ul>
<b>Isolation Precautions</b>	Avoidance of epidemiologic exposures post-transplantation	<ul style="list-style-type: none"> <li>• See text</li> </ul>
	<i>Mycobacterium tuberculosis</i>	<ul style="list-style-type: none"> <li>• Airborne isolation</li> </ul>
	Varicella zoster virus infection	<ul style="list-style-type: none"> <li>• Avoid contact if VZV nonimmunized</li> </ul>
	Cytomegalovirus infection	<ul style="list-style-type: none"> <li>• Universal precautions</li> </ul>

<sup>1</sup>May also prevent nocardiosis, toxoplasmosis, and some bacterial infections.

## **25 . Patients With Neutropenia & Fever — *David Dockrell, MD & Linda L. Lewis, MD***

### **Essentials of Diagnosis**

- Patients with a polymorphonuclear count of  $< 500/\text{mm}^3$  or between 500 and  $1000/\text{mm}^3$ , and is rapidly falling, are at greatest risk of infection.
- Underlying conditions, risk factors, and duration of neutropenia.
- Physical findings that suggest specific microbial etiology of fever with attention to possible foci of infection (eg, the mouth, lungs, perirectal area, etc).
- Cultures of blood or tissue that yield bacteria, fungus, or virus.

### **General Considerations**

**A. Epidemiology.** The characteristics of patients who develop neutropenic fever have changed over the past 30 years. Neutropenic fever was reported initially in patients treated with chemotherapy for acute leukemia. Current chemotherapeutic regimens are more potent and induce greater myelosuppression. The increasing prevalence of bone marrow transplantation has also altered the host profile at risk of neutropenic fever. Patients with AIDS, aplastic anemia, congenital deficiencies, and Felty's syndrome are also at risk of developing neutropenia.

The extent and duration of neutropenia are critically important in determining the risk of infection in the patient with febrile neutropenia. For example, patients who undergo bone marrow transplantation are at particular risk because of the extent and duration of neutropenia. Similarly, chemotherapeutic agents such as cytosine arabinoside, which induce prolonged neutropenia, are associated with a greater risk of infection.

Alterations to other aspects of host immunity are also critical. Bone marrow transplantation induces neutropenia as well as defects in T-cell and B-cell function, altering the spectrum of pathogens causing febrile episodes. The administration of glucocorticoids modifies the existing immunodeficiency in patients with cancer or other diseases. The underlying diagnosis may modify the immunosuppression as may occur in patients with Hodgkin's disease who may have underlying T-cell dysfunction, and in patients with HIV-associated neutropenia.

Disruption of the host's normal mechanical barriers further facilitates infection. Indwelling intravenous catheters are a common source of infectious complications. Mucositis induced by chemotherapy allows bacteremia with the normal flora of the mouth and gut. Patients treated with prolonged antibacterial therapy become colonized with fungi, and mucositis allows these organisms to cause invasive disease. This may explain the observation that patients who are neutropenic because of chemotherapy are at greater risk for invasive mycoses than patients with HIV-associated neutropenia.

Some diseases may be associated with a lower incidence of infection or an increased susceptibility to particular infecting organisms while the patient is neutropenic. For example, patients with aplastic anemia may have a low risk of bacterial infection but are at particular risk of *Aspergillus* infections.

**B. Microbiology.** Over the last 25 years, changes have occurred in the pathogens that cause documented infection in febrile neutropenic patients. These reflect changes induced by altered host factors and changes in the manner in which antimicrobial therapy is administered to these patients. [Box 25-1](#) lists characteristic pathogens currently encountered in cases of neutropenic fever. Traditionally, gram-negative bacteria were the predominant causes of neutropenic fever, and *Pseudomonas aeruginosa*, in particular, was a common pathogen. Over the years, the spectrum of infectious pathogens has changed and gram-positive infections have increased, accounting for 63% of isolated bacterial pathogens in a recent National Cancer Institute survey. Reasons for this increase include the use of indwelling intravenous catheters and empirical antimicrobial regimens, which are less effective at preventing gram-positive infections than gram-negative infections. The commonest organisms responsible for infections associated with indwelling intravenous catheter use are coagulase-negative staphylococci, *S aureus*, and viridans group streptococci. Other organisms, such as *P aeruginosa*, *Acinetobacter* spp., *Bacillus* spp., *Corynebacterium* spp., *Candida* spp., and *Malassezia furfur*, are also encountered.

Staphylococcal, streptococcal, and enterococcal infections are increasing in frequency. Management of these infections is complicated by increasing methicillin resistance among staphylococci and multidrug resistance among enterococci. Streptococcal infections, including infections with *S mitis* and viridans group streptococci, are associated with oral mucositis and with ciprofloxacin prophylaxis. Fungal infections are increasing at many centers and include *C albicans*, non-*albicans Candida* spp. such as *C tropicalis*, *C kruzei*, and *Torulopsis glabrata*, and filamentous fungi (*Aspergillus* spp., *Mucor*, *Fusarium*, and *Pseudoallescheria boydii*). Filamentous fungi are increasingly recognized in association with prolonged neutropenia resulting in respiratory tract or disseminated infection.

Gram-negative infections are still encountered, but the spectrum of pathogens has changed. *P aeruginosa*, once a frequent pathogen in patients with neutropenic fever, has dramatically decreased in incidence for unclear reasons and has been reported to occur in just 1% of cases enrolled in National Institutes of Health treatment protocols in neutropenic populations. It remains a significant pathogen in some subpopulations, such as children with HIV infection. *Escherichia coli* and *K pneumoniae* are the most frequently isolated gram-negative bacteria, but the emergence of antibiotic-resistant *Enterobacter* spp., *Serratia marcescens*, *Stenotrophomonas maltophilia*, or *Acinetobacter* spp. has become an increasing problem. Other pathogens encountered include *Corynebacterium jeikeium* and *Bacillus* spp. that cause intravenous catheter-associated infections; rapidly growing mycobacteria that cause exit-site or tunnel infections associated with intravenous catheters; *Legionella* spp. that cause nosocomial pneumonia; infection with *Nocardia* spp.; *P carinii* pneumonia; *Clostridium septicum* septicemia; *C difficile* colitis; herpes virus infections, particularly cytomegalovirus in bone marrow transplant recipients; histoplasmosis, blastomycosis, or coccidioidomycosis that cause pneumonia or disseminated infection in endemic areas;

cryptococcal infections; and, occasionally, parasitic infections such as *Strongyloides stercoralis* or *Toxoplasma gondii*.

An identifiable pathogen is documented in ~ 30%-50% of cases of neutropenic fever, which represents a decrease in the number of documented infections causing neutropenic fever as compared with the number documented 20-30 years ago.

## Clinical Findings

The absence of neutrophils and, consequently, signs of inflammation creates a unique challenge for the clinician attempting to determine the cause of neutropenic fever. Although up to 90% of patients become febrile during neutropenia, in most cases, fever is the only sign of infection. This necessitates a thorough history with identification of risk factors for particular types of infection. The history of the underlying illness, its therapy, duration of neutropenia, prophylactic antibiotics administered, previous infections causing neutropenic fever and their treatment, travel and exposure history, thorough knowledge of the most frequent pathogens causing neutropenic fever at the institution and their antimicrobial susceptibilities, and inquiry about specific symptoms and review of systems should be carefully ascertained. A thorough history can help direct the physical examination and subsequent laboratory testing (see [Table 25-1](#)). In many cases, no specific clues are identified, and empirical treatment will be initiated without identification of a specific infectious syndrome to explain fever.

**A. Signs and Symptoms.** The physical examination of patients with neutropenic fever should be thorough and repeated at regular intervals because the clinical status of these patients can change rapidly. The head and neck should be carefully examined. Mucositis, gingivostomatitis, or dental disease should be documented and are clues to infection with viridans group streptococci or anaerobes; sinus tenderness and nasal eschar may suggest fungal sinusitis, especially *Mucor* or *Aspergillus*. The skin should be examined carefully for nodules, which may be found with *Candida* occasionally ([Figure 25-1](#)).

Evidence of ecthyma gangrenosum, which is classically associated with *P aeruginosa* infection but has also been associated with *E coli* bacteremia or candidemia, should be sought. These lesions are small, round, indurated nodules that appear initially as vesicles, become hemorrhagic, and then ulcerate. They are most often located in the perirectal or perivaginal area. Ecthyma gangrenosum must be distinguished from the black, necrotic lesions that may range in size from a centimeter or less to many centimeters and that are most often caused by *Mucor* spp. or dematiaceous fungi. These lesions may be located in any body area. Lesions around the face or within the mouth are often caused by members of the genus *Mucor*, whereas lesions on the extremities or trunk may be caused by dematiaceous fungi or *Mucor* spp. Areas of cellulitis should be searched for, especially in the perirectal area, and infection may be caused by *Pseudomonas* spp. or other gram-negative bacteria. The perianal area should be inspected but a rectal exam avoided because it may induce bacteremia. All sites of indwelling catheters should be inspected and subcutaneous tunnels examined for areas of fluctuance or tenderness. The lungs should be examined for evidence of pneumonitis, and the abdomen palpated for signs of typhlitis (inflammation involving the cecum, seen especially in children with acute lymphocytic leukemia).

**B. Laboratory Findings.** At least two blood cultures should be performed initially. If an indwelling venous catheter is in place, blood for cultures should be obtained through the catheter (all lumens) and peripherally. Only 10-20% of patients with neutropenic fever have documented bacteremia or fungemia.

Techniques such as shell vial for virus or polymerase chain reaction analyses have application in special settings, such as the detection of cytomegalovirus infections after bone marrow transplantation. In addition, an aspirate or biopsy should be obtained from any suspected focus of infection identified by exam and diagnostic imaging. For example, a bronchoalveolar lavage should be considered on any patient with respiratory symptoms or abnormal results from chest radiography. An open-lung biopsy may be necessary in patients who have progressive pulmonary disease without previous diagnosis and who have not responded to empiric therapy.

Specimens should be stained and cultured for bacteria, including anaerobes, and for fungi, mycobacteria, and, in selected patients, viruses. Cryptococcal antigen tests on serum or spinal fluid should be performed in selected patients. Fungal serologies for *Histoplasma* spp., *Coccidioides* spp., or *Blastomyces* spp. should be performed in patients who reside in or have traveled to endemic areas.

Stool samples should be sent for *C difficile* toxin assay for patients with unexplained diarrhea, as pseudomembranous colitis secondary to *C difficile* toxin often complicates the use of antimicrobial agents in patients with neutropenic fever. Other causes of diarrhea in febrile neutropenic patients include neutropenic colitis, enteric pathogens, cytomegalovirus, and parasitic infection. Disseminated strongyloidiasis should be suspected in patients who travel to or reside in endemic areas. If the cause of diarrhea is not established quickly by tests such as *C difficile* toxin assay, stool culture, and examination for parasites, colonoscopy may be necessary to detect cytomegalovirus or neutropenic colitis. Surveillance cultures of the stool are not useful.

**C. Imaging.** A chest radiograph should always be performed on every patient at regular intervals, although the absence of neutrophils often means there is no demonstrable abnormality. Patchy infiltrates may be detected and early in the course of neutropenia often correspond to bacterial infections. If such infiltrates occur in a patient with a longer history of neutropenia, fungal infection becomes an increasingly more likely cause. *Aspergillus* spp. are particularly likely in those with new infiltrates despite antibiotic therapy ([Figure 25-2](#)) and with pleural-based nodules, cavitary lesions, or masses with an area of hyperlucency referred to as a halo sign. In these patients, a bronchoalveolar lavage followed by open biopsy is recommended if bronchoalveolar lavage is nondiagnostic.

Other potential pathogens that present with patchy infiltrates include *Legionella pneumophila*, *Nocardia asteroides* (which is either localized or a diffuse miliary infiltrate), rarely mycobacteria, and in endemic areas *Histoplasma capsulatum*, *Coccidioides immitis*, or *Blastomyces dermatitidis*. Diffuse infiltrates can be seen in infections caused by *Legionella* spp., *Pneumocystis carinii*, viruses (especially cytomegalovirus), and parasitic infection.

Computed tomography or magnetic resonance scanning may be useful if head and neck or abdominal/perirectal infection is suspected. The diagnostic utility of nuclear imaging in the evaluation of neutropenic fever has not been established. Abdominal pain and fever associated with an elevation of hepatic enzymes coinciding with the recovery of the neutrophil count is suggestive of hepatosplenic candidiasis ([Figure 25-3](#)). Computed tomography or ultrasound of the liver and spleen reveals bull's eye lesions, and diagnosis is confirmed by finding pseudohyphae and granulomata upon computed tomography or ultrasound-guided needle biopsy.

## Differential Diagnosis

Although only 30-50% of patients with neutropenic fever have documented infections, it is assumed that many of the remainder have occult infection. However, there may be other causes of a febrile episode or of a particular symptom or sign attributed to infection. Numerous tumors can give rise to fever. This has been noted in Hodgkin's lymphoma, non-Hodgkin's lymphoma, and other solid tumors characterized by necrosis. Drugs, including numerous antibiotics used in the management of neutropenic fever, have been reported to cause fever, but this occurs infrequently. Although chemotherapeutic agents like cytosine arabinoside, bleomycin, and 2-CDA are associated with fever, the fever is usually transient and occurs long before the subsequent development of neutropenia. Use of G-CSF or GM-CSF may also cause fever. Drugs that may mask fever, such as corticosteroids, acetaminophen, and nonsteroidal anti-inflammatory drugs, may also be considered when evaluating neutropenic fever. The administration of blood products and, especially, amphotericin B is a common cause of transient increases in temperature associated with the infusion and should be considered in the differential diagnosis. Finally, patients with cancer are at increased risk of deep venous thrombosis and subsequent pulmonary emboli, which are associated with hypoxia and fever.

The signs and symptoms associated with neutropenic fever may have alternative explanations. Chest radiograph abnormalities and hypoxemia may be caused by noninfectious conditions such as tumor, pulmonary complications of chemotherapeutic agents such as bleomycin or cyclophosphamide, pulmonary emboli, pulmonary edema, radiotherapy, transfusion-related acute lung injury, pulmonary hemorrhage, or transient hypoxemia associated with neutrophil recovery and migration into the lung associated with GM-CSF therapy. Diarrhea may be the result of chemotherapy or use of antibiotics. Skin rashes can be caused by drugs. A rare cause of fever with nodular skin rash, sometimes including vesicles, pustules, or bullae, is Sweet's syndrome (acute febrile neutrophilic dermatosis), which may be associated with acute myelogenous leukemia.

## Complications

Superinfection is a recognized complication of febrile neutropenia in patients receiving antimicrobial agents. It is usually defined as the development of documented infection during or < 1 week after the discontinuation of antimicrobial therapy. Superinfection occurs in = 20% of cancer patients with neutropenic fever. Fungi account for 25-67% of superinfections. Risk factors for superinfection include a longer duration of profound neutropenia (< 100 neutrophils/mm<sup>3</sup>), persistence of fever after 3 days of therapy, and presence of a central venous catheter.

## Treatment

The initiation of empirical antibiotic therapy for any febrile neutropenic patient with a single oral temperature elevation  $> 38.5^{\circ}\text{C}$  or three or more oral temperatures recorded at  $> 38.0^{\circ}\text{C}$  within 24 h has become the standard of care. Even though many patients have no demonstrable infection, it is assumed that most have occult infection. The rapidity with which these patients' clinical status can deteriorate during infectious episodes and the demonstration that empirical therapy decreases mortality have supported the use of empirical therapy for neutropenic fever.

The selection of empirical therapy should be influenced by the epidemiological and pathogenic concerns mentioned. Its design should consider the predominant microorganisms encountered at a given center, their expected susceptibility patterns, and the clinical features and laboratory test results.

The initial empiric regimen should include an antimicrobial agent or combination of drugs with a broad spectrum of coverage against gram-positive and gram-negative bacteria. This regimen should be modified if fever persists or recurs while on treatment. Initial anaerobic coverage is not usually required but should be included in cases with marked oral mucositis or documented bowel or perirectal involvement. Initial empiric antifungal therapy is not necessary but should be added for treatment failure or in cases with signs or symptoms suggestive of fungal infection in association with prolonged neutropenia.

The initial regimen is intended to treat the cause of fever, as well as to prevent subsequent episodes. The selection of an empiric regimen should consider its efficacy as well as its cost, toxicity, and potential to increase antibiotic resistance and superinfection. Because of the emergence of vancomycin-resistant enterococci, many clinicians no longer include vancomycin in initial empiric therapeutic regimens.

[Box 25-2](#) outlines possible empirical regimens. A  $\beta$ -lactam, either alone or in combination with an aminoglycoside or a fluoroquinolone, is often used. The  $\beta$ -lactam used most often is ceftazidime because of its activity against *P aeruginosa* and other such gram-negative bacteria as the *Enterobacteriaceae*. The new fourth-generation cephalosporin, cefepime, may be useful, because of its ability to remain bactericidal against *Enterobacteriaceae* that have developed resistance to ceftazidime as well as its improved gram-positive coverage compared with that of ceftazidime. The choice of an aminoglycoside (gentamicin, tobramycin, or amikacin) is dictated by local resistance patterns and cost. The administration of two  $\beta$ -lactam antibiotics concurrently should be avoided.

An acceptable alternative to combination therapy is monotherapy with ceftazidime, cefepime, piperacillin-tazobactam, or a carbapenem such as imipenem-cilastin or meropenem. The main concern with ceftazidime, but not cefepime, monotherapy is its poor gram-positive coverage and the emergence of resistance in some gram-negative organisms. For these reasons, centers with high rates of gram-positive infections or infections by *Serratia marcescens*, *Enterobacter* spp., or *Citrobacter freundii* should avoid ceftazidime monotherapy.

Clinical trials have shown imipenem-cilastin or meropenem to be equivalent to ceftazidime-containing regimens. Carbapenems are more active against gram-positive and most gram-negative microorganisms, compared with ceftazidime. Imipenem-cilastin therapy may cause seizures in some patients, whereas meropenem has a low risk of associated seizures. Piperacillin-tazobactam monotherapy is also effective empiric therapy for febrile neutropenia patients. Like cefepime and the carbapenems, piperacillin-tazobactam has a broad spectrum of activity against gram-positive and gram-negative microorganisms. Among these regimens, only the carbapenems and piperacillin-tazobactam have activity against anaerobes. If the clinical suspicion of anaerobic infection is high, metronidazole should be added to therapy with either ceftazidime or cefepime. In  $\beta$ -lactam-allergic patients, a combination of ciprofloxacin or aztreonam, together with either clindamycin or vancomycin is appropriate.

Apart from its use in some penicillin-allergic patients and in centers with high incidences of coagulase-negative staphylococci or methicillin-resistant *S aureus*, vancomycin is usually not included in the initial therapeutic regimen because of concerns about the emergence of vancomycin resistance. Studies conducted in the early 1980s suggested that empiric therapy with vancomycin-containing regimens was more effective than therapy that did not include vancomycin. More recent studies showed that patients are not adversely affected by a policy of withholding vancomycin use until there is clinical or microbiological evidence that it is required. Vancomycin therapy may be added in patients with an indwelling intravenous catheter who remain febrile after 3 days of empirical treatment with no other obvious source of infection.

Some patients with febrile neutropenia have a low mortality risk (3%) from infection. Their profiles include the development of neutropenic fever while a clinically stable outpatient; the presence of a tumor responsive to chemotherapy; and the absence of any current comorbidity. These patients account for ~ 40% of patients with febrile neutropenia. Strategies being evaluated for the management of these patients include (a) 48 h of intravenous antibiotics followed by oral antibiotics, (b) parenteral antibiotics administered as an outpatient, or (c) oral antibiotics. A recent randomized clinical trial conducted in carefully selected low-risk patients confirmed that oral antibiotics are as effective as intravenous antibiotics in the hospital setting. Whether this conclusion is generalizable to the outpatient population remains to be determined.

Ciprofloxacin has a special place in the management of low-risk adult patients as described above. While it can be used parenterally, its special advantage is that it is an effective oral agent against *P aeruginosa* and other gram-negative bacteria. Because of its limited gram-positive coverage, however, it should be combined with either amoxicillin-clavulanate or clindamycin. Alternatively, the improved gram-positive spectrum of levofloxacin may make it useful in this setting.

Approximately 66% of patients can be maintained on their empirical regimen throughout the period of neutropenia. The remainder may require modification because of the results of cultures or other tests or because of recurrent or persistent fever.

If microbiological tests identify a specific organism, empiric therapy may be modified if necessary; however, patients should continue to receive broad-spectrum antibiotic

coverage throughout the period of neutropenia. The isolation of a gram-positive organism before or during therapy may require the addition of vancomycin or anti-staphylococcal penicillin. If a gram-negative organism is isolated before the initiation of therapy in a patient who has subsequently defervesced, the initial regimen may not need to be modified. However, if a gram-negative organism is isolated from a sample collected after treatment has been initiated, antimicrobial resistance or superinfection should be suspected, and modification of the gram-negative coverage is warranted.

In patients who remain febrile after 5 days of empiric antimicrobial therapy, antifungal therapy should be added. Fungal infections are associated with prolonged periods of neutropenia. Fungi are difficult to recover ante mortem but are a frequent finding at post mortem in patients who died with neutropenic fever. Once fungal infections disseminate, there is a high associated mortality. Amphotericin B (0.5-0.6 mg/kg/d) is the empiric therapy of choice. Amphotericin-lipid complex formulations have lower nephrotoxicity than amphotericin but have not been shown to be more effective and are much more expensive. Although fluconazole or itraconazole may be equivalent to amphotericin B in managing non-neutropenic patients with candidemia, the role of empiric imidazole therapy in febrile neutropenic patients is not established. Fluconazole resistance is increasing among *Candida* spp.; *C. krusei*, *C. tropicalis*, *Torulopsis glabrata*, and non-*albicans* species are usually resistant. *Aspergillus* infections usually require higher daily doses of amphotericin B (1.0-1.5 mg/kg/d). Hepatosplenic candidiasis usually requires prolonged amphotericin B treatment with total doses of 3-5 g. Some patients receiving empirical amphotericin may develop breakthrough candidiasis. This may be owing to infection with resistant strains of *Candida* or, more commonly, by infection associated with intravascular catheters.

Broad-spectrum antimicrobial therapy should be continued until after recovery from neutropenia. Such therapy results in less relapse of fever than treatment for a 7- to 10-day period. If the period of neutropenia ends shortly after the initiation of antibiotics, therapy should continue for a 7- to 10-day course.

Intravascular catheter infections are usually treated with antibiotics rotated through each port or lumen. As many of the organisms causing these infections are indolent, initial attempts are made to treat without removing the catheter. A catheter should be removed if (a) blood cultures remain positive 48 h after the commencement of antibiotics, (b) *Candida* or *Bacillus* infections are present, or (c) exit-site infections, caused by *A. flavus* or mycobacteria, or tunnel infections are present (indicated by tenderness or induration along the subcutaneous track of the catheter).

The hematopoietic growth factors G-CSF and GM-CSF are emerging as important adjuvants to the management of neutropenic fever. By increasing the proliferation and differentiation of bone marrow progenitor cells, they help restore neutrophil and macrophage function. These agents have been demonstrated to reduce the period of neutropenia, shorten the period of hospitalization, and decrease the incidence of bacteremia. However, they have not been consistently demonstrated to decrease overall mortality. These agents should be considered in patients whose expected duration of neutropenia is > 1 week. Side effects of these agents include fever, rash, hypoxia, bone pain, and fluid retention. Various cytokines are being investigated as

adjuvants to antimicrobial therapy in the management of neutropenic fever.

## Prognosis

The outcome of neutropenic fever can be defined in terms of microbiologic response and clinical outcome and is related to recovery from neutropenia. Among patients with documented bacterial infections, treatment with ceftazidime or cefepime monotherapy, cephalosporin-aminoglycoside combinations, piperacillin-tazobactam, or carbapenem monotherapy have been associated with microbiologic cure rates > 90%. Fungal microbiological response rates are much lower.

Clinical response rates are often defined in terms of resolution of fever after 4 days of treatment, need to alter initial empirical antimicrobial agents, and survival. Overall  $\beta$ -lactam monotherapy has been associated with resolution of fever after 4 days of therapy in ~ 60%, need for subsequent antimicrobial-agent modification in ~ 60%, and overall survival of 90-98%. The mortality rate associated with documented bacterial causes of neutropenic fever has fallen from 90% in the 1950s to <10% in the 1990s.

Fungal and vancomycin-resistant enterococcal infections are associated with a higher mortality—> 50%. The incidence of superinfection is between 20% and 25%, and their mortality is > 50%. The ultimate prognosis for most patients is closely linked to their underlying malignancy. For example, in an analysis of hepatosplenic candidiasis, the prognosis of the underlying leukemia was the most important determinant of outcome.

## Prevention & Control

Several strategies have been used to decrease the incidence of neutropenic fever. Trials of antibiotic prophylaxis have had mixed results. Initial trials using trimethoprim-sulfamethoxazole showed some promise, but the emergence of resistance limited its use. In trials, ciprofloxacin therapy reduced the risk of gram-negative infections but not gram-positive infections and did not decrease fever-related morbidity or infection-related mortality. Concerns about the emergence of resistance to this agent have led many authorities to recommend that ciprofloxacin prophylaxis be limited to groups whose length of neutropenia places them at a particularly high risk of infectious complication (eg, bone marrow transplant patients).

Antifungal prophylaxis with fluconazole decreases the incidence of infections by susceptible *Candida* spp. but is also associated with the emergence of resistant *Candida* spp. Oral bowel decontamination regimens have been studied, but they are not palatable and are minimally effective. *Pneumocystis carinii* prophylaxis with trimethoprim-sulfamethoxazole is effective and recommended for febrile-neutropenia patients receiving high doses of glucocorticoids.

Environmental measures should be taken to lessen the incidence of infection in patients who are neutropenic. Simple isolation with careful hand washing has been demonstrated to be as efficacious as and more practical than reverse isolation. The use of a total protective environment with constant positive airflow and vigorous surface decontamination does not merit the extra expense. Despite decreasing the number of infections, no clear survival benefit has been proven.

Some authorities recommend a cooked diet to avoid the acquisition of organisms in uncooked food. Spices such as freshly ground black pepper are best avoided because of potential contamination by fungal spores. Similarly, potted plants should not be part of the patient's environment because of associated fungal spores and bacteria found in the soil. Environmental sources contribute to fungal colonization. Construction work in or around a hospital will significantly increase the number of *Aspergillus* spores in the air. In centers where this is a problem, high-efficiency particulate air filters may be helpful. Similarly, water purification systems will decrease the risk of nosocomial *Legionella* infections.

**Table 25-1.** Assessment of patients with neutropenia.

Assessment	Comments
<b>Physical Examination:</b>	
Skin rashes	Lesions may suggest bacteremia or candidemia
Ecthyma gangrenosum	Consider <i>P aeruginosa</i> but rarely <i>E coli</i> or <i>Candida</i> spp.
Black eschar	Fungi, especially <i>Aspergillus</i> or <i>Mucor</i>
Inspection of all intravascular devices	Potential site of infection (inspect in particular for tunnel or exit-site infections); bacteria include coagulase-negative staphylococci, <i>S aureus</i> , occasional gram-negative bacteria; fungi ( <i>Candida</i> spp., often non- <i>albicans</i> )
Mouth examination	Mucositis is a risk factor for infection with <i>viridans</i> streptococci and anaerobes
Sinus tenderness	Fungal infection
Right lower quadrant abdominal tenderness	Consider cecal inflammation (typhlitis)
Perirectal inflammation	<i>Pseudomonas</i> infection; rarely anaerobic infection
<b>Chest Radiograph:</b>	
Localized infiltrate	Bacterial or mycobacterial infection
Nodular infiltrate or nodular density with surrounding hyperlucency; cavitary lesions	Filamentous fungi or <i>Nocardia</i> spp.; <i>Aspergillus</i> spp.
Diffuse interstitial infiltrate	Viral or <i>Pneumocystis carinii</i>
<b>Other Factors:</b>	
Fever persists or recurs after 1 week of antibiotic therapy	Filamentous fungal infection likely
Fever and abdominal pain at time of resolution of neutropenia	Hepatosplenic candidiasis
Bone marrow transplant recipient	Wide range of potential pathogens (see Chapter 24)

## **26 . Patients with Recurrent Infections and Leukocyte Abnormalities** — *Timothy R. La Pine, MD, & Harry R. Hill, MD*

### **INTRODUCTION**

A critical and delicate balance in both cellular and humoral function is essential for complete immunologic responsiveness to invasive microbial pathogens. Any alteration in immune regulation or responsiveness may render a host susceptible to recurrent or life-threatening infections. Understanding the specific functional mechanisms involved in leukocyte production, activation, migration, and immune regulation leading to cytotoxic killing is of extreme clinical significance when evaluating patients with suspected immunodeficiency.

Leukocyte abnormalities should be suspected in the following patients: (1) those who have an increased frequency of infections compared to patients of similar age and exposure risks; (2) those whose infections with common, often nonpathogenic or usually inconsequential pathogens are more severe than would normally be expected; (3) those whose infections are of prolonged duration and require prolonged antimicrobial therapy often with incomplete clearing between episodes or requiring surgical intervention; (4) those with multiple complicated infections, involving different organ systems; and (5) those who have infections with unusual or opportunistic organisms.

The specific components of immune responsiveness are exceedingly complex and require the close cooperation of a variety of cellular elements (T lymphocytes, B lymphocytes, phagocytes, and natural killer cells) as well as humoral factors (immunoglobulins, lymphokines, monokines, interferons, acute-phase reactants, and the complement system). For clinical utility, defects in leukocyte immunoresponsiveness can be categorized into four functional systems: (1) defects in the T-lymphocyte system (including T cells and lymphokines); (2) defects in the B-lymphocyte system (including B cells and secretory immunoglobulins); (3) defects in the phagocyte system (including neutrophils, monocytes, and macrophages); (4) defects in the complement system. [Box 26-1](#) summarizes the syndromes commonly found with each type of defect. The tests used to screen patients with suspected immunodeficiency are listed in [Table 26-1](#), and further confirmatory tests are listed in [Table 26-2](#).

### **T-LYMPHOCYTE DEFECTS**

#### **Essentials of Diagnosis**

- Systemic illness after vaccinations with live virus or *Mycobacterium* Bacille Calmette-Guerin vaccine.
- Chronic oral candidiasis or mucocutaneous candidiasis persisting after 6 months of age with resistance to therapy.
- Graft-vs-host disease after blood transfusions.

- Persistently low absolute lymphocyte counts.
- Hypocalcemia/tetany with DiGeorge facies.
- Intracellular infections (caused by bacteria, protozoans, viruses, or fungi).

## General Considerations

The T-lymphocyte system is composed of several subtypes of effector cells that include regulatory T cells, helper and suppressor T cells, cytotoxic T cells, and T cells involved in delayed hypersensitivity reactions. The major function of the T-lymphocyte system is in host defense against intracellular pathogens (viruses, fungi, protozoa, and intracellular bacteria such as mycobacteria and *Listeria* spp.). The T lymphocyte system also functions in tumor surveillance, delayed hypersensitivity reactions, and graft-versus-host disease.

Thymus-dependent T cells are derived from pluripotent hematopoietic stem cells residing in developing bone marrow stores. As early as the eighth gestational week, immature T cells infiltrate the thymus where they differentiate and mature before migrating to specific lymphoid tissues. During their intrathymic maturation, T cells develop specific outer membrane glycoproteins. Mature T cells express T-cell antigen receptors as well as the CD3 membrane glycoproteins. Nearly 70% of the T cells also express the CD4 membrane glycoproteins, the helper-inducer T-cell marker. The remaining 30% express the CD8 membrane glycoprotein, the cytotoxic-suppressor T-cell marker. The CD4 and CD8 membrane glycoproteins are typically not presented on the same mature T cell and serve as functional markers of helper and cytotoxic-suppressor T-cell populations in the peripheral blood or tissues.

The T-lymphocyte system orchestrates pathogen annihilation through antigen-dependent cellular interactions. Antigen-presenting cells, mainly the monocytes and macrophages (but also the Langerhans cells of the skin, the Kupffer cells of the liver, and specific endothelial cells) process soluble antigen and present it in combination with HLA class II antigens on their cellular surface. Thymus-dependent CD4 helper-inducer T cells recognize and bind to this altered antigen-HLA class II complex through helper T-cell receptors. During this process, interleukin-1 (IL-1) is released from the antigen-presenting cells. The binding of the free IL-1 to its receptor on the helper T-cell surface initiates T-cell activation. Once activated, the CD4 helper T cells produce IL-2, which functions as a T-cell promoter, causing the T cells to proliferate and release a number of factors, thus initiating a cascade of events that serves to amplify and regulate the immune response with the cooperation and recruitment of many other cell types. IL-2 also interacts directly with CD8 cytotoxic T-cells that bind viral antigens present on the surfaces of infected cells, resulting in cellular destruction.

T-cell immunodeficiency can result from defects in the (1) maturation, differentiation, and activation of hematopoietic stem cells; (2) specific thymic defects, including the thymic microenvironment and associated humoral factors; (3) specific T-cell defects; (4) defective production of cytokines; (5) defective expression of cytokine receptors; (6)

defective production of regulatory proteins needed for T-cell activation; and (7) destruction of T cells. Any defect in T-cell immunity is also associated with variable degrees of B-cell deficiency because most of the maturation, differentiation, and activation processes of B cells requires T cell help. [Box 26-2](#) summarizes treatment options for patients who have leukocyte deficiencies.

## **SEVERE COMBINED IMMUNODEFICIENCY**

### **Clinical Findings**

The most severe forms of leukocyte immunodeficiency are the syndromes of severe combined immunodeficiency (SCID). This immunodeficiency category includes a spectrum of X-linked, autosomal recessive, and sporadic genetic defects characterized by the inability to mount normal T-lymphocyte (cell-mediated) and B-lymphocyte (humoral) immunity. These syndromes include X-linked SCID, adenosine deaminase deficiency, and ZAP-70 deficiency, which are characterized by the onset of viral, bacterial, fungal, or protozoal infections before 6 months of age.

Infants lacking both T- and B-cell immunity whose T lymphocytes are phenotypically normal but unable to respond appropriately should be evaluated for the following:

- Familial defects in the surface expression of the T-cell receptor CD3 glycoproteins.
- Primary abnormalities in the expression of the IL-1 receptor.
- IL-2 unresponsiveness.
- Failure to produce IL-2.
- IL-2 receptor  $\beta$ -chain mutation.
- T-cell signal transduction defects.
- Bare lymphocyte syndrome (aberrant gene regulation of major histocompatibility complex).
- Major histocompatibility complex class II deficiency.

Patients with SCID usually suffer from failure to thrive, persistent oral candidiasis, recurrent diarrhea, and pneumonia (usually interstitial, often caused by *Pneumocystis carinii*) in the first months of life. Several immunologic defects are associated with a similar clinical pattern. Seventy-five percent of the patients with SCID are male.

### **Diagnosis**

Prenatal diagnosis of SCID may be made by fetal blood sampling of T-lymphocyte subsets and T-cell functional studies as early as 20 weeks gestation.

### **Treatment**

The only curative therapy for SCID is allogeneic bone marrow transplantation, although the use of cytokines, particularly recombinant human IL-2, may be of value for SCID patients who fail to produce IL-2.

## **1. X-LINKED SCID**

In X-linked SCID, the failure to express normal IL-2R $\gamma$  may result in impaired early intrathymic T-cell maturation and function, leading to this severe immunodeficiency syndrome. Maternal carriers can be identified by the pattern of T-cell X chromosome inactivation and by the localization of the gene defect to Xq-13 by linkage analysis.

Prenatal diagnosis can be made as early as the 10th gestational week by analysis of unbalanced patterns of X chromosome inactivation in maternal and fetal T cells with the use of somatic cell hybridization or methylation differences between the active and inactive X chromosome. The analysis of X chromosome inactivation has been useful in detecting carriers in the X-linked primary immunodeficiency diseases (X-linked SCID, X-linked agammaglobulinemia, and the Wiskott-Aldrich syndrome). Polymerase chain reaction can also be used to amplify specific DNA sequences used to detect X chromosome inactivation in patients with X-linked SCID and other primary immunodeficiencies.

## **2. ADENOSINE DEAMINASE DEFICIENCY**

### **Introduction**

About 50% of the patients with autosomal recessive SCID have an associated adenosine deaminase (ADA) deficiency. The gene for ADA deficiency has been mapped to chromosome 20q-13. Absence of this enzyme in purine metabolism leads to the accumulation of toxic metabolites including deoxyadenosine triphosphate, which is capable of killing both dividing and resting T cells.

### **Clinical Findings**

In addition to the classic symptoms of SCID, this disease is characterized by the presence of skeletal abnormalities including concavity and flaring of the anterior ribs, an abnormal contour and articulation of the posterior ribs and transverse processes, platyspondylisis and an abnormal bony pelvis.

### **Diagnosis**

The diagnosis is made by measuring ADA levels in hemolyzed red blood cells. Heterozygotes are symptom-free but have half the normal enzyme concentration. Prenatal diagnosis is possible by measuring ADA levels in cultured amniotic cells during the second trimester.

### **Treatment**

Bone marrow transplantation or enzyme replacement with bovine ADA has been used

with some success in the management of this disease. Promising recent attempts to treat patients with ADA deficiency have used autologous lymphocytes or cord blood stem cells corrected in vitro with retroviral vector-inserted normal human ADA DNA.

### **3. ZAP-70 DEFICIENCY**

#### **Clinical Findings**

Another autosomal recessive form of SCID includes the abnormality of the protein kinase ZAP-70. Two families of protein kinases are involved with T-cell receptor signal transduction leading to T-cell maturation and differentiation: (1) the Src family of protein kinases, Fyn and LCK and (2) the ZAP-70 and Syk protein kinases. Patients with ZAP-70 deficiency have compromised T-cell receptor signal transduction, leading to impaired T-cell differentiation.

This disorder is characterized by the presence of normal numbers of peripheral T cells with a deficiency of the CD8, cytotoxic-suppressor, T cells and a T-cell receptor signal transduction defect present in the helper CD4 T cells. These patients have normal immunoglobulin concentrations and natural killer cell function. Some intrathymic CD4 maturation occurs in these patients, but their peripheral blood is deficient in CD8 cells.

#### **Diagnosis**

The diagnosis of this disease is suggested by family history, symptoms of SCID, and the characteristic peripheral T-cell phenotype and function.

#### **Treatment**

At present, bone marrow transplantation is the only curative therapy.

### **4. PURINE-NUCLEOSIDE PHOSPHORYLASE DEFICIENCY**

#### **Clinical Findings**

Purine-nucleoside phosphorylase (PNP) deficiency is an extremely rare autosomal recessive disorder characterized by a deficiency in the enzyme PNP, which is associated with marked T-cell immunodeficiency with a relatively intact humoral immunity. The gene coding PNP is located on chromosome 14q. The accumulation of deoxyguanosine triphosphate destroys dividing T cells.

Patients usually have recurrent viral, bacterial, and fungal infections. Two-thirds of these patients have neurologic disorders ranging from mild developmental delay or muscle spasticity to severe mental retardation.

#### **Diagnosis**

The diagnosis can be made by measuring PNP in hemolyzed erythrocytes. Heterozygotes have half the normal level of this enzyme and associated serum uric acid levels are low in these patients. Prenatal diagnosis is possible by assaying PNP levels

cultured in amniotic cells during the second trimester.

## **Treatment**

Bone marrow or stem cell transplant is the only successful therapy. Enzyme replacement therapy, as well as viral gene transfer, are currently being investigated as promising future therapies.

## **DIGEORGE SYNDROME**

### **Clinical Findings**

DiGeorge syndrome is a polytropic developmental defect consisting of congenital aplasia or dysplasia of the thymus and parathyroid glands, leading to lymphopenia with decreased T-cell populations as a result of monosomy of chromosome 22q-11. DiGeorge syndrome mainly affects the structures derived from the 3rd, 4th, and 5th pharyngeal pouches, but the 1st, 2nd, 5th, and 6th pouches and all branchial arches may also be involved. This is due to the failure of a population of neural crest cells to migrate and interact with endodermally derived cells of the branchial pouches and arches.

**A. Signs and Symptoms.** The syndrome is characterized by neonatal tetany associated with hypocalcemia caused by hypoparathyroidism. Cardiac outflow tract malformations are also seen (interrupted aortic arch, truncus arteriosus, right-sided aortic arch, tetralogy of Fallot, patent ductus arteriosus, or a ventricular septal defect). Abnormal facial features include low-set ears, hypertelorism, short philtrum, and a fish-shaped mouth. The thymus of these infants may be absent, hypoplastic, or atopic, and the parathyroid glands may be absent or reduced in size.

**B. Laboratory Findings.** T-cell immunity in patients with DiGeorge syndrome is variable and ranges from diminished cell numbers to complete absence of T-cell immunity. Some DiGeorge syndrome patients have normal B-cell immunity as measured by normal concentrations of immunoglobulin and normal antibody responses after immunization. Other patients, however, have low immunoglobulin levels and fail to make specific antibody in response to immunizations. Natural killer cell activity is normal.

### **Diagnosis**

Prenatal diagnosis of DiGeorge syndrome can be performed by fluorescence in situ hybridization of fetal tissue to look for the chromosomal monosomy at 22q-11.

### **Treatment**

Treatment of patients with DiGeorge syndrome has included the implantation of fetal thymic tissue, fetal thymic epithelium, or fetal thymus in a diffusion chamber, all of which have demonstrated limited success. Bone marrow transplantation, which provides donor postthymic T cells to reconstitute the patient's immunity, has been successfully used to treat patients with DiGeorge syndrome.

## WISKOTT-ALDRICH SYNDROME

### Clinical Findings

The Wiskott-Aldrich syndrome gene has been mapped to the short arm of the X chromosome. Recently a novel gene has been isolated that is absent in Wiskott-Aldrich syndrome patients. This gene encodes a protein that appears to be an important immunoregulator of both T-lymphocytes and platelets.

**A. Signs and Symptoms.** Wiskott-Aldrich syndrome is an X-linked recessive disease characterized by recurrent pyogenic infections within the first years of life. Thrombocytopenia is characterized by both small-sized and poorly functioning platelets. Eczema is also present at some time in most patients.

**B. Laboratory Findings.** Wiskott-Aldrich syndrome patients have low serum concentrations of IgM. IgA and IgE concentrations are high, and the IgG level is normal, elevated, or only slightly depressed. These patients are unable to produce antibody in response to polysaccharide antigens. T-cell numbers and function progressively decrease in this disorder, leading to a profound leukopenia. Patients have increased susceptibility to autoimmunity and malignancy.

### Diagnosis

Prenatal diagnosis is facilitated by fetal blood sampling and the analysis of thrombocyte numbers and size, as well as an analysis of the pattern of X chromosome inactivation to detect carriers.

### Treatment

Bone marrow transplantation, or more recently stem cell transplantation, may correct the immunologic defects and platelet disorder observed in these patients.

## ATAXIA-TELANGIECTASIA

### Clinical Findings

Ataxia telangiectasia, an autosomal recessive disorder, is thought to be a specific gene defect affecting mitogenic signal transduction, mitotic recombination, and cell cycle control. The defect can result in recombination errors that interfere with the rearrangement of T- and B-cell genes and the inability to repair damaged DNA. The defects observed in DNA repair in these patients after x-ray irradiation results in a high incidence of chromosomal translocation, specifically in chromosomes 7 and 14.

**A. Signs and Symptoms.** Ataxia telangiectasia is characterized by progressive cerebellar ataxia, oculocutaneous telangiectasia, chronic sinopulmonary disease, and a high incidence of malignancy. Clinically progressive ataxia becomes apparent when the child begins to walk, whereas telangiectasia develops between 2 and 8 years of age, predominantly on the bulbar conjunctiva as well as exposed flexor surfaces of the arms.

**B. Laboratory Findings.** Nearly 70% of these patients have a selective IgA deficiency and more than one-half of these patients have an associated IgG-2 subclass deficiency. Eighty percent of the patients have depressed or absent IgE levels. The most notable T-cell abnormalities include leukopenia and a decrease in helper T-cell/suppressor T-cell ratios, in addition to an overall decrease in the total number of cytotoxic T cells.

## **Diagnosis**

Serum a-fetoprotein levels are persistently elevated in these patients, which may be a useful but nonspecific aid in the diagnosis.

## **Treatment**

Therapy consists of intravenous immunoglobulin therapy using IgA-depleted preparations. Gene therapy for ataxia telangiectasia is currently under investigation.

## **B-LYMPHOCYTE DEFECTS**

### **Essentials of Diagnosis**

- Decreased humoral immunity with variable to absent antibody isotype production.
- Recurrent gastrointestinal and/or sinopulmonary infections.
- Recurrent bacterial pneumonia or meningitis and severe sepsis.
- Enteroviral or other viral infections.
- Nodular lymphoid hyperplasia and malignancies.

### **General Considerations**

The B-lymphocyte system is derived from stem cells residing in bone marrow stores. These stem cells produce cytoplasmic IgM heavy chains, which become pre-B cells. These pre-B cells continue to differentiate to become mature surface IgM- or IgM- and IgD-bearing B cells, which seed peripheral lymphoid tissue via the circulation. Upon stimulation, IgM-bearing B cells undergo class switching to IgG, IgA, or IgE-bearing B cells. These B cells can then differentiate to immunoglobulin-secreting plasma cells with the help of T cells and T-cell-derived lymphokines. Some of the B cells further differentiate into small memory B cells, which are involved in secondary immune responses.

The major function of B cells and the plasma cells is to produce antibodies to protein and carbohydrate antigens present on microorganisms, toxins, or other antigenic substances potentially harmful to the host. These antibodies are classified into nine different immunoglobulin isotypes, including IgM, IgD, IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, and IgE. IgM antibodies are made first and are the most efficient in activating the classical complement system, which facilitates the opsonization and subsequent

ingestion of microorganisms.

IgG antibodies are the only maternal antibodies that are transplacentally passed to developing infants. These antibodies are responsible for much of the infant's defense against invading microorganisms and their toxic substances through their opsonization and neutralization effects. IgA antibodies are selectively transported across mucous membranes by a secretory moiety. These IgA antibodies prevent the attachment of microorganisms or absorption of harmful antigens through mucous membranes. IgE antibodies are mainly responsible for allergic reactions and protection against parasites. Any defect in the maturation and differentiation of B cells (from the hematopoietic stem cells to plasma cells and their secretory immunoglobulins) or T cells and their receptors or lymphokines may produce B-cell immunodeficiency syndromes.

Patients with B-cell deficiencies, usually have recurrent pyogenic infections, particularly of the sinopulmonary tract, and to a lesser extent the gastrointestinal tract. Enterovirus infections may also be problematic.

## **BRUTON'S AGAMMAGLOBULINEMIA**

### **Clinical Findings**

Bruton's agammaglobulinemia is an X-linked recessive disease that affects only males. The underlying defect is an arrest in the differentiation of pre-B cells caused by the absence of a Bruton's tyrosine kinase, which functions in B-cell differentiation.

**A. Signs and Symptoms.** This defect is characterized by recurrent pyogenic infections usually starting by 5-6 months of age. Affected individuals may not be symptomatic before 6 months of age because of transplacentally acquired maternal IgG antibodies. Infections are usually caused by encapsulated bacterial pathogens, including *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae* type b. Sinopulmonary infections are predominant. There is an unusual susceptibility to persistent echovirus or coxsackievirus infection, including lethal meningoencephalitis as well as vaccine-associated poliomyelitis.

**B. Laboratory Findings.** Immunoglobulins of all classes are absent as are circulating immunoglobulin-bearing mature B cells. Absent plasma cells from lymphoid tissue and functional serum antibody are hallmarks of Bruton's agammaglobulinemia. T lymphocytes are normal in number and function. Approximately half of the patients have a family history of an affected male sibling or maternal male relative who is affected.

### **Diagnosis**

Female carriers do not exhibit antibody deficiency and can be detected by analyzing the unbalanced pattern of X chromosome inactivation in peripheral blood mononuclear cells. Prenatal diagnosis of suspected patients is facilitated by sex determination of the fetus and direct sampling of fetal blood for mature B cells or by DNA markers.

### **Treatment**

Therapy ([Box 26-2](#)) consists of the administration of intravenous immunoglobulin and clinical surveillance for infections and the development of lymphoreticular and other malignancies.

## **X-LINKED HYPOGAMMAGLOBULINEMIA WITH NORMAL TO INCREASED IgM CONCENTRATIONS**

### **Clinical Findings**

Patients with this immune deficiency have an increased IgM concentration, recurrent pyogenic infections, autoimmune disease, and lymphoproliferative disease, especially IgM surface-bearing B-cell lymphomas of the intestinal tract. The hyper-IgM syndrome can be inherited in an X-linked or an autosomal recessive fashion. The underlying cause of the X-linked hyper-IgM syndrome is a deficiency in the expression of the T-cell CD40 ligand, which specifically binds B cells and drives the immunoglobulin isotype switch. The gene for the CD40 ligand has been cloned and mapped to Xq-26.

**A. Signs and Symptoms.** Neutropenia is commonly associated with this disease, and nearly half of these patients have hepatosplenomegaly. Chronic liver disease and lymphomas are the long-term associated consequences of this disorder.

**B. Laboratory Findings.** These patients have normal or increased concentrations of serum IgM and, in some cases, IgD but decreased or absent IgG, IgA, and IgE. T-cell numbers and function, other than the absence of the CD40 ligand, appear to be normal. The interaction of CD40 with its ligand, however, may also be involved in early thymic T-cell maturation. This may explain an increased susceptibility to opportunistic infections such as *Pneumocystis carinii* pneumonia seen in some patients.

### **Diagnosis**

Prenatal diagnosis can be performed by DNA analysis and from cytometry for the CD40 ligand on T cells.

### **Treatment**

Bone marrow transplantation has recently been tried in the treatment of hyper-IgM syndrome. Stem cell transplantation has also been attempted. Replacement therapy with a recombinant, soluble form of the CD40 ligand or gene therapy may be developed for these patients in the future.

## **SELECTIVE IgA DEFICIENCY**

### **Clinical Findings**

The incidence of selective IgA deficiency is ~1/400-1/1000. Studies of the IgA heavy-chain constant-region genes, situated on chromosome 14, have revealed that there are no structural deletions in individuals with selective IgA deficiency. A gene located in the major histocompatibility complex class III region on chromosome 6 recently has been implicated for both selective IgA deficiency and common variable

immunodeficiency, suggesting a relationship in these two disorders. The cause of selective IgA deficiency appears to be a terminal block in B-cell differentiation to plasma cells capable of secreting the IgA isotype.

Symptomatic patients usually have recurrent infections of the respiratory and gastrointestinal tracts, autoimmune disease, allergy, and malignancy. Approximately two-thirds of the patients do not have an increased susceptibility to infection, presumably because of the protective effects of IgG and IgM.

## **Diagnosis**

Selective IgA deficiency has been defined as a serum IgA concentration of  $< 5$  mg/dL in severe deficiency and less than two standard deviations below the mean of age-matched control in partial deficiency. In some IgA deficient patients, secretory IgA is low but present; the serum concentration of IgA may return to normal within 4 years of diagnosis. These patients have normal T-cell immunity.

## **Treatment**

Therapy with IgA is not possible in patients with selective IgA deficiency because (1) the half-life of IgA is short (~7 days), (2) administered IgA is not transported to the mucosal surfaces, and (3) the presence of anti-IgA autoantibodies in IgA-deficient patients may cause anaphylactic reactions when blood components containing IgA are transfused. In ~20% of the IgA-deficient patients who have frequent infections, there is an associated IgG-2 subclass deficiency.

Some of these patients, including those with anti-IgA antibodies, can benefit from treatment with intravenously administered immune globulin containing low levels of IgA.

## **COMMON VARIABLE IMMUNODEFICIENCY**

### **Clinical Findings**

The underlying clinical defect in common variable immunodeficiency (CVID), or late-onset hypogammaglobulinemia, is that the B cells do not differentiate into plasma cells. This may be caused by a primary B-cell defect (failure to terminally glycosylate and secrete immunoglobulins), a failure of helper T-cell factor production, or an increase in specific suppressor T-cell effects. The immunologic defect seen in this disorder is not limited only to B cells but also includes macrophages and immunoregulatory T cells. The defects in T-cell immunity include abnormalities of activation and lymphokine production, which usually progresses with age.

Many patients (11%) with CVID have a first-degree relative with selective IgA deficiency or CVID. It appears that a susceptibility gene or group of genes for both CVID and selective IgA deficiency are located within the major histocompatibility complex class III region of the chromosome 6. It is likely that in both these disorders there are exogenous factors that act intrinsically or extrinsically on genetically susceptible individuals to determine the degree of expression of the immunoglobulin genes in these patients.

**A. Signs and Symptoms.** Patients with CVID commonly have chronic diarrhea and associated malabsorption. Autoimmune diseases, hepatitis, gastric carcinoma, and lymphoreticular malignancy have been observed in older patients. Nodular intestinal lymphoid hyperplasia and a sarcoidlike syndrome associated with hepatosplenomegaly are additional features of this disease.

**B. Laboratory Findings.** Common variable immunodeficiency is characterized by markedly decreased serum immunoglobulin levels, normal or nearly normal numbers of circulating immunoglobulin-bearing mature B cells, impaired antibody responses, and recurrent bacterial sinopulmonary infections associated with chronic progressive bronchiectasis.

## **Diagnosis**

Assessing a male patient with recurrent infections and significant hypogammaglobulinemia, the absence of mature immunoglobulin B cells in the peripheral blood or X chromosome inactivation analysis of the patient's mother can be helpful in distinguishing sporadic cases of X-linked agammaglobulinemia from cases of CVID.

## **Treatment**

Management of CVID includes immunoglobulin replacement therapy, antimicrobial therapy and pulmonary drainage, and immunomodulatory therapies including recombinant human IL-2 conjugated with polyethylene glycol and cimetidine.

## **DEFECTS IN THE PHAGOCYtic SYSTEM & ITS RELATED IMMUNODEFICIENCY SYNDROMES**

### **Essentials of Diagnosis**

- Cutaneous bacterial abscesses, cellulitis, and mucocutaneous candidiasis.
- Frequent pneumonias, otitis media, and sinusitis.
- Osteomyelitis.
- Periodontitis and lymphadenitis.
- Granulomatous lesion.

### **General Considerations**

The phagocytic system includes polymorphonuclear leukocytes (neutrophils and eosinophils) and mononuclear phagocytes (circulating monocytes, tissue macrophages, and fixed macrophages). Major phagocytic functions include adherence to endothelium, aggregation, diapedesis, chemotaxis, attachment, phagocytosis, and degranulation, leading to pathogen destruction. The phagocytic system is responsible for defense

against extracellular bacterial or fungal invasion in association with opsonins, antibodies, complement, and some acute-phase proteins. Neutrophils are one of the first lines of defense against bacterial invasion and neutrophil disorders include leukocyte adhesion deficiency, Chediak-Higashi syndrome, chronic granulomatous disease, and Job's syndrome.

## LEUKOCYTE ADHESION DEFICIENCY

### Clinical Findings

Neutrophil adherence to and migration through capillary endothelium is a critical early event in the acute inflammatory response. The adhesive interactions between neutrophils and endothelial cell surfaces are regulated by two novel families of glycoproteins: the integrins and the selectins. The  $\beta$ -2 integrins are membrane-bound glycoprotein receptors found on the surface of neutrophils. The  $\beta$ -2 integrins CD11/CD18 are required for neutrophil adherence to endothelial cell surfaces. The selectins also are membrane-bound glycoproteins that mediate neutrophil adhesion to endothelial cells. These include L-selectin, which is found on the surface of neutrophils, and P-selectin and E-selectin, which are expressed on the surface of activated endothelial cells.

The interaction between the  $\beta$ -2 integrins and the selectins serves to regulate neutrophil responses during inflammation. In general, P-selectin and E-selectin on the activated endothelial cell surface and L-selectin on the neutrophil cell surface function to facilitate neutrophil rolling and tethering to activated capillary endothelium. Once this tethering has occurred and the neutrophil itself is activated, the  $\beta$ -2 integrin CD11/CD18 receptors on the neutrophil form a tight adhesion with the endothelial cell surface that facilitates neutrophil polarization, leading to migration.

Two types of leukocyte adhesion deficiency (LAD) have been described. The first is congenital  $\beta$ -2 integrin CD11/CD18 deficiency (LAD-I). A second type, LAD-II, has been described for a deficiency of Sialyl Lewis X, the neutrophil ligand for E-selectin on endothelial cells. Deficiency of the CD11/CD18 complex (LAD-I) is transmitted as an autosomal recessive trait. The gene encoding CD18 has been mapped to chromosome 21. The underlying defect results from heterogeneous mutations affecting the CD18 gene, which impair its synthesis.

This disorder is characterized by frequent infections, poor wound healing, leukocytosis, and a history of delayed umbilical cord separation. Patients usually suffer from recurrent bacterial skin abscesses, otitis media, periodontitis, omphalitis, perirectal abscesses, pneumonia, and sepsis.

The striking feature of these infections is the almost total absence of leukocytes in the lesions. The most prevalent invading microorganisms are *Staphylococcus aureus*, group A streptococci, *Proteus mirabilis*, *Pseudomonas aeruginosa*, and *Escherichia coli*. Based on the severity of the deficiency, two phenotypes (severe and moderate) have been defined.

The severe form is associated with complete absence of CD11/CD18 expression,

whereas the moderate form demonstrates ~10-20% of normal expression. The degree of deficiency is closely related to the severity of the patient's clinical manifestations; patients with the severe form of leukocyte adhesion deficiency usually die within the first few years of life. In contrast, the patients with at least some expression of these adhesive glycoproteins usually have a milder disease course and can survive into adulthood.

## Diagnosis

The diagnosis can be made by assessing the expression of CD11b or CD18 on the patient's neutrophils by flow cytometry. Further confirmation can be made by assessing expression of these glycoproteins after exposure to a degranulating stimuli. The expression of these glycoproteins is increased 5- to 20-fold after stimulation with degranulating agents. This method is also helpful for identification of symptom-free heterozygotes where the expression of these glycoproteins is about half that seen in normal carriers and for prenatal diagnosis.

## Treatment

Therapy consists mainly of early, aggressive antibiotic therapy to reduce bacterial infections (see [Box 26-2](#)). During severe infections, granulocyte transfusions in addition to antibiotic therapy have had therapeutic benefit. Bone marrow transplantation has been successfully used to treat some patients. Gene therapy, replacing the defective CD18 gene in the patient's myeloid precursor cells, may become available in the future. In vitro correction of CD18-deficient lymphocytes by retrovirus-mediated gene transfer has been accomplished. A transfection efficiency of 5-10% may be sufficient to change the disease course from severe to moderate.

## JOB'S SYNDROME

### Clinical Findings

Job's syndrome of hyperimmunoglobulin E and recurrent infections is transmitted by autosomal dominant inheritance with incomplete penetrance. It is characterized by extremely high serum IgE values (often > 1000-2000 IU/mL), recurrent serious infections, and chronic eczematoid dermatitis usually beginning early in infancy. The infections primarily involve the skin and sinopulmonary tract and usually present as recurrent furunculosis, cutaneous abscess formation, bronchitis, pneumonia, and chronic otitis media and sinusitis. Some of the skin abscesses are cold without classical signs and symptoms of inflammation: redness, heat, and pain.

The most common infecting microorganisms are *S aureus*, and *C albicans*, but infections caused by *H influenzae* group A streptococci, gram-negative pathogens, and fungi are also observed. Pneumatocoles, bronchiectasis, and bronchopleural fistula formation are not uncommon after episodes of acute or chronic pneumonia. Chronic mucocutaneous candidiasis, primarily involving the mouth, nails, skin, and vagina, is also found in about half of the patients.

Associated features include coarse facial features with a broad nasal bridge and broad

nasal alae, growth retardation, osteoporosis and bone fractures, keratoconjunctivitis, asymmetric sterile polyarthritis, and eosinophilia.

In addition to markedly elevated serum IgE concentrations, other immunologic abnormalities include elevated specific anti-*S aureus* and anti-*Candida* IgE antibodies, an intermittent defect in neutrophil chemotaxis, low antibody response to booster immunizations, and poor antibody and cell-mediated responses to newly encountered antigens. The underlying defect is most likely associated with a T-cell abnormality characterized by inadequate production of  $\gamma$ -interferon, which normally suppresses IgE production. The intermittent neutrophil chemotactic abnormality, which likely has a major role in the pathogenesis of the recurrent abscesses seen in these patients, most likely results from this  $\gamma$ -interferon deficiency.

## Diagnosis

Differentiation of patients with the Job syndrome from those with atopic dermatitis is sometimes difficult and is dependent on the presence of recurrent deep abscesses along with the classic facial features.

## Treatment

Management consists of controlling the pruritic eczematoid dermatitis with emollient creams, topical steroids, and antihistamines. Prophylactic oral dicloxacillin or trimethoprim-sulfamethoxazole for *S aureus* infections or oral fluconazole for preventing *C albicans* infections usually benefit patients. Intravenous immunoglobulin therapy should be reserved for patients with confirmed IgG subclass deficiency, a finding rarely observed in our experience. Plasmapheresis has been attempted for a few patients who do not respond to more conservative therapies. Reported experimental immunomodulatory therapies include the use of levamisole, ascorbic acid, cimetidine, and transfer factor.  $\gamma$ -Interferon therapy has been shown to increase these patient's neutrophil chemotactic response in vitro and decrease eczema and respiratory secretions in vivo.

## CHRONIC GRANULOMATOUS DISEASE

### Clinical Findings

Chronic granulomatous disease (CGD) is a group of genetic disorders characterized by recurrent infections with catalase-positive microorganisms of the respiratory tract, skin, and soft tissues. Symptoms usually occur by 2 years of age. CGD has X-linked (65%) or autosomal-recessive (35%) inheritance.

This defect is due to lesions in membrane-associated NADPH-oxidase necessary for the production of oxygen radicals, which are required in intracellular killing ([Figure 26-1](#)). This results in the inability of phagocytes to generate superoxide anion, hydrogen peroxide, and other oxygen radicals needed to kill catalase-positive bacteria. The catalase-negative species, including pneumococci, streptococci, and *H influenzae*, rarely cause serious infections in these patients. CGD should be suspected in any patient with subcutaneous abscesses or furunculosis associated with abscess formation

in a lymph node, the liver, or lung, or in patients with infections with organisms normally of low virulence (*Staphylococcus epidermidis*, *Serratia marcescens*, and *Aspergillus* spp.), which are catalase positive.

The underlying defect in X-linked CGD is due to a defect in a gene encoded on the X chromosome that has been identified as the cytochrome b heavy-chain gene.

## Diagnosis

The diagnosis of CGD is demonstrated by an absent or greatly diminished respiratory burst by stimulated phagocytes. Available assays include nitroblue tetrazolium dye reduction, chemiluminescence, measurement of oxygen consumption, and the products of oxidative metabolism, superoxide anion, and hydrogen peroxide. A documented inability of blood granulocytes to kill ingested catalase-positive bacteria confirms CGD. Symptom-free carriers of the X-linked form of CGD can be identified by determining the respiratory burst activity of their neutrophils, which is approximately half of normal, and by genetic analysis.

Prenatal diagnosis can be made during the second trimester by sampling of fetal blood and nitroblue tetrazolium testing, which serves as a screen for superoxide production. Molecular reagents prepared from cloned DNA may also prove to be clinically useful for prenatal diagnosis in the future.

## Treatment

Prophylaxis with trimethoprim-sulfamethoxazole may prolong infection-free intervals by preventing infections, especially with staphylococci. Therapy also includes treatment with  $\gamma$ -interferon, which has decreased infections by as much as 70%, and bone marrow transplantation, which to date has shown only limited success and should be reserved for those patients who cannot be optimally treated in other ways. Patients with CGD are excellent candidates for future gene therapy because the genetic lesions have been identified and the genes cloned.

## CHEDIAK-HIGASHI SYNDROME

### Clinical Findings

The Chediak-Higashi syndrome is an autosomal recessive disorder, which is characterized by recurrent pyogenic infections, a bleeding tendency caused by a platelet storage pool deficiency, partial oculocutaneous albinism, and giant granules in the cytoplasm of many cells, particularly peripheral leukocytes. The underlying defect results from abnormal cell membrane fluidity, which leads to abnormal granular fusion as well as other defects, including the inability of neutrophils to move normally, concentrate serotonin into platelets, and express normal lytic functions.

Symptoms generally begin in early childhood with recurrent pyoderma, subcutaneous abscesses, otitis, sinusitis, severe periodontal disease, bronchitis, and pneumonia. The most common microorganisms are *S aureus* and  $\beta$ -hemolytic streptococci. Approximately 85% of patients have an associated organ infiltration by histiocytes and

atypical lymphocytes. Hepatosplenomegaly, lymphadenopathy, neurologic abnormalities, pancytopenia, and a bleeding tendency are also commonly seen.

## Diagnosis

The diagnosis is made by identification of the characteristic giant cytoplasmic granules in the patient's leukocytes or microscopic examination of hair shafts for abnormal giant melanosomes. Prenatal diagnosis is possible by measuring the large acid phosphatase-positive lysosomes in cultured amniotic fluid cells, chorionic villus cells, or fetal blood leukocytes.

## Treatment

In addition to prophylaxis with antibiotics and the prompt treatment of acute infection with antimicrobial agents, high doses of ascorbate may be beneficial. Bone marrow transplantation may be curative. Splenectomy has been used in the treatment of patients unresponsive to other forms of therapy and has resulted in clinical, hematologic, and immunologic improvement.

# THE COMPLEMENT SYSTEM & ITS RELATED DEFECTS

## Essentials of Diagnosis

- Recurrent infections with encapsulated bacteria.
- Recurrent sepsis with *Neisseria* species.

## General Considerations

The complement system is composed of an interacting series of glycoproteins, which upon activation, interact in an orderly sequence to produce biologically active substances that enhance leukocyte reactions and that result in the lysis of cells or invading pathogens. The system can be activated through two major pathways: (1) the classical pathway, which is activated by binding of IgG1, IgG2, IgG3, or IgM to antigens; and (2) the alternative pathway, which is initiated by direct attachment of activated C3 to the surface of bacteria, viruses, fungi, and virus-infected cells ([Figure 26-2](#)).

Once the alternative pathway is triggered, an amplification loop is activated that induces more C3b formation. Surface-bound C3b in conjunction with C3 convertase, C4b2a (classical pathway), or C3bBb (alternative pathway) serves as a C5 convertase, which initiates the formation of the membrane attack complex (C5b678[9]n). All of the activated components of the complement system are tightly controlled by regulatory proteins including C1 esterase inhibitor, factor I, C4-binding protein, factor H, decay-accelerating factor, S protein, and C8-binding protein.

The major effects of active complement components include anaphylotoxic (C3a and C5a), opsonic (C3b, C3bi, and C4b), chemotactic (C5a), and cytolytic activity (membrane attack complex). Deficiency of early components of the classical pathway result in a high incidence of collagen vascularlike disease (C1q, C1r, C1s, C4, or C3

deficiency). Patients who lack these components often present with some combination of recurrent infections (usually pneumococcal), arthritis, skin rash, and glomerulonephritis. [Box 26-2](#) summarizes treatment options for patients who have these deficiencies. This infection risk is most likely a result of suboptimal removal of circulating immune complexes from the circulation from failure to attach C3b and iC3b to the particles.

### **DEFICIENCY OF C1 COMPLEX & C4**

These deficiencies are also transmitted by autosomal recessive inheritance. Because activation of the alternative pathway may be sufficient for host defense against many pathogens, deficient patients generally have few infectious complications. Lupuslike illness and other autoimmune disorders occur in a majority of the patients.

### **DEFICIENCY OF C2**

C2 deficiency is transmitted as an autosomal recessive trait and is the most commonly reported complement deficiency. The incidence of homozygous C2 deficiency is ~1 in 28,000 to 40,000, whereas the heterozygous carrier rate is estimated at ~1.2% in the general population based on screening of normal blood donors. Patients can have recurrent pneumonia, bacteremia, or meningitis caused by *S pneumoniae* (present in about two-thirds of reported infections), *H influenzae*, and *N meningitidis*. Autoimmune or rheumatic complications are present in about half of the patients. The lupuslike disease in C2-deficient patients is characterized by early onset, marked photosensitivity, low-titered or absent antinuclear antibody, and a low incidence of renal involvement.

### **DEFICIENCY OF C3**

C3 deficiency is transmitted by autosomal recessive inheritance. C3 is positioned at the junction of the classical and alternative complement pathways and is important for opsonization of most encapsulated bacteria; generation of C3a and C5a; and initiation of the membrane attack complex. Patients with total C3 deficiency usually have severe episodes of recurrent pneumonia, sepsis, meningitis, and peritonitis. The most common pathogens isolated are *S pneumoniae*, *H influenzae*, *N meningitidis*, and *S aureus*. Lupuslike illness and glomerulonephritis occur in 15-21% of patients.

### **DEFICIENCY OF C5-C9**

Individuals with these deficiencies are completely asymptomatic, whereas others have unusual susceptibility to recurrent *Neisseria* infections (*N meningitidis* or *N gonorrhoeae*). Deficiency of the terminal complement components is also transmitted by autosomal recessive inheritance. Recurrent episodes of meningococemia, meningococcal meningitis, and disseminated gonococcal infection have occurred in ~50% of reported patients. The rate of C5-C9 deficiency in patients with disseminated *Neisseria* infections may be as high as 10-15%. In contrast to early complement component deficiencies, autoimmune diseases are only occasionally diagnosed in these patients.

### **PROPERDIN DEFICIENCY**

This is the only deficiency of complement that is transmitted by X-linked recessive inheritance. Properdin acts to stabilize the alternative pathway C3 convertase (C3bBb). Affected patients have recurrent pyogenic infections and fulminant meningococemia.

## Section IV. Viral Infections

### 27 . Enteroviruses — *W. Lawrence Drew, MD, PhD*

#### Essentials of Diagnosis

- Isolation of enterovirus in tissue culture.
- Detection of antigen or antibody not practical for routine diagnosis.
- Detection of enterovirus in cerebrospinal fluid (CSF) by polymerase chain reaction.
- CSF usually has lymphocytic pleocytosis with normal glucose and protein.
- Typical illness is febrile rash, macular or vesicular (hand, foot, mouth syndromes).
- Most clinical illness occurs in patients < 20 years old.

#### General Considerations

Enteroviruses are one of three types of picornaviruses that cause disease in humans. As the name indicates, picornaviruses are small (pico) ribonucleic acid (RNA) viruses that have a naked capsid structure. The family includes > 230 members divided into five genera but only three—enteroviruses, rhinoviruses, and hepatoviruses (hepatitis A virus)—cause human disease. These genera can be distinguished by their stability at pH 3, optimum temperature for growth, mode of transmission, and the diseases they cause. Rhinoviruses are discussed in [Chapter 28](#) and the hepatitis A virus is discussed in [Chapter 39](#).

Nearly 70 serotypes of human enteroviruses exist, and they are divided into three subgroups: polio-, coxsackie-, and echoviruses. The capsids of these viruses are very stable in harsh environmental conditions (eg, sewage systems) and in the gastrointestinal tract, which facilitates their transmission by the fecal-oral route. Although they may initiate their infection in the gastrointestinal tract, the enteroviruses rarely cause enteric disease. Instead they cause myriad illnesses, especially diseases of the central nervous system and other systemic diseases. Several different disease syndromes may be caused by one enterovirus serotype, and several different serotypes may cause the same disease. The most well-known and well-studied picornavirus is poliovirus.

Coxsackieviruses are named after the town of Coxsackie, New York, where the viruses were first isolated. They are divided into two groups, A and B, on the basis of certain biologic and antigenic differences. These two groups are further subdivided into numeric serotypes by additional antigenic differences.

The name echovirus is derived from "Enteric Cytopathic Human Orphan," because

these agents were not thought to be associated with clinical disease. Thirty-one serotypes are now recognized. These viruses have a greater tendency than polioviruses to affect the meninges and cause meningitis, but a lesser tendency to infect anterior horn cells.

**A. Epidemiology.** The incubation period for enterovirus disease is usually 2-10 days but may be longer depending on the virus, the target tissue, and the age of the individual. Enteroviruses are highly contagious; poor sanitation and crowded living conditions foster transmission of enteroviruses, and sewage contamination of water supplies can result in enterovirus epidemics.

Humans are the major natural hosts of enteroviruses, and there is no evidence of spread from animals to humans. The enteroviruses are primarily spread person to person by enteric routes but may also be spread in droplets and cause respiratory infections. The most frequently isolated enteroviruses are coxsackieviruses A9, A16, and B1 to B5; and echoviruses 6, 9, 11, 16, and 30. These viruses are found worldwide, and each year there is a tendency for one of these to be the dominant circulating virus. Disease is most frequent in persons < 20 years of age but, as with poliovirus infection, it is generally less severe in children. However, coxsackie B virus and some of the echoviruses can cause severe disease. Secondary infections occur in = 70% of susceptible individuals living in households where the viruses have caused infection. Summer and fall are the major seasons for contracting enterovirus disease.

**B. Microbiology.** As with all picornavirus RNA, the RNA of the enteroviruses is surrounded by a very small icosahedral capsid ~ 30 nm in diameter. The genome of these viruses resembles messenger RNA (mRNA). It is a single strand of (+)-sense RNA of ~ 7.2-8.5 kilobases. It encodes a polyprotein that is proteolytically cleaved to produce the enzymatic and structural proteins of the virus. In addition to the capsid proteins, these viruses encode at least one protease and an RNA-dependent RNA polymerase.

The specificity of enterovirus interaction with cellular receptors is the major determinant of their tissue tropism and the diseases they cause. The VP<sub>1</sub> proteins at the vertices of the virion contain a canyon into which the receptor binds. The receptors for polioviruses have recently been identified as tissue-specific intercellular adhesion molecules (ICAMs), which are members of the immunoglobulin super- family. Several serotypes of coxsackievirus recognize intercellular adhesion molecule 1 (ICAM-1). ICAM-1 is expressed on epithelial cells, fibroblasts, and endothelial cells. Poliovirus binds to a molecule of similar structure. The cells in which the poliovirus receptor is expressed correlate directly with the organs infected by poliovirus infection.

On binding to the receptor, the enteroviruses are internalized by receptor-mediated endocytosis, and the virions dissociate in the acidic environment of the endosome, releasing the genome into the cytoplasm. The genome then binds to ribosomes, and a polyprotein is synthesized within 10-15 min of infection. The polyprotein is initially cleaved by cellular proteases until a viral protease is generated to cleave the rest of the polyprotein.

The RNA-dependent RNA polymerase generates a negative-strand RNA template from

which the new mRNA genome and templates can be synthesized. The amount of viral mRNA increases rapidly in the cell, with the number of viral RNA molecules reaching 400,000/cell.

Cellular RNA and protein synthesis are inhibited during infection by several enteroviruses; a viral protease blocks translation of cellular mRNA, and permeability changes induced by enteroviruses reduce the ability of cellular mRNA to bind to the ribosome. Viral mRNA also competes with cellular mRNA for the factors required in protein synthesis. These activities contribute to the cytopathic effect of the virus on the target cell.

As the viral genome is being replicated and translated, the structural proteins are cleaved from the polyproteins. After insertion of the viral genome, assembly of viral RNA into the viral capsid occurs in the cytoplasm, and the virion is released when lysis and destruction of the cell occur.

**C. Pathogenesis.** Differences in pathogenesis of the enteroviruses mainly result from differences in tissue tropism of the various subgroups. Poliovirus has been studied extensively and is the prototype for the pathogenesis of the enteroviruses.

The upper respiratory tract, the oropharynx, and the intestinal tract are the portals of entry for the enteroviruses. The virus initiates replication in the mucosa and lymphoid tissue of the tonsils and pharynx and later infects the gut. The virions are impervious to stomach acid, proteases, and bile and infect lymphoid cells of Peyer's patches and the intestinal mucosa. Primary viremia spreads the virus to receptor-bearing target tissues, where a second phase of viral replication may occur, resulting in symptoms and a secondary viremia. Virus shedding from the oropharynx can be detected for a short time before symptoms begin, whereas virus production and shedding into stool may last for = 4 months, even in the presence of a humoral immune response.

The nature of the enterovirus disease is determined by the tissue tropism of the virus. Poliovirus has one of the narrowest tissue tropisms, recognizing a receptor expressed on anterior horn cells of the spinal cord, dorsal root ganglia, motor neurons, and few other cells. Coxsackieviruses and echoviruses recognize receptors expressed on more cell types and tissues and cause a broader repertoire of diseases. Coxsackievirus and echovirus receptors may be found in the central nervous system and on heart, lung, pancreatic, and other cells. Differences in the susceptibility to and severity of poliovirus and coxsackievirus infection with age may also be attributed to differences in distribution and amount of receptor expression. Adults are generally more susceptible to serious disease with poliovirus, whereas newborns experience the most serious symptoms from coxsackie B and echovirus infections.

Most enteroviruses are cytolytic, replicating rapidly and causing direct damage to the target cell. Histologic examination reveals cell necrosis and mononuclear cell infiltrates.

The production of antibody is the major protective immune response to enteroviruses. Secretory antibody can prevent the initial establishment of infection in the oropharynx and gut, and serum antibody prevents viremic spread to the target tissue. However, in the individual with poor immune response, antibody production may be too late to block

infection of the target tissue, and patients with a deficiency of antibody production may have persistent enterovirus infections. Serum-neutralizing antibody generally develops 7-10 days after the initial onset of infection.

Cell-mediated immunity is not likely to be involved in protection but may play a role in pathogenesis. T cells appear to contribute to coxsackie B virus-induced myocarditis in mice. Indeed, certain late enterovirus syndromes (eg, myocarditis, myositis, and nephritis) may be immunologically mediated rather than resulting from direct viral invasion. Immune responses to the virus may cross-react with cellular antigens.

## CLINICAL SYNDROMES

### INTRODUCTION

The clinical syndromes of the enteroviruses are determined by several factors, including the viral serotype, infecting dose, tissue tropism, portal of entry, age, sex, pregnancy status, and state of health ([Box 27-1](#)).

### POLIOVIRUS INFECTION

#### Introduction

Polio vaccines and global eradication efforts have eliminated poliomyelitis from the Western Hemisphere and are expected to eliminate "wild" polio infections from the world in the near future. However, vaccine-associated cases of polio do occur.

#### Clinical Findings

**A. Signs and Symptoms.** Poliovirus may cause one of four outcomes, depending on the progression of the infection:

- Asymptomatic illness results if the virus is limited to infection of the oropharynx and the gut. At least 90% of poliovirus infections are asymptomatic.
- Abortive poliomyelitis, the minor illness, is a nonspecific febrile illness occurring in ~5% of infected individuals. Symptoms of fever, headache, malaise, sore throat, and vomiting occur within 3-4 days of exposure.
- Nonparalytic poliomyelitis or aseptic meningitis occurs in 1-2% of patients with poliovirus infections. The virus progresses into the central nervous system and the meninges, causing stiff neck and back pain in addition to the symptoms of minor illness.
- Paralytic polio, the major illness, occurs in 0.1-2.0% of persons with poliovirus infections and is the most severe outcome. Major illness follows 3-4 days after minor illness has subsided, thereby producing a biphasic illness. In this disease the virus spreads from the blood to the anterior horn cells of the spinal cord and the motor cortex of the brain. The severity of the paralysis is determined by the extent of the neuronal infection and the neurons affected. Spinal paralysis may involve one or more limbs, whereas bulbar (cranial) paralysis may involve a combination of cranial nerves and even

the medullary respiratory center.

Paralytic poliomyelitis is characterized by an asymmetric flaccid paralysis with no sensory loss. The degree of paralysis may vary from involving only a few muscle groups (eg, one leg) to complete flaccid paralysis of all four extremities. The paralysis may progress over the first few days and may result in complete recovery, residual paralysis, or death. Most recovery occurs within 6 months.

Bulbar poliomyelitis can be more severe and may involve the muscles of the pharynx, vocal cords, and respiratory system, resulting in death in 75% of patients.

**B. Laboratory Findings.** The peripheral blood white blood cell (WBC) level is only moderately elevated with a relative lymphopenia. The CSF WBC count is elevated with a lymphocytosis, and the protein level is > 35 mg/100 mL.

**C. Differential Diagnosis.** With the disappearance of poliomyelitis from the Western Hemisphere, it is more likely that a patient presenting with febrile flaccid paralysis is suffering from the Guillain-Barre syndrome, whose etiology is unknown. The CSF examination shows elevation of protein but no pleocytosis. Alternatively there are rare instances of paralytic illness associated with entero-, echo-, or coxsackieviruses. Rheumatic fever, cytomegalovirus (CMV) polyradiculopathy, bacterial meningitis, and infectious mononucleosis are other illnesses that may be mistaken for poliomyelitis.

**D. Complications.** Pneumonia, urinary tract infections, and decubiti are early complications, whereas the post-polio syndrome is a late complication. This entity is characterized by a recrudescence of increased fatigue and impaired motor function many years after the acute poliomyelitis illness.

## COXSACKIEVIRUS & ECHOVIRUS INFECTIONS

### INTRODUCTION

Several clinical syndromes may be caused by either coxsackievirus or echovirus (eg, aseptic meningitis) (see [Box 27-1](#)), but certain illnesses are especially associated with coxsackieviruses. For example, coxsackie A viruses are highly associated with herpangina, whereas myocarditis and pleurodynia are more frequently caused by coxsackie B serotypes.

### 1. HERPANGINA

#### Clinical Findings

**A. Signs and Symptoms.** This syndrome is inappropriately named because it has no relation to herpesvirus. Rather, it is caused by several types of coxsackie A virus. Fever, sore throat, pain on swallowing, anorexia, and vomiting characterize herpangina. The classic finding is vesicular, ulcerated lesions around the soft palate and uvula. Less typically the lesions may affect the hard palate.

**B. Laboratory Findings.** The coxsackie A virus can be recovered from throat, feces, or

vesicular lesions. There are no consistent blood abnormalities.

**C. Differential Diagnosis.** Primary herpes simplex virus (HSV) stomatitis may resemble herpangina, but the latter is usually confined to the posterior pharynx, whereas HSV also affects the anterior mouth, gums, and lips.

**D. Course.** The disease is self-limited and requires only symptomatic management.

## 2. PLEURODYNIA (BORNHOLM DISEASE)

### Clinical Findings

**A. Signs and Symptoms.** This syndrome, also known as the *devil's grip*, is an acute illness caused by coxsackie B virus. Patients have sudden onset of fever and unilateral low thoracic, pleuritic chest pain, which may be excruciating. Abdominal pain and even vomiting may also occur. Although a pleural friction rub may be heard, the physical findings of pneumonia are not present. Muscles on the involved side may be extremely tender. The pain tends to appear and disappear abruptly and repeatedly, for example, hourly, and can be very severe.

**B. Laboratory Findings.** Chest x-ray films are almost always normal, as are blood leukocyte counts. The virus can be recovered from throat samples, stool samples, or both.

**C. Course.** Pleurodynia lasts an average of 4 days and may relapse after the patient has been asymptomatic for several days. High fever and the waxing and waning of the pain help to distinguish pleurodynia from other pleuritic processes, for example, pulmonary embolism. The absence of lung abnormalities eliminates pneumonia as a diagnosis.

## 3. MENINGITIS

### Clinical Findings

**A. Signs and Symptoms.** Viral, or aseptic, meningitis is an acute febrile illness accompanied by headache and signs of meningeal irritation, including nuchal rigidity, Kernig's or Brudzinski's sign, or both. Petechiae or skin rash may occur in patients with enteroviral meningitis. Both echo- and coxsackieviruses cause viral "aseptic" meningitis.

**B. Laboratory Findings.** Examination of the CSF reveals a predominantly lymphocytic pleocytosis, but very early in the disease, polymorphonuclear leukocytes (PMNs) may be more numerous. CSF glucose levels are usually normal but may be slightly low. CSF protein levels are normal to slightly elevated. Blood counts and chemistry examinations are normal. The causative virus can be recovered from throat, stool, and CSF, but culture of enteroviruses requires an average of 5 days. Polymerase chain reaction of CSF is becoming a most useful rapid diagnostic test.

**C. Differential Diagnosis.** The major differential diagnosis is bacterial meningitis, which

is characterized by more severe illness and prostration. The CSF reveals elevated PMNs, low glucose, high protein, and a positive Gram stain. Other viruses, for example, mumps, Epstein-Barr (EB), and lymphocytic choriomeningitis (LCM) viruses, may cause an indistinguishable meningitis, but associated clinical features help to identify these etiologies.

**D. Course.** Unless associated encephalitis (meningoencephalitis) exists, recovery is uneventful. If encephalitis is present, permanent neurologic sequelae may ensue.

#### **4. ENTEROVIRAL EXANTHEMS**

##### **Clinical Findings**

**A. Signs and Symptoms.** This syndrome may occur in patients infected with either echo- or coxsackieviruses and is usually accompanied by fever. The rash is usually maculopapular but occasionally may appear as petechial or even vesicular.

**B. Laboratory Findings.** The virus can be recovered from throat samples, stool samples, or both.

**C. Differential Diagnosis.** The petechial type of eruption must be differentiated from that of meningococcemia. The child with enteroviral infection is not as ill and does not usually have a PMN leukocytosis in blood like the child with meningococcemia.

#### **5. HAND-FOOT-AND-MOUTH DISEASE**

##### **Clinical Findings**

**A. Signs and Symptoms.** This syndrome is a vesicular exanthem usually caused by coxsackievirus A16. The name is descriptive, since the main features of this infection are vesicular lesions of the hands, feet, mouth, and tongue. The oral lesions are identical to those of herpangina.

**B. Laboratory Findings.** There are no consistent laboratory abnormalities, but the virus can be recovered from throat and stool samples in an average of 5 days.

**C. Course.** The patient is mildly febrile, and the illness subsides in a few days.

#### **6. ACUTE BENIGN PERICARDITIS**

##### **Clinical Findings**

**A. Signs and Symptoms.** The chest pain, pericardial friction rub, and clinical illness often follow a preceding febrile illness, which may have been associated with a rash.

**B. Laboratory Findings.** EKG reveals changes characteristic of pericarditis, but there are no consistent blood abnormalities. Pericardial fluid cultures may be positive for virus, but throat and stool cultures are often negative due to the time lag between the

viral illness and the development of this late complication.

**C. Differential Diagnosis.** Pericarditis is usually a disease of young adults but may be seen in older individuals, in whom the distinction from myocardial infarction may be difficult. Usually the symptoms are similar, but in pericarditis, fever may be greater and more prolonged than in a patient with myocardial infarction. Other causes of pericarditis, for example, bacterial causes, must be considered, including complications of pneumonia and tuberculosis.

## 7. MYOCARDITIS

### Clinical Findings

**A. Signs and Symptoms.** Myocarditis is caused by coxsackie B virus and occurs in older children and adults but is most threatening in newborns. Neonates with these infections have febrile illnesses and the sudden, unexplained onset of heart failure. Cyanosis, tachycardia, cardiomegaly, and hepatomegaly occur. In older children or adults the cardiac involvement is usually late, ie, days to weeks after initial symptoms.

**B. Laboratory Findings.** Electrocardiographic changes are those found in patients with myocarditis, but there are no characteristic blood abnormalities. Viral culture of pericardial fluid or myocardial biopsy may be positive but is often negative due to the late-onset nature of this complication.

**C. Course.** Myocarditis is usually self-limited but may be fatal due to arrhythmia or heart failure, especially in newborns.

**D. Complications.** Myocarditis may progress to chronic cardiomyopathy.

## 8. OTHER SYNDROMES

### Introduction

Echoviruses may also produce severe disseminated infection in infants. Enterovirus 70 and a variant of coxsackie A24 have recently been associated with an extremely contagious ocular disease, acute hemorrhagic conjunctivitis. The infection causes subconjunctival hemorrhages and conjunctivitis. The disease has a 24-h incubation period and resolves within 1 or 2 weeks.

Respiratory disease, hepatitis, and diabetes are some additional syndromes attributed to enteroviruses. Coxsackieviruses A21 and A24 and echoviruses 11 and 20 can cause coldlike symptoms if the upper respiratory tract becomes infected. Enterovirus 72, or hepatitis A virus, causes hepatitis A (see [Chapter 39](#)). Coxsackie B infections of the pancreas have been suspected to cause insulin-dependent diabetes because of the destruction of the islets of Langerhans.

### Diagnosis

**Poliovirus.** Poliovirus grows well in monkey kidney tissue culture, and the virus may be

isolated from the pharynx during the first few days of illness and from the feces for = 30 days. The CSF is rarely positive for the virus, although a pleocytosis of 25-300 leukocytes usually occurs. Neutrophils may predominate early, especially in aseptic meningitis. Protein and glucose levels in CSF are usually normal or only slightly abnormal. Serologic tests can document seroconversion to one of the three poliovirus serotypes.

**Coxsackievirus and Echovirus.** Coxsackievirus and echovirus can usually be isolated from the throat and stool during acute infection and often from CSF in patients with meningitis. Virus is rarely isolated in pericarditis or myocarditis, since the symptoms occur several weeks after the initial infection. The coxsackie B viruses can be grown on primary monkey or human embryo kidney cells. Many coxsackie A virus strains do not grow in tissue culture and must be grown in suckling mice.

Polymerase chain reaction analysis of CSF appears to be more sensitive than culturing and is becoming the diagnostic procedure of choice for documenting enteroviral meningitis.

Serologic confirmation of poliovirus infection can be made by detection of specific immunoglobulin M (IgM) or a fourfold increase in antibody titer between acute illness and convalescence; however, the many serotypes for echo- and coxsackieviruses make this approach impractical.

## Treatment

No specific antiviral therapy is approved for enterovirus infections, but pleconaril, a drug active against picornaviruses in vitro, is being evaluated for the treatment of enteroviral meningitis and viremia. Immune globulin has been used in immunocompromised patients with chronic enteroviral infection of the central nervous system ([Box 27-2](#)) and can diminish viral titers in body fluids.

## Prevention & Control

**Poliovirus.** The prevention of paralytic poliomyelitis is one of the triumphs of modern medicine. In the western world, complete control has been achieved by the use of vaccines, and worldwide eradication of poliomyelitis is expected soon.

Two types of poliovirus vaccine exist: a formalin-inactivated product known as the inactivated, killed, or Salk vaccine, and an attenuated one known as the live, oral, or Sabin vaccine ([Box 27-3](#)). Both vaccines can induce a protective antibody response.

Oral vaccine is attenuated (ie, rendered less virulent) by passage in cell cultures. Attenuation yields a virus capable of replicating in the oropharynx and intestinal tract and of being shed in feces for weeks, but not of being invasive. The remote potential for reverting to virulence and causing paralytic disease is the major drawback of the live vaccine and is estimated to occur in 1 per 4 million doses administered (versus 1 in 100 of those infected with "wild" poliovirus).

The risk of vaccine-associated paralytic poliomyelitis is increased in

immunocompromised individuals and is more likely to occur in susceptible adults than susceptible children. Since the live vaccine strain may spread to close, especially household, contacts (a virtue in achieving mass immunization), vaccine-associated poliomyelitis may occur in those contacted by the original recipient, rather than the actual vaccine recipient. Because of the above considerations, killed vaccine is now the recommended prophylaxis, and oral live polio vaccine is used only for those refusing injections or for those traveling to areas with endemic poliomyelitis.

**Coxsackievirus and Echovirus.** No vaccines exist for these viruses (see [Box 27-3](#)). Transmission can presumably be reduced by improvements in hygiene and living conditions.

## 28 . Rhinoviruses — *W. Lawrence Drew, MD, PhD*

### Essentials of Diagnosis

- Leading cause of upper respiratory infection.
- Virus grows preferentially at 33 °C in diploid fibroblast cells.
- Typical illness includes rhinorrhea and low-grade fever but little evidence of lower respiratory illness.

### General Considerations

Rhinoviruses are the most frequent cause of the common cold. One hundred two serotypes have been identified by neutralization with specific antisera, and additional strains have been isolated but are not yet typed.

**A. Epidemiology.** Rhinoviruses can be transmitted by two mechanisms: aerosols and direct contact (eg, with contaminated hands or inanimate objects). Surprisingly, aerosols may not be the major route, and hands appear to be an important vector. Rhinoviruses can be recovered from the hands of 40-90% of persons with colds and from 6-15% of inanimate objects around them. The virus can survive on these objects for many hours.

Rhinoviruses produce clinical illness in only half of those infected, and thus many asymptomatic individuals are capable of spreading the virus. Rhinovirus "colds" affect people in temperate climates most frequently in the early fall, which may reflect the return to school rather than any change in the virus itself. Rates of infection are highest in infants and children, who are also the primary vector introducing colds into family units. Secondary infections occur in ~50% of family members, especially other children.

Although many different rhinovirus serotypes may be found in a given community, only a few predominate during a specific cold season. They tend to be the newly categorized serotypes, suggesting that a gradual antigenic drift occurs.

**B. Microbiology.** Many microbiological features of rhinoviruses are similar to those of enteroviruses (see [Chapter 27](#)). As with all picornaviruses, the RNA of rhinoviruses is surrounded by a very small icosahedral capsid approximately 30 nm in diameter. The genome of these viruses resembles messenger RNA (mRNA). It is a single strand of (+)-sense RNA of ~7.2-8.5 kb. It encodes a polyprotein that is proteolytically cleaved to produce the enzymatic and structural proteins of the virus. In addition to the capsid proteins, these viruses encode at least one protease and an RNA-dependent RNA polymerase. A virus-encoded protease blocks translation of cellular mRNA.

**C. Pathogenesis.** In contrast to enteroviruses, rhinoviruses are unable to replicate in the gastrointestinal tract. This contrast probably reflects differences in surface receptors between the two groups of viruses rather than degradation of rhinovirus by gastric acid. Also rhinoviruses replicate optimally at 33 °C, which may explain their predilection for

the anterior nares.

At least 80% of the rhinoviruses share a common receptor, ICAM-1, which is a member of the immunoglobulin family and is expressed on epithelial, fibroblast, and lymphoblastoid cells.

Secretory and serum antibodies are generated in response to the rhinovirus and can be detected within a week of infection. No antigen is common to all rhinoviruses. Although secretory immunoglobulin A (IgA) is probably more important than serum antibody in preventing and controlling infection, its half-life is brief. A better correlate of immunity is the level of serum antibody that begins to wane ~18 months after infection.

Interferon, generated in response to the infection, may both limit the progression of the infection and contribute to the symptoms. The release of cytokines during inflammation can promote the spread of the virus by enhancing the expression of viral receptors. Cell-mediated immunity does not appear to play an important role in controlling rhinovirus infections.

Infection can be initiated by as little as one infectious viral particle. During the peak of illness, titers of 500 to 1,000 infectious virions are reached in nasal secretions. Most viral replication occurs in the nose, and the severity of symptoms correlates with the quantity (titer) of virus in nasal secretions. Biopsies of nasal mucosa taken during a "cold" reveal severe edema of the subepithelial tissue but minimal inflammatory cell response. Infected ciliated epithelial cells may be sloughed from the nasal mucosa.

## **RHINOVIRUS INFECTION**

### **Clinical Findings**

**A. Signs and Symptoms.** Upper respiratory infections (URIs) caused by rhinoviruses usually begin with sneezing, soon followed by rhinorrhea ([Box 28-1](#)). The rhinorrhea increases and is then accompanied by nasal stuffiness. Mild sore throat also occurs, along with headache, malaise, and chills. The illness peaks in 3-4 days, but cough and nasal symptoms may persist for 7-10 days longer. High fever and shaking chills are not usual features of rhinovirus URIs.

**B. Laboratory Findings.** The clinical syndrome of the common cold is usually so characteristic that laboratory diagnosis is unnecessary. Rhinoviruses cause up to one half of URIs, but coronaviruses, parainfluenza viruses, and other agents also cause a sizable proportion of colds. Also at times it may be difficult to distinguish allergic rhinitis from an URI.

Nasal washings are the best type of clinical specimen for recovering the virus. Rhinoviruses grow in vitro only in cells of primate origin, with human diploid fibroblast cells (eg, WI-38) as the optimum system. As already stated, these viruses grow best at 33 °C, which is not the optimum temperature for any other clinically important viruses. Thus their isolation may require a separate incubator. Isolation in tissue culture occurs 4-5 days on average. The virus is identified by typical cytopathic effects and the demonstration of acid lability. Serotyping is rarely necessary but is done by using pools

of specific neutralizing sera.

Serologic testing to document rhinovirus infection is not practical. No antigen is common to all rhinoviruses; thus it would be necessary to have the patient's viral isolate or a prototype of the specific rhinovirus prevalent in the community in order to perform this kind of testing.

**C. Differential Diagnosis.** Several other viruses can cause similar syndromes, especially coronaviruses, adenoviruses, and parainfluenza viruses. Allergic rhinitis is not associated with fever and often is accompanied by an itching conjunctivitis. Also the peripheral blood may show eosinophilia.

**D. Complications.** In otherwise healthy individuals, rhinovirus illnesses are uncomplicated, but in those with chronic lung disease, exacerbations of bronchitis may occur. In severely immunocompromised patients, lower respiratory disease may occur.

## Treatment

There is no specific therapy for rhinovirus ([Box 28-2](#)). Nasal vasoconstrictors may provide relief, but their use may be followed by rebound congestion and worsening symptoms. Antibacterial agents are not beneficial unless a true bacterial infection (eg, sinusitis) occurs. Even when nasal secretions have become purulent, a carefully performed Gram's stain will usually show few if any bacteria. Rigorous studies of vitamin C therapy have not shown efficacy. Topical interferon provides antiviral activity but itself produces upper respiratory symptoms. Drugs that block viral attachment, penetration, or replication have been discovered and are being evaluated in clinical trials.

## Prognosis

Because rhinovirus illnesses are usually uncomplicated, the prognosis for recovery is excellent, but as mentioned above in the complications section, exacerbations of chronic lung disease may occur, and fatal illnesses in immunocompromised patients have been reported.

## Prevention & Control

There are three potential methods of prevention or control of rhinoviruses: vaccines, antiviral agents (especially interferon), and interruption of transmission ([Box 28-3](#)).

The multiple serotypes and apparent antigenic drift in rhinovirus antigens suggest that successful vaccines are unlikely. Formalin-inactivated, parenterally administered vaccines induce antibody in serum but not in nasal secretions and are not as useful as those given intranasally.

Prophylactic topical interferon is effective but associated with unacceptable side effects. Since transmission is person to person, infection may be reduced by minimizing finger to nose and hand to hand spread as well as by covering coughs and sneezes.

## 29 . Influenza — *Lisa Danzig, MD & Keiji Fukuda, MD, MPH*

### Essentials of Diagnosis

- Acute onset of fever, chills, myalgia, headache, sore throat, nonproductive cough, and severe malaise
- Winter or epidemic setting
- Variable white blood cell counts
- Nasopharyngeal specimen ideally collected within 2-3 days of illness; placed into viral transport media; virus usually isolated within 2-6 days of inoculation into tissue culture
- Direct antigen assay positive on nasopharyngeal specimens for influenza A
- Increased school absenteeism or emergency room visits signal outbreak

### General Considerations

Influenza is a highly contagious, acute, febrile respiratory illness caused by influenza A and B viruses. The hallmark of these viruses is their ability to undergo rapid ongoing antigenic change and to cause annual or near-annual epidemics of febrile respiratory disease affecting all age groups. In addition, the unpredictable emergence of new influenza A subtypes can lead to explosive global pandemics of disease. Although most cases are self-limited, influenza is a major source of mortality among those at increased risk for influenza-related complications. Annual vaccination of persons at high risk for serious complications is the most effective approach for reducing influenza-related morbidity and mortality.

Influenza viruses, which include influenza A virus, influenza B virus, influenza C virus, and thogotovirus, belong to the *Orthomyxoviridae* family. Influenza A and B viruses cause epidemic disease in humans (influenza C viruses usually cause a mild, coldlike illness) and are designated by type, site, and year of isolation. Influenza A (but not B or C) viruses are further designated by subtype. For example, influenza A/Texas/36/91/(H1N1) refers to an influenza type A virus of the H1N1 subtype that was isolated in Texas in 1991 and has a strain designation of 36 to distinguish it from other 1991 Texas isolates of this subtype.

**A. Epidemiology.** In the United States, epidemic influenza activity often begins each year in the late fall or early winter months and may continue in different regions of the country through the spring. From year to year, the onset, duration, and geographic distribution of regional epidemics can vary greatly, and sporadic cases and outbreaks can occur anytime, including during the summer months. Within more circumscribed communities and institutions, epidemics or outbreaks usually last ~6-8 weeks.

Influenza A(H1N1), influenza A(H3N2), and influenza B viruses are in worldwide

circulation. Any one or any combination of these three viruses may be the cause of a season's epidemic activity. During each influenza season, an estimated 10-20% of the U.S. population may develop influenza, but attack rates of 40-50% within institutions are not unusual. In communities, influenza cases often appear first among school-age children, and attack rates in this group are usually the highest (and lowest among the elderly).

By contrast, rates of serious complications are highest among the elderly, the very young, and those with underlying chronic cardiopulmonary conditions that place them at high risk for complications. Influenza-related mortality is usually tabulated in terms of "excess" deaths. This concept was developed by William Farr and refers to the idea that influenza-related mortality can be quantified during influenza epidemics by determining the increase in deaths beyond the expected number of deaths if there was no epidemic. In the United States, the average annual toll of excess deaths from influenza-related complications is ~20,000; > 40,000 deaths may occur during severe years. Although pandemics are often associated with dramatic increases in mortality, the cumulative death toll from seasonal epidemic influenza since the 1968 pandemic exceeds the total for the 1918 pandemic (see below).

Pandemics of influenza occur when a new subtype of influenza A virus emerges and leads to increased morbidity and mortality in all age groups. This is a dramatic event that occurs relatively infrequently and unpredictably. The most devastating pandemic of the twentieth century began in 1918 and was associated with the emergence of the influenza A(H1N1) virus. Between the spring of 1918 and the spring of 1919, three waves of "Spanish flu" swept around the world leading to > 550,000 deaths in the United States and > 20 million deaths worldwide. In contrast to the usual mortality pattern, influenza-related deaths in this pandemic occurred for unknown reasons predominantly among people 20-40 years of age.

Two subsequent pandemics, which began in 1957 (the "Asian flu") and in 1968 ("Hong Kong flu"), were associated with the emergence of the influenza A (H2N2) virus and the influenza A (H3N2) virus, respectively. In contrast to these events, the reappearance of influenza A (H1N1) virus in 1977 was not considered a true pandemic because illness largely was confined to people younger than 20 years of age. Based on these events, evidence of earlier pandemics, and the continuing evolution of influenza A viruses, the occurrence of another pandemic is likely.

The ability of influenza viruses to cause recurrent epidemics and pandemics can be attributed in large part to their propensity for antigenic change. This occurs through two distinct processes known as antigenic "drift" and "shift." In antigenic drift, which both influenza A and B viruses exhibit, point mutations in the viral RNA result in immunologically significant alterations to HA and NA. Drift occurs more rapidly in influenza A subtypes than in influenza B viruses. Eventually, one of the newer influenza strains becomes the predominant strain because neutralizing antibody levels to older strains rise in the general population and exert a selective evolutionary pressure favoring the emergence of a new strain. Typically, a virus strain may predominate for a few years before a significantly different variant emerges to replace it.

Antigenic shift refers to the appearance of a virus bearing either a novel HA or a novel

combination of HA and NA. Shift is exhibited only by influenza A viruses and may occur in one of two ways. Genes from influenza A viruses normally in circulation among pigs or birds may reassort (ie, mix) with genes from influenza A viruses circulating among humans, resulting in the appearance of a new influenza A virus subtype containing genes from both viruses. Pigs are thought to serve as a "mixing vessel" for genetic reassortment among influenza viruses because they are susceptible to avian, swine, and human influenza A viruses. Avian species are thought to serve as the ultimate reservoir of influenza A viruses. Alternatively, new influenza A virus subtypes may appear among humans as a result of direct transmission of animal viruses to humans. An example of this type of antigenic shift was seen recently in Hong Kong. During May through December 1997, a total of 18 people in Hong Kong were hospitalized because of disease related to influenza A (H5N1) infections. Previous to this outbreak, H5N1 viruses had been known to cause disease only in birds. The potential for this influenza A virus to cause a pandemic remains uncertain.

Antigenic shift results in a radical alteration in antigenicity. The emergence of a novel influenza A virus can lead to a pandemic but only if the new virus is sufficiently transmissible among humans to maintain epidemic activity and is capable of causing disease.

**B. Microbiology.** Influenza A and B viruses are single-stranded, negative-sense (complimentary to mRNA) RNA viruses, which contain eight segments of RNA, associated nucleoprotein, and three polymerases. Segmentation of the RNA is an important feature because it facilitates the exchange of genes (ie, genetic reassortment) among influenza viruses. The genome is surrounded by a lipid bilayer from which hemagglutinin (HA) and neuraminidase (NA) proteins protrude as "spikes." HA and NA are glycoproteins and contain the major antigenic determinants of influenza viruses. HA is responsible for the attachment of virus to oligosaccharide-containing terminal sialic acids and the penetration of virus into cells. HA is the major antigen against which the host's protective antibody response is directed. NA is less abundant on the viral surface, and its function is less well understood but is related, in part, to the release of virus from infected cells. Antibody to NA restricts the spread and severity of influenza infection. Currently, 15 HA and 9 NA subtypes are known. Among these, two HA subtypes (H1 and H3) and two NA subtypes (N1 and N2) are found on currently circulating human influenza viruses.

The viral envelope also contains two matrix proteins (M1 and M2), which form the basis for classifying influenza viruses into types A or B. M1 protein is thought to add rigidity to the lipid bilayer, whereas M2 protein functions as a pH-activated ion channel. The M2 protein is therapeutically important because it appears to contain the site of action for amantadine and rimantadine, two antiviral agents with specific activity against influenza A (but not influenza B) viruses.

**C. Pathogenesis.** Aerosol produced by the coughing or sneezing of infectious individuals is thought to be the primary way in which influenza viruses are spread. However, transmission of virus by direct contact with infected respiratory secretions may also occur. The incubation period for influenza is typically 1-4 days. Virus can be isolated from the nasopharynx of adults for = 3-4 days after illness develops. Infection and viral replication occur primarily in the columnar epithelial cells of the respiratory tract

and result in the loss of cilia, inflammation,, and the eventual necrosis and desquamation of the respiratory epithelium. Regeneration of the epithelial cells takes ~3-4 weeks during which pulmonary abnormalities may persist. Although constitutional manifestations are pronounced in influenza, viremia has been difficult to document.

Infection leads to the induction of both B- and T-cell responses. Neutralizing serum and mucosal antibodies to HA are the primary mediators of protection against infection and clinical illness. Serum antibodies to HA can persist for decades. Antibodies to NA are inefficient in neutralizing influenza viruses but help restrict the release of virus from infected cells, reduce the intensity of infection, and enhance recovery. The role of T-cell-mediated immunity is less well understood.

## **INFLUENZA INFECTION**

### **Clinical Findings**

The spectrum of influenza infection ranges from subclinical cases to fulminating viral pneumonia.

**A. Signs and Symptoms (Box 29-1).** There are no specific physical examination findings associated with influenza. The patient usually appears ill and has fever. A clear nasal discharge is common. A typical uncomplicated case of influenza illness begins abruptly and is manifested by sore throat, headache, fever, chills, myalgias, anorexia, and extreme fatigue. Fever is usually between 38 and 40 °C but may be higher and usually lasts for ~3 days (but = 5 days). Other respiratory tract manifestations include cough, which is usually nonproductive, and a runny or stuffy nose. Substernal tenderness, photophobia, abdominal pain, and diarrhea occur less frequently. Despite severe sore throat, the mucous membranes of the pharynx may be unremarkable or hyperemic without exudates. Small tender cervical lymph nodes may be palpable, and the lungs are usually clear, although scattered rhonchi and crackles can be heard in as many as a quarter of patients.

In the elderly, fever may be absent and the presenting signs may be anorexia, lassitude, confusion, and rhinitis. In children, fevers are often higher and can lead to febrile seizures. Gastrointestinal manifestations, such as vomiting, abdominal pain, and diarrhea, and other complications such as myositis, croup (tracheobronchitis), and otitis media also occur more frequently in children. Unexplained fever may be the primary manifestation in neonates.

**B. Laboratory Findings.** Results of routine laboratory tests are not specific for influenza. Leukocyte counts are variable. Severe leukopenia has been described in overwhelming illness. Leukocytosis of > 15,000 cells/mL should raise the suspicion of a secondary bacterial process. Specific laboratory tests to confirm influenza include viral culture, rapid antigen detection, and serology.

Virus can be isolated from nasal washing and nasopharyngeal swab specimens obtained within 3-4 days of illness. Virus is grown either in embryonated hens' eggs or in primary tissue culture systems, such as Madin-Darby canine kidney cells. Viral culture offers specific information and the ability to further characterize the isolate, but the

sensitivity of this technique is highly dependent on the timing of when the specimen is obtained. Results usually are not available for at least 3 days.

Rapid diagnostic techniques to identify viral antigens in clinical specimens include immunofluorescence, enzyme immunoassay, and time-resolved fluoroimmunoassay. Several rapid test kits are now commercially available that either can 1) detect influenza A but not influenza B virus; 2) detect influenza A or B virus but not distinguish between them; or 3) detect influenza A or B virus and distinguish between them. In general, these tests are more specific than sensitive but head-to-head comparison data are not available. These tests can yield results within 30 min. Reverse transcriptase polymerase chain reaction assays have also been used to detect influenza virus RNA in clinical specimens.

Serologic techniques for measuring antibody against influenza include hemagglutination inhibition, neutralization, enzyme immunoassay, and complement fixation. In general, serology is a sensitive technique for establishing influenza infections. However, serologic tests usually require acute and convalescent serum samples to demonstrate a significant increase in antibody level. The measurement of influenza antibody levels in a single-serum sample is rarely helpful. Ideally, acute and convalescent blood samples should be collected, respectively, within 2-3 days of illness and at 3 weeks after the start of illness. The most commonly used serologic test to document influenza virus infection is hemagglutination inhibition because it (and neutralization) is more sensitive than complement fixation and allows subtype and strain-specific antibody to be measured.

**C. Imaging.** A chest X-ray may show an infiltrate in those with primary viral pneumonia or a complicating bacterial pneumonia.

### **Differential Diagnosis**

Other respiratory viruses, including respiratory syncytial virus, adenovirus, parainfluenza virus, and rhinovirus, as well as other organisms, such as *Mycoplasma pneumoniae*, can produce illness similar to influenza. However, outbreaks of febrile respiratory illness cases during the winter through spring months are characteristic of influenza. Information on local influenza activity is usually available from the local health department.

### **Complications**

The most common serious complications of influenza include exacerbation of underlying chronic pulmonary and cardiopulmonary diseases, such as worsening of chronic obstructive pulmonary disease, asthma, and congestive heart failure, as well the development of pneumonia. Secondary bacterial pneumonias occur much more frequently than primary viral pneumonia and usually are associated with *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*. With complicating bacterial pneumonia, the patient typically reports a period of improvement followed by the appearance of signs and symptoms suggestive of pneumonia, such as pleuritic chest pain, productive cough, and fever. On chest radiography, lobar consolidation can be seen and sputum smears show polymorphonuclear leukocytes with bacteria.

Primary viral pneumonia is an infrequent but often fatal complication in which influenza progresses within the first 24-48 h of illness and leads to increasing dyspnea, tachypnea, and cyanosis. On presentation, fever and cough are usually present and the patient appears uncomfortable and dyspneic. On chest auscultation, diffuse fine rales with wheezes or coarse breath sounds may be evident. Sputum may be scanty but can be blood streaked. Chest roentgenograms usually show bilateral interstitial infiltrates or a picture consistent with acute respiratory distress syndrome. The Gram stain of the sputum often shows few polymorphonuclear cells or bacteria. Virologic cultures of the respiratory secretions often yield virus. The value of antiviral medications in this setting is unknown. Cases of viral pneumonia described in the 1918 and 1957 pandemics were associated with underlying cardiac valvular disease (frequently mitral stenosis from rheumatic heart disease) and pregnancy.

In addition to these pneumonias, mixed viral and bacterial pneumonias with features of both etiologies have been described. Other respiratory tract complications include bacterial sinusitis, croup, and otitis media.

Reye's syndrome has been described primarily in children < 18 years of age. In almost all cases, Reye's syndrome appears to be a complication resulting from the use of salicylates, most commonly aspirin, to treat certain viral illnesses. Reye's syndrome usually presents several days after an unremarkable viral illness. The syndrome usually presents with nausea and vomiting followed by central nervous system (CNS) changes such as lethargy, delirium, seizures, or coma. Reye's syndrome has been primarily seen in children treated with aspirin for influenza B virus and varicella-zoster virus infections but also for infections by influenza A virus. Since the 1980s, the incidence of Reye's syndrome has decreased dramatically in the United States after warnings were issued regarding the link between the treatment of children with aspirin and this syndrome.

Myocarditis and pericarditis were reported in association with influenza during the 1918-1919 pandemic but have been documented infrequently since then. Minor electrocardiogram changes in the setting of influenza can often be seen in patients with underlying heart disease. Myositis with rhabdomyolysis and myoglobinuria has been reported but is uncommon. Toxic shock syndrome associated with secondary staphylococcal infection after acute influenza also has been reported. In addition, a number of CNS complications including encephalopathy, encephalitis, transverse myelitis, and Guillain-Barre syndrome have all been reported, but their association with influenza remains unclear.

## **Treatment**

Uncomplicated cases of influenza are usually treated symptomatically. Salicylates should be avoided in children < 18 years of age because of the risk of Reye's syndrome. There are two classes of licensed antiviral agents, the adamantines and the neuraminidase inhibitors, with specific activity against influenza viruses. The adamantines, amantadine hydrochloride and rimantadine hydrochloride, have specific activity against influenza A virus but not B virus. The neuraminidase inhibitor drugs, zanamivir and oseltamivir, have activity against both influenza A and B viruses. Amantadine is licensed for use in children and adults, whereas rimantadine is licensed for use in adults. Both drugs can be given for treatment of or prophylaxis against

influenza A virus but are ineffective against influenza B virus. These chemically related drugs are equally effective and appear to inhibit viral replication by blocking the ion channel function of the viral M2 protein. Viral resistance to both compounds is associated with changes in the M2 protein. Although the rapid emergence of resistant viruses has been demonstrated both in vitro and in vivo, the risk of transmission of these resistant viruses remains unclear. Resistant viruses have been most often isolated from individuals receiving treatment and less often from contacts.

When administered prophylactically, both agents are ~70-90% effective in preventing illness caused by influenza A viruses. Subclinical infections still can occur while taking these drugs. Although chemoprophylaxis can be used alone in persons for whom vaccination is contraindicated, it is preferable to administer these agents as an adjunct to vaccination in high-risk groups. Since these drugs do not interfere with antibody response to vaccination, they can be used to provide prophylaxis to persons who were vaccinated but who have not yet had adequate time (usually 2 weeks) to mount a vaccine antibody response. To control an institutional influenza outbreak, antiviral agents are most effective when administered to all residents.

When administered within 48 h of illness onset, these agents have also been shown to reduce the severity and duration of influenza in young and healthy adults and children. Similar controlled studies have not been conducted among persons at high risk for complications.

The major pharmacological differences between these agents are their pharmacokinetic and side-effect profiles. More than 90% of amantadine is excreted unchanged by the kidneys, whereas ~75% of rimantadine is metabolized by the liver (however, unmetabolized rimantadine and its metabolites are renally excreted).

Both medications can lead to CNS and gastrointestinal side effects. In one study, the incidence of CNS side effects in young and healthy adults using 200 mg/d was higher among those taking amantadine (14%) than rimantadine (6%) or placebo (4%). CNS side effects include nervousness, anxiety, difficulty concentrating, and light-headedness. More serious side effects (eg, marked behavioral changes, delirium, hallucinations, agitation, and seizures) have been associated with high plasma drug concentrations, particularly among persons with renal insufficiency, seizure disorders, or certain psychiatric disorders, or among elderly persons who were taking amantadine at doses of 200 mg/d. Approximately 3% of those taking either drug develop gastrointestinal side effects, such as nausea and anorexia. Side effects cease soon after stopping the drug, and lower doses appear to be associated with a lower incidence of side effects.

The usual therapeutic and prophylactic dosage of amantadine and rimantadine in adults < 65 years is 100 mg orally twice a day ([Box 29-2](#)). Doses should be reduced in children younger than 10 years, adults 65 years and older, especially those in nursing homes, and persons with renal insufficiency or severe hepatic dysfunction (for rimantadine).

The neuraminidase inhibitors were approved in 1999 for treatment of uncomplicated influenza. Zanamivir is orally inhaled and was approved for treatment of persons > 7 years. Oseltamivir is orally administered and was approved for treatment of persons > 1 year. Similar to the adamantines, both neuraminidase inhibitors can be effective in

reducing illness by approximately one day when used within 2 days of illness. Although only oseltamivir has been approved for chemoprophylaxis, recent community studies suggest that both zanamivir and oseltamivir are approximately 80% effective in reducing febrile influenza illness when administered as chemoprophylaxis. Oseltamivir was approved in 2000 for chemoprophylaxis of persons > 13 years.

In placebo controlled studies of persons with uncomplicated influenza, persons receiving zanamivir or placebo reported similar rates of adverse events including diarrhea, nausea, sinusitis, nasal signs and symptoms, bronchitis, cough, headache, dizziness, and ear, nose throat infections. In patients with asthma or chronic obstructive pulmonary disease, more patients taking zanamivir than placebo had a > 20% decrease in forced expiratory volume in 1 second (FEV1) or peak expiratory flow. In addition, persons with underlying asthma or chronic obstructive pulmonary disease have been reported to experience respiratory deterioration following use of zanamivir. Caution should be exercised when prescribing zanamivir to patients with asthma or chronic obstructive pulmonary disease. Such patients should have a fast acting bronchodilator available when inhaling zanamivir. Oseltamivir has been associated with higher levels of nausea or vomiting (approximately 9-10%) than in persons taking placebo.

Resistance to the neuraminidase inhibitors can be induced in influenza A and B viruses in-vitro but there is little information to indicate the clinical significance of these findings. Available information suggests that resistance to these compounds develops less frequently than with the adamantines.

The recommended dosage of zanamivir is two inhalations (a total of 10 mg) twice daily about 12 hours apart for five days. The manufacturer does not recommend changes in dosage based on age or renal function. Inhaled zanamivir has a half-life of about 2.5-5.1 hours and is excreted unchanged in urine. The recommended dosage of oseltamivir for treatment in persons > 13 years or for younger children who weigh > 40 is 75 mg twice daily. In children < 13 years and who weigh < 40 kg the recommended dosages vary by weight: 30 mg twice daily for children < 15 kg; 45 mg twice daily for children > 15 kg to 23 kg; and 60 mg twice daily for children > 23 to 40 kg. Oseltamivir is approved for chemoprophylaxis in children > 13 years and the dosage is 75 mg once a day. There is no recommended change in dosage for elderly persons. However, in patients with renal dysfunction and a creatinine clearance between 10 and < 30, the recommended treatment dosage is 75 mg once a day and the recommended chemoprophylaxis dosage is 75 mg every other day. No recommendations are available for patients undergoing renal dialysis.

Ribavirin has been reported to have efficacy against influenza A and B infections when administered as an aerosol for treatment.

## **Prognosis**

In most cases, illness from influenza resolves within a week, but cough and malaise may persist for several days to a few weeks longer. In a minority of patients, fatigue may persist for months.

## **Prevention & Control**

Annual administration of influenza vaccine is the most effective approach for preventing illness caused by influenza. In the United States, the currently licensed vaccine is an inactivated vaccine (either killed whole virus or subunit preparations) that contains three contemporary circulating strains of influenza A (H1N1), influenza A (H3N2), and influenza B virus. Because influenza viruses exhibit ongoing antigenic changes, one or two of the vaccine viruses are updated almost every year.

The recommended timing for influenza vaccination is from September through mid-November. However, influenza activity frequently peaks after December and unvaccinated persons who are at high risk for complications should continue to be offered vaccine after November.

Live attenuated influenza virus (LAIV) vaccines have been under development since the 1960s. LAIVs have several potential advantages over inactivated influenza vaccine, including greater induction of mucosal IgA and intranasal administration as a spray or nose drops. Currently, studies on trivalent formulations of LAIV vaccines are under way.

The effectiveness of inactivated influenza vaccine depends in large part on the degree of match between circulating viral strains and vaccine strains as well as the age and health status of the recipient. In controlled trials among children and young adults, influenza vaccines are ~70-90% effective in reducing influenza when there is a good match between vaccine and circulating viruses. A meta-analysis of influenza vaccine studies among the elderly found the effectiveness of vaccines to be 56% in preventing illness, 50% in reducing hospitalization, and 68% for preventing death. In elderly nursing home residents, vaccine effectiveness is ~30% for preventing illness, but ~47-95% for reducing hospitalization, pneumonia, and death.

Each year, comprehensive recommendations on the use of influenza vaccines are published by the Centers for Disease Control and Prevention in an April or May issue of *Morbidity and Mortality Weekly Report* ([Table 29-1](#), adapted from Centers for Disease Control and Prevention, 2000). In general, influenza vaccination is recommended for the groups listed in [Table 29-1](#).

Information on vaccinating people with human immunodeficiency virus (HIV) infection against influenza is limited. The main issues in question are whether persons with HIV are at elevated risk of influenza or serious complications from influenza, whether immunization poses a risk of accelerating HIV replication, and whether immunization is protective. Recent studies suggest that persons with HIV are at high-risk for developing complications from influenza. Because vaccine may result in protective antibody levels, it is felt that influenza vaccination will benefit many HIV-infected patients.

**A. Side Effects of Vaccinations.** The most common side effects of influenza virus vaccine consist of local effects, particularly soreness around the vaccination site, which occurs in as many as one-third of recipients. Fever, malaise, and myalgia are infrequent, and recent studies suggest that split-virus influenza vaccine does not lead to higher rates of systemic symptoms than placebo in young adults and the elderly.

**B. Complications of Influenza Vaccination.** The most serious potential neurologic

complication of influenza vaccine is Guillain-Barre syndrome (GBS), a demyelinating condition of the peripheral nerves. The association between this disorder and influenza vaccine remains unclear, in large part because the disorder is uncommon both among persons who receive and do not receive influenza vaccine. The baseline annual incidence of GBS is about one to two cases per 100,000 adults. In 1976, administration of "swine flu" vaccine was associated with an increase of slightly under one case of GBS per 100,000 adults administered the vaccine. In addition, most of the risk for developing swine flu vaccine-associated GBS occurred within the 6 weeks after vaccine administration and peaked at 3 weeks after vaccination. These vaccine-associated GBS cases were also less likely to be associated with antecedent illnesses and surgical procedures than other non-vaccine-associated GBS cases. Since then, four studies of influenza seasons between 1977 and 1991 did not find a statistically significant increase in the risk of GBS among vaccine recipients. However, a study of the 1992-93 and 1993--94 seasons found an increased risk of approximately one additional GBS case per million vaccinated persons. At this point, the association of GBS and influenza vaccines subsequent to the 1976 swine flu vaccine remains uncertain, but if these vaccines do pose a risk of GBS, the risk is quite small. Influenza vaccine is recommended for people at high risk for influenza-related complications because the risk of serious disease in these persons outweighs their risk of GBS.

**C. Contraindications for Influenza Vaccination.** Influenza vaccine is contraindicated in infants younger than 6 months because of the high risk of febrile reactions. Only split-virus preparations should be used in children = 13 years of age. Inactivated influenza vaccine is also contraindicated in people with acute febrile disease and persons known to have anaphylactic hypersensitivity reactions to eggs or other components of influenza vaccine. A physician should be consulted when a person at high risk for serious complications has such an allergic history; desensitization therapy and antiviral agents are options for preventing influenza in such persons.

**Table 29-1. Target population for influenza vaccination.\***

I. Groups at increased risk for complications of influenza:

- Persons aged  $\geq$ 65 years.
- Residents of nursing homes and other chronic-care facilities housing persons who have chronic medical disorders.
- Adults and children with chronic pulmonary and cardiac diseases, including children with asthma.
- Adults and children with chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression.
- Children and teenagers (aged 6 months to 18 years) receiving continuous aspirin therapy and therefore may be at risk for developing Reye's syndrome following influenza.
- Women who will be in the second or third trimester of pregnancy during the influenza season.

II. Groups that can transmit influenza to persons at high risk:

Persons who are clinically or subclinically infected can transmit influenza virus to persons for whom they care or with whom they live. As some persons at high risk (eg, the elderly, transplant recipients, and persons with AIDS) can have a low antibody response to influenza vaccine, efforts to protect these members of high-risk groups against influenza might be improved by reducing the likelihood of influenza exposure from their care givers.

The following groups should be vaccinated:

- Physicians, nurses, and other personnel in both hospital and outpatient care settings.
- Employees of nursing homes and other chronic care facilities who have contact with residents.
- Providers of home care to persons at high risk (eg, visiting nurses and volunteer workers).
- Members (including children) of a household containing high-risk persons.

### III. Other groups:

A. Persons infected with HIV: Limited data are available regarding the frequency and severity of influenza illness in the setting of HIV infection. Decreased immunogenicity may occur with advanced disease, and booster immunization does not improve the immune response for these persons. In addition, the effect that influenza immunization has been shown to have on the replication of HIV type 1 has been inconsistent in studies. Because influenza can result in serious illness and complications and because influenza vaccination may result in protective antibody titers, vaccination will benefit many HIV-infected patients.

B. Breastfeeding mothers: Influenza vaccine does not affect the safety of breastfeeding for mothers or infants. Breastfeeding does not adversely affect immune response and is not a contraindication for vaccination.

C. Persons traveling to foreign countries: Exposure risk varies by season and destination. In the tropics, influenza can occur throughout the year; in the Southern Hemisphere, most activity occurs from April through September. Because of the short incubation period for influenza, exposure to the virus during travel can result in clinical illness that begins while traveling, which can be a potential danger, in particular for persons at increased risk for complications. Persons preparing to travel to the tropics at any time of year, or to the Southern Hemisphere from April through September should review their influenza vaccination histories and, if not vaccinated the previous fall or winter, should consider influenza vaccination before travel. Persons in high-risk groups should be especially encouraged to receive the most current vaccine. Persons at high risk who received the previous season's vaccine before travel should be revaccinated in the fall or winter with the current vaccine.

D. Among the general population:

- Anyone who wishes to avoid influenza.
- Persons who provide essential community services (to minimize disruption of essential activities during influenza outbreaks).
- Students or other persons in institutional settings (eg, those who reside in dormitories), in order to minimize the disruption of routine activities during epidemics.

IV. Persons who should NOT be vaccinated:

- Persons with known anaphylactic hypersensitivity to eggs or to other components of the influenza vaccine (use of antiviral agent is optional at preventing influenza) without first consulting a physician.
- Adults with acute febrile illness usually should not be vaccinated until their symptoms have abated; however, minor illness with or without fever should not contraindicate the use of influenza vaccine, particularly among children with mild upper respiratory tract infection or allergic rhinitis.

<sup>a</sup>The drug package insert should be consulted for dosage recommendations for administering amantadine in persons with creatinine clearance =50 ml/min/1.73m<sup>2</sup>.

<sup>b</sup>5mg/kg of amantadine or rimantadine syrup = 1 tsp./22 lbs.

<sup>c</sup>Children = 10 years of age who weigh <40 kg should be administered amantadine or rimantadine at a reduced dosage.

<sup>d</sup>A reduction in dosage to 100 mg/day of rimantadine is recommended for persons who have severe hepatic or renal dysfunction with creatinine clearance =10 ml/min. Other persons with less severe hepatic or renal dysfunction taking rimantadine should be observed closely, and the dosage should be reduced or the drug discontinued, if necessary.

<sup>e</sup>Only approved for treatment in adults.

<sup>f</sup>Elderly nursing-home residents should be administered only 100 mg/day of rimantadine. A reduction in dosage should be considered for all persons = 65 years of age if they experience possible side effects when taking rimantadine.

<sup>g</sup>Zanamivir administered via inhalation using a plastic device included in the package with the medication. The device should be used according to instruction and demonstration of proper use of the device.

<sup>h</sup>Zanamivir is not approved for prophylaxis.

<sup>i</sup>A reduction in the dose of oseltamivir is recommended for persons with creatinine clearance <30 ml/min.

<sup>j</sup>The dose recommendation for children who weigh <15 kg is 30 mg twice a day, for >15 to 23 kg child a day, for >23 to 40 kg children the dose is 60 mg twice a day, and for children >40 kg, the dose is 75 mg twice a day. NA=Not applicable.

## 30 . Parainfluenza Virus — Gregory Sonnen, MD, & Nancy Henry, MD, PhD

### Essentials of Diagnosis

- Ubiquitous viral agent.
- Usually diagnosed on clinical findings.
- Can infect upper and lower respiratory tract in all ages.
- Most common etiology of acute laryngotracheobronchitis (croup) in infants and toddlers.
- Frequent cause of lower respiratory tract infection in children.
- Yearly reinfection is common.

### General Considerations

**A. Epidemiology.** Parainfluenza is a ubiquitous virus. It is the primary cause of acute laryngotracheobronchitis (croup) in children aged 6 months to 3 years. It is capable of infecting the lower respiratory tract as well by manifesting as bronchiolitis or pneumonia ([Box 30-1](#)). Outbreaks can follow regular epidemic patterns or be sporadic. Certain antigenic types (described below) do follow epidemic patterns.

**B. Microbiology.** Parainfluenza virus is a spherical, enveloped RNA virus of the *Paramyxoviridae* family. It ranges in size from 100 to 300 nm. The virus has six structural proteins: HN (hemagglutinin-neuraminidase), F (fusion), M (matrix), NP (nucleoprotein), P (phosphoprotein), and L (large). Parainfluenza is not related to influenza virus. The virus has been divided into four types (1, 2, 3, and 4) and two subtypes (4A and 4B) based on antigenic composition. Antigenic shift does not occur as is common in the influenza virus. The virus is labile and sensitive to low pH, heat, and lipid solvents.

**C. Pathogenesis.** The virus is spread person to person commonly via respiratory droplet nuclei. Other routes include direct contact with respiratory secretions and fomites. The virus adheres to and invades the respiratory epithelium and is transferred from cell to cell. Viremia is uncommon. Pathologic epithelial changes have been noted from the nasal mucosa to the alveoli.

## CLINICAL SYNDROMES

### ACUTE LARYNGOTRACHEOBRONCHITIS (CROUP)

#### Clinical Findings

**A. Signs and Symptoms.** Acute laryngotracheobronchitis, often referred to as croup, is a respiratory illness commonly seen in children 6 months to 3 years of age ([Table 30-1](#)). Symptoms, usually nocturnal, include a harsh "seal bark" cough, inspiratory stridor, and, in severe cases, respiratory distress. Rarely the airway may be compromised. Low-grade fever and rhinorrhea may be present. Respiratory symptoms usually recur for 3-5 nights and lessen in severity as the illness progresses.

**B. Laboratory Findings.** Viral isolation is usually not necessary for appropriate clinical management. If an etiology is sought, culture may be taken from respiratory secretions. The preferred medium is monkey kidney cell medium. Viral antigen may be isolated from respiratory secretions by either enzyme immunoassay or immunofluorescence assay. Serologic evidence is of little clinical value.

**C. Imaging.** Radiography is usually not necessary for the diagnosis of croup. If the diagnosis is in question, an anterior-posterior radiograph of the neck will demonstrate subglottic narrowing. This finding is commonly called the "steeple sign." Lateral films should also be obtained to rule out other processes such as epiglottitis.

**D. Differential Diagnosis.** The differential diagnosis of croup includes any situation resulting in upper airway narrowing. Included in this category would be epiglottitis, bacterial tracheitis, foreign body aspiration, retropharyngeal abscess, diphtheria, allergic angioedema, and spasmodic croup.

**E. Complications.** Children with a medical history involving narrowing of the upper airway are at higher risk of airway compromise from croup. Diagnoses such as subglottic stenosis and tracheomalacia would fall into this category.

## Diagnosis

Croup is usually diagnosed based on history and physical examination alone. Radiography can help confirm the diagnosis but is often not needed.

## Treatment

Treatment is aimed at reducing upper airway edema and inflammation to optimize the upper airway ([Box 30-2](#)). In the vast majority of cases, cool, humidified air is optimal. Home use of a humidifier in the child's room is an optimal home therapy. If the child is in distress or fails to respond to humidified air, nebulized racemic epinephrine is indicated. If racemic epinephrine is used, the patient should be closely observed for an appropriate amount of time (usually 4 h). Some patients will experience a "rebound" swelling of the laryngeal mucosa after epinephrine administration. Dexamethasone, administered either orally or intramuscularly, will help reduce inflammation and prevent recurrence of symptoms. Dexamethasone is preferred for its long half-life. An inhaled helium-oxygen mixture can be helpful in refractory cases. Nebulized budesonide is very efficacious, but is not yet FDA approved for use in the United States. Intubation is indicated for severe distress or airway collapse.

## BRONCHIOLITIS

## Clinical Findings

**A. Signs and Symptoms.** Bronchiolitis is an acute respiratory illness in children aged 6 weeks to 2 years (see [Table 30-1](#)). Respiratory syncytial virus is the most common cause (see [Chapter 31](#)), with parainfluenza being a much less common cause. Patients present with clear rhinorrhea, fever, tachypnea, cough, and expiratory wheezing. Auscultation of the lungs will also reveal a prolonged expiratory phase. Severe cases will be hypoxemic. Some patients advance to respiratory failure.

**B. Laboratory Findings.** Laboratory findings are the same as for croup (above).

**C. Imaging.** Chest radiography will reveal hyperexpansion. Patchy infiltrates and atelectasis may be present.

**D. Differential Diagnosis.** The differential diagnosis of bronchiolitis includes pneumonia, asthma exacerbation, foreign body aspiration, pulmonary edema, and noxious chemical inhalation.

**E. Complications.** Children with underlying cardiac or pulmonary disease (eg, congenital heart disease, pulmonary hypertension, bronchopulmonary dysplasia, asthma, or cystic fibrosis) are at significant risk of serious morbidity from bronchiolitis.

## Diagnosis

Bronchiolitis is usually diagnosed based on history and physical examination alone (see [Table 30-1](#)). Air trapping will result in hyperexpansion as revealed by chest radiography. Hypoxia and hypercarbia are poor prognostic indicators and warrant aggressive therapy.

## Treatment

Therapy is aimed at maintaining oxygenation and adequate air exchange. Supportive care is effective in the vast majority of cases. Tachypneic infants will have increased insensible fluid losses. Intravenous fluids may be needed if dehydration is present. Nasal suctioning to maintain clear nasal passages is warranted in all infants. Oxygen should be provided immediately if hypoxia is present. Bronchodilators may provide some benefit. Mechanical ventilation is indicated if signs of respiratory failure are present. Corticosteroids will be of benefit if the patient has asthma.

## PNEUMONIA

### Clinical Findings

**A. Signs and Symptoms.** Pneumonia from parainfluenza may occur at any age (see [Table 30-1](#)). Typical presenting symptoms may include fever, dyspnea, tachypnea, purulent sputum, and hypoxemia. Diffuse or localized rales may be auscultated.

**B. Laboratory Findings.** Laboratory findings are the same as for croup (above).

**C. Imaging.** Chest radiography may demonstrate patchy or localized infiltrates.

**D. Differential Diagnosis.** A bacterial or mycoplasmal pneumonia often cannot be excluded.

**E. Complications.** Patients with underlying pulmonary, immunologic, and cardiac diseases are at risk for serious morbidity.

## Diagnosis

Diagnosis is based on physical and radiographic evidence (see [Table 30-1](#)). The etiology of pneumonia may be difficult to differentiate, especially in children. A sputum sample is often difficult to obtain from infants and toddlers. If a bacterial source cannot be ruled out, antibiotics are warranted.

## Treatment

Antibiotics should be used to cover all appropriate community acquired pneumonias unless a specific etiology can be isolated. Oxygen should be used for hypoxia. Mechanical ventilation should be utilized for respiratory failure.

## Prevention & Control

Thorough hand washing will limit the spread of parainfluenza ([Box 30-3](#)). No vaccine is currently available. Droplet isolation of the hospitalized patient is indicated. Symptomatic children should be excluded from school or daycare.

## **BOX 30-2. Treatment of Parainfluenza Syndromes**

### **Croup**

- Cool, humidified oxygen
- Racemic epinephrine, 2.25%, 0.05 cc/kg nebulized in 3 cc saline (max = 0.5 cc)
- Dexamethasone, 0.6 mg/kg IM or 0.15 to 0.6 mg orally (max = 10 mg)
- Helium-oxygen mixture can reduce the work of breathing in severe respiratory distress
- Nebulized budesonide is useful, but is not yet FDA approved
- Intubation if airway is severely compromised

### **Bronchiolitis**

- Supportive care
- Humidified oxygen, if needed
- Bronchodilators remain controversial
- Steroids provide no benefit in uncomplicated bronchiolitis
- Mechanical ventilation for severe disease

### **Pneumonia**

- Supportive care
- Humidified oxygen, if needed
- Parenteral antibiotics if bacterial etiology cannot be ruled out

### **URI**

- Supportive care

### **Host with Severe Combined Immunodeficiency**

- Aerosolized ribavirin may modify the infection

## 31 . Respiratory Syncytial Virus — Gregory Sonnen, MD, & Nancy Henry, MD, PhD

### Essentials of Diagnosis

- Most important respiratory pathogen of infancy.
- Passively acquired maternal antibodies provide no protection.
- Can infect upper and lower respiratory tract.
- Symptomatic reinfection occurs throughout life.
- Children with pulmonary or cardiac disease can have serious morbidity from infection.
- Yearly reinfection is common throughout life.

### General Considerations

**A. Epidemiology.** Respiratory syncytial virus (RSV) produces a yearly epidemic in temperate climates. Most commonly, it causes bronchiolitis but can also cause upper respiratory infections, tracheobronchitis, and pneumonia ([Table 31-1](#)). In the United States, RSV activity is greatest from December through April. Some variation occurs year to year. The epidemic lasts from 2 to 5 months. Essentially all children are infected during the first 3 years of life. Yearly reinfection is common throughout life. The virus is responsible for ~90,000 hospital admissions and 4,500 deaths/year in the United States.

**B. Microbiology.** RSV is a 120- to 300-nm enveloped RNA virus of the *Paramyxoviridae* family. It is in the genus *Pneumovirus*. The viral RNA encodes 10 proteins, 7 of which are structural (F, G, L, M, N, P, and SH). Two antigenic strains have been identified and are differentiated based on the G surface glycoprotein. The epidemiologic and clinical significance of the antigenic variation is unknown. The virus is very labile regarding temperature variation; however, the lability of this virus does not reflect on its high degree of communicability.

**C. Pathogenesis.** The virus is transferred via droplet nuclei, direct contact, and fomites. The virus has been shown to remain viable on fomites for hours and on the human hand for = 30 min. Nosocomial infections are very frequent and warrant strict adherence to hospital isolation procedures.

RSV adheres to and invades the respiratory epithelium. It has an incubation period of 2-8 days. The virus spreads cell to cell via intracytoplasmic bridges. It has potential to cause pathologic changes along the entire respiratory tract. Pulmonary pathology commonly noted during autopsy of infants with RSV bronchiolitis includes peribronchiolar mononuclear infiltration, epithelial necrosis of bronchioles, luminal plugging, airway hyperinflation, and atelectasis. Patients with RSV pneumonia also show evidence of mononuclear interstitial infiltration.

## CLINICAL SYNDROMES

### BRONCHIOLITIS

#### Clinical Findings

**A. Signs and Symptoms.** Bronchiolitis is an acute respiratory illness affecting primarily infants ([Box 31-1](#)). RSV is the most common etiology. Patient ages range from 6 weeks to 2 years, with a peak incidence from 2 to 6 months of age. Presenting symptoms commonly include low-grade fever, clear rhinorrhea, tachypnea, cough, and expiratory wheezing. Hypoxemia and respiratory failure may occur in advanced or complicated cases. Dehydration may be present owing to increased insensible fluid losses and poor intake of fluids.

**B. Laboratory Findings.** Viral isolation and antigen testing are performed from nasopharyngeal washings. Instillation of 1-2 cc of sterile saline in a nasal passage followed by prompt suction with an in-line suction trap will obtain a good specimen. Culturing requires 3-5 days and is optimal on human heteroploid, monkey kidney, human kidney, and fibroblast cells. Viral antigen can be detected with an immunofluorescence assay or enzyme immunoassay.

**C. Imaging.** Chest radiographs commonly display hyperinflation. Occasionally atelectasis or diffuse infiltrates are seen.

**D. Differential Diagnosis.** The differential diagnosis of bronchiolitis includes pneumonia, asthma exacerbation, foreign-body aspiration, and noxious-chemical inhalation.

**E. Complications.** In healthy infants, the disease lasts 3-7 days. Children with an underlying pulmonary or cardiac disease can have prolonged courses lasting weeks. Recurrent episodes of wheezing may occur in = 50% of infants infected by RSV. The wheezing may last until 3 years of age.

### PNEUMONIA

#### Introduction

**A. Signs and Symptoms.** Pneumonia from RSV typically occurs in infants and the elderly. Typical presenting symptoms may include fever, dyspnea, tachypnea, and hypoxemia. Diffuse, fine rales may be auscultated.

**B. Laboratory Findings.** Same as laboratory findings for bronchiolitis (above).

**C. Imaging.** Chest radiography demonstrates diffuse interstitial infiltrates.

**D. Differential Diagnosis.** Exclusion of a bacterial etiology may be difficult.

**E. Complications.** Patients with underlying pulmonary, immunologic, and cardiac disease are at risk for serious morbidity.

## Diagnosis

Diagnosis of most RSV infections is based on physical and radiographic findings (see [Table 31-1](#)). Rapid antigen detection is often helpful, especially in compromised infants. Evidence of hypoxemia at presentation warrants aggressive therapy.

## Treatment

Therapy is aimed at maintaining oxygenation and adequate air exchange. Supportive care is effective in the vast majority of cases. Tachypneic infants will have increased insensible fluid losses. Intravenous fluids may be needed if dehydration is present. Nasal suctioning to maintain clear nasal passages is warranted in all infants. Oxygen should be provided immediately if hypoxia is present. Bronchodilators may provide some benefit in bronchiolitis. Mechanical ventilation is indicated if signs of respiratory failure are present. Corticosteroids will benefit if the patient has asthma.

Immunoprophylaxis is highly effective if used appropriately ([Box 31-2](#)). Administration of ribavirin should be reserved for severe, refractory cases and infants compromised by cardiac, pulmonary, or immunologic disease. A history of prematurity also warrants consideration of ribavirin use. Ribavirin does interfere with some mechanical ventilators and small endotracheal tubes. Extreme caution should be observed with its use.

## Prevention & Control

Thorough hand washing will limit the spread of RSV ([Box 31-3](#)). No vaccine is currently available. Immunoprophylaxis is effective in high-risk infants. Droplet isolation of the hospitalized patient is indicated. Strict isolation may be indicated in some hospital environments. Hospital isolation procedures should be strictly enforced. RSV is a common source of nosocomial infection. Symptomatic children should be excluded from school or daycare. Viral shedding usually lasts from 3 to 8 days after the onset of symptoms. Rare cases may shed virus for as long as 4 weeks.

## **BOX 31-2. Treatment of RSV**

### **Condition**

### **Supportive Care**

### **Mechanical Ventilation**

### **Immunoprophylaxis with Palivizumab Intramuscular Monoclonal Antibody Injection**

### **I- $\beta$ -D-Ribofuranosyl-1,2,4-triazole-3-carboxamide (Ribavirin)**

### **Corticosteroids**

### **Bronchodilators**

### **Indications**

- All uncomplicated cases of bronchiolitis and pneumonia
- Respiratory failure
- Infants < 2 years old with bronchopulmonary dysplasia who require oxygen or have needed oxygen in the 6 months before RSV season
- Infant < 1 year old with bronchopulmonary dysplasia who are on any chronic respiratory treatment
- Infants < 1 year old with a gestational age of  $\geq$  29 weeks at birth
- Infants < 6 months old with a gestational age of 29-32 weeks at birth
- Infants < 6 months old with a gestational age of 32-35 weeks who have passive exposure to smoke, attend day care, or experience other pulmonary risk factors
- Not FDA approved alone for congenital heart disease
- Contraindicated in cyanotic congenital heart disease
- Complex congenital heart disease
- Pulmonary hypertension
- Bronchopulmonary dysplasia
- Chronic lung disease, including cystic fibrosis
- Immunosuppressed state
- Premature birth (less than 37 weeks gestation)
- Healthy infants less than 6 weeks of age
- Severely ill and recalcitrant to supportive measures
- Virus-induced asthma
- No proven benefit in healthy infants with uncomplicated bronchiolitis
- Asthma or clinical evidence of bronchospasm
- Benefit is controversial in healthy infants with uncomplicated bronchiolitis

##### BOXES

BOX 31-3. Prevention & Control of RSV

---

## 32 . Adenoviruses — *W. Lawrence Drew, MD, PhD*

### Essentials of Diagnosis

- Respiratory symptoms (plus conjunctivitis).
- Disseminated infection in immunocompromised patients.
- Intranuclear inclusions in infected epithelial cells;
- Growth in tissue culture, especially in human embryonic epithelial cells (eg, kidney, lung).
- Antigen detection in clinical samples (eg, respiratory by immunofluorescence).
- Detection of antibody to the adenovirus group antigen by several different assays (eg, complement fixation, hemagglutination inhibition).

### General Considerations

Adenoviruses were first isolated in 1953 in human adenoid cell culture. Since then approximately 100 serotypes, at least 47 of which infect humans, have been recognized. All human serotypes are included in a single genus within the family *Adenoviridae*. Based on homology studies and hemagglutination patterns, each of the 47 serotypes belongs to one of six subgroups. Disorders caused by the adenoviruses include respiratory tract infection, conjunctivitis, hemorrhagic cystitis, and gastroenteritis.

**A. Epidemiology.** From 5% to 10% of pediatric respiratory disease can be attributed to adenoviruses. Adenoviruses spread by either respiratory or fecal-oral contact but have been cultured from semen and may also be spread by sexual transmission. Adenoviruses may be shed intermittently from the pharynx and especially in the feces. Most infections are asymptomatic, which greatly facilitates their spread in the community.

Infections with serotypes 1, 2, and 5 are very common in children under 2 years of age and may occur as outbreaks especially in older children. Adenoviruses serotypes 4 and 7 seem especially able to spread and cause outbreaks among military recruits owing to very close, crowded living conditions. Outbreaks of swimming pool conjunctivitis have resulted from inadequate chlorination and the low antibody prevalence to these serotypes in children and young adults.

**B. Microbiology.** Adenoviruses are double-stranded DNA viruses with a genome molecular weight of  $20 \times 10^6$  to  $25 \times 10^6$  daltons. The core complex within the capsid includes viral DNA and at least two major proteins. In addition there are nine structural proteins.

The virions are nonenveloped icosahedrons with a diameter of 70-90 nm. Projections, or fibers, originate from each of the 12 vertices of the protein capsid. The capsid is composed of 240 capsomeres, which consist of hexons and pentons.

Replication of adenoviruses has been studied extensively in HeLa cell culture. One virus cycle takes ~ 32-36 h and produces 10,000 virions. The replicative cycle is divided into several stages: attachment, penetration, uncoating, and early and late events. Attachment is probably mediated by the viral fiber protein and a receptor on the host cell membrane. There are approximately 100,000 fiber receptors per cell. The virus enters the cell by endocytosis and is uncoated in the cytoplasm, with subsequent replication in the nucleus. This entire process requires 2 h. Early transcriptional events, after shutdown of host cell macromolecular synthesis, lead to gene products involved in viral DNA replication and cell transformation.

Viral DNA replication in the nucleus signals the beginning of the late phase. In addition, late transcripts encode viral structural proteins at a maximum rate 20 h after infection. Virion capsomeres are produced in the cytoplasm and then transported to the nucleus for viral assembly. DNA possibly enters the capsid through an opening at one of the vertices. The mature particle is stable and infectious. Infected host cells release the virus upon degeneration and cell disruption.

**C. Pathogenesis.** Adenoviruses infect epithelial cells lining respiratory and enteric organs. After local replication, viremia may occur with spread to visceral organs. This dissemination is more likely to occur in immunocompromised patients. Variations in target cell specificity among adenovirus serotypes result from differences in viral attachment proteins. The virus has a propensity to become latent in lymphoid tissue, such as adenoids, tonsils, or Peyer's patches, and can be reactivated by immunosuppression.

The histologic hallmark of adenovirus infection is a dense central intranuclear inclusion within an infected epithelial cell. Superficially, this inclusion may resemble those seen in cytomegalovirus infection, but one distinguishing feature is the absence of cellular enlargement (cytomegaly) in adenovirus-infected cells. These inclusions are concentrations of viral DNA and protein. In addition to inclusions, adenovirus infections are characterized by mononuclear cell infiltrates and epithelial cell necrosis. Type-specific neutralizing antibody is associated with protection from reinfection.

## CLINICAL SYNDROMES

### INTRODUCTION

Adenoviruses cause primary infection in children and, less commonly, adults. Reactivation of virus occurs in immunocompromised children and adults. Several distinct clinical syndromes are associated with adenovirus infection ([Box 32-1](#)).

### ACUTE RESPIRATORY DISEASE

**A. Signs and Symptoms.** Acute pharyngitis is usually nonexudative but is associated with fever. Acute respiratory disease is a syndrome of fever, cough, pharyngitis, and

cervical adenitis seen primarily in outbreaks among military recruits usually with serotypes 4 and 7. Adenoviruses are definite but infrequent causes of true viral pneumonia in both children and adults including military recruits. Laryngitis, croup, and bronchiolitis may also occur. Pertussis-like illness with a prolonged clinical course has been associated with adenoviruses. Adenovirus conjunctivitis may occur concurrently with acute respiratory disease and may be the clue to an adenovirus etiology.

**B. Laboratory Findings.** The blood leukocyte count is normal as is the rest of the complete blood count and blood chemistry assays.

**C. Imaging.** In patients with clinical evidence of pneumonia, chest x-ray may reveal scattered interstitial infiltrates, usually in the lower lung fields.

**D. Differential Diagnosis.** Influenzal and other viral pneumonias, as well as nonbacterial pneumonias, eg, mycoplasma and chlamydial, are the major components of the differential diagnosis. Influenzal pneumonia has a pronounced seasonal epidemiology, but adenovirus does not.

## CONJUNCTIVITIS

**A. Signs and Symptoms.** Adenoviruses cause a follicular conjunctivitis in which the mucosa of the palpebral conjunctiva becomes pebbled or nodular, while both conjunctivae (palpebral and bulbar) become inflamed. Conjunctivitis may occur sporadically or in outbreaks that can be traced to a common source, eg, swimming pools. Corneal involvement may occur with mechanical irritation of the eye and is most striking when it spreads in epidemic form, eg, shipyard conjunctivitis, also described as epidemic keratoconjunctivitis.

**B. Differential Diagnosis.** Adenovirus conjunctivitis is frequently bilateral and has a granular or follicular appearance. *C trachomatis* conjunctivitis is similar but is more severe in the bulbar conjunctiva than is adenovirus. Coexisting acute respiratory disease suggests adenovirus, as does preauricular adenopathy.

**C. Complications.** Keratitis may develop as the conjunctivitis subsides and may persist for months.

## ACUTE GASTROENTERITIS

**A. Signs and Symptoms.** Adenovirus serotypes 40 and 41, which are very difficult to isolate in tissue culture, appear to be responsible for episodes of diarrhea in infants.

**B. Laboratory Findings.** Adenovirus does not cause an acute inflammatory response. Polymorphonuclear leukocytes are not present in stool smears and are not increased in peripheral blood counts.

**C. Complications.** Although mesenteric adenitis and intussusception may be complications of adenovirus infections, these associations remain unproven.

## ACUTE HEMORRHAGIC CYSTITIS

**A. Signs and Symptoms.** Acute hemorrhagic cystitis with dysuria and hematuria is associated with serotypes 11 and 21. This condition occurs predominantly in young boys with blood in urine persisting for an average of 3 days. The associated dysuria and frequency persist for an additional several days.

**B. Laboratory Findings.** Gross and, subsequently, microscopic hematuria is present for several days.

**C. Imaging.** No renal or bladder abnormalities are present in x-rays.

**D. Differential Diagnosis.** Other causes of hematuria include bacterial cystitis, stones, or tumors, but an acute self-limited illness suggestive of urinary tract infection is compatible with adenovirus infection, especially in young boys.

## SYSTEMIC INFECTION IN IMMUNOCOMPROMISED PATIENTS

### Introduction

Immunocompromised patients (especially transplant recipients) are at risk of serious adenovirus infections, although not as often as from infections caused by the herpes viruses. Diseases include pneumonia and hepatitis as well as disseminated disease. These illnesses are severe and may be fatal. Infection appears to be from exogenous or endogenous (reactivation) sources. In AIDS patients, adenoviruses appear to be responsible for gastrointestinal disease, as revealed by biopsy. Adenoviruses are also recovered from urine or semen of AIDS patients, but their significance is unknown. There is no known effective treatment for adenovirus infections in patients.

### Diagnosis of Adenovirus Infection

Direct detection of adenovirus antigens by fluorescent antibody immunoassays have been used with partial success to rapidly identify adenovirus in clinical samples, such as those from the respiratory tract. Enzyme immunoassay and electron microscopy are used to identify enteric adenovirus serotypes 40 and 41, which do not grow in heteroploid cell cultures but may be responsible for infant diarrhea ([Table 32-1](#)). Characteristic intranuclear inclusions can be seen in infected tissue during histologic examination. Inclusions, however, are rare and must be distinguished from those resulting from cytomegalovirus.

Isolation of the virus is best accomplished in cell cultures derived from epithelial cells, for example, primary human embryonic kidney (HEK) cells or continuous (transformed) lines such as HeLa or human epidermal carcinoma (Hep-2) cells. Recovery in cell culture requires an average of 6 days. Isolation of adenovirus in culture has variable significance. If the isolate is from a site not frequently colonized by adenovirus, isolation may be diagnostic of the etiology (eg, recovery from conjunctiva, bloody urine, or viscera such as the lung). However, recovery from stool but not the respiratory tract of a patient with pharyngitis provides little diagnostic help. Adenoviruses may be shed in feces for weeks to months after infection. Isolation of adenovirus from the throat of a

patient with pharyngitis is usually diagnostic, if laboratory findings eliminate other common etiologies such as *Streptococcus pyogenes*.

Complement fixation, hemagglutination inhibition, enzyme immunoassay, and neutralization techniques have been used to detect specific antibodies after adenovirus infection. A seroconversion between acute and convalescent serum specimens is necessary before the result can be considered diagnostic of active infection, although a fourfold or greater rise in titer may also be of diagnostic significance. Serologic diagnosis is rarely used except occasionally to confirm the significance of a fecal or upper respiratory isolate.

### **Prevention & Control**

Live, oral enteric-coated vaccines have been used to prevent adenovirus 4 and 7 infections in military recruits, but they are not used in the civilian population ([Box 32-2](#)). Because the virus may be oncogenic, it is unlikely that live virus vaccines will be widely used. However, genetically engineered subunit vaccines could be prepared and used in the future.

### **33 . Herpesviruses — W. Lawrence Drew, MD, PhD**

#### **INTRODUCTION**

The herpesvirus group of the family *Herpesviridae* comprises large, enveloped, double-stranded DNA viruses found in both animals and humans. They are ubiquitous and produce infections ranging from painful skin ulcers to chickenpox to encephalitis. The major members of the group to infect humans are the two herpes simplex viruses (HSV-1 and -2), cytomegalovirus (CMV), varicella-zoster virus (VZV), Epstein-Barr virus (EBV), herpesvirus 6, and the recently discovered human herpesvirus types 7 and 8. Occasionally, the simian herpesvirus, herpes B virus, has caused human disease.

All herpesviruses are morphologically similar with an overall diameter of 180-200 nm. The nucleic acid core is ~ 30-45 nm in diameter, surrounded by an icosahedral capsid. The capsid is covered by a tegument and a lipoprotein envelope derived from the nuclear membrane of the infected host cell. The envelope contains at least nine glycoproteins that protrude beyond it as spikelike structures, while the tegument is a protein-filled area between the capsid and the envelope. Despite the morphologic similarity between these agents, substantial differences in the molecular composition of their genomes are reflected in their structural glycoproteins and polypeptides. Antigenic analysis is an important means for differentiation among herpesviruses despite some cross-reactions (eg, between HSV and VZV).

Susceptible tissue cultures vary significantly for the individual agents. HSV has the widest range; it replicates in numerous animal and human host cells. VZV is best grown in cells of human origin, although some laboratory-adapted strains can grow in primate cell lines. Human CMV replicates well only in human diploid fibroblast cell lines. EBV does not replicate in most commonly used cell culture systems but can be grown in continuous human or primate lymphoblastoid cell cultures. Human herpesvirus type 6 grows in lymphocyte cell cultures.

Characteristically, all of these agents produce an initial infection followed by a period of latent infection in which the genome of the virus is present in the cell, but infectious virus is not recovered. Reactivation of virus may then result in the first episode of clinically apparent disease or as recurrent disease. Complex host-virus interactions determine the expression of disease. With all of these agents, immunocompromised patients, especially those with altered cellular immunity, have more frequent and severe episodes, including clinically severe disease from reactivation of virus.

#### **HERPES SIMPLEX VIRUS**

##### **Essentials of Diagnosis**

- Intranuclear inclusions and multinucleated giant cells in tissue cytology.
- Grows rapidly in many types of tissue culture.

- HSV antigen can be detected in tissue by immunofluorescence.
- Polymerase Chain Reaction (PCR) analysis of cerebrospinal fluid (CSF) now considered best assay for HSV encephalitis.

## General Considerations

**A. Epidemiology.** The term *herpes* (from the Greek *herpein*, to creep) and the clinical description of cold sores date back to Hippocrates. Two distinct epidemiologic and antigenic types of HSVs exist (HSV-1 and HSV-2). HSVs have worldwide distribution. There are no known animal vectors, and humans appear to be the only natural reservoir ([Box 33-1](#) shows the syndromes caused by HSV). Direct contact with infected secretions is the principal mode of spread. Seroepidemiologic studies indicate that the prevalence of HSV antibody varies directly with the age and socioeconomic status of the population studied. In most underdeveloped countries, 90% of the population have HSV-1 antibody by the age of 30. In the United States, HSV-1 antibody is currently found in ~ 50-60% of the middle-class population. Among lower socioeconomic groups, however, the percentage approaches 90%.

Detection of HSV-2 antibody before puberty is unusual. The virus is associated with sexual activity, and direct sexual transmission is the major mode of spread. Approximately 15-30% of sexually active adults in western industrialized countries have HSV-2 antibody. The virus can be isolated from the cervix and urethra of ~ 5-12% of adults attending sexually transmitted disease clinics; many of these patients are asymptomatic or have small, unnoticed lesions on penile or vulvar skin. Genital herpes is not a reportable disease in the United States, but it is estimated that 500,000 new cases occur per year.

**B. Microbiology.** The DNA genomes of both types of HSV are linear, double-stranded molecules with molecular weights of ~  $10^8$  and are composed of ~ 160 kilobase pairs. Their nucleic acids demonstrate ~ 50% base sequence homology, which is considerably greater than that shown between these viruses and other herpesviruses. HSV-1 and HSV-2 share antigens in almost all their surface glycoproteins and other structural polypeptides. Numerous strains of both HSV-1 and HSV-2 exist. In fact, by restriction endonuclease analysis of the viral genome, most isolates of HSV-1 or HSV-2 are found to differ somewhat, except in epidemiologically related cases such as mother-infant and sexual partner transfer.

**C. Pathogenesis.** Herpes simplex virus produces both acute and latent infections.

**1. Acute Infection.** In acute infections, the initial stages entail envelope glycoprotein-mediated attachment of the virus to unidentified receptors and fusion with the host cell membrane. Viral DNA released in the cytoplasm is transported through nuclear pores to the nucleus. New viral DNA synthesis and transcription of mRNA occur in the nucleus. The virus buds through the nuclear membrane; this process adds the envelope material to the virus particles, which are then transported through the cytoplasm and out of the cell in a manner similar to the movement of other proteins.

The molecular events involving synthesis of virus-specific gene products are

coordinated and regulated. Three classes of mRNA coding for three groups of virus polypeptides have been identified. The products, designated the alpha or immediate early (IE) polypeptides, are synthesized 2-4 h after infection. These IE polypeptides probably function as regulators of viral transcription. The beta or early (E) polypeptides include virus-specified thymidine kinase (TK) and DNA polymerase (Pol). These virus-specified enzymes differ from host cell enzymes and are therefore important targets of antiviral chemotherapy. The synthesis of early polypeptides shuts off the synthesis of immediate early polypeptides and induces the synthesis of a third group of gamma or late (L) polypeptides. The late polypeptides, synthesized 12-15 h after infection, are the major structural components of the viral particle.

Pathologic changes during acute infections consist of development of multinucleated giant cells, ballooning degeneration of epithelial cells, focal necrosis, eosinophilic intranuclear inclusion bodies, and an inflammatory response characterized by an initial polymorphonuclear neutrophil infiltrate and a subsequent mononuclear cell infiltrate. The virus can spread intra- or interneuronally or through the supporting cellular networks of an axon or nerve, resulting in latent infection of sensory and autonomic nerve ganglia. The spread of virus can occur by cell-to-cell transfer and can therefore be unaffected by circulating immune globulin.

**2. Latent Infection.** In humans, latent infection by HSV-1 has been demonstrated, by co-cultivation techniques, in trigeminal, superior cervical, and vagal nerve ganglia and occasionally in the S2-3 dorsal sensory nerve root ganglia. Latent HSV-2 infection has been demonstrated in the sacral (S2-3) ganglia. Latent infection of neural tissue by HSV does not result in the death of the cell; however, the exact mechanism of viral genome latency is incompletely understood. The HSV genome exists in a circular form in latently infected neuronal cells. Transcription of only a small portion of the viral genome is abortive and does not appear to be associated with detectable amounts of early eg, (Pol) or TK, or late polypeptides. Therefore, unfortunately, antiviral drugs directed at the viral DNA polymerase do not eradicate the virus in its latent state.

Reactivation of virus from latently infected ganglionic cells with subsequent release of infectious virions appears to account for most recurrences of both genital and oralabial infections. The mechanisms by which latent infection is reactivated are unknown. Precipitating factors that initiate reactivation of herpes simplex include fever, trauma (eg, oral intubation), and exposure to ultraviolet light.

**D. Immunity.** Host factors have a major effect on clinical manifestations of HSV infection. Many episodes of HSV infection are either asymptomatic or mildly symptomatic. If initial clinical episodes of the disease are symptomatic, they are more severe than recurrent episodes, probably because of the presence of anti-HSV antibodies and immune lymphocytes in persons with recurrent infections.

Neutralizing antibodies directed against HSV envelope glycoproteins appear to be important protective responses, particularly those that mediate antibody-dependent cellular cytotoxicity (ADCC) reactions. ADCC may be important in limiting early spread of HSV. By the second week of infection, cytotoxic T lymphocytes can be detected that are able to destroy HSV-infected cells before completion of the replication cycle. Prior infection with HSV-1 may protect against or shorten the duration of symptoms and

lesions during subsequent infection with HSV-2. In immunosuppressed patients, especially those with depressed cell-mediated immunity, reactivation of HSV may be associated with prolonged viral excretion and persistence of lesions.

## **CLINICAL SYNDROMES**

### **1. HERPES SIMPLEX TYPE 1 (HSV-1)**

Clinical manifestations of infection with HSV-1 usually are found above the waist. They consist characteristically of grouped or single vesicular lesions that become pustular and coalesce to form single or multiple ulcers. On dry surfaces, these ulcers scab before healing; on mucosal surfaces, they re-epithelialize directly. HSV can be isolated from almost all ulcerative lesions, but the titer of virus decreases as the lesions progress. Infections generally involve ectoderm (skin, mouth, vagina, conjunctiva, and nervous system).

Primary infection with HSV-1 is often asymptomatic. When clinically evident, it appears most frequently as gingivostomatitis with fever, and vesicular or ulcerative lesions involving the buccal mucosa, tongue, gums, and pharynx. The lesions are quite painful, and the illness usually lasts 5-12 days. After this initial infection, HSV may become latent within sensory nerve root ganglia of the trigeminal nerve.

Recurrent lesions usually appear on an area of the lip and the immediately adjacent skin; these lesions are described as mucocutaneous and are commonly called cold sores or fever blisters. Because reactivation is usually from a single latent source, these lesions are typically unilateral. Their recurrence may be signaled by premonitory tingling or burning in the area. Systemic complaints are unusual, and the episode generally lasts approximately 7 days. HSV may be reactivated and excreted into the saliva with no apparent mucosal lesions present. HSV has been isolated from saliva in 5-8% of children and 1-2% of adults who were asymptomatic at the time.

HSV sometimes infects the finger or nail area. This infection, termed *herpetic Whitlow*, usually results from the inoculation of infected secretions through a small cut in the skin. Painful vesicular lesions of the finger develop and pustulate and are often mistaken for bacterial infection and mistreated accordingly. Health care workers, especially nurses and respiratory therapists, are at particular risk for this entity.

HSV infection of the eye is one of the most common causes of corneal damage and blindness in the developed world. Infections usually involve the conjunctiva and cornea, and characteristic dendritic ulcerations are produced. With recurrence of disease, there may be deeper involvement with corneal scarring. Occasionally there may be extension into deeper structures of the eye, e.g., iritis, especially if topical steroids are used.

HSV encephalitis is a rare result of HSV-1 infection, occurring in ~ 1-10 humans/million/year. Although rare, herpes encephalitis accounts for ~ 10% of all cases of documented viral encephalitis in the United States. Most cases occur in adults with high levels of anti-HSV-1 antibody, suggesting reactivation of latent virus in the trigeminal nerve root ganglion and extension of productive (lytic) infection into the temporoparietal area of the brain.

Since the disease usually affects one temporal lobe, focal neurologic signs are frequent. Clinically, the disease can resemble brain abscess, tumor, or intracerebral hemorrhage.

## **2. HERPES SIMPLEX TYPE 2 (HSV-2)**

Genital herpes is a common sexually transmitted disease. Both HSV-1 and HSV-2 can cause genital disease, and the symptoms and signs of acute infection are similar for both viruses. Of first episodes of genital HSV infection in the United States, 70% are caused by HSV-2. As with type 1 oral infection, the majority of genital infections are asymptomatic without lesions, and patients do not know they have been infected. Patients with asymptomatic genital HSV may be culture or PCR positive in genital secretions and are able to transmit the virus to sex partners.

**A. Primary Genital Herpes Infection.** The mean incubation period from sexual contact to onset of lesions is 5 days. Lesions begin as small erythematous papules that soon form vesicles and then pustules. Within 3 to 5 days the vesiculopustular lesions break to form painful coalesced ulcers that subsequently dry; some form crusts and heal without scarring. With primary disease the genital lesions are usually multiple, bilateral, and extensive. The urethra and cervix are also infected frequently, with discrete or coalesced ulcers on the exocervix. Bilateral enlarged tender inguinal lymph nodes are usually present and may persist for weeks to months. About one-third of patients show systemic symptoms such as fever, malaise, and myalgia, and 1-10% develop aseptic meningitis with neck rigidity and severe headache. First episodes of disease usually last 20-30 days.

**B. Recurrent Genital Infection.** In contrast to primary infection, recurrent genital herpes is a disease of shorter duration, usually localized in the genital region, without systemic symptoms. Prodromal paresthesias in the perineum, genitalia, or buttocks occur 12-24 h before the appearance of lesions. Recurrent genital herpes usually presents with grouped vesicular lesions in the external genital region. Local symptoms such as pain and itching are mild, lasting 4-5 days, and lesions usually last 10-14 days. Recurrent meningitis due to HSV-2 does occur.

## **3. NEONATAL HERPES**

### **Introduction**

Neonatal herpes usually results from transmission of virus during delivery, as the neonate passes through infected genital secretions of the mother. True congenital in utero infection, although possible, is uncommon. The prevalence rate of neonatal herpes varies greatly among populations but is estimated at ~ 1/2500 live births in the United States. This estimate is based on the observation that ~ 0.5-1.0% of women excrete HSV from the cervix at the onset of labor and ~ 6% of babies born through infected birth canals develop neonatal HSV.

Manifestations of neonatal herpes vary. To a considerable degree, this is determined by the mother's antibody status. If she is experiencing primary HSV infection and has no antibody to pass to the baby, the consequences can be severe. If she is experiencing a

reactivation, the baby can be completely protected by maternal antibody. Some infants show disseminated skin lesions only; others have widespread internal organ involvement; still others have involvement of the central nervous system only, with listlessness and seizures. Less commonly, HSV-1 causes neonatal herpes infection, usually resulting from genital HSV-1 lesions or colonization.

## Diagnosis

Herpes simplex virus is easily isolated from lesions or tissue by using fibroblasts or a variety of other tissue culture cells. The cytopathic effects of HSV can usually be demonstrated 24-48 h after inoculation. Isolates of HSV-1 and HSV-2 (see below) can be differentiated by staining virus-infected cells with type-specific monoclonal antibodies to the two types or by analyzing restriction enzyme digests of purified viral DNA. Restriction endonuclease digests can also be used to define epidemiologic relationships, that is, identify strains acquired between sexual partners or through mother-infant transmission. A direct smear prepared from the base of a suspected lesion and stained by either the Giemsa or Papanicolaou method may show intranuclear inclusions or multinucleated giant cells typical of herpes (as demonstrated by the Tzanck test) but is less sensitive than a viral culture and doesn't distinguish HSV-1 from HSV-2. Enzyme immunoassays have been developed for direct detection of herpes antigen in lesions. Although early versions of these noncultural tests lacked sensitivity, more recent assessments show ~ 90% correlation with results from cultures. Rapid diagnosis of HSV mucocutaneous lesions can be accomplished with immunofluorescence or other antigen detection methods. Serology should not be used to diagnose active HSV infection, for example, genital or encephalitis; frequently there is no change in antibody titer when reactivation occurs. PCR on CSF is now the test of choice to diagnose HSV encephalitis. PCR positivity eliminates the need for brain biopsy, but the latter should still be performed if PCR is negative in a patient with highly suggestive clinical findings.

## Treatment

Several antiviral drugs have been developed that inhibit HSV ([Box 33-2](#)). The most commonly used is the nucleoside analog acyclovir, which is converted by a viral enzyme (thymidine kinase) to a monophosphate and then by cellular enzymes to the triphosphate form, which is a potent inhibitor of the viral DNA polymerase. Acyclovir significantly decreases the duration of primary infection but has much less effect when used for treating recurrent infection. Valacyclovir is a prodrug of acyclovir that is better absorbed and can be used in lower and less frequent doses. Famciclovir is an oral drug that is converted to penciclovir, has good bioavailability, is equivalent to acyclovir but can also be given less frequently.

## Prognosis

At least 80% of patients with clinically evident primary HSV infection develop recurrent episodes of herpes within 12 months. In patients whose lesions recur, the median number of recurrences is four or five per year. They are not evenly spaced, and some patients experience a succession of monthly attacks followed by a period of quiescence. Most recurrences result from reactivation of virus from dorsal root ganglia. Rarely,

recurrent diseases may be caused by reinfection with a different strain of HSV. Ultimately recurrences of herpes diminish in frequency, especially with genital HSV-2 infection. Genital HSV-1 infection recurs to recur less frequently.

If untreated, HSV-1 encephalitis has a mortality of 70%, but intravenous acyclovir reduces mortality especially if given before coma occurs.

Because a normal immune response is absent in the neonate, neonatal HSV infection is an extremely severe disease with an overall mortality of ~ 60%, and neurologic sequelae are high in those who survive.

## **Prevention & Control**

Avoiding contact with individuals with lesions reduces the risk of spread; however, virus may still be spread by individuals shedding virus asymptomatically from the saliva, urethra, and cervix. When lesions are present, sexual intercourse should be avoided. Condoms should be used when individuals with a history of type 2 HSV or antibodies have sexual contact with susceptible people, even when lesions are absent. Daily acyclovir, valacyclovir, or famciclovir suppresses recurrences of HSV infections and is indicated for patients who have frequent attacks ([Box 33-3](#)). Because of the high morbidity and mortality of neonatal infection, special attention must be paid to preventing transmission during delivery. In some cases Cesarean section may be used to minimize contact of the infant with infected maternal genital lesions; however, Cesarean section may not be effective if rupture of the membranes precedes delivery by several hours. A recently completed trial of a recombinant HSV-2 vaccine in HSV-2-infected patients had no impact on the rate of recurrences. It is not known whether a vaccine would prevent primary infection, although an effective vaccine offers the best hope for controlling the spread of genital herpes infections. Several different vaccines are at various stages of development and testing. Subsequently a recombinant HSV vaccine was similarly ineffective in preventing primary genital HSV-2 infection.

## **VARICELLA-ZOSTER VIRUS**

### **Essentials of Diagnosis**

- Vesiculopustular, generalized rash in a febrile child (varicella or chicken pox)
- Dermatomal pustular eruption in elderly or immunocompromised patient (herpes zoster or shingles)
- Multinucleated, giant epithelial cells with intranuclear inclusions in skin scrapings, tissue biopsy

Slow growth of virus (5-7 days) in diploid fibroblast cells if fresh vesicles are cultured

- Detection of VZV antigen by immunofluorescence of skin vesicles (best diagnostic test)

### **General Considerations**

**A. Epidemiology.** VZV infection, the cause of both varicella (chickenpox) and herpes zoster, is ubiquitous ([Box 33-4](#)). Nearly all persons contract chickenpox before adulthood, and 90% of cases occur before the age of 10. The virus is highly contagious, with attack rates among susceptible contacts of 75%. Varicella occurs most frequently during the winter and spring months. The incubation period is 11-21 days. The major mode of transmission is respiratory, although direct contact with vesicular or pustular lesions may result in transmission. Infectivity is greatest 24-48 h before the onset of rash and lasts 3-4 days into the rash. Virus is rarely isolated from crusted lesions.

**B. Microbiology.** VZV has the same general structure as HSV but has its own DNA sequence and envelope glycoproteins. Cellular features of infected cells, such as multinucleated giant cells and intranuclear eosinophilic inclusion bodies, are similar to those of HSV-infected cells. VZV is more difficult to isolate in cell culture than HSV and grows best but slowly in human diploid fibroblast cells.

**C. Pathogenesis.** The viruses isolated from lesions of chickenpox and zoster (or shingles) are identical. Latency of VZV occurs in sensory ganglia, as shown by in situ hybridization detection of viral DNA in dorsal root ganglia of adults many years after varicella infection.

**D. Immunity.** Both humoral immunity and cell-mediated immunity are important factors in determining the frequency of reactivation and severity of varicella-zoster. Circulating antibody prevents reinfection, and cell-mediated immunity appears to control reactivation. In patients with depressed cell-mediated immune responses, especially those who have received bone marrow transplants or have Hodgkin's disease, AIDS, or lymphoproliferative disorders, reactivation can occur, and be severe.

## Clinical Findings

VZV produces a primary infection in healthy children which is characterized by a generalized vesicular rash termed chickenpox. Chickenpox lesions generally appear on the head and ears, then spread centrifugally to the face, neck, trunk, and extremities. Lesions appear in different stages of evolution; this characteristic was one of the major features to differentiate varicella from smallpox, in which lesions were concentrated on the extremities and appeared at the same stage of disease. Varicella lesions are pruritic, and the number of vesicles may vary from 10 to several hundred. Involvement of mucous membranes is common, and fever may occur early in the course of disease.

Immunocompromised children may develop progressive varicella, which is associated with prolonged viremia, visceral dissemination, and the development of pneumonia, encephalitis, hepatitis, and nephritis. Progressive varicella has an estimated mortality of ~ 20%. In thrombocytopenic patients, the lesions may be hemorrhagic. Adult patients with varicella are more ill and may develop pneumonia.

Reactivation of VZV is associated with the disease herpes zoster. Although zoster is seen in patients of all ages, it increases in frequency with advancing age, when cell-mediated immunity is waning. Clinically, pain in a sensory nerve distribution may herald the onset of the eruption, which occurs several days to a week or two later. The

vesicular eruption is usually unilateral, involving one to three dermatomes. New lesions may appear over the first 5-7 days. Multiple attacks of VZV infection are uncommon; if recurrent attacks of a vesicular eruption occur in one area of the body, HSV infection should be considered.

## **Complications**

The complications of VZV infection are varied and depend on age and host immune factors. Post-herpetic neuralgia is a common complication of herpes zoster in elderly adults. It involves persistence of severe pain in the dermatome after resolution of the skin lesions and appears to result from damage to the involved nerve root. Immunosuppressed patients may develop disseminated lesions with visceral infection, which resembles progressive varicella. Bacterial superinfection of varicella occurs and is usually caused by gram-positive cocci. Encephalitis may complicate varicella or zoster and may be associated with seizures and in some cases cerebellar signs.

## **Diagnosis**

Varicella or herpes zoster lesions can usually be diagnosed clinically. Scrapings or swabs from the base of lesions may reveal characteristic cells with intranuclear inclusions or multinucleated giant cells identical to those produced by HSV. VZ virus can be isolated from aspirated vesicular fluid inoculated onto human diploid fibroblasts; however, the virus is difficult to grow from zoster (shingles) lesions older than 5 days, and cytopathic effects are usually not seen for 5-9 days. For rapid viral diagnosis, varicella zoster antigen may be demonstrated in cells from lesions by immunofluorescent antibody staining. PCR analysis of CSF may be useful to diagnose VZV encephalitis; cultures are rarely positive.

## **Treatment**

Acyclovir has been shown to reduce fever and skin lesions in patients with varicella ([Box 33-5](#)), and its use is recommended in healthy patients over 18 years of age if treatment is begun within 24-48 h of onset of rash. There is insufficient data to justify universal treatment of all healthy children and teenagers with antiviral agents. In immunosuppressed patients, controlled trials of acyclovir have shown efficacy in reducing dissemination, and its use is definitely indicated. In addition, controlled trials of acyclovir have demonstrated effectiveness in the treatment of herpes zoster in immunocompromised patients. Acyclovir may be used to treat herpes zoster in immunocompetent adults, but it appears to have little or no impact on the development of post-herpetic neuralgia, the most important complication of zoster. Treatment should be started within 3 days of the onset of zoster. VZ virus is less susceptible than HSV to acyclovir, so the dosage for treatment is substantially higher. Famciclovir or valacyclovir are more convenient and may be more effective in preventing post-herpetic neuralgia. Some authorities recommend systemic corticosteroids for patients with zoster who are over 60 and have no contraindications. Although steroids do not prevent post-herpetic neuralgia, patients feel better and return to activity faster.

## **Prevention & Control**

High-titer immune globulin administered within 72-96 h of exposure is useful in preventing infection or ameliorating disease in patients at risk for primary infection (ie, varicella) and serious complications ([Box 33-6](#)). Immunosuppressed children who are household or play contacts of patients with primary varicella are candidates for this immunoprophylaxis.

Once infection has occurred, high-titer immune globulin has not proved useful in ameliorating disease or preventing dissemination. Immune globulin is also not indicated for the treatment or prevention of reactivation (ie, zoster or shingles). In nonimmunosuppressed children, varicella is a relatively mild disease, and passive immunization is not indicated. Patients with varicella spread the virus by the respiratory route. In both syndromes virus is also present in the skin lesions. Varicella is a highly contagious disease, and rigid isolation precautions must be instituted in all hospitalized patients.

A live vaccine developed by a group of Japanese workers is effective and a single dose is now recommended for healthy children aged 12 months to 12 years and for selected healthy adults who are susceptible.

In immunocompromised children, chickenpox can be extremely serious, even fatal. For these children, the live vaccine is being evaluated and is not currently recommended.

## **CYTOMEGALOVIRUS**

### **Essentials of Diagnosis**

- "Owl eye" cells in tissue biopsy, cytology
- Cultured in diploid fibroblast cells
- Antibody detection of those patients seroconverting or at risk for reactivation
- CMV detection in blood or bodily fluids by antigenemia, PCR, or other DNA-based assays, eg hybrid capture, or by culture

### **General Considerations**

**A. Epidemiology.** CMV is ubiquitous, and in developed countries ~50% of adults have developed antibody ([Box 33-7](#)). Age-specific prevalence rates show that ~ 10-15% of children are infected by CMV during the first 5 years of life, after which the rate of new infections levels off. The rate subsequently increases during young adulthood, probably through close personal contact or sexual transmission of the virus. CMV has been isolated from saliva, cervical secretions, semen, urine, and white blood cells.

Excretion of virus is prolonged after congenital and perinatal infections, probably because of immunologic tolerance, and high titers of virus may be shed for more than 5 years after birth. Transmission of infection in daycare centers has been shown to occur from asymptomatic excretors to other children and, in turn, to seronegative parents. Infected adults, especially immunocompromised adults, also excrete virus for prolonged

periods after primary infection or reactivation of latent infection. Latent infection, which may reside in leukocytes and their precursors, can be transmitted by transfusion and organ transplantation.

**B. Microbiology.** Human CMV possesses the largest genome of the herpesviruses (~240 kilobase pairs), and its replication, although slow, is similar to that of HSV with the sequential appearance of immediate early, early, and late gene products. Strains of CMV demonstrate considerable genomic and phenotypic heterogeneity, and restriction endonuclease analysis of viral DNA has been useful for distinguishing strains epidemiologically. Antigenic variations have been observed but are not of clinical importance.

**C. Pathogenesis and Immunity.** Cytomegalovirus infects epithelial cells and leukocytes. In vitro, CMV DNA can be demonstrated in monocytes showing no cytopathology, indicating a restricted growth potential in these cells. In addition to nuclear inclusions ("owl eye cells"), CMV produces perinuclear cytoplasmic inclusions and enlargement of the cell (cytomegaly), a property which gives the virus its name.

After primary CMV infection, the virus becomes latent. The exact site(s) of latency and the mechanisms of persistence are not completely understood, but leukocytes, especially mononuclear leukocytes, are suspected to contain latent virus and account for transmission of the virus by blood and leukocyte transfusions. Also, organs such as the kidneys and heart harbor the virus, but the exact cell is not known. Latent CMV infection appears to be reactivated by immunosuppression (eg, by corticosteroids or HIV infection) and possibly by allogeneic stimulation (ie, the host response to transfused or transplanted cells). Cellular damage appears to be caused directly by the viral lytic infection or indirectly by the immune response of the host. An example of cellular damage resulting from a direct cytopathic effect is retinitis in severely immunocompromised AIDS patients, in which blindness occurs as a result of a necrotizing infection by the virus. The beneficial effects of ganciclovir therapy support this notion. In contrast, HCMV pneumonitis in transplant recipients frequently manifests subtle histologic alterations in the face of life-threatening clinical symptomatology and extensive inflammation accompanied by mild viral replication, suggesting that immune-mediated injury is the primary pathologic mechanism. In other instances, both direct and immunopathogenic mechanisms seem to be at work.

## Clinical Findings

**D. Congenital.** Worldwide, 1% of infants excrete CMV in urine at delivery, as a result of infection in utero. On physical examination, 90% of these infants appear normal; however, long-term follow-up has indicated that up to 20% go on to develop sensory nerve hearing loss, psychomotor mental retardation, or both. The infants with symptomatic illness (~ 0.1% of all births) may have a variety of congenital defects or other disorders (such as hepatosplenomegaly, jaundice, anemia, thrombocytopenia, low birth weight, microcephaly, and chorioretinitis). Almost all babies with clinically evident congenital CMV infection are born of mothers who experience primary CMV infection during the pregnancy. Congenital infection frequently also results from reactivation in the mother with spread to the fetus, but such infection rarely leads to congenital abnormalities due to protection by passively transferred maternal antibody.

**E. Perinatal.** Most population-based studies have indicated that 10-15% of all mothers are excreting CMV from the cervix at delivery. Approximately one-third to one-half of all infants born to these mothers acquire infection. Almost all of these perinatally infected infants have no discernible illness unless the baby is premature or immunocompromised. CMV can also be efficiently transmitted from mother to child by breast milk, but these postpartum infections are also usually benign.

**F. Post neonatal.** As with intrapartum acquisition of infection, most CMV infections during childhood and adulthood are totally asymptomatic. In adults, CMV may cause a mononucleosis-like syndrome. In immunosuppressed patients, latent CMV may be reactivated and cause very serious disease. In patients receiving bone marrow transplants, interstitial pneumonia caused by CMV is the leading cause of death (90% mortality). In AIDS patients with low CD4 lymphocyte counts CMV often disseminates to visceral organs, causing chorioretinitis, gastroenteritis, neurologic disorders, and disease in other organs.

## Diagnosis

Laboratory diagnosis of CMV infection depends on (1) detecting CMV cytopathology, antigen, or DNA in infected tissues or bodily fluids, (2) isolating the virus from tissue or bodily fluids, or (3) demonstrating seroconversion. CMV can be grown in serially propagated diploid fibroblast cell lines but generally requires 3-14 days, depending on the concentration of virus in the specimen. The time for detection can be shortened by centrifugation and immune staining, but culture of blood is less sensitive than antigenemia or DNA-based assays.

Because of the high prevalence of asymptomatic carriers and the known tendency of CMV to persist weeks or months in infected individuals, it may be difficult to attribute a specific disease to CMV by isolation of the virus from a peripheral site. Thus, the isolation of CMV from urine of immunosuppressed patients with interstitial pneumonia does not constitute evidence for CMV as the etiology of that illness. CMV pneumonia or gastrointestinal disease is best diagnosed by demonstrating CMV inclusions in biopsy tissue.

## Treatment

Ganciclovir, a nucleoside analog of acyclovir, inhibits CMV replication and reduces the severity of CMV syndromes, such as retinitis and gastrointestinal disease ([Box 33-8](#)). When given with hyper immune globulin, ganciclovir is thought to reduce the mortality of CMV pneumonia in transplant recipients.

Foscarnet is an approved drug for therapy of CMV retinitis. Its toxic effects are primarily renal with electrolyte disturbances, whereas ganciclovir is most apt to inhibit bone marrow function. Ganciclovir inhibits CMV DNA polymerase as does foscarnet, but they act on different sites and cross-resistance is rare. Cidofovir is a third approved anti-CMV drug and is the first nucleotide analog to be used in clinical practice. It has a long half-life, which allows it to be given every 2 weeks during maintenance treatment of CMV retinitis, but it is significantly nephrotoxic.

## Prevention & Control

The use of blood from CMV seronegative donors or blood that is treated to remove white cells decreases transfusion-associated CMV ([Box 33-9](#)). Similarly, the disease can be avoided in seronegative transplant recipients by using organs from CMV-seronegative donors. Hyperimmune human anti-CMV globulin has been used to ameliorate CMV disease associated with renal and hepatic transplants. Prophylactic or preemptive ganciclovir and valacyclovir reduce the frequency of CMV disease in both transplant and AIDS patients. There are experimental and clinical data indicating that the use of condoms decreases sexual transmission of CMV. CMV vaccines are being evaluated in clinical trials.

## EPSTEIN-BARR VIRUS

### Essentials of Diagnosis

- Atypical lymphocytes in peripheral blood smear
- Heterophile antibody present in high titer in serum
- Immunoglobulin G (IgG) seroconversion or development of antibody to EB nuclear antigen
- Adolescent, young adult with fever, lymphadenopathy, splenomegaly, pharyngitis, and prolonged fatigue
- Infectious mononucleosis may be complicated by laryngeal obstruction, CNS disease, splenic rupture

### General Considerations

EBV is the etiologic agent of infectious mononucleosis and certain lymphoproliferative syndromes ([Box 33-10](#)).

**A. Epidemiology.** EBV can be cultured from the saliva of 10-20% of healthy adults. Excretion may persist weeks to months. Infection with EBV is by contact with infected secretions such as saliva. It is of low contagiousness, and most cases of infectious mononucleosis are contracted after repeated contact between susceptible persons and those asymptotically shedding the virus. Secondary attack rates of infectious mononucleosis are low (< 10%), because most family or household contacts already have antibody to the agent. Antibodies to EBV are found in up to 90% of adults, although the percentage of susceptible adults is increasing in developed countries.

**B. Microbiology.** The complete 172-kilobase-pair nucleotide sequence of EBV has been mapped. At present there appear to be many fewer genomic strain variations among EBV isolates than among other herpesviruses. Although morphologically similar to the other herpesviruses, EBV can be cultured easily only in lymphoblastoid cell lines derived from B-lymphocytes of humans and higher primates. The virus generally does

not produce cytopathic effects or the characteristic intranuclear inclusions of other herpesvirus infections. After infection with EBV, lymphoblastoid cells containing the viral genome can be cultivated continuously in vitro; they are thus transformed or immortalized.

Recent studies suggest that most of the viral DNA in transformed cells remains in circular, nonintegrated form as an episome, and a lesser amount is integrated into the host cell genome. Viral antigen expression has been studied by immunofluorescent staining of transformed cell lines under various conditions. One group of proteins called EBV nuclear antigens (EBNAs) appears in the nucleus before virus-directed protein synthesis. Viral capsid antigen (VCA) can be detected in cell lines that produce mature virions. Other cell lines, called nonproducers, contain no mature virions, but express certain virus-associated antigens called early antigens (EA). The latter may be seen as diffuse (D), and as restricted (R) aggregates of staining. Antibodies against these antigens can be detected by serological tests.

**C. Pathogenesis.** Although EBV initially infects epithelial cells, the hallmark of EBV disease is infection of B-lymphocytes. The virus enters B-lymphocytes by means of envelope glycoprotein binding to surface complement (C3d) receptor; 18 to 24 h later, EBV nuclear antigens are detectable within the nucleus of infected cells. Expression of the viral genome is associated with immortalization and proliferation of the cell. The EBV-infected B-lymphocytes are polyclonally activated to produce immunoglobulin and express a lymphocyte-determined membrane antigen that is the target of host cellular immune responses. During the acute phase of infectious mononucleosis, ~ 20% of circulating B-lymphocytes demonstrate EBV antigens. After infection subsides, EBV can be isolated from only ~ 1% of such cells.

EBV has been associated with several lymphoproliferative diseases including African Burkitt's lymphoma, nasopharyngeal carcinoma, and lymphomas in immunocompromised patients. The factors that render the EBV infections oncogenic in these cases are obscure. The distribution of EBV infections in Africa has suggested an infectious cofactor, such as malaria, which may cause immunosuppression and predispose to EBV-related malignancy. In the case of nasopharyngeal carcinoma, environmental carcinogens probably create the precancerous lesion, which then stimulates the EBV to reactivate. EBV-associated lymphomas have been shown to be of both monoclonal and polyclonal origin. Chromosomal translocations in B cells are characteristic of Burkitt's lymphoma and involve specific breaks in chromosomes at sites of genes encoding immunoglobulins. These translocations lead to expression of oncogenes that may contribute to clonal activation and ultimately to malignancy. Some breakdown in immune surveillance also appears to play a role in the development of malignancy because immunosuppressed patients are more prone to develop B-cell lymphomas. Transplant recipients may develop a lympho-proliferative syndrome with very high titers of EBV in blood.

**D. Immunity.** EBV-infectious mononucleosis results in the synthesis of circulating antibodies against viral antigens, as well as against unrelated antigens found in sheep, horse, and some beef red blood cells. These heterophile antibodies, a heterogeneous group of predominantly IgM antibodies, are commonly used as diagnostic tests for the disease. Some other immunologic functions are also affected by EBV infection.

Cutaneous anergy and decreased cellular immune responses to mitogens and antigens are seen early in the course of mononucleosis.

Although EBV infects B-lymphocytes, the lymphocytosis associated with infectious mononucleosis is caused by an increase in the number of circulating T cells, which appear to be activated cells developed in response to the virus-infected B-lymphocytes. With recovery from illness, the atypical lymphocytosis gradually resolves, and cell-mediated immune functions return to preinfection levels.

## **Clinical Findings**

As with most of the herpesviruses (except varicella), most primary EBV infections are asymptomatic. The clinical syndrome of infectious mononucleosis is characterized by fever, malaise, pharyngitis, tender lymphadenitis, and splenomegaly. These symptoms persist for days to one or more weeks but slowly resolve. Complications such as laryngeal obstruction, ruptured spleen, or a variety of CNS manifestations (aseptic meningitis, encephalitis, etc.) may occur in 1-5% of patients.

Patients with primary or secondary immunodeficiency are susceptible to EBV-induced lymphoproliferative disease. The risk is greatest in those experiencing primary EBV infection rather than reactivation. The most characteristic clinical findings are persistent fever, lymphadenopathy, and hepatosplenomegaly. In AIDS patients, several distinct additional EBV-associated syndromes occur, including hairy leukoplakia of the tongue, interstitial lymphocytic pneumonia, especially in infants, and lymphoma of the CNS and elsewhere.

## **Diagnosis**

Laboratory confirmation of EBV infectious mononucleosis is usually documented by the demonstration of atypical lymphocytes, heterophile antibodies, or positive EBV-specific serologic findings. Hematologic examination reveals a markedly raised lymphocyte and monocyte count with > 10% atypical lymphocytes. Atypical lymphocytes, although not specific for EBV, are present with the onset of symptoms and disappear with resolution of disease. Alterations in liver function tests may also occur.

Although not specific for EBV, tests for heterophile antibodies are used most commonly for diagnosis of infectious mononucleosis. In commercial kits, animal erythrocytes are used in simple slide agglutination methods, which incorporate absorption to remove cross-reacting antibodies that may develop in other situations, such as serum sickness. The infectious mononucleosis heterophile antibody is absorbed by sheep erythrocytes but not by guinea pig kidney cells. Heterophile antibodies can usually be demonstrated by the end of the first week of illness but may occasionally be delayed until the third or fourth week. They may persist many months.

Approximately 5-15% of EBV-induced cases of infectious mononucleosis in adults and a much greater proportion in young children and infants fail to induce detectable levels of heterophile antibodies. In these cases EBV-specific serologic tests may be used to establish the diagnosis. Antibodies to VCA rise quickly and persist for life. The presence of IgM antibody to VCA is theoretically diagnostic of acute, primary EBV infection, but

low levels may occur during reactivation of EBV, and cross-reactivation with antigens of other herpesviruses occur. Antibodies to EBNA rise later in disease (after ~ 1 month) and also persist in low titers for life. Thus, a high titer to VCA and no titer to EBNA suggest recent EBV infection, whereas antibody titers to both antigens are indicative of past infection. Persistent antibody to early antigens (anti-EA, -D, or -R) may be correlated with severe disease, nasopharyngeal carcinoma (anti-D), or African Burkitt's lymphoma (anti-R) but are not useful in diagnosing infectious mononucleosis. Isolation of EBV from clinical specimens is not practical because it requires fresh human B cells or fetal lymphocytes obtained from cord blood. PCR is being developed to assay EBV DNA in blood.

## **Treatment**

Treatment of infectious mononucleosis is largely supportive. More than 95% of patients recover uneventfully. In a small percentage of patients, splenic rupture may occur; thus, restriction of contact sports or heavy lifting during the acute illness is recommended. The DNA polymerase enzyme of EBV has been shown to be sensitive to acyclovir, and acyclovir can decrease the amount of replication of EBV in tissue culture and in vivo ([Box 33-11](#)). Despite this antiviral activity, systemic acyclovir makes little impact on the clinical illness. Corticosteroids appear to be beneficial in reducing laryngeal edema and severe toxicity. They may also be indicated for CNS complications. Treatment of EBV lymphoproliferative disease includes diminution of immunosuppression as much as possible; acyclovir is also used.

## **Prevention & Control**

Because EBV may be spread by direct person-to-person contact from even asymptomatic individuals, it is unavoidable. Isolation is not practiced owing to ubiquitous infection. The occurrence of Burkitt's lymphoma and nasopharyngeal carcinomas in restricted geographic areas offers the possibility of prevention by immunization with virus-specific antigen(s). This approach is under exploration at present. A subunit vaccine has proved effective in preventing the development of tumors in tamarind monkeys, which are highly susceptible to the oncogenic effects of the virus under experimental conditions.

## **HUMAN HERPESVIRUS TYPE 6**

### **Essentials of Diagnosis**

- Infant with high fever for several days; maculopapular rash after defervescence
- Can be isolated in cultures of monocytes but takes 10-30 days and may be false negative
- Detection of specific IgG and IgM by indirect immunofluorescence are diagnostic tests of choice
- Blood or saliva PCR for HHV-6 DNA may be positive, but diagnostic significance uncertain due to intermittent excretion in asymptomatic patients

- PCR positively in CSF diagnostic of encephalitis

## **General Considerations**

In 1986 a human herpesvirus, now called human herpesvirus type 6 (HHV-6), was identified in cultures of peripheral blood lymphocytes from patients with lymphoproliferative diseases ([Box 33-12](#)). The virus, which is genetically distinct but morphologically similar to other herpesviruses, replicates in lymphoid tissue, especially CD4+ T lymphocytes, and has two distinct variants, A and B.

Initially it was thought that HHV-6 would grow only in freshly isolated B-lymphocytes, and the virus was referred to as the human B-lymphotropic virus (HBLV); now it is clear that the virus is preferentially tropic for CD4+ T lymphocytes. HHV-6 establishes a latent infection in T cells but may be activated to a productive lytic infection by mitogenic stimulation. Resting lymphocytes and lymphocytes from healthy immune individuals are resistant to HHV-6 infection. In vivo, HHV6 replication is controlled by cell-mediated immune factors. It appears to be capable of reactivating in immunosuppressed patients, but its clinical significance in this situation is unknown.

Serologic studies indicate that almost all children are infected by age 2. This makes HHV-6 the most communicable of all human herpesviruses. Most adults shed HHV-6 in saliva, and close personal contact is the most likely route of spread; vertical transmission also occurs.

## **Clinical Findings**

Exanthem subitum occurs in infants and is characterized by fever, eg, 39 °C for several days followed by defervescence and a light maculopapular rash spreading from the trunk to the extremities. CNS complications may occur with febrile seizures, meningitis and encephalitis. HHV-6 may also be a cause of febrile episodes in transplant recipients.

## **Diagnosis**

Virus infection is best documented by seroconversion. Active virus infection can be documented by culture, antigenemia, or DNAemia, but since reactivation or is common, it is very difficult to use these tools to diagnose HHV-6 as the cause of disease. Also, culture takes 10-30 days.

## **Treatment**

HHV-6 appears to be susceptible in vitro to ganciclovir and foscarnet and less susceptible to acyclovir, but no clinical data are available.

## **Prevention & Control**

Because HHV-6 infection is ubiquitous and almost all infants excrete the virus by 2 years of age, no preventative measure is practical. No vaccine is in development, and

isolation is not practical owing to ubiquitous infection.

## **OTHER HERPESVIRUSES**

### **1. HERPESVIRUS TYPE 7**

Isolation of human herpesvirus type 7 (HHV-7) was first reported in 1990. The virus was isolated from activated CD4+ T lymphocytes of a healthy individual. HHV-7 is distinct from all other known human herpesviruses but is most closely related to HHV-6.

Seroepidemiologic studies indicate that this virus usually does not infect children until after infancy, and ~ 50% of infants are antibody positive by 2-4 years of age. As with HHV-6 this virus is frequently isolated from saliva, and close personal contact is the probable means of transmission. Also like HHV-6 this virus appears to be a cause of exanthem subitum. The diagnosis of acute infection can be made by the demonstration of seroconversion. No treatment has been identified.

### **2. HUMAN HERPESVIRUS TYPE 8 (Kaposi's sarcoma-associated herpes virus [KSHV])**

KSHV was discovered in 1994 by identification of unique viral DNA sequences in an AIDS patient's Kaposi's sarcoma (KS) tissue. The method used was representational difference analysis. Specific HHV-8 DNA sequences are found in the great majority of KS tissues in the United States, including those from non-AIDS cases, and occasionally in other specimens including lymphomas. Recently the virus was isolated in culture and, when characterized, seemed most closely related to EBV. Serologic and virologic data suggest that this virus is at least a cofactor in the pathogenesis of KS.

## 34 . Measles — Gregory Sonnen, MD, & Nancy Henry, MD, PhD

### Essentials of Diagnosis

- Epidemic systemic viral illness, primarily of children and young adults.
- Exanthematous disease with fever, cough, coryza, and conjunctivitis.
- Exanthem is a maculopapular, confluent rash that is centrifugally spread from the head to the extremities.
- Koplik's spots are a pathognomonic enanthem that occurs on the buccal mucosa.
- Incidence has drastically dropped in the postvaccination era.

### General Considerations

**A. Epidemiology.** Rubeola, commonly known as measles, is a virus spread primarily in the winter and early spring. Like mumps and rubella, vaccination has drastically changed the epidemiology of measles. In the prevaccination era, rubeola followed a biannual epidemic cycle. It is prevalent throughout the world.

Measles vaccine was introduced for commercial use in 1963. From 1963 to 1967, ~900,000 children received the inactivated measles vaccine. The attenuated, live-virus vaccine was introduced in the late 1960s. By 1973, the inactivated vaccine was no longer available. Before 1963, between 200,000 and 600,000 cases were reported annually in the United States. However, even these reports represent only a fraction of the actual case rate. The number of reported cases dropped from 22,231 in 1968 to 1,497 in 1983.

In the mid-1980s a resurgence of reported cases occurred primarily in the preschool population. Nearly 19,000 cases were reported in 1989. The majority of these cases were in vaccine-eligible, unvaccinated preschool children living in urban areas. In the late 1980s and early 1990s several outbreaks occurred among adolescents and young adults, primarily on college campuses. Most of the cases were in patients with a history of receiving only a single dose of the vaccine. Since 1993, < 1,000 cases have been reported per year. This is likely owing to aggressive revaccination efforts. A second measles vaccination is now standard at ages 4-6 years.

**B. Microbiology.** Measles is caused by a pleomorphic 100- to 250-nm RNA virus of the *Paramyxoviridae* family. It is a member of the genus *Morbillivirus*. The virus has three structural proteins complexed within its helical nucleocapsid. The lipoprotein envelope contains three proteins (F, H, and M). The F glycoprotein facilitates host cell adhesion and penetration. The H glycoprotein is a hemagglutinin. The M protein is a nonglycosylated protein that lines the inner lipid bilayer and facilitates viral maturation. The virus is labile and sensitive to heat, ultraviolet (UV) light, and extremes of pH.

**C. Pathogenesis.** Measles virus is spread primarily via respiratory droplet nuclei. Direct contact is also a mode of transmission. Humans are the only natural reservoir for the virus. The primary site of adhesion and invasion is the respiratory epithelium, with quick spread to lymphatic tissues and subsequent viremia.

Measles virus is communicable for 3-5 days before the outbreak of the rash. It remains communicable up to 4 days after the appearance of rash. Immunocompromised patients can shed virus for an extended period of time. Patients who develop subacute sclerosing panencephalitis do not continue to shed virus.

## CLINICAL SYNDROMES

### TYPICAL MEASLES

#### Clinical Findings

**A. Signs and Symptoms.** Typical measles, also referred to as "natural measles," can occur at any age ([Table 34-1](#)). Immunity is lifelong, so recurrence is extremely rare. A prodromal phase of 2-4 days is marked by fever, malaise, cough, coryza, conjunctivitis, and pharyngitis. A pathognomonic enanthem of measles (Koplik's spots) erupts on the buccal mucosa during this phase. These appear as small blue to white plaques.

The exanthem phase begins ~2 weeks after exposure. The maculopapular rash first appears on the brow and posterior auricular area. It progresses to cover the face and spreads to the distal extremities within 72 h. Large areas of the rash will progress to confluence, then desquamate leaving transient hyperpigmented areas. The rash usually begins to clear on the 3rd or 4th day. The fever peaks on the 2nd or 3rd day of the rash.

**B. Laboratory Findings.** The virus can be isolated from a nasopharyngeal swab, conjunctival swab, blood, and urine during the febrile course of the illness. Isolation of the virus can be technically difficult. A variety of tissue cultures can be used to grow the virus. Human and monkey kidney cell lines are typically used with clinical specimens. Acute and convalescent serologies can be helpful. Serologies should be drawn 2-4 weeks apart to monitor progression. Immunoglobulin M (IgM) is detectable from 3 to 30 days after the onset of rash. Measles antibody is detectable in the cerebrospinal fluid of patients with subacute sclerosing panencephalitis. These patients often have a high IgG titer in the serum as well.

**C. Imaging.** Chest radiographs may demonstrate diffuse infiltrates if pneumonia is present.

**D. Differential Diagnosis.** The differential diagnosis of measles includes Kawasaki disease, Stevens-Johnson syndrome, and other viral exanthems.

**E. Complications.** Acute complications can include meningoencephalitis, pneumonia, otitis media, and laryngotracheitis ([Box 34-1](#)). Measles meningoencephalitis occurs in 1 per 1000 cases. It has a high morbidity and mortality rate. "Black measles" is a severe, hemorrhagic variation of typical measles. It is extremely rare in the postvaccination era. It has a high mortality rate. Patients present with a confluent hemorrhagic skin rash,

encephalitis, and pneumonia. Bleeding often occurs via nose, mouth, and gastrointestinal tract.

Measles infection during pregnancy produces significant fetal morbidity and mortality, especially if infection occurs during the first trimester. Measles uncommonly produces severe abdominal pain during the acute febrile phase. Etiologies for this pain can be mesenteric lymphadenitis or appendicitis. Evidence of peritonitis warrants prompt surgical evaluation.

Subacute sclerosing panencephalitis (SSPE) is a rare, late-onset, lethal neurodegenerative sequela of measles infection. It occurs with an incidence of 0.6-2.2 cases/100,000 infections and 1 case/1 million vaccinations. SSPE results from a slowly progressive chronic infection with the virus. SSPE becomes clinically evident an average of 7 years after initial measles exposure. Symptoms include unusual behavior, developmental regression, ataxia, myoclonic jerks, visual impairment, and aphasia. All of these symptoms are progressive, leading ultimately to decorticate rigidity and death, which usually occurs 6-9 months after onset of symptoms. Confirmation of the diagnosis can be made by electroencephalogram, serology, and analysis of the cerebrospinal fluid. Cerebrospinal fluid shows high IgG as does serum. No current therapy is effective.

## **MODIFIED MEASLES**

Modified measles occurs in individuals receiving an incomplete live virus vaccination series and subsequently being infected by the natural virus. It can also occur in infants under 9 months owing to the presence of maternally derived antibodies. It is similar to natural measles infection but less severe (see [Table 34-1](#)). The prodromal phase may be shorter and less severe. Koplik's spots may be scant or absent. The exanthem rash usually does not progress to confluence, but has a similar duration. Viral isolation is unaffected. All the complications and sequelae of typical measles can occur.

## **ATYPICAL MEASLES**

### **Introduction**

Atypical measles occurs in some individuals who received the inactivated virus vaccine in the 1960s and were subsequently exposed to the natural virus. These patients have a prodromal phase noted by sudden onset of high fever, headache, myalgia, and abdominal pain (see [Table 34-1](#)). Lobar pneumonia with effusion is common. These patients rarely have Koplik's spots. The exanthem phase begins on the 2nd or 3rd day of illness. The maculopapular rash begins on the palms and soles and spreads centrally. It can progress to vesiculation. Urticaria, purpura, and petechiae are common.

Chest radiographs will commonly show lobar consolidation. Acute and convalescent titers and viral culture are useful. The differential diagnosis of this exanthem includes rickettsial disease, meningococemia, and hemorrhagic fever.

### **Diagnosis**

Diagnosis of measles is usually based on physical findings. Finding Koplik's spots and

monitoring the usual progression of the exanthem are helpful clues. An attempt should be made to culture the virus during the febrile course of the illness. Culture can often be technically difficult. Serology should be obtained as well. Confirmation of a diagnosis should be promptly reported to a local government health agency for epidemiologic tracking.

## **Treatment**

Treatment of measles is often supportive. Hospitalization is not warranted unless the patient is dehydrated, in respiratory distress, encephalopathic, or otherwise compromised. Young patients requiring hospitalization ([Box 34-2](#)) should receive vitamin A. Recent clinical studies have shown a decrease in morbidity and mortality in patients receiving vitamin A supplementation. Patients of any age may benefit from vitamin A supplementation if their cases are clinically severe. All patients in areas of known vitamin A deficiency (ie, Third World countries) should receive supplementation if measles is endemic to the area.

Immune globulin may be used to protect susceptible contacts of confirmed measles cases. Immune globulin must be used within 6 days of exposure for maximum efficacy. Contacts who received at least one dose of measles vaccine at age = 12 months do not need immune globulin if they are immunocompetent. Candidates for immune globulin would include nonimmunized pregnant women, the immunocompromised, and infants < 1 year of age. Infants < 5 months of age do have passive maternal antibodies if their mother can be confirmed to be measles immune. If maternal immunity is confirmed, these infants do not need immune globulin. If children receive immune globulin, they should not receive measles vaccine for 5 months (if receiving 0.25 cc/kg immune globulin) or 6 months (if receiving 0.5 cc/kg immune globulin).

The live virus vaccine can modify the infection in a nonimmunized person, if given within 72 h of exposure. Clinical response varies. Usual vaccine contraindications apply to the vaccine if used in this modality (see [Box 34-2](#)).

## **Prevention & Control**

Measles is highly communicable. Any hospitalized patient suspected of harboring the virus should be in droplet isolation. Good hand washing and appropriate handling of fomites should be observed as well. This isolation should be maintained during the prodromal phase and 4 days from the onset of the exanthem. Children should also be excluded from school and daycare during this period. Isolation may need to be extended in complicated cases. Some immunocompromised patients can shed virus for an extended period.

School quarantine issues are often difficult. Virus is shed and communicable in the prodromal phase. The diagnosis of measles is often not suspect in this phase. The index case may have many contacts before diagnosis. Quarantine issues should be addressed individually and in conjunction with a local government health agency.

Live attenuated measles vaccine should be administered to healthy individuals at two intervals. The first dose is recommended at age 12-15 months. The second dose should

be at age 4-6 years. Children who miss the second dose should receive it before age 12 years.

In epidemic conditions, a dose may be given from ages 6 to 11 months. These patients will still need a dose at age 12-15 months and at 4-6 years ([Box 34-3](#)).

### **BOX 34-3. Control of Measles**

#### **Vaccine**

- Live attenuated measles vaccine is administered 0.5 cc SQ. Commonly given in combination with MMR (measles, mumps, rubella) vaccine
- First dose is recommended at from 12 to 15 months of age
- Second dose is recommended at school entry (age 4 to 6 years)
- If no preschool dose is given, the second dose should be administered before age 12
- Improperly stored vaccine may result in failure
- A dose may be given to infants age 6 to 11 months during epidemic conditions; these infants must still follow the two-dose guideline above

#### **MMR Vaccine**

#### **Contraindications**

- Pregnancy
- Febrile illness
- Planned pregnancy within 3 months
- Severe immunocompromised state
- Blood product or immune globulin within 3 to 6 months (dose dependent)
- Anaphylaxis to neomycin

#### **MMR Vaccine Should Be Used with Caution in These Situations**

- Seizure disorder
- Thrombocytopenia
- Egg allergy

#### **Isolation Precautions**

- Respiratory isolation required during the prodromal phase through 4 days from the onset of rash in healthy patients
- Immunocompromised patients usually shed virus for an extended period

## 35 . Mumps — *Gregory Sonnen, MD & Nancy Henry, MD, PhD*

### Essentials of Diagnosis

- Epidemic parotitis, usually seen in childhood.
- Most common heralding symptom is painful parotid swelling.
- Headache and meningismus common.
- Orchitis is uncommon late complication seen in post-pubertal males; rarely leads to sterility.
- Other glandular tissue may be inflamed.

### General Considerations

**A. Epidemiology.** Mumps, historically known as epidemic parotitis, was one of the most common early childhood infections before the routine use of mumps vaccination starting in 1968. Reported cases of mumps have dropped 98% when compared with the prevaccine era. It is spread primarily during the late winter and early spring. Before the vaccination era, mumps epidemics occurred in 3- to 4-year cycles.

**B. Microbiology.** Mumps virus is a 150-nm paramyxovirus. It is composed of single-stranded RNA contained in a helical nucleocapsid. The viral envelope contains hemolysin, hemagglutinin, and neuraminidase.

**C. Pathogenesis.** Mumps virus is spread via respiratory secretions, with humans being the only natural reservoir. The latent phase of the virus is from 12 to 25 days. The host is communicable from 2 days before to 9 days after the onset of parotid swelling. Mumps is often inappropriately thought to be "less communicable" than other pediatric viruses. This concept is probably owing to the high incidence (20-40%) of subclinical infections.

### Clinical Findings

**A. Signs and Symptoms.** Mumps virus typically infects the parotid glands but has the ability to infect other glandular tissue ([Box 35-1](#)). Mumps parotitis rarely has prodromal symptoms. Children can have a prodrome of fever, myalgia, and headache. In two-thirds of infections, parotid pain and swelling are the heralding symptoms. Headache and meningismus are common. Fever and parotid swelling usually begin resolving within 1 week.

**B. Laboratory Findings.** Infection can be confirmed by viral culture or serology. Culture samples can be obtained by pharyngeal swab or from urine or cerebrospinal fluid during the febrile course of disease. The virus can be cultured on a variety of cell lines including embryonated chicken egg and chick embryo fibroblast. Serology can be

confirmed via enzyme immunoassay, complement fixation, or hemagglutination inhibition. Acute and convalescent serologies are helpful to monitor the course of disease.

**C. Differential Diagnosis.** The differential diagnosis of mumps parotitis includes suppurative parotitis and salivary calculus. Anterior cervical lymphadenitis can often be confused with parotitis.

**D. Complications.** Orchitis is an uncommon complication of mumps in adults and adolescents, with the highest rate found in the 15- to 29-year age group. It is rare in children. Orchitis is suspected when the patient has a high fever at the end of the first week of illness. This is soon accompanied by swelling, tenderness, and severe pain in the testis. Roughly 75% of mumps orchitis is unilateral. Rarely, testicular atrophy follows orchitis. Sterility is rare and is seen in cases of bilateral orchitis. Orchitis usually lasts 4-6 days.

Mumps infection during the first trimester of pregnancy confers an increased risk of spontaneous abortion but no increased risk of fetal malformation. Other uncommon complications include meningoencephalitis, deafness, arthritis, pancreatitis, thyroiditis, mastitis, and oophoritis.

## Diagnosis

Diagnosis is based on physical findings and culture or serology. History of a mumps contact can be difficult to find owing to the significant number of subclinical cases. Cerebrospinal fluid will demonstrate a lymphocytic pleocytosis if meningitis is present.

## Treatment

Therapy is aimed primarily at analgesia ([Box 35-2](#)). Opioids are often needed for the pain of orchitis, which can be quite severe. Local application of cool compresses may also help relieve some of the orchitis pain. Intravenous hydration may be needed for some patients. Lumbar puncture may be therapeutic for patients with severe headache. Mumps immune globulin has little clinical value. It is no longer available in the United States.

## Prevention & Control

Virus is shed 1 day before onset of symptoms and continues to shed for 9 days after the onset of parotitis. Droplet isolation should be maintained on hospitalized patients during this period. Children should be excluded from school and daycare during this period.

The live virus vaccine is usually given in combination with the MMR vaccine (measles, mumps, and rubella). The first vaccine should be given between 12 and 15 months of age. The second dose is usually given between ages 4 and 6 years. If the second dose is missed, it should be given before age 12 years. Various contraindications exist for the vaccine ([Box 35-3](#)).

## 36 . Rubella — *Gregory Sonnen, MD, & Nancy Henry, MD, PhD*

### General Considerations

**A. Epidemiology.** The epidemiology of rubella, commonly referred to as German measles or 3-day measles, has changed dramatically in the past 30 years, owing exclusively to the widespread use of the rubella live attenuated virus vaccine. Before the use of this vaccination (1969), the virus had an epidemic cycle of 6-9 years. It is primarily a winter and early spring infection. The incidence of rubella infection in developed countries has declined by 99%, compared with pre-vaccine era data. In the vaccine era, current data suggest that 10% of young adults are still susceptible. The majority of these young adults lack vaccination.

A major concern of rubella is infection of nonimmune pregnant women. Polysystemic fetopathy is the hallmark of congenital rubella syndrome. Infection before 20 weeks of gestation confers a significant risk of congenital malformation with the highest risk before 12 weeks of gestation.

**B. Microbiology.** Rubella is a 70-nm single-stranded RNA virus of the *Togaviridae* family. It is the only virus in the genus *Rubivirus*. It has three polypeptide constituents (E1, E2, and C). E1 and E2 are glycosylated membrane peptides. The nucleocapsid is composed of polypeptide C and genomic RNA. The viral envelope is a lipoprotein complex. The virus is sensitive to heat, light, and pH extremes.

**C. Pathogenesis.** Humans are the only natural reservoir of the virus. Spread is chiefly via respiratory secretions and direct contact. The virus is communicable for 3-5 days before the rash and 7 days after the rash has appeared. The virus has a latent phase of 2-3 weeks before clinical disease appears.

### POSTNATALLY ACQUIRED RUBELLA

#### Essentials of Diagnosis

- Exanthematous viral illness.
- A prodrome of cough, fever, myalgia, cervical lymphadenopathy, and pharyngitis is common in adults.
- Prodrome is rare in children.
- Exanthem is a fine maculopapular rash spreading from the face to the extremities within 24 h and lasting 3 days.
- Nonimmune pregnant women are at high risk for having a fetus with congenital rubella syndrome.

#### Clinical Findings

**A. Signs and Symptoms.** Postnatal infection is usually a mild illness accompanied by an exanthem rash ([Box 36-1](#)). Adults commonly have prodromal symptoms including pharyngitis, fever, headache, cough, lymphadenopathy, myalgia, and nausea for 1-5 days. Children rarely have a prodrome.

The exanthem is similar in adults and children. The erythematous, fine maculopapular rash first erupts on the face, then spreads to the distal extremities within 24 h and lasts 2-3 days. In children, the exanthem phase has little to no fever. Lymphadenopathy is common, as is mild, transient leukopenia. The exanthem phase in adults commonly involves arthritis, headache, and eye pain. Generalized pruritus may last 2 weeks.

**B. Laboratory Findings.** Culture may be obtained from nasopharyngeal secretions, blood, urine, cerebrospinal fluid, synovial fluid, and breast milk. The preferred medium is African green monkey kidney cells. No reliable clinical viral antigen test exists. Serology is performed via hemagglutination inhibition, latex agglutination, fluorescence immunoassay, passive hemagglutination, single radial hemolysis, and enzyme immunoassay. Serology should be performed on a suspected case. Absence of immunoglobulin G (IgG) indicates nonimmunity. Repeat serology at 4 and then 6 weeks. Seroconversion is indicative of infection.

**C. Differential Diagnosis.** The differential diagnosis includes measles, fifth disease, roseola, scarletina, and infectious mononucleosis.

**D. Complications.** Complications for children include encephalitis and thrombocytopenia. Adults can have myocarditis, orchitis, neuritis, erythema multiforme, and congenital rubella syndrome.

## Diagnosis

Postnatally acquired rubella is diagnosed based on history and physical findings (see [Box 36-1](#)). All suspected cases that are nonimmune should have cultures and serology performed to confirm the diagnosis. If serology shows no rubella-specific IgG (eg, nonimmune), convalescent titers should be drawn at 4 and then 6 weeks postexposure. Seroconversion is indicative of active infection. If active infection is identified in a nonimmune pregnant woman before 20 weeks' gestation, pregnancy termination should be discussed. The patient's religious, cultural, and personal values must be considered in this situation. Infection after 20 weeks gestation has a decreased risk of teratogenic effects on the fetus.

## Treatment

Postnatally acquired rubella requires no specific treatment. Therapy should be symptomatic ([Box 36-2](#)). Use of immunoglobulin as postexposure prophylaxis in nonimmune patients is controversial. Routine administration of immunoglobulin for postexposure prophylaxis of rubella is not recommended. Symptoms in the mother may be reduced, but fetopathy may still occur. Immunoglobulin may be considered in cases where pregnancy termination was indicated but not possible.

## CONGENITAL RUBELLA SYNDROME

### Essentials of Diagnosis

- Polysystemic fetopathy.
- Infection before 20 weeks' gestation confers greatest risk to fetus.
- Common defects include cataracts, deafness, microcephaly, heart defects, hepatosplenomegaly.
- Late complications include mental retardation, developmental and behavioral disorders, endocrinopathies.
- Infant will shed virus up to 1 year.

### Clinical Findings

Nonimmune pregnant women infected with rubella are at risk for having a fetus with congenital rubella syndrome (CRS). The risk and severity of the defects are higher earlier in the pregnancy. Roughly 85% of fetuses infected in the first trimester will have some anomalies.

Hallmarks of CRS include sensorineural deafness, intrauterine growth retardation, cataracts, retinopathy, and cardiac defects ([Box 36-3](#)). Some infections will result in spontaneous abortion. Uncommon findings also include dermal erythropoiesis, meningoencephalitis, glaucoma, microphthalmia, myocarditis, pneumonitis, hepatitis, thrombocytopenic purpura, and craniofacial deformities. Many of these infants will grow to have mental retardation, developmental delay, and behavioral disorders. Some will also have late-onset endocrinopathies such as insulin-dependent diabetes mellitus. The virus can be isolated as outlined above.

### Diagnosis

CRS is diagnosed based on history and physical findings (see [Box 36-3](#)). Some neonates, especially those affected later in pregnancy, may appear normal or have very mild findings at birth. Suspected CRS neonates should have a rubella-specific IgM drawn. Cultures should be obtained from nasal secretions, blood, urine, and cerebrospinal fluid.

### Treatment

No medical therapy is available for CRS (but see [Box 36-2](#)). Cardiac defects warrant early intervention by a pediatric cardiologist. Early audiologic evaluation should be performed. A physician experienced with patients who have developmental disabilities should be involved. Early intervention for developmental delays and mental retardation is important. The primary care provider should be aware of potential endocrinopathies. Children with CRS often have very difficult behavioral disorders. Parents will benefit from behavioral management counseling.

## Prevention & Control of Rubella

Rubella is communicable 3-5 days before the rash and = 7 days after it appears in postnatally acquired cases. Hospitalized patients should be in droplet isolation. Pregnant hospital staff should avoid contact if their immunity status is in question. Infected children should be excluded from school and daycare during this period. CRS infants may shed the virus for = 1 year. Parents should be aware of this factor and restrict the infant's exposure to pregnant women.

Universal vaccination has been key in reducing the occurrence of CRS. Prenatal screening of pregnant women's immunity status has also been important. Rubella immunization is usually given in combination with the MMR (measles, mumps, rubella) vaccine. The first vaccine should be given at 12-15 months of age. The second should be given at 4-6 years of age. If the second dose is missed, it should be given before 12 years of age. Various contraindications and precautions exist for the vaccine ([Box 36-4](#)).

## **BOX 36-2. Treatment of Rubella Infection**

### **Congenitally Infected Neonates**

- Specific IgM should be drawn
- Cultures taken from nasal secretion, blood, urine, & cerebrospinal fluid
- Auditory assessment
- Early intervention for developmental and behavioral disorders
- No medical therapy available

### **Children (Postnatal Infection)**

- Supportive care
- Manage fever with acetaminophen (10-15 mg/kg every 4 h orally or rectally) or ibuprofen (6 to 8 mg/kg every 6 to 8 h orally)

### **Adults**

- Supportive care
- Analgesia with NSAIDs
- Antihistamines for pruritus

---

### **BOX 36-3. Congenital Rubella Syndrome**

#### **More Common Findings at Birth**

- Intrauterine growth retardation
- Cataracts
- Retinopathy
- Sensorineural deafness
- Microcephaly
- Long bone radiolucencies
- Patent ductus arteriosus
- Pulmonary artery stenosis
- Hepatosplenomegaly
- Dermal erythropoiesis (producing the "Blueberry Muffin" appearance)

#### **Less Common Findings at Birth**

- Active meningoencephalitis
- Congenital glaucoma
- Microphthalmia
- Myocarditis
- Interstitial pneumonitis
- Hepatitis
- Thrombocytopenia purpura
- Craniofacial abnormalities

#### **Late Complications**

- Mental retardation
- Developmental delay
- Behavioral disorders
- Endocrinopathies

---

## **BOX 36-4. Control of Rubella**

### **Vaccine**

- Live attenuated virus rubella vaccine (RA 27/3 strain) is administered 0.5 cc SQ. Commonly given in combination with MMR (measles, mumps, rubella) vaccine
- First dose is recommended from 12 to 15 months of age
- Second dose is recommended at school entry (age 4 to 6 years)
- If no preschool dose is given, the second dose should be administered prior to age 12
- Susceptible persons should be screened for immunization status; these include prepubertal girls & boys, college students, military personnel, child care workers, health care workers, postpartum women

### **MMR Vaccine Contraindications**

- Pregnancy
- Febrile illness
- Planned pregnancy within 3 months
- Severe immunocompromised state
- Blood product or immune globulin within 3 to 6 months (dose dependent)
- Anaphylaxis to neomycin

### **MMR Vaccine Should Be Used with Caution in These Situations**

- Seizure disorder
- Thrombocytopenia
- Egg allergy

### **Isolation Precautions**

- Postnatally acquired rubella requires respiratory isolation for 5 days before the rash through 1 week after appearance of the rash; this includes exclusion from school or daycare
- Congenitally infected infants are considered contagious until 1 year of age unless nasal and urine cultures are negative at 3 months; parents must be made aware of the potential risk to nonimmunized pregnant mothers

## 37 . Rotavirus — *Gregory M. Sonnen, MD & Nancy Henry, MD, PhD*

### Essentials of Diagnosis

- Nonbloody diarrhea of 2-8 days' duration.
- Vomiting, fever, anorexia, and dehydration common.
- May infect any age group.
- Most common etiology of acute gastroenteritis in children < 2 years of age.
- Yearly reinfection common in infants and young children.

### General Considerations

**A. Epidemiology.** Rotavirus is the most common etiology of acute diarrheal illness in children < 2 years old. It is responsible for > 1 million cases of reported diarrheal illness each year in children ages 1-4 years in the United States. Rotavirus is responsible for an average of 150 deaths per year in this same group. All of these deaths are secondary to severe dehydration. Worldwide, rotavirus is estimated to be responsible for 125 million cases of diarrhea in children < 5 years old. This effect results in mortality in 873,000 of these children. Mortality in developed countries has been reduced by aggressive rehydration therapy.

**B. Microbiology.** Rotavirus is a 70-nm icosahedral RNA reovirus that has five distinct antigenic groups (A, B, C, D, and E). Group A also has six serotypes. Group A is responsible for the majority of reported diarrheal illnesses in children in the United States. Groups B and C are responsible for adult diarrheal illnesses in Asia.

**C. Pathogenesis.** The virus is transmitted human to human via the fecal-oral route. The incubation time in humans is 1-3 days. Clinical disease is most prevalent in the winter. Rotavirus is also the most common cause of nosocomial diarrheal illness in children. Investigators have hypothesized a possible respiratory transmission route.

### Clinical Findings (see [Box 37-1](#))

**A. Signs and Symptoms.** Infants and children present with nonbloody diarrhea, which is often profuse. Emesis, anorexia, fever, and irritability are also common. In immunocompetent individuals, the disease is self-limited and lasts 2-8 days. The key to management is evaluation of the level of dehydration at presentation. Children in the category of severe dehydration are usually acidotic and require immediate intervention. Clinically, children with severe dehydration can appear lethargic, obtunded, or in shock. Rarely, respiratory symptoms are present including rhinorrhea, cough, and wheeze. Some children with moderate dehydration also warrant prompt intervention.

**B. Laboratory Findings.** Group A rotavirus antigen may be detected from stool through

either enzyme immunoassay (EIA) or latex agglutination (LA). Both are equally sensitive and specific for detection of rotavirus during the acute diarrheal phase of the disease. EIA has higher sensitivity when used late in the course of disease.

**C. Imaging.** Imaging has little value in rotavirus-induced gastroenteritis. Rare cases of paralytic ileus secondary to hypokalemia have been observed by abdominal radiography.

**D. Differential Diagnosis.** The differential diagnosis of acute winter childhood diarrheal illness should always include rotavirus, Norwalk virus, calcivirus, astrovirus, and coronavirus (see [Chapter 38](#)). In warm weather diarrhea, adenovirus is more common. If blood is present in the stool, bacterial agents should be considered, including, enteropathogenic *E coli*, *Shigella*, *Salmonella*, *Yersinia*, and *Campylobacter* species. If symptoms are prolonged or atypical, malabsorptive or maldigestive diarrhea, as well as intestinal parasites, should be considered.

**E. Complications.** Common complications are dehydration, uncommonly accompanied by electrolyte imbalances. Owing to mucosal damage of the small bowel lumen, transient lactose intolerance is uncommonly observed. Prolonged diarrhea or severe cramping, gas, or colic can be the result of lactase deficiency. If lactase deficiency is suspected, the patient should be placed on a lactose-free diet for 2-5 days.

## Diagnosis

Diagnosis of rotavirus is based on history and physical findings. Since this virus produces a self-limiting disease in healthy individuals, identification of the virus is not needed in most cases. In immunocompromised patients, identification of an etiology is a higher priority, and stool should be sent promptly for analysis. Serum electrolytes and glucose should be evaluated in patients with moderate to severe dehydration.

## Treatment

The primary therapy for rotavirus gastroenteritis is hydration ([Box 37-2](#)). If appropriate oral hydration can maintain fluid balance, no other intervention is needed. Small children and infants are prone to dehydration. Assessing the level of dehydration is key to deciding on therapy. Oral rehydration is appropriate for most children with mild to moderate dehydration. Parenteral rehydration is often needed if oral rehydration fails. Patients with severe dehydration warrant prompt parenteral rehydration. Careful attention should be paid to their hemodynamic status. Patients with either hypo- or hypernatremia should be slowly rehydrated to account for sodium or free-water deficits.

Orally administered immunoglobulin may modify the course of the illness in patients with immunodeficiencies who experience a prolonged rotaviral illness. Routine use is not recommended.

## Prevention & Control

Rotavirus is spread by direct contact. Hand washing should limit spread of the virus ([Box 37-3](#)). Careful attention should be paid to potential fomites, especially in the

hospital setting. Strict enteric isolation should be observed for all symptomatic hospitalized patients. Nosocomial infections with rotavirus are common. Infants and children should be excluded from school or daycare if their stool can not be contained. An oral, live-attenuated tetravalent vaccine was licensed by the FDA in 1998. In clinical trials, it significantly reduced morbidity. In 1999, the vaccine was taken off the market to investigate a possible relationship to intussusception. The results of this investigation are pending.

-

## **BOX 37-2. Treatment of Rotavirus Gastroenteritis**

- Primary Treatment**
- Oral rehydration should be utilized for patients with mild (5%) to moderate (10%) isotonic dehydration
  - Parenteral rehydration should be reserved for moderate to severe dehydration, to correct electrolyte abnormalities, and for patients failing oral rehydration
  - Acetaminophen (10 to 15 mg/kg every 4 h orally or rectally) or ibuprofen (6 to 8 mg/kg every 6 to 8 h orally) for fever and irritability
  - Age appropriate oral feeding should resume slowly when vomiting subsides and rehydration is complete
  - Withholding lactose does not improve outcome in the majority of patients
- Pediatric Considerations**
- Correct sodium abnormalities slowly
  - Consider transient lactase deficiency if diarrhea persists more than 5 days
  - Antidiarrheal agents are contraindicated in children

---

### HUMAN ENTERIC CALICIVIRUSES: NORWALK & RELATED VIRUSES

#### Essentials of Diagnosis

- Diarrhea, occurring in an outbreak especially in a closed environment.
- Tends to infect older children and adults rather than infants.
- Nausea and vomiting are common; bloody stools are rare.
- Incubation period 1-2 days; illness 1-4 days.
- Laboratory diagnosis by seroconversion; only performed in epidemiologic studies.

#### General Considerations

**A. Epidemiology.** Even in developed countries, antibodies to caliciviruses are nearly universal by age 5. Infections tend to occur in family or community outbreaks. In underdeveloped countries, infection by these viruses occurs presumably as a result of poor sanitation. In developed countries, outbreaks that occur year-round have been described in schools, resorts, hospitals, nursing homes, restaurants, and cruise ships. The primary method of spread is fecal-oral, but contaminated water or shellfish has accounted for common-source outbreaks. A measure of the importance of these agents is that ~ 10% of all gastroenteritis outbreaks and up to 90-95% of those that are nonbacterial are attributed to them. In contrast to infants, who are more often infected by rotaviruses, calicilike viruses cause disease primarily in older children and adults ([Box 38-1](#)). Immunity is probably short-lived at best, suggesting that humoral antibody is not adequately protective. The incubation period is 1-2 days, and shedding can persist for 1-2 weeks. The virus is not inactivated by chlorine, freezing, or heating to 60(C).

**B. Microbiology.** The Norwalk agent and related viruses are classified as caliciviruses, although they are also similar in appearance to parvoviruses and hepatitis A virus. Among the other human enteric caliciviruses are the Hawaii, Snow Mountain, and Sapporo viruses, which are named for where these strains were first detected. The human enteric caliciviruses are now divided into two genera, provisionally named "Norwalk-like viruses" and "Sapporo-like viruses." None of these viruses can be isolated in tissue culture, but their viral nature was established by electron microscopic (EM) examination of feces, using antibodies to enhance detection (immune electron microscopy [IEM]).

Norwalk and human enteric caliciviruses are among the smallest of all viruses, only 27-38 nm in diameter. They are spherical, with 32 cup-shaped surface depressions. No envelope exists, and they exhibit icosahedral symmetry. The nucleoprotein of calicivirus is single-stranded RNA with a molecular weight of approximately  $2.6 \times 10^6$  daltons. The

details of attachment and penetration are uncertain. Replication occurs in the cytoplasm, with release of viral particles accomplished by cell destruction.

**C. Pathogenesis.** Jejunal biopsy in human volunteers infected with Norwalk viruses reveals blunting of villi, cytoplasmic vacuolation, and infiltration with mononuclear cells, but virus particles are not detected by EM of epithelial cells. The virus appears to cause a decrease in brush border enzymes and in turn malabsorption. Infection is not associated with a leukocyte response in stool samples.

## Clinical Findings

**A. Signs and Symptoms.** Although calicilike viruses are typically associated with diarrheal illness, nausea and vomiting may occur frequently, especially in children. Bloody stools do not occur. Fever may be present in up to one-third of patients. The incubation period is 24-48 h, and the illness lasts 1-4 days.

**B. Laboratory Findings.** There are no characteristic blood or stool abnormalities; fecal leukocytes are absent.

**C. Differential Diagnosis.** The differential diagnosis includes gastroenteritis of any etiology, especially other viruses. Winter diarrhea in infants and children is more likely caused by rotavirus.

## Diagnosis

**A. Culture.** None of the Norwalk or human enteric caliciviruses can be grown in tissue culture, although the development of a sensitive culture assay is a high priority.

**B. Direct Detection.** Standard EM of feces is usually negative for the Norwalk agent because they are present in low titer. Other caliciviruses may be present in sufficient concentration to permit detection. IEM is the main method of detection of Norwalk-type viruses but is rarely used except in research settings. IEM consists of examining the sample by EM after the addition of an antibody directed against the suspected agent. The antibody causes the virus to aggregate, facilitating recognition. Reverse transcription-polymerase chain reaction, enzyme immunoassay, and radioimmunoassay (RIA) detection of Norwalk antigen are alternative methods that are more sensitive than IEM, but are generally available only in research settings.

**C. Serology.** Seroconversion is the method used to identify most infections. Antibody to the Norwalk agent may be detected by RIA or immune adherence hemagglutination assay (IAHA). Antibodies to the other calicilike agents are more difficult to detect.

## Treatment ([Box 38-2](#))

No specific treatment is available. Bismuth subsalicylate may reduce gastrointestinal symptoms.

## Prognosis

The prognosis is excellent for full recovery.

### **Prevention & Control ([Box 38-3](#))**

Outbreaks may be minimized by handling food carefully and maintaining the purity of the water supply.

## **ASTROVIRUSES**

### **General Considerations**

Astroviruses are small (28- to 38-nm) RNA viruses that exhibit five or six points on their surface. They have been seen in fecal specimens by EM, especially in infants and children with mild gastroenteritis. There are at least seven human serotypes. The route of spread is probably fecal-oral; > 70% of children acquire antibody by age 5 years. Infections occur sporadically rather than in outbreaks. Although detection by culture procedures or techniques is only partly successful, astroviruses have been isolated from humans, cows, cats, dogs, pigs, and sheep.

## **ADENOVIRUS**

Adenoviruses, particularly the high numbered serotypes (38 and, especially, 40 and 41) are associated with gastroenteritis. (See [Chapter 32](#) for an extensive consideration of adenoviruses.) The enteric adenoviruses are very difficult to grow in tissue culture but are detected by EM or EIA. They cause 5-15% of viral gastroenteritis in young children. The average incubation period is 10 days, much longer than the average of 1-2 days for the other viral causes of gastroenteritis. Most disease is in infants and young children and occurs sporadically rather than in outbreaks. The method of spread is fecal-oral.

## 39 . Hepatitis — *W. Lawrence Drew, MD, PhD*

### INTRODUCTION

The causes of hepatitis are varied and include viruses, bacteria, and protozoa, as well as drugs and toxins (eg, isoniazid, carbon tetrachloride, and ethanol). The clinical symptoms and course of acute viral hepatitis can be similar, regardless of etiology, and determination of a specific cause depends primarily on the use of laboratory tests ([Box 39-1](#)). Hepatitis may be caused by at least six different viruses whose major characteristics are summarized in [Table 39-1](#). Non-A-non-B (NANB) hepatitis is a term previously used to identify cases of hepatitis not caused by hepatitis A or B. With the discovery of hepatitis viruses C, E, and G, most of the viral etiologies of NANB disease can be identified. Other viruses, such as Epstein-Barr virus and cytomegalovirus, can also cause inflammation of the liver, but hepatitis is not the primary disease they cause. Yellow fever is a form of hepatitis but is now rare. The relative contributions of the hepatitis viruses to acute and chronic viral hepatitis are shown in [Table 39-1](#) and [Table 39-2](#).

### HEPATITIS A

#### Essentials of Diagnosis

- Increased risks in promiscuous homosexual men, travelers to underdeveloped areas, and institutionalized individuals.
- Malaise, anorexia, fever, dark urine, pale stools, jaundice, right upper quadrant pain, and tender hepatomegaly.
- Increased liver enzymes (ALT, AST), bilirubin, prothrombin time, and globulin.
- Serum positive for hepatitis A immunoglobulin M (IgM) antibody.
- May have history of recent (ie, 3-6 weeks previously) ingestion of undercooked shellfish or sewage-contaminated water.

#### General Considerations

**A. Epidemiology.** Hepatitis A virus is the cause of what was formerly termed infectious hepatitis or short-incubation hepatitis. It was first detected in the early 1970s in stools of patients incubating the disease. Humans appear to be the major natural hosts of hepatitis A virus. Several other primates (including chimpanzees and marmosets) are susceptible to experimental infection, and natural infections of these animals may occur.

The major mode of spread of hepatitis A is fecal-oral. Inoculation of infectious material intramuscularly can produce disease; transmission through blood transfusion rarely, if ever, occurs. Most cases of hepatitis A occur sporadically rather than being linked to a single contaminated source. The disease is common under conditions of crowding, and

it occurs at high frequency in mental hospitals, schools for the developmentally disabled, and daycare centers. Because a chronic carrier state has not been observed with hepatitis A, perpetuation of the virus in nature presumably depends on sporadic subclinical infections and person-to-person transmission. Outbreaks of hepatitis A have been linked to the ingestion of undercooked shellfish from waters contaminated with human feces. Common-source outbreaks related to other foods, including vegetables, have also been reported.

The disease is widespread, but seroepidemiologic studies have shown marked variation in infection rates among different population groups. For example, rates are higher among those of lower socioeconomic status and among male homosexuals. Less than one-half of the general population of the United States now has serologic evidence of prior hepatitis A virus infection. Rates have been decreasing since 1970, apparently because of better sanitation and less crowding. In contrast, in many underdeveloped countries, > 90% of the adult population shows evidence of previous hepatitis A infection; in most cases, however, the evidence is of asymptomatic infection during childhood. The risk of overt disease is much higher in nonimmune infected adults than in children; travelers from developed countries who enter endemic areas are particularly susceptible.

**B. Microbiology.** Hepatitis A virus is an unenveloped, single-stranded small RNA (picorna)virus with cubic symmetry and a diameter of 27 nm ([Figure 39-1](#)). It is not inactivated by ether and is stable at -20 °C and low pH. These properties are similar to those of enteroviruses (see [Chapter 27](#)), but hepatitis A virus is distinct and now classified in a separate genus, *Hepatovirus*. The virus has been successfully cultivated in cell cultures but grows poorly.

**C. Pathogenesis.** The virus is believed to replicate initially in the enteric mucosa. It can be demonstrated in feces by electron microscopy for 10-14 days before onset of disease. In most patients with symptoms of the disease, complete virus is no longer found in fecal specimens; however, viral antigen has been demonstrated in feces for = 14 days thereafter. Multiplication in the intestines is followed by a period of viremia with spread to the liver. The response to replication in the liver consists of lymphoid cell infiltration, necrosis of liver parenchymal cells, and proliferation of Kupffer cells. The extent of necrosis often coincides with the severity of disease. A variable degree of biliary stasis may be present. Detectable levels of IgG antibody to hepatitis A virus persist indefinitely in serum, and patients with anti-hepatitis A virus antibodies are immune to reinfection.

## Clinical Findings

**A. Signs and Symptoms.** In hepatitis A virus infection, an incubation period of 10-50 days (mean, 25 days) is usually followed by the onset of fever, poor appetite, nausea, pain in the right upper abdominal quadrant, and, within several days, jaundice. The patient may notice dark urine and clay-colored stools 1-5 days before the onset of clinical jaundice. The liver is enlarged and tender. Many persons who have serologic evidence of acute hepatitis A infection are asymptomatic or only mildly ill, without jaundice (anicteric hepatitis A). The infection-to-disease ratio is dependent on age; it may be as high as 20:1 in children and approximately 4:1 in adults. Most (99%) of cases

of hepatitis A are self-limiting.

**B. Laboratory Findings.** Serum aminotransferase levels are elevated as a result of hepatic inflammation and damage. The serum bilirubin levels and prothrombin time are also elevated, the latter being a sensitive marker of hepatocyte damage. The total leukocyte count is low because of neutropenia. Alkaline phosphatase is elevated especially in patients with a cholestatic picture, but it tends to subsequently decrease even when the bilirubin is still rising.

**C. Imaging.** Radiographic and radionucleotide studies may show hepatomegaly. Gall bladder and common bile duct examinations are usually normal.

**D. Differential Diagnosis.** All of the causes of acute hepatitis mentioned in the introduction to this chapter must be considered, but epidemiologic, age, and risk factors may help to predict a probable cause. See also [Table 39-3](#).

**E. Complications.** In 0.1% of cases, fulminant fatal hepatitis associated with extensive liver necrosis may occur.

## Diagnosis

The best method for documentation of acute hepatitis A virus infection is the demonstration of high titers of virus-specific IgM antibody in serum drawn during the acute phase of illness. Because IgG antibody persists indefinitely, its demonstration in a single serum sample is not indicative of recent infection; a rise in titer between acute and convalescent sera must be documented. Immune electron microscopic identification of the viral antigen in fecal specimens and isolation of the virus in cell cultures remain research tools. Past infection is best demonstrated by anti-HAV IgG but absent IgM.

## Treatment

There is no specific treatment for patients with acute episodes of hepatitis A infection ([Box 39-2](#)). Supportive measures include adequate nutrition and rest.

## Prognosis

The prognosis is excellent for > 99% of patients with hepatitis A infection. Only 0.1% of patients develop fatal acute hepatic necrosis.

## Prevention & Control

**A. Passive Immunization.** Passive (ie, antibody) prophylaxis for hepatitis A has been available for many years. Immune serum globulin (ISG), manufactured from pools of plasma from large segments of the general population, is 80-90% protective if given before or during the incubation period of the disease. In some cases, infection occurs, but disease is ameliorated; that is, the patient develops anicteric, usually asymptomatic, hepatitis A.

At present, ISG should be administered to household contacts of hepatitis A patients

and those known to have eaten uncooked foods prepared or handled by an infected individual. Once clinical symptoms have appeared, the host is already producing antibody, and administration of ISG is not indicated. Persons from areas of low endemicity who travel to areas with high infection rates may receive ISG before departure and at 3- to 4-month intervals as long as potential heavy exposure continues, but active immunization is preferable (see below).

**B. Active Immunization.** For hepatitis A, live attenuated vaccines have been evaluated but have demonstrated poor immunogenicity and have not been effective when given orally. Formalin-killed vaccines induce antibody titers similar to those of wild-virus infection and are almost 100% protective. Use of this vaccine is preferable to passive prophylaxis for those with prolonged or repeated exposure to hepatitis A.

## HEPATITIS B

### Essentials of Diagnosis

- Malaise, anorexia, fever, dark urine, pale stools, jaundice, right upper quadrant pain, and tender hepatomegaly.
- Increased risk in promiscuous homosexual men, injection drug users, transfusion recipients, hemophiliacs, hemodialysis patients, and patients with Down's syndrome.
- Increased liver enzymes (ALT, AST), bilirubin, prothrombin time, and globulin.
- Serum positive for hepatitis B core IgM antibody.
- Chronic hepatitis may be caused by hepatitis B and be diagnosed by the presence of hepatitis B surface antigen (HbsAg) in blood.

### General Considerations

**A. Epidemiology.** Hepatitis B infection is found worldwide, with prevalence rates varying markedly among countries. Chronic carriers constitute the main reservoir of infection: in some countries, particularly in the Far East, ~ 5-15% of all persons carry the virus, though most are asymptomatic. Of patients with HIV infection, 10% are chronic carriers of hepatitis B.

In the United States, it is estimated that 1.5 million people are infected with hepatitis B, and it is estimated that 300,000 new cases occur annually. Approximately 300 of these individuals die with acute fulminant hepatitis, and 5-10% of infected patients become chronic hepatitis B virus carriers. As many as 4000 people die yearly of hepatitis B-related cirrhosis, and 1000 of hepatocellular carcinoma. Approximately 50% of infections in the United States are sexually transmitted, and the occurrence of hepatitis B surface antigen (HBsAg) is higher in certain populations, such as male homosexuals, patients on hemodialysis or immunosuppressive therapy, patients with Down's syndrome, and injection drug users.

Routine screening of blood donors for HBsAg has markedly decreased the incidence of

post-transfusion hepatitis B; > 90% of cases developing after transfusion are now caused by other NANB hepatitis viruses. Multiple-pool blood products occasionally cause cases, and inadequately sterilized, blood-contaminated needles are still significant vehicles of transmission. Exposure by direct contact with blood or other bodily fluids, probably through small lesions, has resulted in hepatitis B infection of medical personnel. Attack rates are also high in spouses and sexual partners of infected patients.

Most hepatitis B infections of infants do not appear to be transplacentally transmitted to the fetus in utero, but are acquired during the birth process by the swallowing of infected blood or fluids or through abrasions. The rate of virus acquisition is high (~ 90%) in infants born to mothers who have acute hepatitis B infection or who carry HBsAg and hepatitis B e antigen (HBeAg). Most infants do not develop clinical disease; however, infection in the neonatal period is associated with failure to produce antibody to HBsAg and, thus, with chronic carriage in ~100% and perpetuation of infection by transmission in the family setting.

Hepatocellular carcinoma has been strongly associated with persistent carriage of hepatitis B virus, by serologic tests and detection of viral nucleic acid sequences integrated in tumor cell genomes. In many parts of Africa and Asia, primary liver cancer accounts for 20-30% of all types of malignancies, but only 1-2% in North and South America and Europe. The estimated risk of developing the malignancy for persons with chronic hepatitis B is increased between 10- and 300-fold in different populations. The mechanism of the association is unclear.

**B. Microbiology.** Hepatitis B virus is an enveloped DNA virus belonging to the family Hepadnaviridae. It is unrelated to any other human virus; however, related hepatotropic agents have been identified in woodchucks, ground squirrels, and kangaroos. A schematic of the hepatitis B virus is illustrated in [Figure 39-2](#). The complete virion is a 42-nm, spherical particle that consists of an envelope around a 27-nm core. The core comprises a nucleocapsid that contains the DNA genome.

The viral genome consists of partially double-stranded DNA with a short, single-stranded piece. It comprises 3200 nucleotides, making it the smallest DNA virus known. Closely associated with the viral DNA is an RNA-dependent DNA polymerase, ie reverse transcriptase. Other components of the core are a hepatitis B core antigen (HBcAg) and HBeAg, which is a low-molecular-weight glycoprotein.

The envelope of the virus contains HBsAg, which is composed of one major and two other proteins. Antigenically there exist a group-specific determinant, termed *a*, and a number of subtypes that are important in epidemiologic typing, but not in immunity, because there is antigenic cross-reactivity and cross-protection between subtypes. Aggregates of HBsAg are often found in great abundance in serum during infection. They may assume spherical or filamentous shapes with a mean diameter of 22 nm and may contain portions of the nucleocapsid. Hepatitis B DNA can also be detected in serum and is an indication that infectious virions are present there. In infected liver tissue, evidence of HBcAg, HBeAg, and hepatitis B DNA is found in the nuclei of infected hepatocytes, whereas HBsAg is found in cytoplasm.

Despite extensive attempts, hepatitis B virus has not been propagated in the laboratory. Humans appear to be the major host; however, as with hepatitis A, infection of subhuman primates has been accomplished experimentally.

The replication of hepatitis B virus involves a reverse transcription step and, as such, is unique among DNA viruses. In viral replication, full-length positive viral RNA transcripts are inserted into maturing core particles late in the replicative cycle. These mRNA strands form a template for a reverse transcription step in which negatively stranded DNA is synthesized. The RNA template strands are then degraded by ribonuclease activity. A positive-stranded DNA is then synthesized, although this step is not completed before virus maturation and release. This results in the variable-length short positive DNA strands found in the virions together with complementary negative long strands. Release is by a secretory mechanism (**reverse endocytosis**) and does not cause cell lysis.

**C. Pathogenesis.** In the past, hepatitis B was known as post-transfusion hepatitis or as hepatitis associated with the use of illicit parenteral drugs (serum hepatitis). Over the past few years, however, it has become clear that the major mode of acquisition is through close personal contact with body fluids of infected individuals. HBsAg has been found in most body fluids, including saliva, semen, and cervical secretions. Transmission by person-to-person contact has been documented, as has vertical mother-to-child transmission, usually at the time of birth. Under experimental conditions, as little as 0.0001 mL of infectious blood has produced infection. Transmission is therefore also possible by vehicles such as inadequately sterilized hypodermic needles or instruments used in tattooing and ear piercing.

The factors determining the different clinical manifestations of acute hepatitis B are largely unknown; however, some appear to involve immunologic responses of the host. The serum sickness-like rash and arthritis that may precede the development of symptoms and jaundice appear related to circulating immune complexes that activate the complement system. Antibody to HBsAg is protective and associated with resolution of the disease. Cellular immunity also may be important in the host response, because patients with depressed T lymphocyte function have a high frequency of chronic infection with the hepatitis B virus. Antibody to HBcAg, is present in chronic carriers with persistent hepatitis B virion production and it does not appear to be protective.

The morphologic lesions of acute hepatitis B resemble those of hepatitis A and NANB hepatitis. In chronic active hepatitis B, the continued presence of inflammatory foci of infection results in necrosis of hepatocytes, collapse of the reticular framework of the liver, and progressive fibrosis. The increasing fibrosis can result in the syndrome of postnecrotic hepatic cirrhosis.

Integrated hepatitis B viral DNA can be found in nearly all hepatocellular carcinomas. The virus has not been shown to possess a transforming gene but may well activate a cellular oncogene. It is also possible that the virus does not play such a direct molecular role in oncogenicity, because the natural history of chronic hepatitis B infection involves cycles of damage or death of liver cells interspersed with periods of intense regenerative hyperplasia. This significantly increases the opportunity for spontaneous mutational changes that may activate cellular oncogenes. Whatever the mechanism, the

association between chronic viral infection and hepatocellular carcinoma is clear, and liver cancer is a major cause of disease and death in countries in which chronic hepatitis B infection is common. The proven success of immunization in aborting hepatitis B infection makes hepatocellular carcinoma of the liver a potentially preventable disease.

## Clinical Findings

**A. Signs and Symptoms.** The clinical picture of hepatitis B is highly variable. The incubation period is from 45 days to as long as 160 days (mean, ~10 weeks). Acute hepatitis B is usually manifested by the gradual onset of fatigue, loss of appetite, nausea and pain, and fullness in the right upper abdominal quadrant. Early in the course of disease, pain and swelling of the joints and occasionally frank arthritis may occur. Some patients develop a rash. With increasing involvement of the liver, there is increasing cholestasis and, hence, clay-colored stools, darkening of the urine, and jaundice. Symptoms may persist for several months before finally resolving.

In general, the symptoms associated with acute hepatitis B are more severe and more prolonged than those of hepatitis A; however, anicteric disease and asymptomatic infection regularly occur. The infection-to-disease ratio, which varies according to age and method of acquisition, has been estimated to be approximately 6:1 or 7:1.

**B. Laboratory Findings.** In acute illness, the laboratory findings are as with hepatitis A; persistence of blood abnormalities beyond 6 months may indicate the development of chronic hepatitis B disease.

**C. Imaging.** As with hepatitis A

**D. Differential Diagnosis.** As with hepatitis A

**E. Complications.** Chronic hepatitis occurs in ~10% of all patients with hepatitis B infection. The risk of chronic hepatitis B infection is much higher for newborns (100%), children (50%), and immunocompromised patients. Chronic infection is associated with ongoing replication of virus in the liver and usually with the presence of HBsAg in serum. Chronic hepatitis may lead to cirrhosis, liver failure, hepatocellular carcinoma, or some combination of these. It is estimated that 10% of all chronic liver disease in the United States and Canada is caused by hepatitis B. Fulminant hepatitis, leading to extensive liver necrosis and death, develops in ~0.1% of cases.

## Diagnosis

Nonspecific findings in blood are elevations of hepatic enzymes, globulin, and prothrombin time and decreases of albumin and blood leukocytes. The sequential appearance of hepatitis B antigens and antibodies is shown in [Figure 39-3](#). During the acute episode of disease, when there is active viral replication, large amounts of HBsAg and hepatitis B virus DNA can be detected in the serum, as can fully developed virions and high levels of DNA polymerase and HBeAg. Although HBcAg is also present, antibody against it invariably occurs and prevents its detection. With resolution of acute hepatitis B, HBsAg and HBeAg disappear from serum with the development of antibodies (anti-HBs and anti-HBe) against them. The development of anti-HBs is

associated with elimination of infection and protection against reinfection. Anti-HBc is detected early in the course of disease and persists in serum for years. It is an excellent epidemiologic marker of infection but is not protective.

In patients with chronic hepatitis B, evidence of viral persistence can be found in serum. HBsAg can be detected throughout the active disease process, and anti-HBs does not develop, which probably accounts for the chronicity of the disease. Anti-HBc is, however, detected. Two types of chronic hepatitis can be distinguished. In one, HBsAg is detected, but not HBeAg; these patients usually show minimal evidence of liver dysfunction. In the other, both antigens are found; the process is more active with continued hepatic damage that may result in cirrhosis. The presence of HBsAg and hepatitis B DNA (HB DNA) is indicative of active viral replication. The laboratory diagnosis of acute hepatitis B is best made by demonstrating the IgM antibody to HBcAg in serum. HBsAg may also be detected in serum. *Past* infection with hepatitis B is best determined by detecting anti-HBc IgG, anti-HBs IgG, or both. Chronic infection with hepatitis B is best detected by persistence of HBsAg in blood for > 6-12 months. Vaccine recipients demonstrate an IgG antibody to HbsAg but not to HbcAg.

## **Treatment**

There is no specific treatment for typical acute hepatitis B. A high-calorie diet is desirable. Corticosteroid therapy has no value in uncomplicated typical acute viral hepatitis, and recent studies suggest that it may increase the severity of chronic hepatitis caused by hepatitis B virus. Chronic hepatitis B is a treatable disease. Interferon alpha, 5-10 million U thrice weekly for 4-6 months, provides long-term benefit in a minority (~ 33%) of patients with chronic hepatitis B infection (see [Box 39-2](#)). Those who already demonstrate an acute immune response with low serum viral-DNA levels are the most likely to respond to treatment. Lamivudine (3Tc), a potent inhibitor of human immunodeficiency virus (HIV), is also active against hepatitis B virus, both in vitro and in initial clinical trials, but the virus can become resistant to this agent.

## **Prognosis**

Ninety percent of acute hepatitis B cases resolve within 6 months; 0.1% are fatal due to acute hepatic necrosis; and ~10% progress to chronic hepatitis. Of these, = 10% will develop cirrhosis, hepatocellular carcinoma, or both.

## **Prevention & Control**

Both active prophylaxis and passive prophylaxis of hepatitis B infection can be accomplished. Most preparations of ISG contain only moderate levels of anti-HBs; however, specific hepatitis B immune globulin (HBIG) with significant protective activity is now available. HBIG is prepared from sera of subjects who have high titers of antibody to HbsAg but are free of the antigen itself. Administration of HBIG soon after exposure to the virus greatly reduces the development of symptomatic disease. Postexposure prophylaxis with HBIG should be followed by active immunization with vaccine.

Inactivated hepatitis B vaccines have been available for several years. The first was

developed by purification and inactivation of HbsAg from the blood of chronic carriers, but this vaccine is no longer in use. The current vaccine is a recombinant product derived from HBAg grown in yeast. Excellent protection has been shown in studies on homosexual men and medical personnel. These groups and others, such as laboratory workers and injection drug users, who come into contact with blood or other potentially infected materials, should receive hepatitis B vaccine as the preferred method of preexposure prophylaxis. Recently, immunization of all children has been recommended.

A combination of active and passive immunization is the most effective approach to prevent neonatal transmission and, thus, the development of chronic carriage in the neonate. Most hospitals recommend routine screening of pregnant women for the presence of HbsAg. Infants born to women who are positive should receive HBIG in the delivery room followed by three doses of hepatitis B vaccine beginning 24 h after birth.

A similar combination of passive and active immunization is used for nonimmunized persons who have been exposed by needle-stick or similar injuries from a hepatitis BsAg positive individual.

## **HEPATITIS D (DELTA HEPATITIS)**

### **Essentials of Diagnosis**

- Occurs only in patients with preexisting or concurrent hepatitis B.
- Occurs in the same groups at risk for hepatitis B.
- May be associated with fulminant hepatitis or rapid progression of chronic hepatitis B.
- Diagnosed by presence of IgM antibody to hepatitis D antigen or by IgG seroconversion to this antigen.

### **General Considerations**

**A. Epidemiology.** Delta hepatitis is spread just as hepatitis B and is most prevalent in groups at high risk of hepatitis B infection. Injection drug users are those at greatest risk in the western world, and ~ 50% of such individuals may have IgG antibody to the delta virus antigen. Delta virus infection is rare in the U.S., northern Europe, and Japan but largely prevalent in southern Europe, Africa, and South America. Because blood is not yet routinely screened for the delta agent, blood products and dialysis transmission are possible sources for those who have prior hepatitis B. Nonparenteral and vertical transmission can also occur.

**B. Microbiology.** Delta hepatitis is caused by the hepatitis D virus. This small single-stranded RNA virus requires the presence of hepatitis B to provide its protein shell and is thus found only in persons with acute or chronic hepatitis B infection.

**C. Pathogenesis.** The method of replication of hepatitis D viral RNA is not clear. Associated with the RNA are proteins of 27 and 29 kDa that constitute the delta antigen.

This protein-RNA complex is surrounded by HBsAg ([Figure 39-4](#)). Thus, although the delta virus produces its own antigens, it utilizes HBsAg in assembling its coat.

## Clinical Findings

**A. Signs and Symptoms.** Two major types of delta infection have been noted.

- Simultaneous delta and hepatitis B infection: This infection is clinically identical to acute hepatitis A or B, except for a higher rate of fatal hepatic necrosis than is seen with hepatitis B alone.
- Delta superinfection in those with chronic hepatitis B: This infection increases the severity and progression of chronic hepatitis B. Death due to liver disease may occur in 20% of superinfected patients.

**B. Laboratory Findings.** Similar to hepatitis A and B

**C. Imaging.** Similar to hepatitis A and B

**D. Differential Diagnosis.** Simultaneous infection with both delta and hepatitis B results in clinical hepatitis that is indistinguishable from acute hepatitis A or B; however, fulminant hepatitis is much more common than with hepatitis B virus alone.

**E. Complications.** Persons with chronic hepatitis B who acquire infection with hepatitis D suffer relapses of jaundice and have a high likelihood of developing chronic cirrhosis. Rapidly progressive liver disease and death may occur in = 20% of doubly infected persons.

## Diagnosis

Diagnosis of hepatitis D is made by demonstrating IgM or IgG antibodies, or both, to the delta antigen in serum. IgM antibodies appear within 3 weeks of infection and persist for several weeks. IgG antibodies persist for years.

## Treatment

Response to interferon alpha treatment is less than in patients who have only hepatitis B. Recommended doses are higher (5-10 million U daily).

## Prognosis

Superinfection with hepatitis D worsens the prognosis of preexisting hepatitis B, increasing the rate and rapidity of developing cirrhosis.

## Prevention & Control

Because the capsid of delta hepatitis is HbsAg and hepatitis D depends on hepatitis B for its replication, measures aimed at limiting the transmission of hepatitis B, for example, through vaccination, prevent the transmission of delta hepatitis.

## HEPATITIS C

### Essentials of Diagnosis

- Acute hepatitis C usually is asymptomatic.
- First recognition of chronic hepatitis C is the presence of elevated liver enzymes in an asymptomatic patient.
- Unexplained chronic hepatitis is most commonly caused by hepatitis C.
- Diagnosis is by presence of hepatitis C IgG antibody.

### General Considerations

Most NANB hepatitis is caused by an RNA virus termed hepatitis C virus. Its existence and role in the etiology of hepatitis was identified by preparing numerous complementary DNA clones from the presumed RNA virus in infectious serum. Peptides encoded by these clones were then tested for reaction with sera from cases of NANB hepatitis, and one was found to be highly specific.

**A. Epidemiology.** The transmission of hepatitis C by blood is well documented: indeed, it caused the great majority of post-transfusion NANB hepatitis. It is estimated that 2% of U.S. citizens have been infected with hepatitis C. Screening of donor blood for hepatitis C has markedly decreased transmission of the virus by blood products. Currently, the major mechanism of transmission is by intravenous drug abuse. Transmission of this virus in nontransfusion, community-acquired cases is less well understood. It may be sexually transmitted but to a much lesser degree than hepatitis B, and vertical transmission may occur. In the United States, 3.5 million people have antibody to hepatitis C, but the number of new cases of hepatitis C has decreased from 80,000 to ~30,000 yearly. Since the 1980s, outbreaks of what is now known as hepatitis C have been associated with intravenous immune globulin (IVIG). To reduce this risk, all U.S.-licensed IVIG products now have viral inactivation steps included in the manufacturing process. In addition all immunoglobulin products (including intramuscular immunoglobulin products that have not been associated with hepatitis C) that lack viral inactivation steps are now excluded if hepatitis C virus is detected by polymerase chain reaction (PCR) analysis.

**B. Microbiology.** Hepatitis C virus is an RNA virus in the flavivirus family (other members include the agents of yellow fever and dengue). It has a very simple genome consisting of just three structural and five nonstructural genes. There are at least six major genotypes, two of which have subtypes (1a and b, 2a and b). These genotypes have quite different geographic distributions and may be associated with differing severities of disease as well as response to therapy.

**C. Pathogenesis.** Hepatitis C does not cause acute hepatic cellular necrosis. Rather, there is an insidious infection with a progressive inflammatory response, leading to, in many cases, hepatic fibrosis and cirrhosis. The determinants of progression are not

understood.

## Clinical Findings

**A. Signs and Symptoms.** The incubation period of hepatitis C averages 6-12 weeks. The infection is usually asymptomatic or mild and anicteric but results in a chronic carrier state in 70-85% of adults. The average time from infection to the development of chronic hepatitis is 13-18 years. Cirrhosis is a late sequela of chronic hepatitis, which may occur in 15-33% of infected adults and is the leading reason for liver transplants. Chronic hepatitis tends to wax and wane and is often asymptomatic.

**B. Laboratory Findings.** Hepatitis C may be associated with elevated or normal ALT values in serum.

**C. Complications.** The risk of hepatocellular carcinoma is 1-5% after 30 years of chronic infection. Cirrhosis may occur in 15-33% of hepatitis C-infected adults.

## Diagnosis

Antigens of hepatitis C are not detectable in blood, so diagnostic tests consist of attempts to demonstrate antibody. Unfortunately, the antibody responses in acute disease remain negative for 1-3 weeks after clinical onset and may never become positive in = 20% of patients with acute, resolving disease. These antibody assays can be helpful in chronic hepatitis, especially when multiple antigens are sought. The first test developed to assist the diagnosis of hepatitis C measured antibody to the C-100 antigen of the virus. It is now acknowledged that this antibody is an inaccurate marker for the disease, and current second-generation tests measure antibodies to multiple hepatitis C antigens by either enzyme immunoassay or immunoblot testing. Even with these newer assays, IgG antibody to hepatitis C may not develop for = 4 months, making the serodiagnosis of acute hepatitis C difficult. Assays of hepatitis C virus RNA by PCR or other methods may be used for diagnosis, estimating prognosis, predicting interferon responsiveness, and monitoring therapy.

## Treatment

Interferon alpha is approved for the treatment of chronic hepatitis C, but it often provides only a transient benefit (see [Box 39-2](#)). The commonly used dose is 3 million U 3 times weekly for = 6 months. Amino transferase levels decrease in only 40-70% of patients, but sustained improvement occurs in only 10-15% of patients. Responses are better in patients with genotypes other than 1 and those with low initial titers of viral RNA. Increasing dosage to 10 million U or extending treatment from 24 to 48 weeks may increase the number of sustained responses. Combination therapy with ribavirin appears to improve efficacy. Corticosteroids are not beneficial

## Prognosis

Hepatitis C has a worse prognosis than, for example, hepatitis B, since such a high proportion of cases develop cirrhosis—= 33% of infected patients.

## **Prevention & Control**

It is not clear whether prophylactic immune serum globulin protects against hepatitis C. Also, the development of a vaccine is complicated because of the antigenic variability of the virus and patients may be reinfected by different strains of wild-type virus. Reduction of needle sharing by intravenous drug users would greatly reduce the incidence of new cases. ([Box 39-3.](#))

## **HEPATITIS E**

### **General Considerations**

Hepatitis E is the cause of another form of hepatitis, but this virus is spread by the fecal-oral route and therefore resembles hepatitis A. Hepatitis E virus is an RNA virus that appears similar to caliciviruses. The viral particles in stool are spherical, 20-32 nm in diameter, and unenveloped and exhibit spikes on their surface. Like hepatitis A, this virus causes only acute disease and may be fatal, especially in pregnant women. Most cases have been identified in India, Southeast Asia, the Middle East, and other areas with poor sanitation. Rarely have cases been identified in the United States, and these have been in visitors or immigrants from endemic areas.

### **Diagnosis**

Diagnosis of hepatitis E infection may be confirmed by demonstrating the presence of specific IgM antibody.

### **Treatment**

No treatment is available for hepatitis E infection (see [Box 39-2.](#))

### **Prognosis**

Hepatitis E does not appear to eventuate in chronic hepatitis, so the prognosis is good, except in the instance of fulminant hepatitis E of pregnancy, which may be fatal.

## **Prevention & Control**

It is not known whether immune serum globulin provides protection.

## **HEPATITIS G**

### **General Considerations**

Although hepatitis C virus is the major cause of NANB hepatitis, additional etiologic agent(s) continue to be sought. In 1995 a newly discovered agent, hepatitis G, was identified in the sera of two patients. This agent is an RNA virus similar to hepatitis C and members of the flavivirus family. Up to 2% of volunteer blood donors are seropositive for hepatitis G antibody, and it is a transmissible blood-borne virus.

In addition to being closely related to hepatitis C, there are data to suggest that many patients infected by hepatitis C are also infected by hepatitis G. Given this close association, it has been difficult to ascertain the contribution of hepatitis G to clinical disease. Patients infected with both viruses do not appear to have worse disease than those infected by hepatitis C virus only.

## Diagnosis

So far, it has not been possible to develop an antibody assay so that seroprevalence could be determined. Instead detection of infection with this virus requires a PCR assay for viral RNA in patients' sera.

## Treatment

In very limited clinical studies, hepatitis G appears to be susceptible to interferon alpha treatment. Because it is not clear that hepatitis G virus causes disease, treatment is not currently indicated (see [Box 39-2](#)).
