## 40 . HIV & Other Retroviruses — *W. Lawrence Drew, MD, PhD*

### Essentials of Diagnosis

- Human immunodeficiency virus (HIV) RNA is detected and quantitated by polymerase chain reaction or branched DNA methods.
- Major diagnostic clues to HIV infection are a low CD4 lymphocyte count or an unexplained opportunistic infection.
- Human T-lymphotropic virus type 1 (HTLV-1) infection should be suspected in an adult patient with a T-cell malignancy or spastic paraparesis who is from Japan or the Caribbean basin.

### General Considerations

**A. Epidemiology.** Two major groups of retroviruses are considered in this chapter: the oncoviruses ("onco-," related to a tumor) and the lentiviruses ("lenti-," slow). Oncoviruses have long been associated with a variety of cancers in animals, including leukemia, lymphoma, and sarcoma; however, until recent years, oncoviruses had not been found to infect humans. The first human retrovirus, human T-lymphotropic virus type 1 (HTLV-1), was discovered in the late 1970s. It was shown to cause adult T-cell leukemia, a rare malignancy found only in Japan, Africa, and the Caribbean (although serologic evidence shows that the virus also occurs in the United States and may be associated with some chronic neurologic conditions). A related virus, HTLV-2, has been associated with some cases of human leukemia, including hairy cell leukemia, however its precise role in these diseases remains unclear. The most important disease resulting from human retrovirus infection—the acquired immunodeficiency syndrome (AIDS)—is caused by lentiviruses termed HIV-1 and HIV-2. This chapter focuses on the virology of oncoviruses and lentiviruses and also describes the clinical presentations of the retroviruses other than HIV. See [Chapter 23](#) for a discussion of the clinical presentation of HIV.

**B. Microbiology.** All retroviruses are remarkably similar in their basic composition. They are enveloped, single-stranded RNA viruses. They encode reverse transcriptase (an RNA-dependent DNA polymerase) that copies the genome into double-stranded DNA, which becomes integrated into the host cell genome. The structure of HIV-1 is depicted in [Figure 40-1](#). In addition to the structural proteins shown in [Figure 40-1](#), the virion contains three virus-specific proteins that are essential for viral replication: reverse transcriptase, protease, and an integrase. The *gag* (group-specific antigen) gene encodes the structural proteins of the virus. The *pol* (polymerase) gene encodes the reverse transcriptase. The *env* (envelope) gene encodes the two membrane glycoproteins found in the viral envelope. Not surprisingly, the surface protein (gp120 in HIV-1) is responsible for the host range of the virus and its antigenicity.

**C. Pathogenesis.** Like most enveloped viruses, all retroviruses are highly susceptible to inactivation and are thus not transmissible through air, dust, or fomites under normal

conditions; that is, they require intimate, direct contact with tissue or bodily fluids from the infecting source. Oncoviruses do not kill the cell they infect but instead usually continue to produce new virus indefinitely. This property, combined with the fact that oncoviruses can transduce growth-promoting genes called oncogenes into the recipient cell, accounts in part for the ability of oncoviruses to cause malignancies.

With lentivirus infections, the cell-virus relationship is quite different. Some lentiviruses can persist for years in a latent state without causing much cell killing, only to become highly cytolytic when the infected cells are subjected to certain stimuli. The prototype lentivirus is the visna virus, which causes a slowly degenerative neurologic disease in sheep. Other lentiviruses, for example, HIV-1, can persistently replicate at high levels resulting in cell death. Although HIV-1 can infect a variety of human cell types, its most drastic effects appear to result from destruction of the CD4<sup>+</sup> subclass of T lymphocytes, which play a central role in the capacity of the host to mount effective immunologic responses to a wide range of infections.

## VIROLOGY OF THE RETROVIRUSES

### Introduction

The genomes of transforming oncoviruses have a variety of structures, but one feature is common to nearly all of them. Some viral genes are replaced by genes derived from their hosts that render them oncogenic (see below).

A comparison of the genetic makeup of HIV-1 with that of other retroviruses reveals a larger number of genes and a much more complex organization. HIV-1 contains, in addition to the usual ensemble of genes, an array of other genes (*tat*, *rev*, *nef*, *vif*, *vpr*, and *vpu*) (Figure 40-2). These additional genes apparently encode proteins that serve regulatory roles important in determining the long period of latency exhibited by the virus (see below). HTLV-1 encodes a similar array of regulatory proteins. To date, approximately nine subtypes of HIV-1 clads and five of HIV-2 have been discovered, based on their *env* and *gag* sequences.

Figure 40-3 depicts the life cycle of a typical retrovirus and illustrates the many unique steps in retroviral replication that could be potential targets of therapeutic intervention.

### Viral Entry

The virions adsorb to cellular membrane receptors and enter the cell probably by direct fusion with the plasma membrane. For HIV-1, the virion attachment protein is the surface glycoprotein gp120, and the cell receptor is the CD4 molecule that occurs primarily on the plasma membrane of CD4<sup>+</sup> T lymphocytes, cells of the monocyte macrophage series, and some other target cells. The HIV-1 transmembrane protein gp41 is responsible for fusion of viral and cell membranes, a process that is important for entry of the virus into the host cell.

HIV-1 can also infect cells such as fibroblasts and certain brain cells that lack the CD4 surface molecule, apparently because the fusion-inducing activity of the transmembrane protein is sufficient in these cases to promote entry. An additional aspect of fusion

activity is that infected cells expressing viral glycoproteins in their membranes readily fuse with uninfected CD4<sup>+</sup> T lymphocytes to form large syncytia. This process appears to provide a means for cell-to-cell transmission of the virus that bypasses the usual extracellular phase and also damages the membrane of uninfected cells and affects their viability.

### **Viral RNA Replication**

Among the RNA viruses, retroviral replication is unique. Soon after entry of the viral core into the cytoplasm of the infected cell, the RNA is copied into double-stranded DNA by reverse transcriptase, the virion-associated DNA polymerase. The process of reverse transcription results in a linear DNA molecule that enters the nucleus and integrates into the host cell chromosome. The viral integrase catalyzes the reaction required for the integration of the linear DNA into host DNA. Once the viral genetic information has been converted to DNA and integrated, it essentially becomes part of the cellular genome. The viral genes, called the provirus, replicate together with the host genome as long as the infected cell continues to divide.

Special sequences contained within the RNA are duplicated during the reverse transcription process so that the integrated provirus contains identical long terminal repeats at its ends. The long terminal repeat sequences contain the appropriate promoter and enhancer and other signals required for transcription of the viral genes by the host RNA polymerase II. Transcription produces both a full-length RNA genome and one or more spliced messenger RNAs (mRNAs). The predominant spliced mRNA is translated to produce the envelope glycoproteins, but, in HIV-1, a series of spliced mRNAs are produced that also encode a variety of viral regulatory proteins. With the exception of these regulatory proteins, all retroviral proteins are initially translated as polyproteins that are subsequently processed by proteolysis into the individual protein molecules. The enzyme responsible for most of these protein cleavages is the virus-specific protease that is encoded in either the *gag* gene or the *pol* gene of the virus. Of all the known retroviruses, HIV-1 possesses the most error-prone reverse transcriptase. This property accounts for the many nucleotide differences observed between isolates (even from the same infected individual) and for the variability of the gp120 antigen. It may explain in part the failure of the immune system to control the infection and the increases in viral virulence that appear to occur during the course of the infection.

### **Unique Feature of the Lentiviruses**

A unique feature of HIV-1 and other members of the lentivirus subfamily is the ability to produce a complex array of regulatory proteins. Although much remains to be determined about the regulatory circuits that modulate HIV-1 gene expression, several features of the process have been established.

Regulation appears to occur at three levels: mRNA production, transport of unspliced versus spliced mRNAs from the nucleus to the cytoplasm, and maturation of viral proteins during budding. Regulation may also occur at the level of mRNA translation. The HIV-1 regulatory proteins and their functions are listed in [Table 40-1](#).

Two of the regulatory proteins, TAT and REV, play a positive role in promoting viral gene expression. The TAT protein increases the rate of viral mRNA synthesis, and REV promotes the transport of full-length mRNA to the cytoplasm before it can be spliced. The combined action of these two regulatory proteins is to promote the production of virus particles. The VIF protein promotes virus production at the level of maturation.

Superimposed on this complex regulatory network is the fact that the viral promoter contains elements that are sensitive to specific cellular transcription factors. This observation may help explain why virus production in CD4<sup>+</sup> T lymphocytes is greatly increased when the cells are activated.

## **HIV Latency**

### **Introduction**

Until recently, it was thought that the virus entered a latent stage in an infected host and became activated at a later date. Now it is understood that even during the asymptomatic period before clinical AIDS, the virus duplicates at a very high rate with a half-life of 2 days. Billions of HIV viruses are produced daily.

The long asymptomatic period after HIV infection (clinical latency) occurs despite active virus replication in the host. Several factors can terminate the long latent period of HIV-1. Mutations occur during viral replication that appear to increase cytopathic capacity and alter cell tropisms. In the same patient, the mutated forms of HIV-1 isolated from later stages of disease infect a broader range of cell types, grow more rapidly than those isolated in the asymptomatic period, and may induce syncytial formation (SI variants).

The virus replicates in macrophages, and these cells may serve as a reservoir for spread of the infection to other cell types by cell-to-cell fusion, which allows the virus to spread without being exposed to neutralizing antibodies. In addition to CD4<sup>+</sup> T lymphocytes and macrophages, the most prominent cell types infected are glial cells and astrocytes in the brain and cells of the bowel mucosa. Infected macrophages may participate in the breakdown of the blood-brain barrier, allowing exposure of the central nervous system. Although central nervous system and intestinal disturbances are a prominent part of full-blown AIDS, it is not clear whether they are a direct result of infection of these cells or mediated by cytokines from infected macrophages and T lymphocytes.

The primary immune defect in AIDS results from the reduction in number and effectiveness of CD4<sup>+</sup> helper-inducer T lymphocytes, both in absolute numbers and relative to CD8<sup>+</sup> suppressor T lymphocytes. This reduction is caused by direct killing of CD4<sup>+</sup> T lymphocytes by the virus but may also involve other mechanisms as well. These mechanisms include autoimmune processes that lead to the elimination of CD4<sup>+</sup> T lymphocytes by opsonophagocytosis and antibody-dependent cell-mediated cytotoxicity directed at gp120 expressed on the CD4<sup>+</sup> cell surface. There are also functional defects in CD4<sup>+</sup> T lymphocytes affecting lymphokine production and leading to inhibition of some macrophage functions.

Effects on CD4<sup>+</sup> T lymphocytes lead to a generalized failure of cell-mediated immune responses, but there is also an effect on antibody production caused by polyclonal activation of B cells, possibly associated with other viral infections of these cells. This overwhelms the capacity of infected individuals to respond to specific antigens. The result of these processes is a disturbance of immune balance that can give rise to malignancies as well as to a range of opportunistic viral, fungal, and bacterial infections.

### **Transformation by Retroviruses**

Oncogenic retroviruses appear to transform cells to an oncogenic state by three distinct mechanisms. First, the transforming viruses have acquired a cellular gene (called an "oncogene") that, when expressed in the infected cell, results in the loss of normal growth control. On infection, the oncogene is expressed, resulting in the rapid onset of malignant disease. Persistent transformation by oncogene transduction is possible only for those retroviruses that are not cytotoxic. More than 25 different oncogenes have been identified in a variety of animal retroviruses, but no human retroviruses are known that transform by this mechanism.

The second mechanism is called "insertional mutagenesis." Integration of a retrovirus near particular cellular genes can cause inappropriate expression of the gene, resulting in uncontrolled cell growth. These cellular genes are called "proto-oncogenes," and insertional activation by the virus is apparently caused by the close proximity of the integrated viral promoter or enhancer to the gene. Cancers that are caused by this mechanism have very long latent periods because integration is random and only rarely occurs near a cellular proto-oncogene. No human cancers are known to be caused by this mechanism.

The causative agent of adult T-cell leukemia, HTLV-1, exemplifies the third mechanism. In this case, the integrated provirus in the leukemic cells from any one patient is found at a unique location on a particular chromosome. Thus the tumors are probably monoclonal. However, the cancer is not the result of insertional mutagenesis because the chromosomal location of the provirus is never the same in any two patients. Instead, transformation results from the continual expression of the viral *tax* gene (the HTLV-1 homolog of the HIV-1 *tat* gene). Apparently, the TAX protein not only can activate viral transcription in the same manner as TAT but can also activate the expression of one or more cellular genes (possibly proto-oncogenes) resulting in malignant transformation. These leukemia viruses cause cancer after a long latency period.

## **ONCOVIRUSES (HTLV-1)**

### **Clinical Findings**

HTLV-1 infection is usually asymptomatic but can progress to adult T-cell leukemia in ~1 in 20 persons ([Box 40-1](#)). Adult T-cell leukemia caused by HTLV-1 is a neoplasia of CD4 helper T cells that can be acute or chronic. In addition to an elevated and abnormal lymphocyte count, lymphadenopathy, splenomegaly, and hepatomegaly also occur. The skin lesions vary from localized maculas, papule nodules, and plaques to generalized erythroderma. Adult T-cell leukemia is usually fatal within 1 year of diagnosis,

regardless of treatment. A second syndrome associated with HTLV-1 infection is tropical spastic paraparesis. This is a slowly progressing neurologic disorder that usually begins as bilateral weakness of the lower extremities with hyper-reflexia. Numbness, back pain, and symptoms of bladder irritation also develop.

HTLV-1 infection is detected immunologically by the presence of HTLV-1 antibody in blood. A diagnosis of adult T-cell leukemia is supported by a high number of abnormal lymphocytes in blood and is confirmed by identification of HTLV-1 DNA in these cells.

### **Treatment & Control**

Adult T-cell leukemia may respond briefly to chemotherapy, but no treatment has been proved effective against HTLV-1 infection. Zidovudine (azidothymidine [AZT]) and other inhibitors of reverse transcriptase are active against HTLV-1 in tissue culture, but controlled studies are needed. See [Boxes 40-2](#) and [40-3](#) for additional comments.

**Figure 40-3.** HIV life cycle and its inhibition. The nucleoside analogs exert their effect on HIV replication at the reverse transcription stage—that is, after the virus has entered the host cell genome. The affinity of HIV-reverse transcriptase for nucleoside analogs is greater than that for the endogenous substrates; the triphosphate form of the analogs preferentially attaches to a nucleotide-binding site of the enzyme, competitively inhibiting binding of the endogenous 5'-triphosphate molecule. The protease inhibitors block cleavage of polyproteins at a stage prior to assembly of immature viral proteins into particles.

## 41 . Poxviruses — *W. Lawrence Drew, MD, PhD*

### Essentials of Diagnosis

- Multiple, large, eosinophilic cytoplasmic inclusions in epithelial cells (H & E stain).
- Vesicular or nodular skin lesions.
- Exposure by occupation or close personal contact.
- High index of suspicion in patients with skin lesions and exposure to sheep, goats, or cows.

### General Considerations

Poxviruses are a large, complex family of viruses that cause disease in humans and other animals ([Table 41-1](#)). Of the many genera in this family, only species of Orthopoxvirus and Molluscipoxvirus are associated specifically with humans. The former contains variola virus (smallpox), which is currently of historical interest only, and the latter molluscum contagiosum virus. Poxviruses in other genera naturally infect animals (zoonoses) but cause incidental infection of humans.

**A. Epidemiology.** Molluscum contagiosum infection is spread through direct person-to-person contact or through sharing of common towels etc. The agents of the zoonotic poxvirus diseases spread by direct contact.

**B. Microbiology.** Poxviruses are the largest of all viruses, measuring 230 by 300 nm, and are ovoid to brick shaped. They have a capsid that is referred to as complex because it has neither helical nor icosahedral symmetry. An outer membrane and envelope enclose the core and core membrane. The viral genome is a single strand of large, linear, double-stranded DNA (molecular weight approximately  $100 \times 10^6$ - $100 \times 200^6$ ).

Replication of poxviruses is unique among DNA-containing viruses, because the entire multiplication cycle takes place within the host cell cytoplasm. Viral penetration occurs within phagocytic vacuoles. Uncoating of the outer membrane occurs in the vacuole. Early gene transcription occurs within the viral core. Among the early proteins produced is an uncoating protein that removes the core membrane, liberating viral DNA into the cell cytoplasm. Replication of viral DNA follows in electron-dense cytoplasmic inclusions, referred to as factories. Late viral mRNA is translated into structural proteins, which are glycosylated, phosphorylated, and cleaved before assembly. Unlike other viruses, poxvirus membranes form de novo in the cytoplasm, rather than as part of a host cell membrane that is picked up during a budding process. About 10,000 viral particles are produced per infected cell.

**C. Pathogenesis.** The pathologic hallmark of poxviruses is cell proliferation, manifested

by the skin lesions that give this family of viruses its name. Most of the viruses of current human importance are primary pathogens in vertebrates other than humans (eg, cow, sheep, and goats) and infect humans only through accidental occupational exposure (zoonosis). As stated earlier, the exception to this is molluscum contagiosum.

## CLINICAL SYNDROMES

### MOLLUSCUM CONTAGIOSUM

#### Clinical Findings

**A. Signs and Symptoms.** The incubation period is 2-8 weeks. The lesions differ significantly from pox lesions in that they are nodular to wartlike. They begin as papules and progress to pearly, umbilicated nodules 2-10 mm in diameter, with a central caseous plug that can be readily expressed. They are most common on the trunk, genitalia, and proximal extremities and usually occur in a cluster of 5-20 nodules ([Box 41-1](#)). Lesions disappear in 2-12 months even without treatment. Often a history can be elicited of contact with an individual with skin lesions, eg, from wrestling or sexual contact.

**B. Laboratory Findings.** The lesions of molluscum contagiosum are caused by a poxvirus that is unclassified because it does not grow in cell cultures but can be confirmed histologically by finding large eosinophilic inclusions in the cytoplasm (molluscum bodies) of epithelial cells.

**C. Differential Diagnosis.** Molluscum contagiosum lesions may be mistaken for warts but can be distinguished by expression of cheesy material from the center of each lesion, by histologic examination, and by location.

### ZOONOTIC POXVIRUSES

#### 1. ORF & COWPOX

##### Introduction

The poxviruses of animals such as sheep or goats (orf) and cows (cowpox) can infect humans, usually as a result of accidental direct contact.

##### Clinical Findings

**A. Signs and Symptoms.** Single or multiple nodular lesions are usually found on the fingers or face and are vesicular or pustular (cowpox) or granulomatous (orf). After progressing from a vesicular lesion to a nodular mass, the lesion usually regresses in 25-35 days.

**B. Laboratory Findings.** There are no characteristic abnormalities in blood counts or chemistries.

**C. Differential Diagnosis.** The lesion may be mistaken for anthrax. The anthrax lesion, however, is vesicular, then ulcerative, and finally, a black eschar and does not develop a nodular appearance.

**D. Complications.** Because orf and cowpox lesions resolve completely, there are no complications.

## 2. PSEUDOCOWPOX OR MILKER'S NODULES

### Clinical Findings

**A. Signs and Symptoms.** Pseudocowpox or Milker's nodules is a cutaneous disease of cattle, distinct from cowpox, that can cause localized papular lesions which progress to purplish nodules. Healing of the skin lesions may take 4-8 weeks.

**B. Differential Diagnosis.** The lesions can resemble the eschar of anthrax or the early lesion of orf or cowpox, but milker's nodules are nonulcerating.

## 3. MONKEYPOX

### Introduction

Over 100 cases of an illness resembling smallpox have been attributed to the monkeypox virus. Multiple vesiculopustular lesions occur, but the illness is not as severe. All have occurred in western and central Africa, especially Zaire. There has been concern that this agent might replace the smallpox virus and become epidemic in humans, but this has not materialized probably because animal poxviruses seem highly adapted to their particular host and require very close, usually direct, contact for transmission.

### Treatment

**Molluscum Contagiosum.** Treatment of molluscum contagiosum, if lesions are extensive or cosmetically disfiguring, is curettage, forceps removal of central core, or application of liquid nitrogen or iodine solutions ([Box 41-2](#)).

**Zoonotic Poxviruses.** Since the lesions of zoonotic poxviruses heal in 4-6 weeks, treatment is unnecessary.

### Prevention & Control

**Molluscum Contagiosum.** Prevention of molluscum contagiosum consists of avoiding direct or indirect contact with individuals exhibiting characteristic skin lesions ([Box 41-3](#)).

**Zoonotic Poxviruses.** The zoonotic poxviruses can be avoided by avoiding contact with animals exhibiting skin lesions, especially when the human has potentially infected cuts or abrasions.

## 42 . Parvoviruses — *W. Lawrence Drew, MD, PhD*

### Essentials of Diagnosis

- Erythema infectiosum: "slapped cheek" rash in a child.
- Aplastic crisis in patients with chronic hemolytic anemia or AIDS.
- Giant pronormoblasts seen in bone marrow.
- Specific antibody (immunoglobulin G [IgG] and IgM), although these may not develop in certain immunocompromised patients.
- Detection of specific nucleic acids (eg, by polymerase chain reaction [PCR] assay) or antigens in blood.

### General Considerations

Parvoviruses are widespread bird and mammalian viruses. More than 50 types have been identified, but the most common identified human pathogen is parvovirus B19. It is the cause of erythema infectiosum (Fifth disease) and is responsible for episodes of aplastic crises in patients with chronic anemia, especially those with hemolytic anemia and AIDS ([Box 42-1](#)). B19 is also associated with arthritis and intrauterine infection.

**A. Epidemiology.** Up to 90% of the adult population have antibodies to B19. Most infections with this virus occur by 40 years of age. As many as 25% of these infections are asymptomatic and one half are unaccompanied by a rash. Erythema infectiosum is most common in children from ages 4 to 15 years, and it tends to occur in winter and spring. The route of natural transmission is presumably by respiratory droplets. Parenteral transmission of B19 has been described.

**B. Microbiology.** B19 virus is an extremely small (18- to 26-nm diameter), nonenveloped, icosahedral virion. The B19 virus genome contains one linear single-stranded DNA molecule with a molecular weight of  $1.5\text{-}1.8 \times 10^6$  (5.5 kb in length). The viral genome codes for three structural and one nonstructural protein.

The replicative cycle includes infection of mitotically active cells such as erythroid precursor cells. The receptor molecule for B19 is a glycolipid antigen on the surface of erythrocytes. Transcription, replication, and assembly occur in the host cell nucleus. Steps in DNA replication most likely require host cell functions present only in the late "S" phase, necessitating a mitotically active host cell.

**C. Pathogenesis.** Intranasal inoculation of volunteers with B19 virus suggests that the virus first replicates in the upper respiratory tract, followed by viremia and replication in erythroid precursor cells in the bone marrow. This replication inhibits proliferation of precursor erythrocytes. Infection of a normal host may result in mild nonspecific symptoms such as sore throat, malaise, and myalgia, and a slight drop in hemoglobin.

Infection of hosts with chronic hemolytic anemia (eg, sickle cell anemia) may result in life-threatening reticulocytopenia, referred to as aplastic crisis.

The initial course of B19 virus infection in healthy children includes the symptoms just described, resulting from lytic virus infection, and a noninfectious, immunologic phase approximately 2-3 weeks after initial infection. The immunologic phase, which includes rash and arthralgia, is termed erythema infectiosum and appears to be immune mediated, since symptoms accompany the appearance of virus-specific IgM and circulating immune complexes. Antibody produced during infection presumably confers life-long immunity.

## **ERYTHEMA INFECTIOSUM**

### **Clinical Findings**

**A. Signs and Symptoms.** Erythema infectiosum (Fifth disease) begins with a distinctive rash on the face resembling a cheek that has been slapped. The rash then usually spreads, especially to exposed skin such as the arms and legs, and then subsides over a 1-2 week period. Relapse of the rash may occur often. In adults, arthritis of hands, wrists, knees, and ankles predominates, and the rash often does not occur or it may precede the arthritis.

**B. Laboratory Findings.** There are no distinctive blood abnormalities in patients with erythema infectiosum. In patients with aplastic crisis, there is profound anemia with no reticulocytosis.

**C. Complications.** The most serious complication of parvovirus infection is the aplastic crisis that occurs in patients with chronic anemia, including those with human immunodeficiency viral infection who cannot control viral replication.

## **APLASTIC CRISIS**

### **Clinical Findings**

**A. Signs and Symptoms.** Aplastic crisis is accompanied by fever and nonspecific symptoms of malaise, myalgia, chills, and itching. Parvovirus infection in these patients may be associated with maculopapular rash with arthralgia and some joint swelling.

**B. Laboratory Findings.** The infection is characterized by transient reduction of erythropoiesis in the bone marrow and results in a transient reticulocytopenia (7-10 days) and a decrease in hemoglobin levels. In AIDS or immunocompromised patients, these abnormalities may persist, constantly or intermittently, for months to years.

### **Other Complications**

In addition to chronic marrow suppression, mentioned above, B19 infection is also associated with fetal infection and stillbirth, although infection of pregnant women may occur without any adverse effect on the fetus. However, there is no evidence that B19 causes congenital abnormalities.

## Diagnosis

B19 virus is not recovered in tissue culture but can be directly detected in serum or throat washes during the prodromal period or aplastic crisis by enzyme and radioimmunoassay, nucleic acid hybridization, and immune electron microscopy. PCR is a very sensitive method for detecting B19 but may remain positive for months after B19 infection. The presence of characteristic "giant" pronormoblasts in bone marrow may provide a clue to parvovirus as the cause of an aplastic crisis.

More readily available and applicable to patients with erythema infectiosum and aplastic crisis is the virus-specific IgM test, which indicates current or recent infection. This test is not useful in AIDS patients because they do not mount an IgM antibody response.

## Treatment

No specific antiviral treatment is known, but chronic B19-induced anemia may be treatable with immune globulin.

## Prognosis

B19 infection can be chronic in immunocompromised patients, with intermittent worsening of anemia for months to years.

## Prevention & Control

Control of respiratory spread could decrease transmission of B19 virus; however, patients with clinically apparent erythema infectiosum are no longer infectious. Transmission therefore would occur before preventive measures (eg, isolation) are enacted ([Box 42-2](#)).

## 43 . Viral Infection of the Central Nervous System — *W. Lawrence Drew, MD, PhD*

### INTRODUCTION

Many viruses causing infection of the central nervous system (CNS) are covered in chapters devoted to each type of virus. For example, enteroviruses, the agents most frequently causing meningitis and occasionally encephalitis, are covered in [Chapter 27](#). The herpes viruses that cause meningitis, encephalitis, or both, especially herpes simplex virus (HSV), varicella-zoster virus (VZV), and Epstein-Barr virus (EBV), are discussed in [Chapter 33](#). This chapter considers viruses that cause CNS diseases ([Box 43-1](#)) as their primary manifestations.

### ARTHROPOD-BORNE VIRAL ENCEPHALITIS

#### Essentials of Diagnosis

- Summer and fall cases, especially if in a cluster or outbreak, suggest arboviruses or enteroviruses.
- History of exposure to mosquitoes suggests arbovirus infection, especially in geographic areas of high endemicity (eg, swamps of Florida).
- Maculopapular rash suggests enterovirus disease.
- Lymphocytic pleocytosis in cerebrospinal fluid (CSF) with normal glucose and protein concentrations suggests viral meningitis.

#### General Considerations

Arthropod-borne (arbo) viruses causing encephalitis are members of the toga-, flavi-, and bunyavirus families. The medically important togaviruses include rubella virus, which is discussed in [Chapter 36](#), and the equine encephalitis viruses. The flavivirus family, which includes St. Louis encephalitis (SLE) and West Nile viruses, also includes dengue and yellow fever viruses; the latter described in detail in [Chapter 44](#). The bunyaviruses causing CNS disease are members of the California encephalitis (CE) virus group, but other pathogenic bunyaviruses include the hantaviruses, which are discussed in [Chapter 44](#). The older term, arbovirus, refers to those encephalitis-causing viruses that have an arthropod vector, eg, mosquitoes or ticks. These viruses have a very broad host range, including mammals, birds, amphibians, and reptiles.

**A. Epidemiology.** Togaviruses and flaviviruses are prototypical arboviruses. As arboviruses, they infect both vertebrates and invertebrates, and they initiate a viremia in a vertebrate host and a persistent, productive infection of the salivary gland of the invertebrate to provide virus for infection of other host animals. If the virus is not in the blood, the arthropod vector cannot pick it up. The infection cycle involves transmission of the virus by the arthropod vector and amplification in a susceptible, natural host to

allow reinfection of other arthropods. Humans are usually dead-end hosts that cannot spread the virus back to the vector because a persistent viremia is not maintained. [Table 43-1](#) lists vectors, natural hosts, and a geographic distribution for representative togaviruses and flaviviruses.

These viruses are usually restricted to a specific genus of arthropod vector and its vertebrate host. The most common vector is the mosquito, but some arboviruses are also spread by ticks and sand flies. Not all arthropods can act as good vectors for each virus. For example, *Culex quinquefasciatus* is resistant to infection by western equine encephalitis (WEE) virus (a togavirus) but is an excellent vector for SLE virus (a flavivirus). As with mosquito-borne viruses, the life cycle of the tick dictates the pattern of spread of tick-borne viruses.

In endemic regions, the risk of arbovirus infection increases during the rainy season. Pools of standing water, drainage ditches, and sumps in cities can provide breeding grounds for mosquitoes, such as *Culex* spp., the vector of SLE and West Nile virus. During the summer months the arboviruses are cycled between a host (eg, bird) and an arthropod (eg, mosquito). This cycle maintains and increases the amount of virus in the environment. In the winter neither the normal host nor the vector remains to maintain the virus. The virus may persist in arthropod larvae or eggs or in reptiles or amphibians that remain in the locale, or it may be blown by the winds or migrate with the birds and then return during the summer.

Birds and small mammals are the usual hosts for the togaviruses and flaviviruses, but reptiles, amphibians, and, rarely, humans can also act as hosts. Development of a large population of viremic animals can occur in these species to continue the infection cycle of the virus. Although some of these viruses are called equine encephalitis viruses, the horse sometimes is a dead-end host. However, as with humans, the horse may develop clinical disease.

CE viruses are arthropod-borne members of the bunyavirus family. Bunyaviruses were known as arboviruses until the discovery of hantaviruses, members of the family that are transmitted to humans without the aid of arthropod vectors. Despite its name, CE occurs almost exclusively in the eastern half of the United States and especially in the North Central States. The name derives from the fact that the first representative of this virus group was isolated in Kern County, Calif., but the most common type causing disease in the United States is the La Crosse virus, which was first isolated in Wisconsin. This virus causes the most prevalent arbovirus infection in children in the United States.

The age distribution of patients with arthropod-borne encephalitis is striking. SLE and West Nile virus cause clinical illness in older adults, CE in school-aged children, and western and eastern equine encephalitis (WEE and EEE) predominately in infants and young children.

**B. Microbiology.** The toga- and flaviviruses are enveloped, single-stranded ribonucleic acid (RNA) viruses. Until recently the flaviviruses were included in the *Togaviridae* family, but differences in size, morphology, gene sequence, and replication have made it necessary to classify them as an independent virus family.

The flaviviruses also have plus-strand RNA and an envelope. However, the virions are slightly smaller than those of the togaviruses (37-50 nm in diameter). All the flaviviruses are serologically related, and antibodies to one virus may cross-neutralize another virus.

CE viruses are intermediate-sized RNA viruses (90-120 nm in diameter) in the bunyavirus genus that are spherical in appearance. They are enveloped and contain three separate pieces of negative-strand RNA of differing lengths.

**C. Pathogenesis.** The togaviruses and flaviviruses can cause lytic or persistent infections of both vertebrate and invertebrate hosts. Infections of invertebrates are usually persistent, with continued virus production.

Female mosquitoes acquire the togaviruses and flaviviruses on taking a blood meal from a viremic vertebrate host. The virus infects the epithelial cells of the mid-gut of the mosquito, spreads through the basal lamina of the mid-gut to the circulation, and then infects the salivary glands. The virus sets up a persistent infection and replicates to high titers in these cells. The salivary glands can then release virus into the saliva; however, certain strains of WEE virus are limited to the mid-gut and cannot infect the salivary glands.

After biting a host, the female mosquito regurgitates virus-containing saliva into the victim's bloodstream. The virus circulates freely in the plasma and comes into contact with susceptible target cells such as the endothelial cells of the capillaries, macrophages, and monocytes.

Following replication of the virus in these cells, the initial viremia produces systemic symptoms such as fever, chills, headaches, backaches, and flulike symptoms within 3-7 days of infection. Some of these symptoms can be attributed to the interferon produced after infection of these target cells. This is considered a mild systemic disease, and most virus infections do not progress beyond this point.

After replication in cells of the reticuloendothelial system, a secondary viremia may result. This can produce sufficient virus to infect target organs such as the brain, liver, skin, and vasculature, depending on the tissue tropism of the virus. Access to the brain is provided by infection of the endothelial cells lining the small vessels of the brain or choroid plexus.

The vertebrate-invertebrate cycle of CE viruses is very similar to that for toga- and flaviviruses and includes *Aedes triseriatus* as the vector mosquito and the squirrel or chipmunk as the usual host.

## **Clinical Findings**

**A. Signs and Symptoms.** Infection by the togaviruses usually causes a low-grade disease characterized by flulike symptoms (ie, chills, fever, rash, and aches) that correlate with systemic infection during the initial viremia. EEE, WEE, and Venezuela equine encephalitis (VEE) virus infections can progress to encephalitis (as the names imply) in humans and horses, with EEE causing the most severe disease. These viruses

are usually more of a problem to livestock than to humans.

Most infections with flaviviruses are relatively benign, although encephalitic or hemorrhagic disease can occur. The encephalitis viruses include St. Louis, Japanese, Murray Valley, and Russian spring-summer viruses. Infections with West Nile and other viruses usually are limited to a mild systemic disease, possibly with a hemorrhagic rash, but the 1999 outbreak on the East Coast of the United States with cases of fatal encephalitis underscores the potential severity of infection with West Nile virus.

Inapparent, mild illnesses or aseptic meningitis occur with CE virus infection, the latter after an incubation period of approximately 48 h. Encephalitis caused by CE occurs approximately 1 week after exposure and is manifested by seizures and generalized cerebral dysfunction mimicking herpes simplex encephalitis. It is most common in school-aged children.

**B. Laboratory Findings.** The togaviruses, flaviviruses, and CE viruses can be grown in both vertebrate and mosquito cell lines but are difficult and dangerous to isolate. When isolation of the virus is necessary, the best systems are suckling mice and mosquito cell lines. In addition to cytopathology, the viruses grown in culture can be detected by immunofluorescence or by hemadsorption of avian erythrocytes. After isolation, the viruses can be distinguished by analysis of the genomic RNA or by monoclonal antibodies.

A variety of serologic methods can be used to diagnose arbovirus infections. Seroconversion or a fourfold increase in titer between acute and convalescent sera is used to indicate a recent infection. The serologic cross-reactivity between viruses in a group or complex limits identification of the actual viral species in many cases.

**C. Imaging.** Magnetic resonance imaging (MRI) may help to distinguish HSV encephalitis from other types; HSV characteristically causes temporal lobe lesions, whereas arboviruses cause focal lesions in basal ganglia and thalami.

### **Differential Diagnosis**

The arthropod-borne encephalitides are similar to each other, but the specific etiology may be suggested by geographic location and age of the patient as well as the severity of the illness. For example, WEE is more apt to occur in the far western United States, Colorado, and Texas; EEE is endemic along the entire East Coast; SLE in the eastern states, Texas, and Mississippi; and CE in the Midwest. The 1999 outbreak of West Nile virus infections in New York was originally thought to be due to SLE, but this virus is now endemic in the Eastern United States. West Nile attacked adults and had a fatality rate of 10%. WEE has its highest attack rate in infants < 1 year of age and is most severe in this age group. EEE is more severe than WEE, with a mortality rate of = 20% in infants and children. SLE is similar in severity to WEE, with 5% mortality in those with encephalitis, but SLE tends to attack adults rather than infants or children. CE, in contrast, attacks patients aged 5-18 years.

Arbovirus encephalitis must be distinguished from that caused by herpes simplex viruses (HSV, VZV, and EBV), especially since the latter infections can be treated with

antiviral agents. Herpesvirus encephalitis occurs sporadically without any seasonal pattern and occurs with or without mosquito exposure. HSV and VZV encephalitis may be preceded or accompanied by characteristic vesiculopustular skin lesions. HSV tends to be localized to the temporal lobe, causing EEG and imaging abnormalities in this location.

## **Complications**

In infants < 1 year old with encephalitis, death may occur in up to 20% and neurologic sequelae in > 50% of survivors. The rates of these complications are less in older children and adults.

## **Treatment**

No treatments exist for arbovirus diseases other than supportive care.

## **Prognosis**

Attack rates for encephalitis are approximately 1 per 1000 infections. In older children and adults, = 95% recover from encephalitis, and sequelae are uncommon, but in infants there is high mortality and frequent residua in survivors.

## **Prevention & Control**

The easiest means to prevent the spread of any arbovirus is elimination or avoidance of its vector and breeding grounds ([Box 43-2](#)). Killed vaccines against Japanese encephalitis, EEE, WEE, and Russian spring-summer encephalitis viruses are available. These vaccines are for individuals working with the specific virus or at risk of contact. A live vaccine against VEE virus is available but only for use in domestic animals.

## **LYMPHOCYTIC CHORIOMENINGITIS (LCM)**

### **Introduction**

Lymphocytic choriomeningitis (LCM) virus is an arenavirus, the same family as Lassa virus. All arenaviruses have a common reservoir in animals, especially small rodents. The infected animals may be asymptomatic or minimally diseased but excreting the virus in their secretions.

### **Epidemiology**

LCM virus infects hamsters and mice; chronic infection is common in these animals and leads to chronic viremia and virus shedding in saliva, urine, and feces. Infection of humans may occur by way of aerosols, contamination of food, or fomites. Bites are not a usual mechanism of spread. Persistently infected rodents do not usually exhibit illness. The incubation period for LCM infections averages 10-14 days.

### **Microbiology**

Arenaviruses are pleomorphic and enveloped with lipid; the virion has a mean diameter of 120 nm. They contain two-stranded RNA in a linear or circular configuration. The total molecular weight of this RNA is  $3.2 \times 10^6$  daltons- $4.8 \times 10^6$  daltons.

## **Pathogenesis**

Arenaviruses are able to infect macrophages and possibly cause the release of mediators of cell and vascular damage. In certain laboratory animals the clinical severity of arenavirus disease appears to be directly related to the host's immunologic response. The greater the immune (especially T lymphocyte) response, the worse the disease. Whether these mechanisms are operative in human infection is not clear. LCM virus may actually produce an encephalitis as well as meningitis. Perivascular mononuclear infiltrates may be seen in neurons of all sections of brain as well as in the meninges.

## **Clinical Syndrome**

LCM illness occurs in most infected individuals but is usually nonspecific or influenzalike. Current estimates show that ~35% of infected persons exhibit clinical evidence of CNS infection. The name of the virus suggests that meningitis is a typical clinical event, but actually a febrile illness, if it occurs, may be subacute and persist for several months. Encephalitis occurs in approximately one-third of patients with CNS manifestations.

## **Laboratory Diagnosis**

The diagnosis of LCM virus infection is usually made through serologic tests, although the virus can be recovered by inoculation of blood (early) or CSF (late in illness) into suckling mice or Vero monkey cells.

## **Treatment & Prevention**

Only supportive therapy for patients with LCM infection is currently available. Prevention of these rodent-borne infections rests on control of the vector's contact with humans. Most human cases of LCM in the United States have resulted from contact with pet hamsters or in rodent-breeding facilities. If hamsters must be kept as pets, scrupulous hand washing is recommended after contact.

## **RABIES**

### **Essentials of Diagnosis**

- Subacute onset of neurologic abnormalities including hallucinations, combativeness, muscle spasms, seizures, and focal paralysis.
- Detection of negri bodies or rabies antigen in animal or human brain tissue (70-90%).
- Rabies-neutralizing antibody in serum or CSF diagnostic in an unimmunized patient.

### **General Considerations**

Rabies is an acute fatal viral illness of the CNS. It can affect all mammals and is transmitted between them by infected secretions, most often by bite. It was first recognized more than 3000 years ago and has been among the most feared of infectious diseases. It is said that Aristotle recognized that rabies could be spread by a rabid dog.

**A. Epidemiology.** Rabies exists in two epizootic forms: the urban form is associated with unimmunized dogs or cats and is essentially nonexistent in the United States; the sylvatic form occurs in wild skunks, foxes, wolves, raccoons, bats, and mongooses. Throughout the world there are striking geographic differences in specific animals. For example, raccoons are a significant reservoir of rabies in the southwestern United States but not on the West Coast; the bat is a frequent vector in Latin America, and the wolf in Eastern Europe. Rodents are not important vectors of rabies. Human or cattle infection is incidental, and does not contribute to maintenance or transmission of the disease.

Human exposures may be from wild animals or from unimmunized dogs or cats. Domestic animal bites are the most frequent vectors in developing countries because of lack of enforcement of animal immunization. Infection in domestic animals usually represents a spillover from infection in wildlife reservoirs. Human infection tends to occur where animal rabies is common and where there is a large population of unimmunized domestic animals. Worldwide, the occurrence of human rabies is estimated to be about 15,000 cases per year, with the highest attack rates in Southeast Asia, the Philippines, and the Indian subcontinent. In the United States, fewer than five cases of human rabies are reported yearly.

**B. Microbiology.** The rabies virus is a bullet-shaped, enveloped, single-stranded RNA virus of the rhabdovirus group. The virion is large, with a diameter of ~180 nm. Knoblike glycoprotein excrescences or projections, which elicit neutralizing and hemagglutination-inhibiting antibodies, cover its surface.

In the past, a single antigenically homogeneous virus was believed responsible for all rabies; however, differences in cell culture growth characteristics of isolates from different animal sources, some differences in virulence for experimental animals, and antigenic differences in surface glycoproteins have indicated strain heterogeneity among rabies virus isolates. These studies may help to explain some of the biological differences noted, as well as the occasional case of vaccine failure.

**C. Pathogenesis.** The essential first event in human or animal rabies infection is the introduction of virus through the epidermis, usually as a result of an animal bite. Inhalation of heavily contaminated material, such as bat droppings, eg, by cave explorers, can also cause infection. Rabies virus first replicates in striated muscle tissue at the site of inoculation. It then enters the peripheral nervous system at the neuromuscular junctions and spreads up the nerves to the CNS, where it replicates exclusively within the gray matter. It then passes centrifugally along autonomic nerves to reach other tissues, including the salivary glands, adrenal medulla, kidneys, and lungs.

Passage into the salivary glands in animals explains transmission of the disease by infected saliva. The incubation period ranges from 10 days to a year, depending on the amount of virus introduced, the amount of tissue involved, the host immune mechanisms, and the distance the virus must travel from the site of inoculation to the CNS. Thus the incubation period is generally shorter with face wounds than with leg wounds. Immunization early in the incubation period frequently aborts the infection.

The neuropathology of rabies resembles that of other viral diseases of the CNS, with infiltration of lymphocytes and plasma cells into CNS tissue and nerve cell destruction. The pathognomonic lesion is the negri body, an eosinophilic cytoplasmic viral inclusion distributed throughout the brain, particularly in the hippocampus, cerebral cortex, cerebellum, and dorsal spinal ganglia.

## **Clinical Findings**

**A. Signs and Symptoms.** Rabies in humans usually results from a bite by a rabid animal or contamination of a wound by an animal's saliva. It presents as an acute, fulminant, fatal encephalitis; human survivors have been reported only occasionally. The disease begins as a nonspecific illness marked by fever, headache, malaise, nausea, and vomiting. Abnormal sensations at or around the site of viral inoculation occur frequently and probably reflect local nerve involvement. The onset of encephalitis is marked by periods of excess motor activity and agitation. Hallucinations, combativeness, muscle spasms, signs of meningeal irritation, seizures, and focal paralysis occur. Periods of mental dysfunction are interspersed with completely lucid periods; as the disease progresses, however, the patient lapses into coma. Autonomic nervous system involvement often results in increased salivation.

Brain stem and cranial nerve dysfunction is characteristic, with double vision, facial palsies, and difficulty in swallowing. The combination of excess salivation and difficulty in swallowing produces the traditional picture of foaming at the mouth. Hydrophobia, the painful, violent involuntary contractions of the diaphragm and accessory respiratory, pharyngeal, and laryngeal muscles initiated by swallowing liquids, is seen in about 50% of cases. Involvement of the respiratory center produces respiratory paralysis, the major cause of death. The median survival after onset of symptoms is 4 days, with a maximum of 20 days unless artificial supportive measures are instituted. Recovery is rare and has been seen only in partially immunized individuals.

**B. Laboratory Findings.** Laboratory diagnosis of rabies in animals or deceased patients is accomplished by demonstration of virus in brain tissue. As negri bodies are not seen in at least 20% of rabies victims, their absence does not rule out the diagnosis. Viral antigen can be demonstrated rapidly by immunofluorescence procedures. Intracerebral inoculation of infected brain tissue or secretions into suckling mice results in death in 3-10 days. Histologic examination of their brain tissue shows negri bodies; both negri bodies and rhabdovirus particles may be demonstrated by electron microscopy. Specific antibodies to rabies virus can be detected in serum, but generally only late in the disease.

## **Differential Diagnosis**

Rabies may initially be mistaken for Guillain-Barre syndrome, an ascending peripheral polyneuritis, but encephalitic symptoms and signs do not develop in the latter illness.

## Complications

Pneumonia and other infectious complications of intensive care are almost invariable. Respiratory paralysis results from infection of the respiratory center.

## Treatment

In the late 1800s Pasteur, noting the long incubation period of rabies, suggested that a vaccine to induce an immune response before the development of disease might be useful in prevention. He apparently successfully vaccinated Joseph Meister, a boy severely bitten and exposed to rabies, with multiple injections of a crude vaccine made from dried spinal cords of rabies-infected rabbits. This treatment emerged as one of the most noteworthy accomplishments in the annals of medicine ([Box 43-3](#) and Prevention & Control section below for more information).

## Prognosis

Of patients with rabies, > 90% die owing to complications of the illness or progressive neurologic dysfunction, especially respiratory paralysis.

## Prevention & Control

Prevention is the mainstay of controlling human rabies. Intensive supportive care has resulted in two or three long-term survivors; despite the best modern medical care, however, the mortality still exceeds 90%. In addition, because of the infrequency of the disease, many cases die without definitive diagnosis. Human hyperimmune antirabies globulin interferon and vaccine do not alter the disease once symptoms have developed. Currently, the prevention of rabies is divided into preexposure and postexposure prophylaxis.

**A. Preexposure prophylaxis.** This type of prophylaxis is recommended for individuals at high risk of contact with rabies virus, such as veterinarians, spelunkers, laboratory workers, and animal handlers. The vaccine currently used in the United States for preexposure prophylaxis uses an attenuated rabies virus grown in human diploid cell culture and inactivated with beta-propiolactone. Preexposure prophylaxis consists of two subcutaneous injections of vaccine given 1 month apart, followed by a booster dose several months later.

**B. Postexposure prophylaxis.** This type of prophylaxis requires careful evaluation and judgment. Every year more than 1 million Americans are bitten by animals, and in each instance a decision must be made whether to initiate postexposure rabies prophylaxis. In this decision the physician must consider (1) whether the individual came into physical contact with saliva or another substance likely to contain rabies virus; (2) whether there was significant wounding or abrasion; (3) whether rabies is known or suspected in the animal species and area associated with the exposure; (4) whether the bite was provoked or unprovoked (ie, the circumstances surrounding the exposure); and

(5) whether the animal is available for laboratory examination. Any wild animal or ill, unvaccinated, or stray domestic animal involved in a possible rabies exposure, such as an unprovoked bite, should be captured and killed. The head should be sent immediately to an appropriate laboratory, usually at the state health department, for search for rabies antigen by immunofluorescence. If examination of the brain by this technique is negative for rabies virus, it can be assumed that the saliva contains no virus and that the exposed person requires no treatment. If the test is positive, the patient should be given postexposure prophylaxis.

Postexposure prophylaxis consists of immediate, thorough washing of the wound with soap and water; passive immunization with 20 IU per kg hyperimmune globulin, of which at least half the dose should be infiltrated around the wound site; and active immunization with antirabies vaccine ([Box 43-4](#)). With human diploid vaccine, five doses given on days 1, 3, 7, 14, and 28 are recommended. Physicians should always seek the advice of the local health department when the question of rabies prophylaxis arises.

## **NIPAH VIRUS**

In 1998, a newly emergent paramyxovirus was identified as the cause of an outbreak of encephalitis, with the first death occurring in the village of Nipah, Malaysia. The cases occurred in farmers and abattoir workers who had close contact with diseased pigs that had a respiratory illness. Nipah virus is closely related to another recently emerged paramyxovirus known as Hendra virus. Thus, the potential for new viral pathogens to emerge continues unabated.

## **PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY**

### **Essentials of Diagnosis**

- Progressive cerebral deterioration in an immunocompromised patient, leading to paralysis and death in < 1 year.
- Multiple lesions in white matter, as revealed by MRI.
- Virions visible on brain biopsy.
- Normal CSF findings (cell count, glucose, protein).
- JC virus (JCV) DNA detectable in CSF by PCR.

### **General Considerations**

**A. Epidemiology.** Progressive multifocal leukoencephalopathy (PML) is a rare syndrome that occurs in immunocompromised patients, including those with AIDS, and is caused by a papovavirus known as JC virus (JCV). The virus was first recovered by coculturing of brain tissue from a patient with progressive multifocal leukoencephalopathy and Hodgkin's disease. Polyomavirus infections are ubiquitous, and most humans are infected with JCV by the age of 15 years.

**B. Microbiology.** The polyomaviruses are small (44 nm in diameter), icosahedral, and lack an envelope. The double-stranded DNA is a circular, supercoiled molecule.

**C. Pathogenesis.** Respiratory transmission is the probable mode of spread. Immune suppression after organ transplantation or during pregnancy is capable of reactivating latent infections.

## **Clinical Findings**

**A. Signs and Symptoms.** Clinical symptoms develop insidiously but progress relentlessly. Patients may have multiple neurologic symptoms unattributable to a single anatomic lesion. Impairment of speech, vision, coordination, mentation, or some combination of these occurs and is followed by paralysis of the arms and legs and finally death in approximately 1 year.

**B. Laboratory Findings.** CSF is normal and does not contain antibody to JCV but may be positive for JCV by PCR. Histologic examination of brain tissue from cases of progressive multifocal leukoencephalopathy reveals cytologic changes within the oligodendrocytes. These cells are adjacent to areas of demyelination. There is little if any inflammatory cell response. Electron microscopy can be used to visualize viral particles in brain tissue, and immunofluorescence can confirm the identity of viral antigen.

JCV grows best in primary human fetal glial cells, which are not readily available. Culture of JCV is therefore performed only in a few research laboratories.

**C. Imaging.** MRI is characteristic with multiple high signal-intense lesions predominantly in white matter.

## **Differential Diagnosis**

Although the MRI is characteristic, similar clinical and radiologic findings can occur with VZV infections in AIDS patients.

## **Complications**

There is progressive worsening of cerebral and neurologic function with death usually occurring 3-6 months from onset.

## **Treatment**

No specific treatment is available, but some stabilization or improvement may occur if the immunosuppression can be reduced, eg, control of HIV infection.

## **Prognosis**

Rarely there may be regression of symptoms especially if immunosuppression can be reduced. Otherwise the disease is fatal and may be especially rapid in AIDS patients.

## **Prevention & Control**

The ubiquitous nature of polyomaviruses and the lack of understanding of their modes of transmission make preventing primary infection unlikely. Minimizing the duration and degree of immunosuppression can decrease reactivation of polyomavirus and the development of PML.

## **DISEASES CAUSED BY UNCONVENTIONAL AGENTS**

### **INTRODUCTION**

Evidence has accumulated during the past 30 years that a variety of progressive neurologic diseases in both animals and humans are caused by viral or other filterable agents that share some of the properties of viruses. These illnesses have been termed slow viral diseases because of the protracted period between infection and the prolonged course of the illness, but a better term is persistent viral infection. Most persistent viral infections involve well-differentiated cells, such as lymphocytes and neuronal cells. These diseases are associated with unconventional viruses that are small, filterable infectious agents transmissible to certain experimental animals, but that do not appear to be associated with immune or inflammatory responses by the host and have not been cultivated in cell culture.

Viral persistence can result from integration of viral nucleic acid into the host genome, mutations that interfere with or severely limit viral replication or antigenicity, failure of host immune systems to recognize virus or infected cells, or some combination of these.

A group of progressive degenerative diseases of the central nervous system with similar pathology has been described. Two of the illnesses, Creutzfeldt-Jakob disease and kuru, occur in humans; two others, scrapie in sheep and goats and progressive encephalopathy in mink, occur in animals. Although the pathogenesis of these four illnesses is not well understood, there are various degrees of neuronal loss, spongiform neurologic changes, and astrocyte proliferation. The incubation periods are months to years, and the diseases have protracted and inevitably fatal courses.

The causes of these diseases are transmissible agents with unusual physical and chemical properties, but their nature is still obscure. They are small and filterable to diameters of 5 nm or less, multiply to high titers in the reticuloendothelial system and brain, produce characteristic infections, and can remain viable even in formalinized brain tissue for many years. They are resistant to ionizing radiation, boiling, and many common disinfectants. Recognizable virions have not been found in tissues, and the agents have not been grown in cell culture. Treatment of infectious material with proteases and nucleases does not decrease infectivity.

Brain extracts from scrapie-infected animals contain a glycoprotein called PrP that is not found in the brains of normal animals. PrP has been termed a prion (proteinaceous infectious particle), and purified proteinaceous extracts of brain tissue in very high dilutions have been shown to transmit disease to experimental animals. Repeated attempts to find associated nucleic acids have been generally unrewarding. PrP is encoded in a host gene, and specific prion mRNA has been found in both normal and

infected tissue. Why the mRNA is translated in the disease and how prion production is apparently initiated by an external source of infectious PrP remain unanswered. During scrapie infection, prion protein may aggregate into birefringent rods and form filamentous structures termed scrapie-associated fibrils, which are found in membranes of scrapie-infected brain tissues.

## **CREUTZFELDT-JAKOB DISEASE**

### **Essentials of Diagnosis**

- Progressive mentation abnormalities leading to disorders of gait and myoclonus.
- Occurs in sixth and seventh decades in previously normal patients.
- May be history of corneal transplant, neurosurgical procedures, or use of human growth hormone.
- Characteristic brain biopsy abnormalities of spongiform degeneration, neuron loss, and astrogliosis.

### **General Considerations**

Creutzfeldt-Jakob disease is a progressive, fatal illness of the central nervous system that is seen most frequently in the sixth and seventh decades of life. The disease is sporadic and found worldwide, with an incidence of disease of 1 case/million people per year. The mode of acquisition is unknown, but a higher incidence of the disease among Israelis of Libyan origin who eat sheep eyeballs has led to speculation that the disease may be transmitted by the ingestion of scrapie-infected tissue. Infection has been transmitted by corneal transplants, by contact with infected electrodes used in a neurosurgical procedure, and by pituitary-derived human growth hormone. In these cases, the incubation period of the disease was ~15-20 months.

Other evidence suggests that a longer latency may follow natural infection. It has been transmitted to chimpanzees, mice, and guinea pigs by inoculation of infected brain tissue, leukocytes, and certain organs. High levels of infectious agent have been found, especially in the brain, where they may reach  $10^7$  infectious doses per gram of brain. Nonpercutaneous transmission of disease has not been observed, and there is no evidence of transmission by direct contact or airborne spread.

### **Clinical Findings**

**A. Signs and Symptoms.** The initial clinical manifestation is a change in cerebral function, usually diagnosed initially as a psychiatric disorder. Forgetfulness and disorientation progress to overt dementia, with the development of changes in gait, increased tone in the limbs, myoclonus, and seizures. The disorder runs a course of 12 months to 4-5 years, eventually leading to death.

**B. Laboratory Findings.** Brain biopsy provides definitive diagnosis and includes spongiform degeneration, neuron loss, and astrogliosis. There are also birefringent rods

and fibrillar structures similar to those in scrapie. Identification of Creutzfeldt-Jakob prion protein (PrP CJD) by fluorescent antibody directed against it is a useful diagnostic adjunct to neuropathologic examination of brain tissue.

**C. Imaging.** EEG is abnormal and characteristic in more than 75% of patients with periodic, symmetric, biphasic or triphasic sharp wavers. Computed tomography (CT) scan or MRI reveals brain atrophy.

### **Differential Diagnosis**

Cases of Creutzfeldt-Jakob disease may resemble PML, but the latter occurs in immunocompromised patients, including those with AIDS, whereas Creutzfeldt-Jakob disease occurs in older, nonimmunocompromised individuals.

### **Treatment**

There is no effective therapy of Creutzfeldt-Jakob disease, and all cases have been fatal.

### **Prevention**

The small risk of nosocomial infection is related only to direct contact with brain tissue. Stereotactic neurosurgical equipment, especially that used in patients with undiagnosed dementia, should not be reused. In addition, organs from patients with undiagnosed neurologic disease should not be used for transplants. Growth hormone from human tissue has now been replaced by a recombinant genetically engineered product. The agent of Creutzfeldt-Jakob disease has not been transmitted to animals by inoculation of body secretions, and no increased risk of disease has been noted in family members or medical personnel caring for patients. Disinfection of potentially infectious material can be accomplished by treatment for 1 h with 0.5% sodium hypochlorite solution or by autoclaving at 121 °C for 1 h.

### **KURU**

Kuru was a subacute, progressive neurologic disease of the Fore people of the Eastern Highlands of New Guinea. In the local Fore dialect, *kuru* means to tremble with fear or to be afraid. The disease was brought to the attention of the western world by Gadjusek and Zigas in the mid-1950s. Although the illness was localized and decreasing in incidence, its study has thrown light on the infectious nature of similar transmissible encephalopathies. Epidemiologic studies indicated that kuru usually afflicted adult women or children of either sex. The disease was rarely observed outside of the Fore region, and outsiders in the region did not contract the disease. The symptoms and signs were ataxia, hyperreflexia, and spasticity, which led to progressive starvation and death. Mental alertness was unaffected until the late stages of illness.

Pathologic examination revealed changes only in the CNS, with diffuse neuronal degeneration and spongiform changes of the cerebral cortex and basal ganglia. No inflammatory response was noted. Inoculation of infectious brain tissue into primates produced a disease that caused similar neurologic symptoms and pathologic

manifestations after an incubation period of approximately 40 months.

Epidemiologic studies indicated that transmission of the disease in humans was associated with ritual cannibalism, practiced mainly by women and young children and occasionally by men. This ritual involved the handling and ingestion of organs of deceased relatives. Inoculation through lesions in the skin and mucous membranes was shown to be the most likely mode of transmission, with clinical disease developing 4-20 years after exposure. Since the elimination of cannibalism from the Fore culture, kuru has disappeared.

## 44 . Miscellaneous Systemic Viral Syndromes — *W. Lawrence Drew, MD, PhD*

### INTRODUCTION

This chapter includes a variety of viral infections that produce severe systemic syndromes ([Table 44-1](#)). In some cases, these infections are transmitted by arthropod vectors; in others, they are acquired by direct contact with the reservoir animal or its excreta. The illnesses may be hemorrhagic fever (eg, dengue, Marburg, Ebola, or Lassa fevers), generalized fever (yellow fever or Colorado tick fever), or pneumonia (caused by hantavirus infection). Only two of these are endemic in the United States, hantavirus infection and Colorado tick fever. All of these viruses are RNA viruses, and vaccine has been developed for one (yellow fever).

### DENGUE & YELLOW FEVER

#### General Considerations

Dengue and yellow fever are both caused by flaviviruses, and each is spread by an arthropod vector. The etiologic agents of dengue are the dengue virus types 1-4, whereas yellow fever is caused by the yellow fever virus. Flaviviruses produce a wide range of diseases including hemorrhagic fevers, arthritis, encephalitis, and hepatitis. Hepatitis C is caused by a flavivirus and is discussed in [Chapter 40](#). Until recently the flaviviruses were included in the *Togaviridae* family, but differences in size, morphology, gene sequence, and replication strategy have made it necessary to classify them as an independent virus family.

**A. Epidemiology.** The flaviviruses are also classified as arboviruses (see [Chapter 43](#)) because they are usually spread by arthropod vectors and as zoonotic viruses because they are spread by animals. These viruses have a very broad host range, including vertebrates (eg, mammals, birds, amphibians, and reptiles) and invertebrates (eg, mosquitoes and ticks).

A cycle of infection occurs in which the virus is transmitted by the arthropod vector and amplified in a susceptible host to allow reinfection of other arthropods. Humans are usually *dead-end* hosts that cannot spread the virus back to the vector because a persistent viremia is not maintained.

These viruses are maintained by *Aedes* spp. mosquitoes in a sylvatic or jungle cycle, in which monkeys are the natural host, and also in an urban cycle, in which humans are the host. *A. aegypti* is a vector for each of these viruses and is a household mosquito. It breeds in pools of water, open sewers, and other accumulations of water in cities.

Dengue occurs throughout the world, with long-known endemic areas in tropical Asia, Polynesia, Micronesia, and East and West Africa. In recent years there has been an upsurge of dengue in South and Central America, the Caribbean, and India, and the spread is predominantly human-mosquito-human, with persistent viremia in the human

allowing infection of mosquitoes. Yellow fever is also found in the Caribbean and the tropics, including Africa but not Asia, and the spread is monkey to mosquito (*A aegypti*) to monkey or to human. In the past decade there has been a major increase in cases especially in Africa. Dengue is the most prevalent flavivirus and causes = 100 million infections/year. In the past, dengue occurred in outbreaks within the United States, and the presence of *A aegypti* and *A albopictus*, another potential vector, in the coastal southern United States means that future outbreaks could occur.

**B. Microbiology.** The flaviviruses are spherical (40-60 nm) enveloped, positive, single-stranded ribonucleic acid (RNA) viruses. They attach to specific receptors expressed on many different cell types from many different species. Flaviviruses can also attach to the Fc receptors on macrophages, monocytes, and other cells when they are coated with antibody. The antibody actually enhances the infectivity of these viruses by providing new receptors for the virus and by promoting its uptake into these target cells.

The virus enters the cell by receptor-mediated endocytosis. The envelope fuses with the membrane of the endosome on acidification of the vesicle to deliver the capsid and genome into the cytoplasm.

Once released into the cytoplasm, the flavivirus genomes are translated via complementary RNA into several proteins. Assembly and budding of flaviviruses occur predominantly in the cytoplasm by using intracellular membranes or vesicles, rather than at the cell surface. Virus release occurs during lysis of the cell.

**C. Pathogenesis.** The flavivirus can cause lytic or persistent infections of both vertebrate and invertebrate hosts. Infections of invertebrates are usually persistent, with continued virus production and no damage to the insect.

Female mosquitoes acquire the flaviviruses on taking a blood meal from a viremic, vertebrate host. The virus infects the epithelial cells of the mid-gut of the mosquito, spreads through the basal lamina of the mid-gut to the circulation, and then infects the salivary glands. The virus sets up a persistent infection and replicates to high titers in these cells. The salivary glands can then release virus into the saliva.

After biting a host, the female mosquito regurgitates virus-containing saliva into the victim's bloodstream. The virus circulates transiently in the plasma, and primary replication occurs in lymph nodes.

The initial viremia, after replication of the virus in these tissues, produces systemic symptoms such as fever, chills, headaches, backaches, and flulike symptoms within 3-7 days of infection. Some of these symptoms can be attributed to the interferon produced after infection of these target cells. Most yellow fever infections do not progress beyond this point, but secondary multiplication of virus occurs in liver, spleen, kidneys, heart, and bone marrow with severe toxicity.

**D. Immune Response.** Both humoral and cellular immunities are elicited and are important to the control of primary infection and prevention of future infections with the flaviviruses. Unlike viruses that initially replicate in the lung, intestine, or viscera, the

primary infection by these viruses is in lymph nodes. This presents the virus immediately to macrophages, the reticuloendothelial system, and the immune response.

Replication of the flaviviruses in the macrophage and endothelial cells produces a double-stranded RNA replicative intermediate that is a good inducer of interferon. The interferon produced soon after infection is released into the bloodstream to limit further replication of virus and stimulate the immune response. The interferon also causes the rapid onset of flulike symptoms characteristic of mild systemic disease.

Circulating immunoglobulin M (IgM) is produced within 6 days of infection, followed by IgG. The antibody blocks the viremic spread of the virus and subsequent infection of other tissues. Immunity to one flavivirus can protect against other flaviviruses by recognition of the common antigens expressed on all members of the viral family. One example of this may be occurring in the Far East, where Japanese encephalitis but not yellow fever virus is endemic despite the presence of the *A aegypti* mosquito vector for yellow fever.

Cell-mediated immunity is also important in control of the primary infection. Natural killer cells, T-cells, and macrophages are activated by interferon and can respond to the cell surface antigens displayed on the infected cells.

Immunity to these viruses is a double-edged sword. Inflammation resulting from the cell-mediated immune response can destroy tissue. Prior immunity can promote hypersensitivity reactions such as delayed-type hypersensitivity, formation of immune complexes with virions and viral antigens, and activation of complement. A non-neutralizing antibody can also enhance uptake of the flaviviruses into macrophages and other cells that express Fc receptors. Such an antibody can be generated to a related strain of virus in which the neutralizing epitope is not expressed or different. The consequences of such partial immunity can be devastating. For example, prior infection by one strain of dengue virus will predispose an individual to dengue hemorrhagic fever (DHF) when infected by another strain of dengue. The weakening and rupture of the vasculature are believed to result from activation of complement and other hypersensitivity reactions. In 1981 an epidemic of dengue-2 virus in Cuba infected a population previously exposed to dengue-1 (between 1977 and 1980). More than 100,000 cases of DHF-dengue shock syndrome (DHF/DSS) resulted, with 168 deaths.

## Clinical Findings

### A. Signs and Symptoms

**Dengue:** After an incubation period of 5-6 days, dengue infection may be asymptomatic or associated with a nonspecific illness or with classical dengue. The latter consists of fever, erythematous rash, and severe myalgias involving the back, head, muscles, and joints. The severity of the myalgia is reflected in the alternative name "breakbone fever." After 1-2 days of fever and rash, the patient's high temperature returns to normal, only to recur 3-4 days later. The recurrence of fever is followed by a second rash that involves face, trunk and limbs but not palms or soles. The fever abates as the second rash develops.

Between the two febrile periods the patient remains symptomatic with gastrointestinal or respiratory symptoms or both. Generalized lymphadenopathy is often present. Resolution occurs in the second week, and fatalities are very rare. On rechallenge with a related strain, dengue can cause severe hemorrhagic disease and shock (DHF/DSS), which occur in tens to hundreds of thousands of cases per year. The hemorrhagic-shock symptoms are attributed to rupture of the vasculature, internal bleeding, and loss of plasma. In addition there is high fever, nausea or vomiting, ecchymosis, and edema of the hands and face.

**Yellow fever:** The incubation period of yellow fever is 3-6 days. Most infections with yellow fever virus are subclinical or anicteric. Icteric yellow fever infections are characterized by severe systemic disease, with failure of the liver, kidney, and heart and hemorrhage of blood vessels. Liver involvement leads to the jaundice from which the disease obtains its name, but massive gastrointestinal hemorrhages (so-called "black vomit") may also occur.

## **Diagnosis**

The principal means of diagnosis is antibody assay, and a variety of serologic methods can be used to diagnose infections. A fourfold increase in titer or seroconversion between acute and convalescent sera is used to indicate a recent infection. The serologic cross-reactivity between viruses in a group or complex limits identification of the actual viral species in many cases. IgM and complement fixing (CF) antibodies are short-lived (1-2 months) and can be useful in documenting acute infection. Demonstrations of viral antigen or viral RNA (by polymerase chain reaction [PCR] assay) in blood or tissue can also prove the diagnosis.

## **Laboratory Findings**

Leukopenia is typical; thrombocytopenia is especially prominent in DHF and yellow fever. Abnormal clotting parameters occur in both, as do increases in liver enzymes. Jaundice occurs in yellow fever, not dengue. Rising creatinine may occur in both diseases.

Flaviviruses can be grown in both vertebrate and mosquito cell lines but are difficult and dangerous to isolate. In addition to cytopathology, the viruses grown in culture can be detected by immunofluorescence or by hemadsorption of avian erythrocytes. After isolation the viruses can be distinguished by RNA analysis or immunoassays.

## **Treatment**

No treatment exists for flavivirus diseases other than supportive care.

## **Prognosis**

The fatality rate from DHF is up to 15% as a result of multiple organ failures. The mortality rate from yellow fever is approximately 10% and also results from multiple organ failures (liver, kidney, and heart).

## Prevention & Control

The easiest means to prevent the spread of flaviviruses is elimination of its vector and breeding grounds. After the discovery by Walter Reed and colleagues that yellow fever was spread by *Aedes aegypti*, the number of cases was reduced by controlling the mosquito population.

Vaccination provides effective protection. A live vaccine (17D) is available against yellow fever virus, for individuals working with the virus or at risk for contact. International travelers to yellow fever-endemic zones should be immunized.

The yellow fever vaccine is attenuated from the 17D strain isolated from a patient in 1927 and passaged extensively in monkeys, mosquitoes, embryonic tissue culture, and embryonated eggs. The vaccine elicits lifelong immunity to yellow fever and possibly other cross-reacting flaviviruses. Vaccines against dengue virus are also being developed.

## MARBURG & EBOLA VIRUS

### General Considerations

Two unique RNA viruses, the Marburg and Ebola viruses, are members of a new family known as filoviruses. These agents can cause severe or fatal hemorrhagic fevers and are endemic in Africa. Laboratory workers have been exposed to the Marburg agent while working with tissue cultures from African green monkeys. Travelers in or residents of central Africa (eg, Zaire or the Sudan) may be infected by the Ebola virus.

**A. Epidemiology.** Marburg virus infection was first detected among laboratory workers in Marburg, Germany, who had been exposed to tissues from apparently healthy African green monkeys. However, it is not clear that these monkeys were, or are, the reservoir for this virus because inoculation of Marburg virus into these monkeys produces death rather than a carrier state. Rare cases of Marburg virus infection have been reported in Zimbabwe and Kenya.

Ebola virus has caused disease only in Zaire and the Sudan. In rural areas of central Africa, = 18% of the population have antibody to this virus, suggesting that subclinical infections do occur. The source of the virus and means of transmission are unknown but are possibly simian viruses. Rarely, secondary cases of filovirus infections have occurred in healthcare workers, usually as a result of accidental needle-stick exposure.

**B. Microbiology.** Filoviruses are single-stranded RNA viruses with a filamentous or threadlike appearance. The filamentous forms have a diameter of 80 nm but may vary in length from 1,000 to ~14,000 nm. Their symmetry is helical, and they are enveloped. Virus is replicated in the cytoplasm and is released by budding from the cell membrane.

### Clinical Findings

**A. Signs and Symptoms.** Illness usually begins with flulike symptoms such as headache and myalgia. Within a few days, nausea, vomiting, and diarrhea occur; a rash

may often develop. Subsequently, there is hemorrhage from multiple sites and death.

**B. Laboratory Findings.** Lymphopenia followed by neutrophilia and severe thrombocytopenia.

## **Diagnosis**

**A. Direct Examination.** Direct fluorescent-antibody (FA) assay can detect viral antigens in tissues; virions can be seen by electron microscopy in serum or liver tissue.

**B. Culture.** Isolation of the virus is the procedure of choice to diagnose filovirus infections. Marburg virus may grow rapidly in tissue cultures (Vero cells), although Ebola virus recovery may require animal (eg, guinea pig) inoculation. All specimens for filovirus diagnosis must be handled with extreme care to prevent accidental infection.

**C. Serology.** IgG and IgM antibodies to filovirus antigens can be detected by immunofluorescence assay (IFA), enzyme-linked immunosorbent assay (ELISA), or radioimmunoassay (RIA). Seroconversion or a fourfold rise of IgG antibody levels is diagnostic of active infection, as is the detection of specific IgM antibody.

## **Treatment**

No treatment is known.

## **Prognosis**

The mortality rate in patients with symptomatic Marburg or Ebola virus infection is = 80%.

## **Prevention & Control**

Since the source of filoviruses is unknown, no measures are available for preventing primary infection. Secondary cases in healthcare workers can be prevented by avoiding exposure to contaminated needles, blood, and so on.

## **HANTAVIRUSES**

### **Essentials of Diagnosis**

- Acute severe respiratory infection in a young adult.
- Exposure to deer mice, eg, in a remote cabin.
- Occurrence of disease in far western United States, especially Four Corners states.
- Diagnosis by serology.
- Can detect viral RNA by PCR of respiratory samples.

## General Considerations

Hantaviruses are members of the bunyavirus group, which is the largest family of viruses and contains several human pathogens including California encephalitis virus (see [Chapter 43](#)). The hantavirus group was first recognized as causing hemorrhagic fevers with renal failure in Asia and Eastern Europe but became much more prominent in the United States when the hantavirus pulmonary syndrome was described in the United States.

**A. Epidemiology.** Unlike other bunyaviruses, which have an arthropod vector, hantaviruses spread from mammal to mammal, including humans, by exposure to aerosolized feces, infected urine, or other secretions.

Hantaviruses have been found throughout the world in a variety of rodents and other species. Most of these viruses are associated with hemorrhagic fever, with or without renal failure. In the United States, however, the most notable hantavirus is the Sin Nombre virus, which is associated with the severe pulmonary syndrome. This virus is found in 10-80% of deer mice in rural areas of North America. Spread of virus from rodents to humans is thought to result from intimate contact with the rodent habitat.

**B. Microbiology.** These viruses are spherical particles 80-120 nm in diameter. The envelope of the virus contains two glycoproteins and encloses three unique nucleocapsids. The nucleocapsids consist of three separate strands of RNA, the RNA-dependent RNA polymerase, and two nonstructural proteins.

**C. Pathogenesis.** In the hemorrhagic fever and hantavirus pulmonary syndromes, the primary lesion is leakage of plasma and erythrocytes through the vascular endothelium. In the former infection these changes are most prominent in the kidney and are accompanied by hemorrhagic necrosis of the kidney; in the latter the primary site of illness is the lung.

## Clinical Findings

**A. Signs and Symptoms.** Hemorrhagic fevers are characterized by fever, petechial hemorrhages, ecchymoses, epistaxis, hematemesis, melena, and bleeding of gums. Death occurs in = 50% of cases with hemorrhagic phenomena.

Hantavirus pulmonary syndrome (HPS) begins with a prodrome of fever, headache, myalgia, and, often, gastrointestinal symptoms lasting approximately 4-5 days. This is followed by the onset of cough and dyspnea. Tachycardia and tachypnea are present, and hypotension may supervene. The respiratory status may progress to acute respiratory distress syndrome (ARDS) and respiratory failure in several hours. HPS should be especially suspected in healthy young individuals who rapidly develop febrile ARDS and who may have been exposed to rodents.

**B. Laboratory Findings.** There are no specific laboratory abnormalities, but hemoconcentration (due to vascular leak) leukocytosis, possibly with left shift, abnormal or increased lymphocytes, thrombocytopenia, or prolonged PTT are seen in the more severe cases. In addition, there is evidence of progressively worsening lung function.

**C. Imaging.** Bilateral, diffuse, interstitial pulmonary infiltrates evolve rapidly in patients with HPS.

**D. Differential Diagnosis.** Acute, severe pneumonia of multiple causes must be distinguished from HPS. In particular, pneumonia caused by influenza A virus, *Legionella* spp., *Chlamydia pneumoniae*, or *Pneumocystis carinii* may be similar, but the epidemiology, age of the patient, and other factors provide clues to the etiology.

**E. Complications.** The principal complication of hantavirus infection is the severe impairment of lung function.

## Diagnosis

**A. Culture.** Virus may be recovered by inoculation of animals or by cell culture.

**B. Direct detection.** Hantavirus RNA can be detected by PCR in clinical specimens from patients with high levels of viremia.

**C. Serology.** IgM-specific assays are the main method to rapidly document acute infection. Seroconversion or a fourfold increase in IgG antibody is useful to document recent infection, but cross-reactions within viral genera are common.

## Treatment

Ribavirin has been used to treat hantavirus pulmonary syndrome, but its efficacy is not established. Supportive therapy of ARDS is critical to survival.

## Prognosis

HPS is fatal in approximately 50% of those who develop clinical illness.

## Prevention & Control

Human disease is prevented by interrupting the contact between humans and rodents. Rodent control also minimizes transmission.

## COLORADO TICK FEVER

### Introduction

Colorado tick fever, an acute disease characterized by fever, headache, and severe myalgia, was originally described in the nineteenth century and is now believed to be one of the most common tick-borne viral diseases in the United States. Although hundreds of infections occur annually, the exact number is not known because it is not a reportable disease. It is caused by a coltivirus, a member of the reovirus family. This family also includes the rotaviruses, which are discussed in [Chapter 37](#).

**A. Epidemiology.** Colorado tick fever has occurred in western and northwestern areas of the United States and western Canada, where the wood tick *Dermacentor andersoni* is distributed. Ticks acquire the virus by feeding on viremic hosts, and they subsequently transmit the virus in saliva when they feed on a new host. Many ticks have been shown to be infected; however, *D andersoni* is the predominant vector and the only proven source of human disease. Natural hosts can be one of many mammals, including squirrels, chipmunks, rabbits, and deer. Exposure to ticks is the major risk factor. Human disease is reported during the spring, summer, and fall months. Colorado tick fever is not contagious but has been transmitted by blood transfusion.

**B. Microbiology.** The coltivirus virion contains double-stranded RNA and is a spherical isohedron measuring 70-85 nm. There is no envelope, and the virus is resistant to lipid solvents.

**C. Pathogenesis.** The viral life cycle includes vertebrates, secondary hosts, and invertebrates (insects). Replication occurs in the cytoplasm of various cells of insect and mammalian origin. Colorado tick fever virus infects hematopoietic cells without severely damaging them. Viremia therefore can persist for weeks or months even after symptomatic recovery.

## Clinical Findings

**A. Signs and Symptoms.** Acute disease occurs after an incubation period of 3-6 days. Although mild or subclinical infections can occur, most infections are symptomatic with fever, chills, headache, photophobia, myalgia, arthralgia, and lethargy. Neither respiratory nor gastrointestinal symptoms are prominent features. Hemorrhagic disease, confusion, and meningeal signs are unusual but, when they do occur, are more likely in children. Few physical signs are present on examination, but fever, conjunctivitis, lymphadenopathy, hepatosplenomegaly, and maculopapular or petechial rash may be present.

**B. Laboratory Findings.** A leukopenia involving both neutrophils and lymphocytes is an important hallmark of the disease. Leukocyte counts are generally less than  $4,500/\text{mm}^3$ , with a relative lymphocytosis. Despite these findings, disease in children and adults is relatively mild, and uncomplicated recovery can be expected.

**C. Imaging.** None reported.

**D. Differential Diagnosis.** Colorado tick fever must be differentiated from Rocky Mountain spotted fever, a tick-borne bacterial infection characterized by extensive rash and severe systemic illness.

**E. Complications.** There are no serious complications.

## Diagnosis

Specific diagnosis can be made by direct detection of viral antigens, viral isolation, or serologic tests. Because the disease is mild and geographically limited, laboratory tests

are not broadly available.

**A. Direct Detection.** Detection of viral antigen in erythrocytes by immunofluorescence staining has been used as a rapid method of diagnosis.

**B. Viral Isolation.** Viral isolation can be performed with serum or plasma during the first few days of disease, before the appearance of neutralizing antibody, and later with the blood clot or washed erythrocytes. Viremia is long lasting and isolation is best accomplished by inoculating suckling mice. Infected mice appear ill in 4-5 days, and viral antigen can be detected by immunofluorescence. Colorado tick fever virus can also be adapted to cell culture, but primary isolation in cell culture is not sensitive.

**C. Serology.** A fourfold rise in antibody between the acute and convalescent specimen or the presence of Colorado tick fever virus-specific IgM in either specimen is presumptive evidence of acute or very recent infection. A sharp decline in IgM antibody occurs ~45 days after onset of illness.

### **Treatment**

No specific treatment is available. The disease is generally self-limited, suggesting that supportive care is sufficient. As mentioned, viremia is long lasting, implying that infected patients should not donate blood soon after recovery.

### **Prognosis**

Recovery occurs in > 99% of cases.

### **Prevention & Control**

Prevention includes avoiding tick-infested areas, using protective clothing and tick repellents, and removing ticks before they bite. In contrast with tick-borne rickettsial disease, in which prolonged feeding is required for transmission, the virus from the tick's saliva can enter the bloodstream rapidly. A formalinized Colorado tick fever vaccine has been developed and evaluated but is not practical for use by the general public.

## **LASSA & OTHER HEMORRHAGIC FEVERS**

### **Introduction**

Lassa fever, with its focus of endemicity in West Africa, is the best known of the arenavirus hemorrhagic fevers. Other agents, such as Junin and Machupo, cause similar syndromes in different geographic areas (Argentina and Bolivia, respectively). Lymphocytic choriomeningitis virus (LCM) is an arenavirus that causes viral meningitis (see [Chapter 43](#)).

**A. Epidemiology.** Each arenavirus infects specific rodents; for example, the natural host of Lassa fever virus is a small Nigerian rodent. Chronic infection is common in these animals and leads to chronic viremia and virus shedding in saliva, urine, and feces. Infection of humans is primarily from droppings and may occur by way of

aerosols, contamination of food, or fomites. Bites are not a usual mechanism of spread. Persistently infected rodents do not usually exhibit illness. Human-to-human infection occurs with Lassa fever virus through contact with infected secretions or body fluids, but this mode of spread rarely if ever occurs with other arenaviruses. Arenaviruses do not require insects for spread. The incubation period for arenavirus infections averages 10-14 days.

**B. Microbiology.** Arenaviruses are pleomorphic, helical, and enveloped, with a size of 50-300 nm. They contain RNA in a linear configuration. Replication is in the cytoplasm, with budding from the host cell cytoplasm.

**C. Pathogenesis.** Arenaviruses are able to infect macrophages and possibly cause the release of mediators of cell and vascular damage. In certain laboratory animals the clinical severity of arenavirus disease appears to be directly related to the host's immunologic response. The greater the immune (especially T lymphocyte) response, the worse the disease. Whether these mechanisms are operative in human infection is not clear. In patients with the hemorrhagic fever, petechiae and visceral hemorrhage occur, as do liver and spleen necrosis, but not vasculitis.

### **Clinical Findings**

Clinical illness is characterized by fever and coagulopathy. Hemorrhage and shock occur and occasionally cardiac and liver damage. Pharyngitis, diarrhea, and vomiting may be very prevalent, especially in patients with Lassa fever. The diagnosis is suggested by recent travel to endemic areas.

### **Diagnosis**

The diagnosis of arenavirus infections is usually made through serologic tests, although the virus can be recovered by inoculation of blood or cerebrospinal fluid into suckling mice or Vero monkey cells. Throat specimens can yield arenaviruses, as can urine. Substantial risk is present for laboratory workers handling body fluids. Therefore, if the diagnosis is suspected, laboratory personnel should be warned and specimens processed only in facilities specialized for the isolation of contagious pathogens.

### **Treatment**

Only supportive therapy for patients with arenavirus infection is currently available. Uncontrolled studies suggest that ribavirin may be useful for those with Lassa fever.

**Prognosis.** Death occurs in = 50% of those with Lassa fever and in a smaller percentage among those infected with the other arenaviruses.

### **Prevention & Control**

Prevention of these rodent-borne infections rests on control of the vector's contact with humans. Laboratory-acquired cases can be reduced by processing samples for arenavirus isolation in at least P<sub>3</sub> biosafety facilities and not in the usual clinical virology laboratory.

TABLES

---

## 45 . Papovaviruses — *W. Lawrence Drew, MD, PhD*

### PAPILLOMAVIRUSES

#### Essentials of Diagnosis

- Causes warts and genital lesions; latter may be premalignant or malignant.
- Hyperplasia of prickle cells and excess keratin in skin biopsy, vacuolated squamous epithelial cells.
- Human papillomavirus (HPV) antigen detected in clinical samples by immunofluorescence assay (IFA), immunoperoxidase.
- HPV DNA detected in biopsies, cervical smears.

#### General Considerations

**A. Epidemiology.** Papillomaviruses (HPVs) cause skin warts, most commonly in children and young adults, which may reflect acquired immunity in older age groups ([Box 45-1](#)). Laryngeal papillomas are found most commonly in young children and middle-aged adults. Genital warts (condylomas) are most common among sexually active patients and are sexually transmitted. Recent studies suggest that genital HPV infections may occur in 20% of females and are associated with cervical dysplasia, neoplasia, or both.

**B. Microbiology.** HPVs are nonenveloped, icosahedral virions measuring 50 nm in diameter. Their DNA is double-stranded and circular. The capsid consists of two structural proteins forming 72 capsomeres. Classification of HPV is based on DNA relatedness because these viruses cannot be grown in tissue culture. Based on DNA sequence homology, at least 77 HPV types have been identified. Viruses in similar groups frequently cause similar types of warts.

**C. Pathogenesis.** HPVs infect and replicate in cutaneous and mucosal epithelium, inducing epithelial proliferations (warts). These growths remain local and generally regress spontaneously. However, the HPV genome can persist in transformed cells and may be involved in maintaining tumor growth by increasing cell proliferation or prolonging the life of epithelial cells.

### CLINICAL SYNDROMES

#### SKIN WARTS

There are two main types of skin warts: flat, or superficial, and plantar, or deep growths. Most persons are infected with the common HPV types (1 through 4), which infect keratinized surfaces, usually on the hands and feet, and occur frequently in childhood or

early adolescence. They regress spontaneously if given time.

## **BENIGN HEAD & NECK TUMORS**

Single oral papillomas are benign epithelial tumors of the oral cavity. They are pedunculated with a stalk and usually have a rough papillary appearance to their surface. They can occur in humans of any age group, are usually solitary, and rarely recur after surgical excision. Laryngeal papillomas are most often caused by HPV-11 and are the most common benign epithelial tumors of the larynx; however, laryngeal papillomatosis is usually considered a life-threatening condition in children because of the danger of airway obstruction. Occasionally, papillomas may extend down the trachea and into the bronchi.

## **ANOGENITAL WARTS**

Genital warts (condyloma acuminata) occur almost exclusively on the squamous epithelium of the external genitalia and perianal areas, and ~90% are caused by HPV-6 and -11. Anogenital lesions infected with these HPV types rarely progress from benign to malignant conditions in otherwise healthy individuals.

## **CERVICAL DYSPLASIA & NEOPLASIA**

### **Introduction**

Cytologic changes characteristic of infection (koilocytotic cells) in cervical smears that are Papanicolaou stained are detected in ~5% of women. Infection of the female genital tract by HPV-16 and -18 and, in 30% by other types is associated with intraepithelial cervical dysplasia, neoplasia, and cancer. The first neoplastic changes noted by light microscopy are termed dysplasia and ~40-70% of these lesions undergo spontaneous regression. The development of cervical cancer is thought to proceed through a continuum of progressive cellular changes from mild (cervical intraepithelial neoplasia I [CIN I]) to moderate (CIN II), to severe (CIN III) dysplasia, carcinoma in situ, or both. This sequence of events has been documented to progress over a period of 1-4 years.

### **Diagnosis**

A wart can be confirmed microscopically by its characteristic histologic appearance, consisting of hyperplasia of prickle cells and the production of excess keratin (hyperkeratosis). HPV infection is suggested by the presence of koilocytotic (vacuolated) squamous epithelial cells that are rounded and occur in clumps. HPV virions can be seen by electron microscopy in lesions as can HPV antigens by immunofluorescent and immunoperoxidase techniques. Use of molecular probes to detect HPV DNA is the method of choice for establishing the presence of HPV genomes in cervical swabs and in tissue. HPVs do not grow in cell cultures, and tests for HPV antibodies are rarely used except in epidemiologic surveys.

### **Treatment**

Spontaneous disappearance of warts is the rule, but because this may take many

months to years, intervention is sometimes warranted, especially for painful or bulky lesions ([Box 45-2](#)). Removal by surgical cryotherapy, electrocautery, or chemical means can be effective, although recurrences are common. Application of podophylline or salicylic acid with formalin or glutaraldehyde is effective. Injection of interferon is also beneficial. Surgery may be necessary for laryngeal papillomas.

## Prevention & Control

Vaccination with formalin-inactivated HPV or autogenous preparations from the patient's own lesions has been at least partly effective, especially for anogenital warts ([Box 45-3](#)). Neither of these approaches is widely used, but vaccines may assume greater importance if an etiologic relationship between HPV and carcinoma is established. At present the best prevention is avoidance of direct contact with infected tissue.

## POLYOMAVIRUSES

### Essentials of Diagnosis

- These viruses are latent in humans and reactivate to cause disease in immunocompromised patients.
- JC virus is the cause of progressive multifocal leukoencephalopathy; BK virus causes urinary tract disease.
- Papovavirus disease is diagnosed by urinary cytology or detection of viral antigens or DNA in clinical specimens.

### General Considerations

**A. Epidemiology.** There are two important human papovaviruses: BK and JC viruses. SV40 is a simian polyomavirus that may be present in monkey kidney cultures and did contaminate certain lots of oral poliovirus vaccine (see below). The most important disease caused by a papovavirus is progressive multifocal leukoencephalopathy (PML) (see [Chapter 43](#)).

Approximately 60-80% of adults have antibody to both BK and JC viruses (BKV and JCV, respectively). There is a major rise in antibody prevalence during childhood, with BKV infections occurring earlier than those caused by JCV. These viruses remain latent and are reactivated by immunosuppression.

**B. Microbiology.** Polyoma virions are nonenveloped icosahedrons ~45 nm in diameter. The genomes of BKV, JCV, and SV40 are closely related and are divided into early, late, and noncoding regions. The early region codes for nonstructural T (transformation) proteins, and the late region codes for three viral capsid proteins (VP1, VP2, and VP3), which are receptor-binding sites. The noncoding region is the site of DNA replication and transcription control. The replicative cycle includes penetration by endocytosis, followed by uncoating and viral multiplication in the nucleus. Infection may result in cell lysis or nonproductive infection. The viral replication cycle takes 48-72 h.

**C. Pathogenesis.** Polyomaviruses have a high specificity for certain hosts and particular cells within that host. In humans both JCV and BKV probably infect via the respiratory tract, spread by viremia, and infect the kidney. In immunocompromised patients, reactivation of virus in the kidney leads to urinary tract infection (BKV) or viremia and central nervous system infection (JCV). Suppressed T cell function appears most responsible for reactivation. Histopathology results from the cytolytic effects of the virus rather than local immunologic factors. BKV and JCV cause tumors when injected into hamsters; however, they are not consistently associated with any human tumors.

Early lots of poliomyelitis vaccine were contaminated with SV40, a simian polyomavirus, which was undetected in the cell cultures of monkey origin used to prepare the vaccine. Although many people were vaccinated with the contaminated lots, no SV40-related tumors have been reported during 25 years of follow-up.

## **CLINICAL SYNDROMES**

### **Introduction**

Primary infection is virtually always asymptomatic, although mild respiratory symptoms might occur, and cystitis has been reported ([Box 45-4](#)). In ~40% of immunocompromised patients, urinary excretion of BKV and JCV is commonly observed. Reactivation also occurs in pregnancy, but no effect on the fetus has been established.

Ureteral stenosis in renal transplant patients appears to be associated with BKV, as does hemorrhagic cystitis in bone marrow transplant recipients. (See [Chapter 43](#) for discussion of PML.)

### **Diagnosis**

Cytologic examination of urine is the simplest method for documenting active polyomavirus infection. Virus may be demonstrated in tissue or cells by immunofluorescent, immunoperoxidase, or DNA hybridization techniques, and biopsy of brain has been the definitive method for diagnosing PML. Polymerase chain reaction analysis of cerebrospinal fluid is replacing biopsy as a noninvasive procedure for diagnosing JCV infection of the CNS. Culturing of polyomaviruses can be performed but requires specialized cells and may take weeks to months. Serology is not useful to diagnose PML because serum antibody is common in the general population.

### **Treatment**

No treatment is established for BKV or JCV infection. PML has been treated with numerous different antiviral agents, and there have been conflicting results, especially with cytosine arabinoside. Spontaneous remission may occur, and diminishing immunosuppression may be beneficial.

### **Prevention & Control**

No preventive or control measures have been established for BKV or JCV infection.

## Section V. Bacterial Infections

### 46 . Staphylococci — *Karen Bloch, MD, MPH*

#### **STAPHYLOCOCCUS AUREUS**

##### **Essentials of Diagnosis**

- Large gram-positive cocci (0.7-1.5 um in size).
- Colonies surrounded by zone of hemolysis on blood agar.
- Colonies pigmented pale yellow to deep orange macroscopically.
- Cluster in grapelike bunches microscopically.
- Biochemically differentiated from streptococci by presence of the enzyme catalase.
- Biochemically differentiated from other staphylococci by presence of the enzyme coagulase.
- Analysis of chromosomal DNA can identify clonal isolates (useful in epidemiologic studies).

##### **General Considerations**

**A. Epidemiology.** *Staphylococcus aureus* colonizes the human skin, vagina, nasopharynx, and gastrointestinal tract. Colonization occurs shortly after birth and may be either transient or persistent. Published studies differ widely in estimates of the prevalence of *S aureus* carriage. Between 10% and 35% of healthy adults have transient or persistent nasopharyngeal colonization. This percentage is increased among health care workers and individuals with repetitive needle exposure such as diabetics, patients on hemodialysis, and injection drug users. Vaginal carriage in premenopausal women approaches 10%, with the highest prevalence rates found at the start of the menstrual cycle.

Phage typing and molecular techniques have demonstrated that invasive disease is usually caused by the colonizing strain; therefore it is not surprising that groups with the highest prevalence of colonization are at the highest risk for *S aureus* infection. Fortunately, progression to infection is relatively unusual, occurring in only 2.5% of colonized nursing home patients and 37% of postoperative patients (compared with 11% of noncolonized postsurgical patients).

Acute infections in noncolonized patients are usually attributed to physical contact with a colonized individual. Studies have proven that health care workers can serve as vectors for transmission of staphylococci. The importance of person-to-person transmission

underscores the need for strict hand washing in hospital settings. Other, less common, methods of acquisition include airborne transmission and spread from clothing and bed linens.

**B. Microbiology.** Staphylococci are aerobic, nonmotile, gram-positive cocci frequently cultured from environmental and clinical specimens. Although these organisms are generally considered commensal (ie, nonpathogenic normal flora) when cultured from the skin, nasopharynx, intestinal tract, and vagina, they may at times cause life-threatening disease. The clinical interpretation of a culture growing staphylococci depends on the bacterial species, host characteristics, and culture source.

Staphylococci share common characteristics that allow differentiation from other gram-positive cocci ([Table 46-1](#)). All species produce the enzyme catalase. Staphylococci are distinguished microscopically from other gram-positive cocci by a propensity to form clusters, as suggested by the genus name, which comes from the Greek *staphule*, meaning "bunch of grapes." Despite these common properties, individual staphylococcal species differ with respect to microbiologic properties, epidemiologic patterns, and clinical manifestations. Many of these differences relate to the production of the enzyme coagulase, and the genus has traditionally been subdivided into *S aureus* (which is coagulase-positive) and the relatively homogeneous coagulase-negative staphylococci (CoNS).

On blood agar media, *S aureus* can be distinguished macroscopically from CoNS by a ring of hemolysis surrounding the colonies. Colonies often have a golden-yellow hue (*aureus* meaning golden in Latin) as a result of the presence of carotenoids. While these morphologic characteristics may serve as general guides for differentiation of *S aureus* from the CoNS, definitive diagnosis is made by demonstrating the presence of coagulase through agglutination of rabbit plasma.

*S aureus* possesses a number of properties that contribute to organism virulence and host disease ([Table 46-1](#)): the presence of an extracellular capsule (sometimes called a slime layer), the enzymes catalase and coagulase, and membrane exotoxins that inhibit host immune defenses. More than 70% of strains harbor transmissible plasmids that produce beta-lactamase under certain conditions. These inducible beta-lactamases inactivate penicillin and some first-generation cephalosporins. In addition, an increasing proportion of isolates have intrinsic (as opposed to inducible) resistance to all beta-lactam-containing antibiotics. These strains, known collectively as methicillin-resistant *S aureus* (MRSA), produce penicillin-binding proteins with low affinity for penicillin, nafcillin, and other beta-lactam drugs. Because antibiotics cannot attach to their target site, the bacteria are not inhibited or killed in the presence of these drugs. Finally, some bacteria produce toxins that damage specific host organ systems such as the gastrointestinal tract (enterotoxins) and dermis (epidermolytic toxins).

**C. Pathogenesis.** Much is now known about the process of *S aureus* infection, which proceeds in a series of steps. Adherence, a necessary condition for colonization, occurs when a bacterium attaches to the teichoic acid component of the host cell wall. Adherence and colonization do not activate the host immune system. Invasion occurs when the epidermis is disrupted through an injury or an iatrogenic procedure, and bacteria gain access to the tissues or bloodstream, activating immune defenses. The

interplay between bacterial virulence factors ([Table 46-1](#)) and host susceptibility factors ([Table 46-2](#)) determines whether bacterial proliferation occurs. The final step in the pathogenesis of clinically apparent infection is tissue injury, either localized, as with an abscess, or systemic, as in toxic shock syndrome.

## CLINICAL SYNDROMES

### INTRODUCTION

*S aureus* causes a wide spectrum of clinical disease, ranking among the most common bacterial causes of skin and soft tissue infection, gastroenteritis, wound infection, septic arthritis, bacteremia, endocarditis, and osteomyelitis. This section focuses on syndromes unique to *S aureus* and on syndromes for which *S aureus* is the most common bacterial agent.

### PYOGENIC CUTANEOUS INFECTIONS

#### Clinical Findings

**A. Signs and Symptoms.** *S aureus* is the leading bacterial cause of pyogenic skin lesions ([Box 46-1](#)). Folliculitis, infection of the hair follicles, is a local suppurative process causing indurated papules or pustules, often with a hair exiting from the center of the lesion. There is local erythema and tenderness, but the patient is not systemically ill.

A furuncle ("boil") begins as a hair follicle infection and extends locally to form an abscess, characterized by liquefaction of necrotic tissue. Clinically, this presents as a well-circumscribed, fluctuant, tender, erythematous collection. Infection on occasion spreads to the surrounding epidermis, causing cellulitis. Common sites for furuncles include the face, neck, axilla, back and groin.

Carbuncles differ from furuncles in that they extend to the deeper subcutaneous tissues. They are most commonly found on the posterior neck and upper back. These infections are less circumscribed than furuncles and may be associated with draining fistulae. Patients with carbuncles are often systemically ill, exhibiting fevers, chills, and malaise.

**B. Laboratory Findings.** Folliculitis and furunculosis are usually localized processes, and the peripheral WBC count is normal. Carbunculosis is associated with a systemic immune response, manifested by leukocytosis and a predominance of immature WBC. Blood cultures are frequently positive in patients with carbuncles.

**C. Differential Diagnosis.** The differential diagnosis of folliculitis includes pseudofolliculitis barbae, insect bites, acne vulgaris, foreign body reactions, and milia. Alternative diagnoses for furunculosis include pilonidal cysts, cystic acne, and hidradenitis suppurativa. A carbuncle may be confused with a furuncle, a deep-seated skin infection such as necrotizing fasciitis, or a kerion.

**D. Complications.** These infections are generally self-limited and do not disseminate beyond the skin. Local complications include cellulitis and osteomyelitis of adjacent

bone. There have been anecdotal reports of facial lesions ascending intracranially to cause septic cavernous vein thrombosis. Bacteremia, a relatively common complication of carbunculosis, may result in secondary infections including endocarditis, hematogenous osteomyelitis, and pneumonia.

### Diagnosis

BR>Pyogenic skin infections are diagnosed by clinical exam, with culture of purulent material obtained by incision and drainage to confirm staphylococcal infection and determine antibiotic susceptibility patterns. Blood cultures may also guide antibiotic therapy in patients with signs of systemic illness.

### Treatment

Treatment for folliculitis and furunculosis is primarily supportive ([Box 46-2](#)). Stringent attention to hygiene is key; the affected areas should be washed at least twice daily with a mild antibacterial soap, and overlying clothing should be loose fitting. Furuncles either spontaneously drain or require incision and drainage once they have matured (come to a head). Antibiotic therapy is rarely necessary for these conditions. Carbuncles require both local surgical debridement and parenteral antibiotic therapy.

Recurrent pyogenic skin infections are common in patients with nasopharyngeal colonization. Eradication of staphylococcal carriage with mupirocin may be indicated after repeated episodes of furunculosis. This regimen has good short-term efficacy; however, recolonization frequently occurs, and emergence of mupirocin resistance has been reported.

## NONPYOGENIC SKIN INFECTIONS

### Clinical Findings

**A. Signs and Symptoms.** Impetigo and staphylococcal scalded skin syndrome (SSSS) are primarily childhood diseases. More than 70% of cases of impetigo are caused by *S aureus*, with the remainder attributed to pyogenic streptococci or mixed infection. Impetigo begins as a scarlatiniform eruption in a previously traumatized area that blisters then ruptures to form a wet, honey-colored crust ([Figure 46-1](#)). Common sites for infection are the face and trunk. The primary symptom in impetigo is localized pain; fever and constitutional symptoms are rarely seen ([Box 46-1](#)). Physical exam often reveals regional lymphadenopathy.

Staphylococcal scalded skin syndrome encompasses three distinct clinical scenarios: bullous impetigo, staphylococcal scarlet fever, and generalized scalded skin syndrome. The histologic finding common to all these conditions is cleavage of the epidermis at the level of the stratum granulosum caused by an exfoliative toxin. Bullous impetigo, the most common of the three types of SSSS, is almost exclusively seen in children < 5 years old. The disease begins as localized erythroderma progressing rapidly to form multiple vesicles, which coalesce into flaccid bullae. Constitutional symptoms are minimal during the early phases, and the bullae spontaneously rupture after 1-2 days to form nontender, brown, varnishlike crusts ([Figure 46-2](#)). Commonly involved areas include the face, trunk, and perineum. A variant of this condition, staphylococcal scarlet

fever, causes a scarlatiniform rash with late, limited desquamation, without an intermediate bullae stage.

Generalized scalded skin syndrome (known as Ritter's syndrome in neonates) differs from the more benign bullous impetigo in that there is diffuse dermal involvement, causing extensive desquamation. Nikolsky's sign, the sloughing of intact skin on light touch, is frequently seen. Following spontaneous bullae rupture, the skin is denuded and painful ([Figure 46-3](#)), and fever is common.

**B. Laboratory Findings.** Patients with generalized SSSS may have leukocytosis with a predominance of immature white cells. Blood cultures, particularly in adults, may be positive.

**C. Differential Diagnosis.** The differential diagnosis of impetigo includes herpes simplex and varicella zoster infections, contact dermatitis, scabies, and tinea corporis. SSSS may be confused with other bullous skin diseases (pemphigus vulgaris and bullous pemphigoid), Stevens-Johnson syndrome, thermal burn, and dermatitis herpetiformis.

**D. Complications.** Suppurative lymphadenitis, cellulitis, and staphylococcal sepsis are uncommon complications of impetigo. Complications of generalized SSSS include dehydration, bacteremia, and secondary infections. Mortality in children with generalized SSSS is 1-10%, whereas the mortality rate among adults is > 50%.

## Diagnosis

Impetigo is diagnosed by the presence of the classic golden crusts on physical examination; a microbiologic diagnosis is rarely necessary. SSSS can be diagnosed by rupturing an intact bulla and culturing the extravasated fluid for *S aureus*. Latex agglutination or ELISA confirms the presence of the staphylococcal exfoliative toxin.

## Treatment

Mild cases of (nonbullous) impetigo may be treated with topical mupirocin; however, more serious infections need oral antibiotics ([Box 46-2](#)). Bullous impetigo requires treatment with an oral antistaphylococcal agent. The high rates of morbidity and mortality in generalized SSSS mandate hospitalization for aggressive hydration and parenteral antibiotics. Extensive desquamation predisposes patients to secondary infections, and they should receive aggressive topical care such as that given to burn victims.

## TOXIC SHOCK SYNDROME

### Introduction

The toxic shock syndrome (TSS) is a heterogeneous complex of symptoms attributed to TSST-1 toxin-producing *S aureus*. Two variants have been described: menstruation-associated and nonmenstrual disease. Cases of menstruation-associated disease are correlated with the use of superabsorbent tampons. Diaphragm

contraception, parturition, indwelling foreign bodies, and recent surgery predispose to nonmenstrual disease.

## Clinical Findings

**A. Signs and Symptoms.** Myalgias, headache, malaise, watery diarrhea, and confusion (in the face of a normal neurologic exam) are early symptoms of TSS, typically preceding the rash by 2-3 days. Erythroderma is initially seen on the palms and soles, progressing to a confluent generalized rash. Hypotension and fever are invariably present at this stage. Multisystem organ failure may be present early or late in the disease course. Dermal desquamation, particularly of the palms and soles is a late sequela of TSS, occurring 7-14 days after the onset of symptoms.

**B. Laboratory Findings.** The laboratory abnormalities in TSS reflect the diverse organ systems involved. Laboratory abnormalities included as criteria for case definition (see [Table 46-3](#)) include an elevation in creatine phosphokinase, acute renal insufficiency, sterile pyuria, elevated liver function tests, and thrombocytopenia. Disordered electrolytes (particularly hypocalcemia and hypophosphatemia), neutrophil predominance on white blood cell differential, and anemia, while not explicitly mentioned in the case definition, may also be found in patients with TSS.

**C. Differential Diagnosis.** Other entities causing rash, hypotension, or fever that may be confused with staphylococcal TSS include streptococcal TSS, Rocky Mountain spotted fever, viral infection with exanthem (such as measles or EBV), meningococemia, leptospirosis, the septic shock syndrome, Kawasaki's disease, and drug-induced reactions (such as erythema multiforme or toxic epidermal necrolysis). A thorough history with particular attention to tick exposures, ill contacts, travel, pets, and medication use is essential in excluding the mimicking conditions.

**D. Complications.** Case fatality rates for TSS range from 3% to 6% and are higher for nonmenstrual disease. Digital gangrene may occur as a result of sustained hypotension and impaired extremity perfusion. Neuropsychiatric symptoms such as emotional lability, impaired memory, and decreased concentration are common sequelae in survivors.

## Diagnosis

Formal criteria for the diagnosis of TSS have been developed to facilitate surveillance and standardize case definition ([Table 46-3](#)). Increased awareness of the association between menstruation, tampon use, and TSS has led to improved diagnosis of menstruation-associated disease. Nonmenstrual disease lacks unifying epidemiologic characteristics, which makes diagnosis more difficult. Postoperative TSS is particularly difficult to diagnose, as surgical wound inflammation may be minimal, and early signs are nonspecific.

The diagnosis of TSS is supported by a culture of TSST-1-producing *S aureus* from an infected focus, although this is not a criterion for case definition. TSST-1-producing staphylococci are isolated from the vagina in 85% of menstruation-associated disease but are isolated from infected foci in only 40-60% of cases of nonmenstrual disease. *S aureus* bacteremia rarely occurs with TSS.

## Treatment

Treatment requires identification and removal of foreign bodies (such as tampons) and irrigation and debridement of infected wounds. Aggressive hydration and close hemodynamic monitoring are essential in the early stages of TSS. All patients should be treated with parenteral agents active against staphylococci ([Box 46-3](#)). In vitro, clindamycin inhibits TSST-1 protein synthesis, providing at least a theoretical basis for combination therapy with this agent and a penicillinase-resistant penicillin.

## PRIMARY BACTEREMIA & ENDOCARDITIS

### Introduction

Staphylococci (both *S aureus* and CoNS) have emerged as the two most common organisms cultured from patients with primary bloodstream infections. The term "primary bacteremia" refers to positive blood cultures without an identifiable anatomic focus of infection. Differentiation of primary bacteremia from infective endocarditis (IE), in which infection of the cardiac valves leads to continuous bacterial seeding of the bloodstream, may challenge even the most experienced clinician. Primary *S aureus* bacteremia is associated with insulin-dependent diabetes, the presence of a vascular graft, and, most significantly, the presence of an indwelling intravascular catheter. Risk factors for IE include structurally abnormal valves, recent injection drug use, and the presence of a prosthetic cardiac valve.

### Clinical Findings

**A. Signs and Symptoms.** Patients with primary *S aureus* bacteremia are systemically ill, with fever, chills, malaise, and hypotension. *S aureus* endocarditis is usually an acute disease, with a presentation indistinguishable from *S aureus* bacteremia. For the most part, patients lack the classic cutaneous stigmata associated with subacute bacterial endocarditis ([Box 46-4](#)). A new or changed cardiac murmur, or evidence of embolic disease, in the setting of *S aureus* bacteremia strongly supports the diagnosis of IE. Endocarditis in injection drug users involves the tricuspid valve in 75% of cases, and respiratory complaints, attributable to septic pulmonary embolization with infarction, predominate.

**B. Laboratory Findings.** Laboratory findings in primary bacteremia and IE are nonspecific; an elevated WBC count is the most common abnormality. The erythrocyte sedimentation rate, which is elevated in subacute IE, may be normal. Because endocarditis causes continuous seeding of the bloodstream, it is common to see "high-grade" bacteremia, with multiple positive blood cultures from different venous sites drawn at disparate time intervals.

**C. Imaging.** The classic radiographic finding in patients with right-sided endocarditis is the presence of multiple pleural-based densities (so-called "cannon-ball lesions") caused by septic pulmonary emboli. Radiologic signs with left-sided disease are manifestations of congestive heart failure, ranging from increased interstitial markings to parenchymal opacification from pulmonary edema.

**D. Differential Diagnosis.** Culture of *S aureus* from the blood should prompt a thorough search for an infected primary focus. Common local infections predisposing to secondary bacteremia include infections of indwelling intravenous catheters or other prosthetic material, postoperative wound infections, septic arthritis, osteomyelitis, and cellulitis. In the absence of an identifiable anatomic focus of infection, the clinician must differentiate primary bacteremia from infective endocarditis.

**E. Complications.** Complications of *S aureus* bacteremia are primarily from bacterial seeding of the viscera, with subsequent end-organ infections such as endocarditis (a sequela of uncomplicated bacteremia in 5-10% of cases), osteomyelitis, septic arthritis, cerebral abscess, and perinephric abscess. Mortality with primary bacteremia ranges from 25% to 40%. Factors associated with a fatal outcome include the absence of a removable source of infection (such as an intravenous line), age > 60 years, and underlying pulmonary disease.

Morbidity in left-sided IE is due to progressive valve destruction or embolic phenomena. Valve failure results in congestive heart failure, which may be insidious or may present as acute pulmonary edema following rupture of the chordae tendineae. New-onset heart block is the earliest sign of a myocardial ring abscess. Recurrent systemic emboli on appropriate therapy or persistent bacteremia are indications for surgical valve replacement. The mortality rate for left-sided IE ranges from 20% to 44%, as compared with < 5% for right-sided disease.

**F. Differential Diagnosis.** Differentiating primary bacteremia from IE causing continuous intravascular seeding is often difficult: the probability that blood cultures growing *S aureus* represent IE varies from 10% to 40%, depending on the population studied. The distinction between these two syndromes is important as IE requires prolonged therapy and carries a worse prognosis.

Several sets of diagnostic criteria for IE have been proposed. The most sensitive is the Duke Criteria, which incorporates echocardiogram findings with clinical factors to stratify the risk of IE. Patients with community-acquired *S aureus* bacteremia or nosocomially acquired cases with known cardiac valvular disease or prosthetic valves have the highest probability of having IE and should be evaluated for cardiac involvement with a transthoracic echocardiogram.

## Treatment

Optimal empiric treatment for primary bloodstream infection is based on the likelihood that an organism is resistant to methicillin (defined as an MIC = 8 ug/ml). Penicillinase-resistant semisynthetic penicillins (PRSP) such as oxacillin or nafcillin are the recommended agents for community-acquired infections, or nosocomial infections in institutions with documented low prevalence rates for MRSA. In facilities with significant isolation rates for MRSA, empiric treatment with vancomycin is indicated. A PRSP should be substituted as soon as the bacteria is proven susceptible, as vancomycin is less active against *S aureus*, and patients treated with this agent have longer duration of fever and bacteremia. Regardless of which agent is used, treatment for uncomplicated bacteremia should be continued 10-14 days.

Bacteremia attributed to an infected indwelling central venous catheter is difficult to eradicate without removal of the foreign body. Subcutaneous infection along the catheter tunnel, hemodynamic instability, fever or rigors more than 48 hours after initiating antibiotic treatment, persistently positive blood cultures, or septic venous thrombophlebitis mandate prompt catheter removal.

Therapy for IE is guided by the clinical scenario ([Box 46-5](#)). Patients with uncomplicated, right-sided, methicillin-sensitive *S aureus* endocarditis respond to 2 weeks of treatment. Extrapulmonary embolic disease, persistent symptoms or bacteremia after more than 96 hours of therapy, high-level aminoglycoside resistance, or concurrent left-sided valvular involvement require a full course of therapy, lasting 4-6 weeks.

Aminoglycosides act synergistically with beta-lactams against staphylococci; their use reduces the time to clearing of the bacteria from the bloodstream, although they do not affect mortality rates in IE. Synergy occurs at relatively low doses of aminoglycosides, with optimal peak and trough levels for gentamicin 3.0 and 0.5  $\mu\text{m/L}$ , respectively.

The penicillin allergic patient with IE presents a treatment challenge. For patients without a history of immediate-type hypersensitivity, a first-generation cephalosporin is the preferred agent. Patients with a history of anaphylaxis or other severe penicillin allergy should receive vancomycin. The potential for antagonism between vancomycin and rifampin exists, and adjuvant therapy with rifampin should be reserved for patients failing monotherapy.

## **OSTEOMYELITIS**

### **Clinical Findings**

**A. Signs and Symptoms.** Osteomyelitis is divided into two subcategories based on the acuity of onset. Acute osteomyelitis, more commonly seen in children, is associated with sudden onset of bony pain, fever, and malaise. Acute disease is often the result of seeding of the bone during *S aureus* bacteremia, with the most common anatomic locations corresponding to highly vascularized osseous areas such as the metaphyses of long bones. Chronic osteomyelitis is a more indolent process, characterized by low-grade fevers and chronic nonhealing ulcers or draining sinus tracts in the skin overlying the infected bone. Bony necrosis is pathognomonic for chronic osteomyelitis. Chronic osteomyelitis commonly affects the feet and lower extremities and is often preceded by minor injury or surgery of tissues adjacent to the affected bone. Individuals with impaired vascular perfusion, such as diabetics, are at a particularly high risk for chronic bone infections.

**B. Laboratory Findings.** The laboratory findings are nonspecific and include an elevated WBC count and erythrocyte sedimentation rate. Blood cultures may be positive in acute osteomyelitis.

**C. Imaging.** Advances in imaging technology have improved the ability to diagnose osteomyelitis. Plain films are of limited use for acute osteomyelitis, as bony

abnormalities are not detectable until at least 10 days after the onset of symptoms. Both the MRI scan and the technetium bone scan have increased sensitivity for detecting early osteomyelitis. The technetium scan uses a radiolabeled isotope, which localizes to areas of osseous regeneration. This technique is limited by the difficulty in differentiating bony regeneration due to injury from that due to infection. Another imaging modality, the indium scan, involves the venous injection of radiolabeled autologous WBC, which localize to sites of granulocyte aggregation in infected bone. The clinical utility of the indium scan is limited by poor discrimination of osteomyelitis from simple cellulitis and low sensitivity for diagnosing the chronic form of osteomyelitis.

**D. Complications.** Bacteremia caused by osteomyelitis may lead to secondary end-organ infections. More commonly osteomyelitis causes extensive local bony destruction. Patients with peripheral vascular disease, particularly diabetics, may require surgical revascularization to cure osteomyelitis of the lower extremities. In situations where surgical revascularization is not an option or has failed, localized amputation may be necessary.

## Diagnosis

Because of the need for prolonged antibiotic therapy with osteomyelitis, a concerted effort to obtain a microbiologic diagnosis before initiating therapy should be made. Culture of cutaneous sinus tracts has an unacceptably low sensitivity and specificity and is not recommended for diagnostic purposes. All patients should have a surgical bone biopsy, as this is the only reliable way of obtaining adequate culture results to guide therapy.

## Treatment

The treatment of osteomyelitis presents a particular challenge as antibiotics penetrate bone poorly; antibiotic concentrations in bone are only 5% that of serum. All successful treatment regimens require high dosing for prolonged durations ([Box 46-6](#)). Standard regimens require intravenous therapy for 4-6 weeks. The requirement of multiple daily doses is impractical for outpatient administration and has led to increasing interest in less complicated regimens. Treatment with parenteral antibiotics followed by oral therapy in children achieves cure rates equivalent to those of standard parenteral regimens but has not been studied sufficiently in adults to make recommendations regarding oral antibiotics for this age group.

Surgical debridement is required for chronic osteomyelitis, particularly in the presence of necrotic bone or sequestrum. Patients with chronic osteomyelitis should receive at least 6 weeks of parenteral therapy after surgical debridement. Infections in patients who are unable to tolerate surgery or who have refractory disease can be suppressed with ciprofloxacin (750 mg orally twice daily) and rifampin (600 mg orally each day), given indefinitely.

## COAGULASE-NEGATIVE STAPHYLOCOCCI

### Essentials of Diagnosis

- Gram-positive cocci.
- No zone of hemolysis surrounding colonies on blood agar.
- Colonies gray or white macroscopically.
- Cluster in grapelike bunches microscopically.
- Biochemically differentiated from streptococci by production of the enzyme catalase.
- Biochemically differentiated from *S aureus* by absence of the enzyme coagulase.
- Analysis of chromosomal DNA can identify clonal isolates (useful in epidemiologic studies).

## General Considerations

**A. Epidemiology.** Like *S aureus*, coagulase-negative staphylococci (CoNS) are normal human flora. *S epidermidis* is the most common bacteria cultured from intact skin, while *S saprophyticus* is commonly cultured from the vagina of asymptomatic women. With the exception of *S saprophyticus*, which causes cystitis in young, sexually active women, infections with CoNS occur almost exclusively in the presence of foreign bodies.

**B. Microbiology.** As with all *Staphylococcus* species, CoNS are aerobic, nonmotile, gram-positive cocci. This group is comprised of > 30 species, of which about half are known human pathogens. The most clinically important are *S epidermidis*, *S saprophyticus*, and *S haemolyticus*. Although species can be differentiated by biochemical tests, this is rarely clinically indicated, as the high prevalence of methicillin-resistance among CoNS mandates treatment with vancomycin. Molecular analysis can determine if organisms from the same species are clonally related, which may be useful for epidemiologic investigations.

**C. Pathogenesis.** Less is known about the mechanisms through which CoNS cause disease. As noted above, adherence, colonization, and invasion occur almost exclusively in the setting of indwelling foreign bodies, such as intravenous catheters or implanted prosthetic devices. CoNS attach to foreign material by the production of an exopolysaccharide slime layer and are able to alter the local immune response through a poorly understood mechanism, hindering host eradication. These organisms are much less virulent than *S aureus* and generally produce indolent infections with inflammation restricted to local tissues.

## BACTEREMIA & ENDOCARDITIS

### Introduction

The rising incidence of CoNS bacteremia in the last decade may be attributed to the increasingly common use of prosthetic devices, especially intravascular catheters, among hospitalized patients. Positive peripheral blood cultures are indicative of infection

rather than skin contamination in only 10% of cases, and the challenge lies in differentiating these two entities.

## **Clinical Findings**

**A. Signs and Symptoms.** Clinical signs of CoNS bacteremia are often minimal; the finding of fever and leukocytosis support infection rather than colonization, particularly in a host with an indwelling vascular catheter or implanted prosthetic material. While erythema or purulence at a catheter site is compelling evidence supporting catheter-associated bacteremia, only 50% of patients with bacteremia from vascular lines develop local signs of infection.

Although CoNS rarely infect native cardiac valves, they are the most common cause of early (defined as occurring < 12 months postoperatively) prosthetic valve endocarditis (PVE). The majority of cases of early PVE are caused by intraoperative seeding. Infections are indolent, with fever the most common sign. Diagnosis may be delayed by the lack of physical findings specific for endocarditis; most patients do not develop audible murmurs until valve destruction is advanced.

**B. Laboratory Findings.** Laboratory abnormalities in CoNS bacteremia and endocarditis are variable. Prosthetic valve endocarditis due to CoNS is usually an indolent process, with nonspecific laboratory findings, including anemia and hematuria. Patients who have CoNS native valve endocarditis present with typical laboratory findings for subacute endocarditis, including elevated erythrocyte sedimentation rate (~90%), anemia (~75%), positive rheumatoid factor (~33%), and hematuria (~33%). Leukocytosis is present in only 40-45% of patients with either bacteremia or endocarditis.

**C. Imaging.** Transthoracic echocardiography may be useful in native valve endocarditis or in the later stages of PVE when there is significant valve dehiscence. Diagnosis of PVE may be difficult in the early stages when bacteremia may be intermittent. A diagnosis of PVE is supported by new conduction abnormalities on the electrocardiogram, suggestive of valve ring abscess. The most sensitive technique for diagnosing valvular infection is the transesophageal echocardiogram, which allows excellent visualization of the valve ring and prosthesis.

**D. Differential Diagnosis.** A positive blood culture for CoNS represents one of two entities: contamination with skin flora (~90% of cases) or a true infection. The presence of prosthetic biomaterial, either in the form of a temporary indwelling venous catheter or an implanted device, increases the probability of infection as the majority of bloodstream infections are caused by seeding from infected foci. Patients with CoNS bacteremia should have all temporary indwelling catheters removed or replaced, and the tip sent for a semiquantitative culture.

**E. Complications.** Hemodynamic instability consistent with septic shock occurs in 10-20% of patients with CoNS bacteremia. Complications of CoNS native valve endocarditis are comparable to those seen with subacute bacterial endocarditis: systemic embolization, valve ring abscess with conduction system disturbance, or congestive heart failure occur in two-thirds of patients, and ~25-50% of patients require

valve replacement. Of early PVE cases caused by CoNS, > 85% are complicated by congestive heart failure or prolonged fever despite appropriate antibiotic therapy.

## Diagnosis

The diagnosis of CoNS bacteremia or endocarditis is supported by multiple positive cultures from separate venipunctures. Molecular techniques proving clonality of two or more species may argue for true infection (rather than contamination), but access to these tests is generally restricted to research laboratories. In health care settings where molecular testing is not available, the finding of multiple isolates with identical antibiotic susceptibility patterns supports infection rather than contamination. However, the finding of even a single positive culture may be clinically significant and should be interpreted in the context of the patient's clinical condition.

## Treatment

The recommended regimens for CoNS bacteremia are given in [Box 46-7](#). Although > 70% of CoNS are resistant to PRSPs, beta-lactam resistance is heterotypically expressed, and antibiograms may falsely suggest methicillin sensitivity.

Bacteremia from infected indwelling vascular lines may be cured in > 75% of cases with the catheter remaining intact. Indications for catheter removal include hemodynamic instability, cutaneous tunnel infections, and persistent fever or bacteremia after > 48 h of antibiotic treatment.

A diagnosis of PVE is usually an indication for surgical replacement of the infected valve. A trial of conservative therapy with antibiotics alone may be attempted in hemodynamically stable patients without evidence of congestive heart failure or ring abscess. Treatment requires at least 6 weeks of therapy, with synergistic dosing of gentamicin for the initial 2-week period ([Box 46-7](#)). The clinician should have a low threshold for surgical intervention in patients with persistent fever or bacteremia, or in patients who develop new signs of congestive heart failure. Patients who complete medical therapy should be followed closely after discontinuation of antibiotics, as relapse is also an indication for surgery.

## URINARY TRACT INFECTIONS

### Introduction

*S saprophyticus* is a common cause of uncomplicated urinary tract infection (UTI) in young women, accounting for as many as 15% of all cases of cystitis in this group. There is a seasonal variation in incidence, with the majority of cases occurring in late summer and fall. Risk factors for *S saprophyticus* UTI include recent sexual intercourse, delayed postcoital urination, and contraception with diaphragm/spermicide combinations.

### Clinical Findings

**A. Signs and Symptoms.** *S saprophyticus* causes typical symptoms of cystitis: fever,

dysuria, and suprapubic pain. Approximately 20% of women show signs of upper tract disease. It is likely that the number of cases of *S saprophyticus* pyelonephritis is significantly higher, as localization studies suggest that renal infections may occur in the absence of flank pain.

**B. Laboratory Findings.** In uncomplicated pyelonephritis and cystitis, the laboratory findings are restricted to hematuria and pyuria. A Gram stain of centrifuged urine sediment typically reveals gram-positive cocci.

**C. Complications.** Complications secondary to *S saprophyticus* are rare. There have been anecdotal case reports of bacteremia and endocarditis complicating *S saprophyticus* urinary tract infections. Infection in males, though unusual, is associated with anatomic abnormalities of the urinary tract or urethral catheterization, and ~40% require hospitalization.

## Diagnosis

Definitive diagnosis of *S saprophyticus* UTI is by culture of organisms from a sterile midstream urine collection. A colony count of  $> 10^2$  bacteria in an appropriate clinical setting (a young woman with symptoms of cystitis) is considered to be diagnostic. However, because cystitis in young women is usually uncomplicated and easily treated empirically, many authorities do not recommend urine cultures and proceed with therapy if microscopy reveals red or white cells in the sediment of a spun urine.

## Treatment

*S saprophyticus* is sensitive to the antibiotics empirically used to treat community-acquired, uncomplicated UTIs (see [Chapter 16](#)). Treatment failures of *S saprophyticus* UTIs have been reported with single-day therapy (particularly with the fluoroquinolones), leading to the current recommendation of 3 days of antibiotics, regardless of which agent is used. Of note, *S saprophyticus* is variably sensitive to vancomycin, and this agent should not be used for empiric therapy.

## Prevention & Control

Prevention efforts for the ubiquitous methicillin-sensitive *S aureus* and CoNS have centered around strict aseptic technique for procedures and compulsive attention to hand washing. Intranasal mupirocin may be effective in eradicating *S aureus* carriage during a hospital outbreak or if epidemiologic investigation implicates a health care worker as a vector for nosocomial infections.

Staphylococcal infection control efforts have concentrated on limiting the nosocomial spread of MRSA ([Box 46-8](#)). Patients colonized or infected with MRSA should be isolated or cohorted, and health care workers should don protective gowns and gloves before patient contact. Hand washing after contact with colonized patients is particularly important as MRSA can survive  $> 3$  h on cutaneous surfaces but is rapidly eradicated by washing with an antibacterial soap. Airborne transmission rarely occurs but is of concern if a patient with respiratory colonization produces copious secretions or requires frequent tracheal suctioning. Both patient isolation and use of masks by

contacts is advisable in this setting.

## 47 . *Streptococcus pneumoniae* — Jeffrey N. Martin, MD, MPH

### Essentials of Diagnosis

- Most common infections include pneumonia, meningitis, sinusitis, and otitis media.
- Predisposing factors include extremes of age (ie, infants and elderly) and underlying host defects in antibody, complement, and splenic function.
- Transmission is human to human both in the community and nosocomially.
- Pneumonia: productive cough, fever, chills, sweats, and dyspnea; lobar or segmental consolidation on chest x-ray; lancet-shaped gram-positive diplococci on Gram stain of sputum or growth of *S pneumoniae* from sputum, blood, or pleural fluid.
- Meningitis: headache, stiff neck, fever, chill, and photophobia; nuchal rigidity, Kernig's or Brudzinski's sign; lancet-shaped gram-positive diplococci on Gram stain of cerebrospinal fluid (CSF), growth of *S pneumoniae* from CSF or blood, or positive counter immunoelectrophoresis or latex agglutination of CSF.

### General Considerations

**A. Epidemiology.** *S pneumoniae* may exist in humans as either a nasopharyngeal colonist or as a pathogen in one of many clinical syndromes ([Box 47-1](#)). Although *S pneumoniae* has been found in other mammals, humans are thought to be the principal reservoir. As a colonist, *S pneumoniae* is found in up to 40% of children and 10% of adults. Infants typically acquire their first colonizing isolate at 6 months. Intermittent colonization then occurs throughout childhood and adult years. There is a seasonal pattern to colonization, with the highest prevalence occurring in winter. Pneumococci are transmitted from human to human by extensive direct contact with secretions harboring the organism. Persons residing in environments that promote such extensive close contact, such as day care centers, prisons, homeless shelters, and military barracks, have historically been at risk for pneumococcal infection.

In the United States, *S pneumoniae* is estimated to account for 500,000 cases of pneumonia, 50,000 cases of bacteremia, 3000 cases of meningitis, and 7 million cases of acute otitis media. Of these syndromes, bacteremia (with or without a site of primary infection such as pneumonia or meningitis) has the most clearly elucidated epidemiology because of its precise blood culture-based definition. The incidence of bacteremia is strongly age related. A surveillance study in South Carolina estimated the incidence of bacteremia among infants, young adults, and elderly (age = 70) to be 160, 5, and 70 cases per 100,000 persons, respectively. African-Americans, American Indians, and Alaskan Natives are at highest risk for bacteremia. As is true for *S pneumoniae* colonization, there is a distinct seasonality to bacteremia with peaks coming at midwinter. Overall, pneumococcal disease accounts for ~ 40,000 annual deaths in the United States. The case fatality rate for bacteremia is 15-20%.

In addition to the numerical incidence of pneumococcal disease, it is instructive to look at the prominent role *S pneumoniae* plays in several common syndromes. In a variety of studies that prospectively identify causes of community-acquired pneumonia, *S pneumoniae* is routinely the most common detectable agent. For example, in patients who require hospitalization for pneumonia, *S pneumoniae* accounts for up to one-third of cases. Aside from areas of the world experiencing meningococcal epidemics, *S pneumoniae* is the most common organism of meningitis in adults and now, with the advent of *Haemophilus influenzae* type b immunization, is also most common in children. One-third to one-half of all cases of acute otitis media with an identifiable etiology is caused by *S pneumoniae*.

Any of the syndromes caused by *S pneumoniae* can occur in normal hosts, but frequently one or more predisposing conditions exist. The best characterized of these are underlying host immunologic defects in antibody, complement, and splenic function. Because of the importance of antibodies in the opsonization of the encapsulated pneumococcus, individuals with defective antibody function (eg, congenital agammaglobulinemia, common variable hypogammaglobulinemia, selective immunoglobulin-G subclass deficiency, multiple myeloma, chronic lymphocytic leukemia, or lymphoma) are at significant risk for invasive infections. Various early complement deficiencies as well as either congenital or acquired asplenia (eg, iatrogenic or sickle cell disease) also convey substantial risk. Asplenic patients deserve special note because of the rapidity at which they can clinically deteriorate from unchecked bacteremia.

In contemporary urban settings, HIV infection is responsible for a large burden of pneumococcal disease. HIV disease, through a variety of host defense defects, places infected persons at ~ 200-fold-greater risk for invasive pneumococcal infection. HIV-infected patients who are African-American, who have a CD4 lymphocyte count <  $200 \times 10^6$ /liter, or who have a history of pneumonia have particularly elevated risk. The presence of pneumococcal bacteremia in patients with no clinically apparent host immunodeficiency should prompt the clinician to obtain patient consent for HIV testing.

Various other chronic illnesses, such as alcoholism, cirrhosis, renal insufficiency, nephrotic syndrome, chronic pulmonary disease, congestive heart failure, and diabetes, place patients at significant risk for pneumococcal disease. Likewise, patients who have received organ or bone marrow transplants or who are being treated with alkylating agents, antimetabolites, or glucocorticoids are also at risk. Finally, a particular anatomic defect, basilar skull fracture, carries risk for pneumococcal meningitis.

**B. Microbiology.** *S pneumoniae* is a gram-positive coccus, but typically the organism grows as pairs in what is termed a lancet-shaped diplococcus. In truth, this shape represents two lancets joined on end, pointing away from each other. In liquid medium, pneumococci may also be found growing in chains. On blood agar plates, pneumococcal colonies are often umbilicated (ie, have central dimpling) and are sometimes grossly mucoid. They are surrounded by a greenish zone, known as  $\alpha$ -hemolysis, which is the result of hemoglobin breakdown by pneumococcus-produced  $\alpha$ -hemolysin. In the clinical microbiology laboratory,  $\alpha$ -hemolysis is the first clue in distinguishing *S pneumoniae* from a variety of other species in a mixed flora sample. In addition to  $\alpha$ -hemolysis, the microbiology laboratory uses catalase negativity, solubility

in bile salts, and susceptibility to optochin to identify *S pneumoniae* ([Table 47-1](#)).

*S pneumoniae* is easy to identify by the above criteria when it grows in normally sterile body sites (eg, blood or pleural fluid). Detection in a mixed-flora environment such as sputum, however, requires a skilled and persevering clinical microbiologist. Given the abundance of other  $\alpha$ -hemolytic oral species, it is incumbent on the microbiologist to look carefully for the characteristic umbilicated or mucoid appearance of *S pneumoniae* and to subculture a number of  $\alpha$ -hemolytic colonies. The clinician can be motivating in this endeavor by communicating the patient's clinical presentation to the microbiologist and by carefully reviewing the Gram stain of the original specimen for the presence of lancet-shaped diplococci.

Once called *Diplococcus pneumoniae*, *S pneumoniae* is now known to belong to the *Streptococcus* genus. Like most other members of this genus, *S pneumoniae* is non-spore forming and nonmotile. Unlike many streptococcal species, *S pneumoniae* does not have a Lancefield serogroup. Yet, within the *S pneumoniae* species, there are 90 identified serotypes. Two numbering schemes for serotyping exist. In the American system, serotypes are numbered starting from 1 to 90 in the order in which they were first described. In the more widely used Danish system, serotypes are grouped based on antigenic similarities and given both a number and a letter (eg, 19A, 19B, and 19C). The basis of the serotype is antigenic differences in the polysaccharides that constitute the pneumococcal external capsule. Almost all clinical strains, with the uncommon exception of some isolates from conjunctivitis, have a capsule. In the microbiology laboratory, the interaction of serotype-specific antibody with capsule results in the enhancement of the microscopic appearance of the capsule, which is known as the quellung reaction. Although serotyping is no longer an important clinical tool, it remains useful for epidemiologic studies; surveys of the most prevalent serotypes found in invasive infections have informed the composition of the current polyvalent vaccine.

Whereas the external capsule is a distinguishing feature of *S pneumoniae*, its cell wall is similar to that of other streptococci. Multilayered peptidoglycan, a heteropolymer of repeating *N*-acetylglucosamine and *N*-acetyl muramic acid, is the principal component. Peptides, attached to *N*-acetyl muramic acid, are cross-linked by *trans*- and carboxypeptidases to provide structure to the cell wall. These peptidases are also known as penicillin-binding proteins because they are the binding sites for a variety of  $\beta$ -lactam antibiotics. The covalent binding of  $\beta$ -lactams inactivates these enzymes resulting in the eventual demise of the organism. Teichoic acid (ribitol- or glycerol-phosphate polymers) is the other principal component of the cell wall and is often covalently bound to peptidoglycan. Lipoteichoic acid exists as a component of both the cell membrane and cell wall. There are other minor components of the cell wall, some of which are common to all streptococci, and some of which, like C-substance (a polysaccharide), are unique to *S pneumoniae*. Various soluble products are produced by *S pneumoniae* and are discussed in the next section.

**C. Pathogenesis.** Diseases caused by *S pneumoniae* are principally the result of an exuberant inflammatory response that the host mounts to the organism. The critical factor in the success of the pneumococcus is its ability to evoke this response but simultaneously, at least until specific anticapsular antibody is produced, to evade nonspecific attempts at phagocytosis. Highly destructive toxins, analogous to those

produced by *Streptococcus pyogenes* or gram-negative species, are not present although some toxins are produced and play a secondary role. Although details vary slightly depending on the organ system involved, the pathogenic progression consists of nasopharyngeal adherence and colonization, spread to adjacent organs with local replication, evasion of nonspecific clearance mechanisms, and finally activation of the host inflammatory reaction.

The initiating event in all cases is nasopharyngeal colonization, in which bacterial surface adhesins join to epithelial cell receptors that contain the disaccharide GlcNAc $\beta$ 1-4Gal. After pneumococci are established in the nasopharynx, they may then gain entry into and replicate in contiguous structures such as the sinuses, eustachian tubes, or bronchi. They may also penetrate the nasopharyngeal mucosa, even without a clinically demonstrable focus of infection, and achieve access to the systemic circulation via the cervical lymphatics. Entry into the lungs is limited in normal hosts by a functioning glottis and larynx, but entry is enhanced when these mechanisms are disturbed, as seen with alcohol intoxication, convulsions, anesthesia, or stroke.

Even after pneumococci gain entry to the above structures, infection rarely occurs because they are typically cleared in the normal host by nonspecific mechanisms (eg, mucociliary motion or cough reflex). Replication can proceed, however, when normal clearance is impaired, as seen, for example, when eustachian tubes or sinus orifices are congested (eg, from viral infection or allergy) or bronchial clearance is altered (eg, from chronic effects of smoking or acute effects of viral infection). In the lung, various mechanisms are now being described that may enhance pneumococcal adherence and replication. These include the finding that pneumococci bind to immobilized fibronectin that is exposed during tissue injury and that cytokines may induce pneumocytes to express the receptor for platelet-activating factor—a receptor that also binds pneumococcal C-substance.

Once established in its target organs, *S pneumoniae* is able to replicate unimpeded because of its ability to evade nonspecific phagocytosis by polymorphonuclear cells. The external capsule provides this crucial protection. As such, the capsule is an essential factor in the virulence of the organism. The exact mechanism of this protective effect is not known; it is likely a combination of the lack of capsular receptors on phagocytes, repellent electrochemical forces on the capsule, and the ability of the capsule to mask opsonizers such as antibody and complement. Whatever the exact mechanism, *S pneumoniae* organisms that are genetically engineered to lack capsules are avirulent.

Once it begins replicating, *S pneumoniae* causes disease by evoking an intense inflammatory reaction. Both the peptidoglycan and teichoic acid components of the cell wall and capsular polysaccharide can activate the alternative pathway of complement. Nonspecific antibodies to cell wall polysaccharides (formed to ubiquitous streptococcal species) are able to activate complement by the classical pathway. Together, these means of activating complement result in the attraction of numerous leukocytes and abundance of exudative fluid. In the lungs, this accumulation of pneumococci and inflammatory material leads to consolidation of alveoli, radiolucency, and impaired gas exchange—the defining characteristics of pneumonia. Although abscess formation is rare, the expanding volume of infected material can spread to uninvolved areas via

Kohn's pores. Extensive direct spread can result in empyema or pericardial infection. If the infection is not contained, pneumococci can spread via lymphatics to hilar lymph nodes, the thoracic duct, and finally into the systemic circulation where metastatic infection may occur in the meninges, peritoneum, joints, or endocardium.

As mentioned, *S pneumoniae* may gain access to the subarachnoid space via hematogenous spread and choroid seeding from either a nasopharyngeal or pulmonary focus. Less commonly, meninges may become infected via direct extension from an infected sinus or middle ear. As in the lungs, an intense inflammatory response is evoked by the presence of pneumococci in the subarachnoid space. Interleukin-1 and tumor necrosis factor, released by macrophages responding to the insult, play a prominent role and contribute to increased blood-brain barrier permeability. The end result is mounting intracranial pressure and ultimately diminished blood flow to the brain.

Before the advent of antibiotics, this pathogenic process could be arrested by the development of specific anticapsular antibody. This typically occurs at 5-8 days after the onset of infection. Hence, outcome depended on whether antibody production occurred before the patient succumbed to the severe manifestations of infection. In the contemporary era, it is now appreciated that the pathogenic process can also be arrested by the administration of antibiotics. However, the persistently high case fatality rate associated with pneumococcal disease (especially bacteremia) despite antibiotic administration bespeaks the continued contributory role of host defenses in successfully responding to infection.

*S pneumoniae* produces several toxins that are currently thought to play a secondary role in pathogenesis. Pneumolysin is a toxin with two functions. It can insert into cell membranes of polymorphonuclear cells and ciliated epithelium, thereby inhibiting their function, and it can activate the classical complement pathway. Other products such as pneumococcal surface protein, hemolysin, and autolysin are also contributory because mutants lacking these typically are less virulent. Autolysin in particular is important because autolysis of organisms may enhance the release and expression of a variety of proinflammatory factors (eg, cell wall components) that were discussed above.

## CLINICAL SYNDROMES

### PNEUMONIA

#### Introduction

This section focuses on the clinical findings, diagnosis, and treatment of pneumococcal pneumonia. Please see [Chapters 9](#) and [10](#) for a general discussion of pneumonia and upper respiratory infection.

#### Clinical Findings

**A. Signs and Symptoms.** The so-called classic presentation of pneumococcal pneumonia consists of an abrupt onset of a shaking chill followed shortly after by fever and production of rusty sputum ([Box 47-2](#)). This classic presentation, however, is not the most common. Typically, patients present because of a change in preexisting

symptoms. Many have had several days of a viral upper respiratory infection marked by coryza, sore throat, and nonproductive cough, or they have chronic pulmonary disease with its attendant persistent productive cough. In these patients, the development of pneumonia is heralded by the onset of fever (which can be as high as 40 °C), chills, sweats, malaise, dyspnea, and a change in the nature of the cough. Cough may either turn productive in those without prior production or increase in volume and change color in those with prior production. Less common symptoms include pleuritic chest pain and—for reasons that are poorly understood—nausea, vomiting, and diarrhea. Some patients, particularly the elderly, will present with merely an alteration in mental status. Thus, the very common entity of pneumococcal pneumonia must be entertained for a wide variety of clinical presentations.

On physical examination, persons with pneumococcal pneumonia are usually markedly ill appearing and may be cyanotic. Altered vital signs such as elevated temperature, tachycardia, and tachypnea (> 22 breaths/min) are common but, as noted above, can be absent in the elderly. In fact, in the elderly, hypothermia may be present. With the exception of the appearance of oral herpes lesions, the majority of the physical findings relate to the lungs. Dullness to percussion, increased tactile fremitus, bronchophony, whispered pectoriloquy, and egophony are sometimes present as clues to underlying consolidation, but often only rales are heard. It must be remembered, however, that even the presence of rales in an otherwise normal individual must be considered an abnormal finding and prompt further radiographic consideration of pneumonia. Conditions associated with pneumonia, meningitis (eg, nuchal rigidity), and endocarditis (eg, murmur) should also be routinely evaluated.

**B. Laboratory Findings.** An elevated leukocyte count, often with early forms (left-shifted), is common. However, in certain patient populations (eg, alcohol abusers and persons with HIV infection), the absence of a high leukocyte count does not have sufficient negative predictive value to exclude pneumococcal disease. In acutely ill patients, a low serum bicarbonate concentration and an anion gap may be seen. This should prompt arterial blood gas determination to document the presence and extent of acidemia. Although determination is not necessarily indicated in all patients presenting with suspected pneumonia, an elevated bilirubin level and lactate dehydrogenase are prevalent. Pulse oximetry on room air should be performed in all patients. Individuals with low pulse oximetry readings and for whom acid-base status is unsettled should have arterial blood gas measurements.

Two sets of blood cultures should be performed on all patients with suspected pneumonia in that this may be the only way (aside from pleural fluid culture) to diagnose definitively the etiologic agent. Nevertheless, the majority of patients with pneumococcal pneumonia are not bacteremic. Hence, particular attention must be paid to the adequate collection and processing of expectorated sputum. Although *S pneumoniae* can be a colonist, its growth in sputum culture in a patient with clinically diagnosed pneumonia is usually satisfactory proof of pneumococcal pneumonia. The sensitivity of culture, however, is often solely dependent on the rigor practiced by microbiology staff in the identification and subculturing of  $\alpha$ -hemolytic colonies. Findings on Gram stain of the sputum can also be helpful but require careful interpretation. The presence of characteristic gram-positive lancet-shaped diplococci accompanied by an abundance of leukocytes (> 25 per low [100 $\times$ ]-power field) and a paucity of epithelial cells (< 10 per

low-power field) on Gram stain suggests pneumococcal pneumonia, but the absence of this Gram stain pattern does not exclude pneumococcal disease. Although there are increasing regulations regarding clinician-prepared Gram stains, clinicians should routinely review stains that are prepared by microbiology staff.

**C. Imaging.** The sine qua non of pneumococcal pneumonia is the presence of an infiltrate on chest radiography. The clinical diagnosis of pneumonia has to be seriously questioned if, after 24 h of observation and volume repletion, a patient has not yet developed an infiltrate. A variety of radiographic findings can be observed. Lobar or segmental consolidation is classic but is less common than subsegmental involvement. Multiple subsegmental consolidation may be seen, and, occasionally, multilobar consolidation may be present. Pleural effusion is the other common finding, and the failure of a patient to improve necessitates prompt investigation of this fluid for the presence of empyema. Lung abscesses are rare, and their presence suggests serotype-3 infection. More commonly, the presence of an abscess suggests preexisting cavitory disease or coinfection with other abscess-producing organisms.

**D. Differential Diagnosis.** In patients presenting with community-acquired pneumonia (ie, acute pulmonary infection in a patient who has not been hospitalized nor has resided in a long-term-care facility in the 14 days prior to the onset of symptoms), a number of agents must be considered along with *S pneumoniae* in the differential diagnosis. *H influenzae*, *Branhamella (Moraxella) catarrhalis*, *Chlamydia pneumoniae*, and *Mycoplasma pneumoniae* are the most common agents, but, in certain populations, *Legionella* spp., *Klebsiella pneumoniae*, *Staphylococcus aureus*, *Escherichia coli*, *Chlamydia psittaci*, *Coxiella burnetti*, *Mycobacterium tuberculosis*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Cryptococcus neoformans*, and several respiratory viruses (eg, influenza virus, adenovirus, parainfluenza virus, and hantavirus) must also be considered. In immunocompromised hosts, the differential diagnosis expands to include a variety of other opportunistic pathogens.

A number of studies have attempted to develop algorithms that can distinguish the causative organism on clinical grounds, but none has provided sufficient predictive value upon which to base pathogen-directed empiric treatment decisions. Hence, a broad differential must be considered upon initial presentation, and definitive diagnosis can be made only with the appropriate microbiologic testing.

**E. Complications.** Bacteremia, progressive respiratory failure, and hemodynamic instability (ie, septic shock) are the most severe complications of pneumococcal pneumonia. As noted above, patients with either anatomic or functional asplenia are at particularly high risk for sepsis. Spread of infection via either contiguous extension or hematogenous routes constitutes the basis of extrapulmonary complications.

Empyema deserves special attention because it both is common and has severe manifestations if unrecognized. Empyema, which can occur either from hematogenous or contiguous spread, is defined by pleural fluid containing frank pus, a positive Gram stain or positive culture, or a pH of  $\leq 7.1$ . Untreated, it can result in persistent fever and may be the focus for further spread of infection. Rarely, rupture through the chest wall (ie, empyema necessitatis) can occur. If empyema fluid is not properly drained, it may heal with residual fibrosis and result in long-term functional pulmonary defects.

Purulent pericarditis, arthritis, endocarditis, and meningitis are also possible complications.

## Diagnosis

The diagnostic approach to pneumococcal pneumonia first involves correctly diagnosing the syndrome of pneumonia and second involves defining *S pneumoniae* as the causative agent. Whether the setting is community acquired or nosocomial, the diagnosis of pneumonia is made by chest radiography of patients with suggestive predisposing factors, symptoms, and physical-examination findings. This avoids the unnecessary costs and medication side effects that are associated with prescribing antibiotics to the large numbers of individuals who have viral upper-respiratory-tract infections and who do not have pneumonia. Although chest radiography has been dismissed by some as being cost ineffective in the outpatient setting, this ignores the incalculable costs of the subsequent development of antibiotic resistance that occurs when antibiotics are inappropriately prescribed. Thus, a chest radiograph is required for all patients in whom pneumonia is suspected.

No constellation of presenting signs or symptoms has proven to be adequately predictive of pneumonia caused by *S pneumoniae*. Hence, once the diagnosis of pneumonia has been established on clinical and radiographic grounds, definitive diagnosis of pneumococcal pneumonia is based on the identification of the organism in normally sterile fluid (see above and [Table 47-1](#) for microbiologic identification of *S pneumoniae*). With the rare exception of when transthoracic biopsies are performed, normally sterile fluid means either blood or pleural fluid. As stated above, detection of *S pneumoniae* in culture of expectorated sputum, although not entirely specific, is sufficient for a probable diagnosis of pneumococcal pneumonia and evidence enough for specific pathogen-directed therapy. The unambiguous sighting of gram-positive diplococci on sputum Gram stain without growth in culture is the least definitive evidence but may be sufficient if other pathogens are excluded and if the patient has an epidemiologic profile consistent with pneumococcal disease.

Obtaining both blood and sputum for culture is the only way to specifically diagnose pneumococcal pneumonia, but there is debate whether to perform these procedures at all, particularly in the outpatient setting. It has been argued that broad-spectrum empiric antibiotics are sufficiently effective in most patients and that specific identification of the pathogen is not required. Until a definitive trial addresses this issue and accounts, by modeling, for the far-reaching effects of broad-spectrum antibiotic use, it is the author's opinion that, when practical to perform, all patients should receive both blood and sputum cultures.

Obtaining cultures can benefit both the individual patient and society. For individuals, determining the specific causative agent allows for altering from empiric broad-spectrum therapy to definitive treatment with an antibiotic that is usually less toxic, expensive, and disruptive to normal flora. In patients who are not responding to initial empiric therapy, a pretreatment culture may be the only opportunity to identify the causative agent and assess its antibiotic resistance patterns. Likewise, the absence of *S aureus* or gram-negative species in well-collected pretreatment sputum specimens essentially

excludes these as pathogens and obviates the need to cover them when reconsidering the antibiotic regimen. For society, in addition to the cost savings derived from cheaper and less toxic antibiotic choices, the benefits of specific pathogen detection include the diminution of antibiotic resistance (and its associated costs) and the epidemiologic surveillance for pathogens such as drug-resistant *S pneumoniae* and *Legionella* spp. Knowledge of the prevalence of these pathogens in the community is essential for health care providers as they make empiric treatment decisions for subsequent patients who present with pneumonia.

## Treatment

The approach to treatment of any of the syndromes caused by *S pneumoniae* must be considered in two parts—empiric and definitive therapy. Empiric therapy is prescribed when a patient presents with a clinical syndrome (eg, pneumonia) and, as is often the case, the causative agent has not yet been identified. Empiric therapy must cover all the epidemiologically likely agents. Definitive treatment is used once *S pneumoniae* has been identified as the causative agent.

On presentation with a clinical syndrome compatible with pneumonia, most patients are treated empirically with broad-spectrum antibiotics (see [Chapter 23](#)). Assuming that a patient is responsive to an empiric regimen that covers *S pneumoniae*, a switch to definitive therapy depends on the confidence that the clinician and microbiology laboratory have that *S pneumoniae* is the sole causative agent. As noted above, growth of *S pneumoniae* in normally sterile body fluids like blood or pleural fluid is definitive proof of pneumococcal disease. In these instances, if other copathogens have been adequately excluded, a switch to definitive therapy is indicated. Growth of *S pneumoniae* in a culture of expectorated sputum offers suggestive but not definitive proof because some persons may have pneumococcal colonization without pneumococcal disease. The isolated appearance of gram-positive lancet-shaped diplococci on sputum Gram stain (without culture growth) is again suggestive but is also the least definitive. Switching to definitive therapy in these latter two patient groups is a matter of clinical judgment and depends on several factors, including the epidemiologic likelihood of *S pneumoniae* compared to other pathogens, microbiologic exclusion of other pathogens, patient tolerance of empiric therapy, and cost.

In the past, definitive therapy of pneumococcal pneumonia routinely consisted of penicillin because *S pneumoniae* was uniformly susceptible. In fact, antimicrobial susceptibility was not routinely tested. This has changed markedly in the past decade. Full susceptibility to penicillin is defined as a minimal inhibitory concentration (MIC) of = 0.06 ug/mL. A recent 30-center survey in the United States found that 14% of isolates had intermediate-level susceptibility (MIC = 0.1-1.0 ug/mL), and 9.5% had high-level resistance (MIC = 2.0 ug/mL). Furthermore, resistance to other antibiotics has also been increasing and is associated with penicillin resistance.

Because of the emergence of resistance, all pneumococcal isolates, including those from expectorated sputum, must undergo antimicrobial susceptibility testing. The choice of definitive therapy must be guided by these results ([Box 47-3](#)). Fully susceptible isolates may be treated with parenteral or oral penicillin, depending on the condition of the patient and gastrointestinal function. Fortunately, isolates demonstrating

intermediate-level penicillin resistance can still be treated with parenteral penicillin. Because of its excellent bioavailability, amoxicillin is recommended for definitive oral therapy of intermediately resistant strains. Although some highly resistant isolates may also respond to parenteral penicillin or oral amoxicillin, clinical experience in this area is lacking. Hence, agents should be used for which in vitro susceptibility has been shown (eg, ceftriaxone disodium; cefotaxime sodium; a fluoroquinolone such as sparfloxacin or levofloxacin; or vancomycin).

When only a characteristic Gram stain serves as evidence of pneumococcal infection, such isolates should be considered at least intermediately resistant for purposes of definitive therapy unless no such resistance has been reported in the area. Whether these isolates should be considered highly resistant (thus necessitating choices other than parenteral penicillin or oral amoxicillin) again depends on the known prevalence of high-level resistance in the community and whether the empiric regimen to which the patient is responding would be expected to cover isolates with high-level penicillin resistance. If the regimen would not be expected to cover high-level penicillin-resistant isolates and if the patient is nonetheless responding, high-level resistance is unlikely.

Adequate duration of therapy for pneumococcal pneumonia is not known precisely, but patients should be treated for at least 5 days after they become afebrile.

## **MENINGITIS**

### **Introduction**

This section focuses on the clinical findings, diagnosis, and treatment of pneumococcal meningitis. Please also see [Chapter 52](#) for a general discussion of meningitis.

### **Clinical Findings**

**A. Signs and Symptoms.** The clinical presentation of pneumococcal meningitis is similar to other bacterial causes of acute meningitis ([Box 47-4](#)). Severe headache, photophobia, neck stiffness, chills, and fever are common. Because of the rapid onset of severe symptoms, most patients present within a short time from the onset of symptoms. Depending on the initiating source of the infection, there may also be pulmonary complaints (see above) or symptoms referable to sinusitis or otitis (see [Chapter 9](#)).

Patients with meningitis usually appear extremely ill. Many seek quiet areas with low light because of headache and photophobia. Tachycardia and fever, except in those who have difficulty mounting an elevated temperature (eg, the elderly or those with end-stage renal disease), are almost always present. The hallmarks of meningitis are the presence of one or more of the following three findings: nuchal rigidity, Kernig's sign, or Brudzinski's sign. If patients present within the initial few hours of symptoms, mental status may be normal. If they present later or if treatment has for some reason been withheld, deterioration in mental status and ultimately obtundation may ensue. Papilledema and focal neurologic signs, including cranial neuropathies, may be present especially later in the course of disease. Hyperesthesia (abnormal acuteness of sensitivity to touch) is common. The remainder of the physical examination may reveal

evidence of the primary source of infection (eg, purulent discharge from nose or ear, bulging tympanic membrane, or consolidative findings on chest examination). Unlike meningococcal meningitis, a rash is not found.

**B. Laboratory Findings.** As with pneumococcal pneumonia, an elevated leukocyte count is common in pneumococcal meningitis. Other routine laboratory tests are typically normal. Lumbar puncture, which must be performed as rapidly as the diagnosis of meningitis is entertained, shows increased intracranial pressure ( $> 180$  mm H<sub>2</sub>O), CSF pleocytosis (from 500 to  $> 10,000$  cells/mm<sup>3</sup>, with polymorphonuclear-cell predominance), an elevated protein concentration (100-500 mg/dL), and depressed glucose ( $< 40$  mg/dL). Gram stain is often positive for characteristic gram-positive organisms. In contrast to the evaluation of pneumonia, in which a positive Gram stain is not always definitive, the presence of gram-positive diplococci on CSF Gram stain is definitive for the diagnosis of pneumococcal meningitis. In untreated patients, the sensitivity of Gram stain has been estimated to be as high as 90%. CSF culture is positive in most cases, and blood cultures may also show growth. In situations in which antibiotics have been administered before lumbar puncture, both Gram stain and culture may be negative. Cell count, protein, and glucose levels, however, are usually abnormal in these situations and not substantially different from the untreated state. Because these abnormalities are not specific for pneumococcal infection, immunologic methods such as counter immunoelectrophoresis or latex agglutination may be helpful for definitive diagnosis. These techniques provide no additional information to routine Gram stain and culture in the evaluation of CSF samples obtained before therapy.

**C. Imaging.** Cranial radiography (computed tomography or magnetic resonance scans) is often not indicated in the evaluation of meningitis. In fact, it is contraindicated if it results in undue delays in performing lumbar punctures or initiating empiric therapy. Radiography is indicated when there is clinical evidence of increased intracranial pressure (eg, papilledema) or focal neurologic findings. In these instances, radiography is performed to evaluate whether it is safe to perform a lumbar puncture and to diagnose central nervous system mass lesions, which may require further diagnostic maneuvers. Radiography is rarely useful to confirm positively the presence of meningitis—this is the task of the clinician and the microbiology laboratory. Radiography can be useful in assessing concomitant sinusitis, mastoiditis, or subdural empyema.

**D. Differential Diagnosis.** The differential diagnosis of acute meningitis is broad and contains both nonbacterial infectious and noninfectious etiologies (see [Chapter 52](#)). Once lumbar puncture has been performed and the profile of CSF findings suggests bacterial infection, the differential can be narrowed significantly. The differential diagnosis of acute bacterial meningitis is dependent on age group. In neonates, *S agalactiae*, members of the family *Enterobacteriaceae*, and *Listeria monocytogenes* predominate. With the marked decrease in *H influenzae* type B infections caused by immunization, *S pneumoniae* and *N meningitidis* are now the most prevalent organisms seen in older infants and children. In adults, *S pneumoniae*, *N meningitidis*, and *L monocytogenes* (in older adults) are most common.

**E. Complications.** The principal immediate and life-threatening complication of meningitis is decreased blood flow to the brain. Rather than a complication, it is best thought of as part of the pathogenic process that occurs if meningitis is unsuccessfully

treated. Decreased blood flow may result either from increased intracranial pressure and loss of cerebrovascular autoregulation or from direct vasculitic effects on blood vessels.

## Diagnosis

In patients with compatible clinical findings of meningitis, a lumbar puncture is always indicated except when evidence on imaging suggests a risk of herniation. Although lumbar puncture is critical to diagnose meningitis in general and to detect *S pneumoniae* specifically, delays in performing it should not delay empiric administration of antibiotics. Blood cultures should also be performed, and it is usually possible to collect them before antibiotic treatment. In such cases in which antibiotics must be given before lumbar puncture, blood cultures may serve as the only definitive means of specific pathogen detection.

## Treatment

As with pneumonia, patients presenting with acute meningitis receive broad-spectrum empiric regimens that should include coverage for *S pneumoniae* (see [Chapter 52](#)). Unlike pneumonia, ascertainment of the causal pathogen is more common in acute bacterial meningitis, thus giving the clinician more frequent opportunities to switch to definitive therapy. Either a characteristic CSF Gram stain or culture for *S pneumoniae* is definitive proof of pneumococcal meningitis.

Antimicrobial susceptibility testing of *S pneumoniae* is the most important factor in determining definitive therapy ([Box 47-5](#)). Unlike the situation in pneumonia cases, in meningitis cases, isolates that are intermediately resistant to penicillin should not be treated with standard or even higher dosages of penicillin. Instead, susceptibility to ceftriaxone disodium or cefotaxime sodium must be determined. Most isolates that are intermediately resistant to penicillin and some that are highly resistant retain susceptibility to cefotaxime sodium and ceftriaxone disodium. In such cases, these third-generation cephalosporins are the drugs of choice. Vancomycin must be used when there is resistance to both cefotaxime sodium and ceftriaxone disodium. Even if there is resistance to both ceftriaxone and cefotaxime, using one of these agents in addition to vancomycin should be considered. If only a positive Gram stain serves as evidence of pneumococcal meningitis and susceptibility results are not available, it is prudent to consider these isolates as resistant and continue the empiric regimen (if the patient is responding) or change to vancomycin if this was not part of the empiric regimen and the patient is not responding. Antibiotic treatment should be given for 10-14 days.

The use of glucocorticoids, although accepted in children, is still controversial in adults. It may be considered for adults in whom the CSF Gram stain is positive, coma is present, or there is evidence of increased intracranial pressure. Glucocorticoids are best considered in the context of empiric therapy because the first dose should be given before antibiotics.

## OTHER SYNDROMES

## Introduction

Primary pneumococcal bacteremia (ie, no identifiable anatomic focus) is common in children but infrequent in adults. *S pneumoniae* is the major pathogen of otitis media in children, being responsible for between 33% and 50% of all cases in which an etiologic agent can be identified. It is also one of the two most important (along with *H influenzae*) agents implicated in acute sinusitis. Empyema, typically a complication of pneumonia but rarely a primary diagnosis, has been discussed above. Less common syndromes include endocarditis and pericarditis (see [Chapter 11](#)), septic arthritis and osteomyelitis (see [Chapter 14](#)), peritonitis (see [Chapter 12](#)), endometritis (see [Chapter 22](#)), brain abscess (see [Chapter 7](#)), and cellulitis (see [Chapter 13](#)). Most of these can occur as either a primary infection or as a complication of an initiating clinical focus (eg, pneumonia). (Refer to other chapters in this text for a complete description of these syndromes, including a discussion of empiric and definitive treatments.)

The principles discussed above regarding the various levels of certainty in the attribution of a syndrome to *S pneumoniae*, knowledge of local prevalence of drug-resistant isolates, and the importance of the antimicrobial susceptibility pattern of the isolate (if obtained) are similarly pertinent when determining empiric and definitive therapy for other syndromes.

## Prevention & Control

A polyvalent vaccine against *S pneumoniae*, manufactured by both Merck (Pneumovax 23) and Lederle (Pnu-Immune 23), contains 25 ug of capsular polysaccharide from each of the 23 most common serotypes responsible for invasive pneumococcal infections in the United States. Vaccine serotypes represent = 85-90% of the isolates responsible for invasive infections. It is important to note that the six serotypes that are the most frequent causes of penicillin-resistant infections are included. The vaccine has been shown to be effective for the prevention of invasive pneumococcal disease (eg, bacteremia with or without pneumonia) in immunocompetent adults aged = 65 years and in persons aged = 2 years with chronic illnesses such as diabetes mellitus, alcoholism, cirrhosis, chronic pulmonary disease, coronary artery disease, and congestive heart failure ([Box 47-6](#)). Although convincing data on vaccine effectiveness in other immunocompromised populations (eg, HIV infection in persons from developed countries [data from sub-Saharan Africa show no vaccine efficacy], leukemia, Hodgkin's disease, multiple myeloma, and chronic renal failure) have not been presented, methodologic constraints or frank absence of dedicated studies has precluded excluding a protective role. Therefore, vaccination is generally recommended for these populations.

For infants < 2 years old, for whom the 23-valent vaccine is ineffective, a heptavalent vaccine (Prenar, Wyeth-Lederle) containing the capsular polysaccharides of serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F conjugated to a nontoxic diphtheria protein has been found effective in the prevention of invasive pneumococcal disease ([Box 47-6](#)). A series of immunizations with this conjugate vaccine in infants 2, 4, and 6 months old followed by a fourth dose when these infants are 12-15 months old is now recommended for all newborns. The vaccine is also recommended for high-risk children (eg, those with sickle cell disease or asplenia) between 2 and 5 years of age.

The Advisory Committee on Immunization Practices of the US Public Health Service has recently published updated recommendations on revaccination. This committee does not recommend routine revaccination but suggests that individuals = 2 years old who are at highest risk for serious pneumococcal infection and for whom rapid declines in antibody titers are known to occur should receive a second vaccination 5 years after the initial vaccine. These individuals include patients with HIV disease, functional or anatomic asplenia, leukemia, lymphoma, Hodgkin's disease, multiple myeloma, generalized malignancy, chronic renal failure, nephrotic syndrome, or transplants and those receiving immunosuppressive therapy. It is also recommended that individuals = 65 years old receive a second vaccination 5 years after the initial vaccine, provided that the first vaccine was administered when they were < 65 years old.

In children with either functional (eg, sickle cell disease) or anatomic asplenia, chemoprophylaxis with daily oral penicillin V provides another means of prevention and is also recommended.

Although human-to-human transmission of *S pneumoniae* is common, illness among contacts is very infrequent in nonepidemic settings. Accordingly, isolation of hospitalized patients or immunization of contacts is not recommended.

**Table 47-1.** Clues to diagnosis of *Streptococcus pneumoniae* infection

- Gram-positive coccus; grows as lancet-shaped diplococci or in chains
- Grows readily in conventional blood culture or solid media, but fastidious nature necessitates rapid transport of clinical material to microbiology laboratory for processing
- a-Hemolytic (greenish) on solid media; colonies are often umbilicated or mucoid
- Catalase-negative
- Bile salt soluble
- Susceptible to optochin
- Counter immunoelectrophoresis or latex agglutination may be useful in evaluation of cerebrospinal fluid that was obtained after antibiotics were administered

## **BOX 47-6. Control of Invasive *Streptococcus pneumoniae* Infections**

### **Prophylactic Measures**

23-valent polysaccharide vaccine is recommended for the following persons<sup>1</sup>:

- Aged = 65 y
- Aged 2-64 y with chronic illnesses such as chronic cardiovascular disease (coronary artery disease, congestive heart failure, and cardiomyopathies), chronic pulmonary disease (chronic obstructive pulmonary disease but not isolated asthma), diabetes mellitus, alcoholism, chronic liver disease (including cirrhosis), cerebrospinal fluid leaks, and functional or anatomic asplenia (including sickle cell disease)
- Aged 2-64 y living in special environment or social settings, such as Alaskan natives and certain American Indian populations as well as residents of nursing homes and other long-term-care facilities
- Aged 2-64 y who are immunocompromised, including those with HIV infection, leukemia, lymphoma, Hodgkin's disease, multiple myeloma, generalized malignancy, chronic renal failure, or nephrotic syndrome; those receiving immunosuppressive chemotherapy (including corticosteroids); and those who have received an organ or bone marrow transplant

Heptavalent conjugate vaccine is recommended for the following persons:

- Aged <2 y and high-risk children between 2 and 5 years of age

Daily oral penicillin V is recommended for children with functional (eg, sickle cell disease) or anatomic asplenia

### **Isolation**

None required

### **Precautions**

<sup>1</sup>See text for recommendations for revaccination.

BOXES

BOX 47-6. Control of Invasive *Streptococcus pneumoniae* Infections

---

## 48 . *Streptococcus pyogenes* — Dennis L. Stevens, PhD, MD

### Essentials of Diagnosis

- Pharyngitis: presence of sore throat, submandibular adenopathy, fever, pharyngeal erythema, exudates.
- Rheumatic fever: migratory arthritis, carditis, Sydenham's chorea, pharyngitis.
- Cellulitis: pink skin, fever, tenderness, swelling.
- Scarlet fever: sandpaper-like erythema, strawberry tongue, streptococcal pharyngitis or skin infection, high fever.
- Post-streptococcal glomerulonephritis: acute glomerulonephritis (hematuria, proteinuria) following pharyngitis or impetigo.
- Impetigo: dry, crusted lesions of the skin, weeping golden-colored fluid.
- Erysipelas: salmon red rash of face or extremity, well-demarcated border, fever, occasionally bullous lesions.
- Streptococcal toxic shock syndrome: isolation of Group A streptococcus from a normally sterile site, sudden onset of shock and organ failure.
- Necrotizing fasciitis, myonecrosis: deep, severe pain, fever, purple bullae shock, tissue destruction of fascia or muscle, organ failure.

### General Considerations

**A. Epidemiology.** *Streptococcus pyogenes* is a human pathogen without an animal reservoir. Group A streptococci (GAS) cause most streptococcal disease, but other groups are important pathogens in some settings ([Box 48-1](#)). Group A streptococcal infections have the highest incidence in children younger than age 10. The asymptomatic prevalence is also higher (15-20%) in children, compared with that in adults (<5%). Age is not the only factor; crowded conditions in temperate climates during the winter months are associated with epidemics of pharyngitis in school children as well as military recruits. Impetigo is most common in children from ages 2 to 5 and generally occurs in the summer in temperate climates and year-round in tropical areas .

Similarly, 90% of cases of scarlet fever occur in children 2 to 8 years old, and, like pharyngitis, it is most common in temperate regions during the winter months. An experiment of nature in the Faroe Islands suggested that susceptibility to scarlet fever is not dependent on young age per se. Scarlet fever had disappeared from that isolated island for several decades until it was reintroduced by a visitor with unsuspected scarlet fever. An epidemic of scarlet fever ensued, with significant attack rates in all age groups, suggesting that other factors (such as the lack of protective antibody against

scarlatina toxin or the introduction of a new strain) rather than age, predisposed those individuals to clinical illness.

In contrast to pharyngitis, impetigo, and scarlet fever, bacteremia has had the highest age-specific attack rate in the elderly and in neonates. Between 1986 and 1988, the prevalence of bacteremia increased 800-1000% in adolescents and adults in Western countries. Although some of this increase is attributable to IV drug abuse and puerperal sepsis, most of the increase is owing to cases of streptococcal toxic shock syndrome (strepTSS).

Human mucus membranes and skin serve as the natural reservoirs of *Streptococcus pyogenes*. Pharyngeal and cutaneous acquisition is spread person to person via aerosolized microdroplets and direct contact, respectively. Epidemics of pharyngitis and scarlet fever have also resulted from ingestion of contaminated nonpasteurized milk or food. Epidemics of impetigo have been reported, in tropical areas, day care centers, and among underprivileged children. Group A streptococcal infections in hospitalized patients occur during child delivery (puerperal sepsis), times of war (epidemic gangrene), surgical convalescence (surgical wound infection, surgical scarlet fever), or as a result of burns (burn wound sepsis). Thus, in most clinical streptococcal infections, the mode of transmission and portal of entry are easily ascertained. In contrast, among patients with strepTSS, the portal of entry is obvious in only 50% of cases.

**B. Microbiology.** Streptococci are gram-positive coccoid bacteria that grow in chains. Streptococci colonize the mucus membranes of animals, produce catalase, and may be aerobic, anaerobic, or facultative. Streptococci require complex media containing blood products for optimal growth. On blood agar plates, streptococci may cause complete (B), incomplete (A), or no hemolysis (C). The exhaustive work of Rebecca Lancefield has allowed hemolytic streptococci to be classified into Groups A through O based on acid extractable antigens of cell wall material. The availability of rapid latex agglutination kits provides even small clinical laboratories the means to identify streptococci according to Lancefield's grouping. Bacitracin susceptibility, bile esculin hydrolysis, and the CAMP test (flame-type synergistic hemolysis on a *Staphylococcus aureus* blood agar streak) are useful presumptive tests for classifying Groups A, D, or B streptococci, respectively. Modern schemes of classification of hemolytic and nonhemolytic streptococci use complex biochemical and genetic techniques.

**C. Pathogenesis.** Complex interactions between host epithelium and streptococcal factors such as M-protein, lipoteichoic acid components, and fimbriae are necessary for adherence. Fibronectin-binding protein (protein F) also contributes to adherence since protein F-deficient mutants are incapable of binding to epithelial cells.

Within the tissues, streptococci may evade opsonphagocytosis by destroying or inactivating complement-derived chemoattractants and opsonins (C5a peptidase) and by binding immunoglobulins. Expression of M-protein, in the absence of type-specific antibody, also protects the organism from phagocytosis by polymorphonuclear leukocytes and monocytes.

## **Bacterial Cell Structure & Extracellular Products**

**A. Capsule.** Some strains of *S pyogenes* possess luxuriant capsules of hyaluronic acid, resulting in large mucoid colonies on blood agar. Luxuriant production of M-protein may also impart a mucoid colony morphology, and this trait has been associated with M-18.

**B. Cell wall.** The cell wall is composed of a peptidoglycan backbone with integral lipoteichoic acid components. The function of lipoteichoic acid components is not well known; however, both peptidoglycan and lipoteichoic acid components have important interactions with the host.

**C. M-proteins.** Over 80 different M-protein types of Group A streptococci are currently described. M-protein also protects the organism against phagocytosis by polymorphonuclear leukocytes, although this property can be overcome by type-specific antisera.

**D. Streptolysin O.** Streptolysin O belongs to a family of oxygen-labile, thiol-activated cytolytic toxins and causes the broad zone of  $\beta$  hemolysis surrounding colonies of *S pyogenes* on blood agar plates. Thiol-activated cytolytic toxins bind to cholesterol on eukaryotic cell membranes, creating toxin-cholesterol aggregates that contribute to cell lysis via a colloid-osmotic mechanism. In situations in which serum cholesterol is high, ie, nephrotic syndrome, falsely elevated anti-streptolysin O antibody (ASO) titers may occur because both cholesterol and anti-ASO antibodies will "neutralize Streptolysin O." Striking amino acid homology exists between Streptolysin O and other thiol-activated cytolytic toxins.

**E. Streptolysin S.** Streptolysin S is a cell-associated hemolysin and does not diffuse into the agar media. Purification and characterization of this protein have been difficult, and its only role in pathogenesis may be in direct or contact cytotoxicity.

**F. Deoxyribonucleases A, B, C, and D.** Expression of deoxyribonucleases (DNases) in vivo elicits production of anti-DNase antibody following both pharyngeal and skin infection; this is most true for DNase B with Group A streptococci.

**G. Hyaluronidase.** This extracellular enzyme hydrolyses hyaluronic acid in deeper tissues, facilitating the spread of infection along fascial planes. Antihyaluronidase titers rise following *S pyogenes* infections, especially those involving the skin.

**H. Pyrogenic exotoxins.** Streptococcal pyrogenic exotoxins types A, B, and C, also called scarlatina or erythrogenic toxins, induce lymphocyte blastogenesis, potentiate endotoxin-induced shock, induce fever, suppress antibody synthesis, and act as superantigens. The identification of these three different types of pyrogenic exotoxins may in part explain why some individuals may have multiple attacks of scarlet fever.

Although all strains of Group A streptococci are endowed with genes for streptococcal pyrogenic exotoxin B, not all strains produce it, and even among producing strains, the quantity of toxin synthesized varies greatly from strain to strain.

Pyrogenic exotoxin C, like streptococcal pyrogenic exotoxin A, is bacteriophage-mediated, and expression is likewise highly variable. Recently, mild cases of scarlet fever in England and the United States have been associated with

streptococcal pyrogenic exotoxin C positive strains.

**I. Other superantigens.** Two new superantigens, mitogenic factor and streptococcal superantigen, have recently been described; however, their roles in pathogenesis have not been fully investigated.

## CLINICAL SYNDROMES

### PHARYNGITIS & THE ASYMPTOMATIC CARRIER

#### Clinical Findings

Patients with streptococcal pharyngitis have abrupt onset of sore throat, submandibular adenopathy, fever, and chilliness but usually not frank rigors. Cough and hoarseness are rare, but pain on swallowing is characteristic. The uvula is edematous, the tonsils are hypertrophied, and the pharynx is erythematous with exudates, which may be punctate or confluent. Acute pharyngitis is sufficient to induce antibody against M-protein, Streptolysin O, DNase and hyaluronidase, and, if present, pyrogenic exotoxins. Depending on the infecting strain, pharyngitis may progress to scarlet fever, bacteremia, suppurative head and neck infections, rheumatic fever, post-streptococcal glomerulonephritis, or strepTSS. Pharyngitis is usually self-limited and pain, swelling, and fever resolve spontaneously in 3-4 days even without treatment ([Boxes 48-2 and 48-3](#)).

#### Diagnosis

Definitive diagnosis is difficult when based only on clinical parameters, especially in infants, among which rhinorrhea may be the dominant manifestation. Even in older children with all of the above physical findings, the correct clinical diagnosis is made in only 75% of patients. Absence of any one of the classic signs greatly reduces the specificity. Rapid antigen detection tests in the office setting have a sensitivity and specificity of 40-90%. A popular approach in clinical practice is to obtain two throat swab samples from the posterior pharynx or tonsillar surface. A rapid strep test is performed on the first, and, if positive, the patient is treated with antibiotics and the second swab discarded. If the rapid strep test is negative, the second is sent for culture, and treatment is withheld, pending a positive culture.

### SCARLET FEVER

During the last 30-40 years, outbreaks of scarlet fever in the Western world have been infrequent and notably mild, and the illness has been referred to as pharyngitis with a rash or benign scarlet fever ([Table 48-1](#)). In contrast, in the latter half of the 19th century, mortalities of 25-35% were common in the United States, Western Europe, and Scandinavia. The fatal or malignant forms of scarlet fever have been described as either septic or toxic. Septic scarlet fever refers to patients who develop local invasion of the soft tissues of the neck and complications such as upper-airway obstruction, otitis media with perforation, meningitis, mastoiditis, invasion of the jugular vein or carotid artery, and bronchopneumonia.

Toxic scarlet fever is rare today, but, historically, patients initially developed severe sore throat, marked fever, delirium, skin rash, and painful cervical lymph nodes. In severe toxic cases, fevers of 107°F, pulses of 130-160 beats per minute, severe headache, delirium, convulsions, little if any skin rash, and death within 24 hours were common. These cases occurred before the advent of antibiotics, antipyretics, and anticonvulsants, and deaths were acutely the result of uncontrolled seizures and hyperpyrexia. In contrast, children with septic scarlet fever had prolonged courses and succumbed 2-3 weeks after the onset of pharyngitis. Complications of streptococcal pharyngitis and malignant forms of scarlet fever have been less common in the antibiotic era. Even before antibiotics became available, necrotizing fasciitis and myositis were not described in association with scarlet fever.

### **STREPTOCOCCAL PYODERMA (Impetigo contagiosa)**

Impetigo is most common in patients with poor hygiene or malnutrition. Colonization of the unbroken skin occurs first, then intradermal inoculation is initiated by minor abrasions, insect bites, etc. Single or multiple thick-crusts, golden-yellow lesions develop within 10-14 days. Penicillin orally or parenterally, or bacitracin or mupirocin topically, are effective treatments for impetigo and also reduce transmission of streptococci to susceptible individuals (see [Box 48-2](#)). None of these treatments, including penicillin, prevents post-streptococcal glomerulonephritis.

### **ERYSIPELAS**

Erysipelas is caused exclusively by *S pyogenes* and is characterized by an abrupt onset of fiery red swelling of the face or extremities. Distinctive features are well-defined margins, particularly along the nasolabial fold, scarlet or salmon red rash, rapid progression, and intense pain. Flaccid bullae may develop during the second to third day of illness, yet extension to deeper soft tissues is rare. Surgical debridement is not necessary, and treatment with penicillin is effective ([Box 48-4](#)). Swelling may progress despite treatment, although fever, pain, and the intense redness diminish. Desquamation of the involved skin occurs 5-10 days into the illness. Infants and elderly adults are most commonly afflicted, and, historically, erysipelas, like scarlet fever, was more severe before the turn of the century.

### **CELLULITIS**

Group A streptococci are the most common cause of cellulitis; however, alternative diagnoses may be obvious when associated with a primary focus, such as an abscess or boil (*Staphylococcus aureus*), dog bite (*Capnocytophaga*), cat bite (*Pasteurella multocida*), freshwater injury (*Aeromonas hydrophila*), seawater injury (*Vibrio vulnificus*), animal carcasses, *Erysipelothrix rhusiopathiae*, and so on. Clinical clues to the etiologic diagnosis are important because aspiration of the leading edge and punch biopsy yield a causative organism in only 15% and 40% of cases, respectively. Patients with lymphedema of any cause, such as lymphoma, filariasis, or postsurgical regional lymph node dissection (eg, mastectomy, carcinoma of the prostate), are predisposed to developing streptococcal cellulitis, as are patients with chronic venous stasis. Recently, recurrent saphenous vein donor site cellulitis has been attributed to Group A, C, or G streptococci.

Group A streptococci may invade the epidermis and subcutaneous tissues, resulting in local swelling, erythema, and pain. The skin becomes indurated and, unlike the brilliant redness of erysipelas, is a pinkish color. If fever, pain, or swelling increase, if bluish or violet bullae or discoloration appear, or if signs of systemic toxicity develop, a deeper infection, such as necrotizing fasciitis or myositis, should be considered (see below). An elevated serum creatinine phosphokinase suggests deeper infection, and prompt surgical inspection and debridement should be performed (see [Box 48-4](#)).

## **LYMPHANGITIS**

Cutaneous infection with bright red streaks ascending proximally is invariably caused by Group A streptococcus. Prompt parenteral antibiotic treatment is mandatory since bacteremia and systemic toxicity develop rapidly once streptococci reach the bloodstream via the thoracic duct.

## **NECROTIZING FASCIITIS**

Necrotizing fasciitis, originally called streptococcal gangrene, is a deep-seated infection of the subcutaneous tissue that results in progressive destruction of fascia and fat but may spare the skin itself. Necrotizing fasciitis has become the preferred term since *Clostridium perfringens*, *Clostridium septicum*, and *S aureus* can produce a similar pathologic process. Infection may begin at the site of trivial or unapparent trauma. Within the first 24 hours, swelling, heat, erythema, and tenderness develop and rapidly spread proximally and distally from the original focus.

During the next 24-48 hours, the erythema darkens, changing from red to purple and then to blue, and blisters and bullae form that contain clear yellow fluid. On the fourth or fifth day, the purple areas become frankly gangrenous. From the seventh to the tenth day, the line of demarcation becomes sharply defined, and the dead skin begins to reveal extensive necrosis of the subcutaneous tissue. Patients become increasingly prostrated and emaciated and may become unresponsive, mentally cloudy, or even delirious. Historically, aggressive fasciotomy and debridement (bearclaw fasciotomy) and irrigations with Dakin's solution (hypochlorous acid) achieved mortalities as low as 20%, even before antibiotics were available ([Box 48-5](#)). The time course of progression of necrotizing fasciitis is more rapid, and mortalities have been higher in the 1980-1990s, suggesting increased virulence of streptococci.

## **MYOSITIS**

Historically, streptococcal myositis has been an extremely uncommon infection, only 21 cases being documented from 1900 to 1985. Recently, the prevalence of streptococcal myositis has increased in the United States, Norway, and Sweden. Translocation of streptococci from the pharynx to the deep site of trauma (muscle) likely occurs hematogenously. Symptomatic pharyngitis or penetrating trauma is uncommon. Severe pain may be the only presenting symptom; swelling and erythema may be the only signs of infection. In most cases, a single muscle group is involved; however, because patients are frequently bacteremic, multiple sites of myositis or abscess can occur.

Distinguishing streptococcal myositis from spontaneous gas gangrene caused by *C perfringens* or *C septicum* may be difficult, although the presence of crepitus or gas in the tissue would favor clostridial infection. Myositis is easily distinguished from necrotizing fasciitis anatomically by surgical exploration or incisional biopsy, although clinical features of both conditions overlap and both necrotizing fasciitis and myonecrosis may occur together.

In published reports, the case-fatality rate of necrotizing fasciitis is between 20 and 50%, whereas that of streptococcal myositis is between 80 and 100%. Aggressive surgical debridement is extremely important because of the poor efficacy of penicillin described in human cases as well as in experimental models of streptococcal myositis (see [Box 48-5](#)).

## **PNEUMONIA**

Pneumonia caused by Group A streptococcus is most common in women in the second and third decades of life and causes large pleural effusions and empyema. Several liters of pleural fluid may accumulate within hours. Chest tube drainage is mandatory, although management is complicated by multiple loculations and fibrinous effusions, resulting in restrictive lung disease.

## **STREPTOCOCCAL TOXIC SHOCK SYNDROME**

### **Introduction**

In the late 1980s, invasive GAS infections occurred in North America and Europe in previously healthy individuals of all ages. This illness is associated with bacteremia, deep soft-tissue infection, shock, multi-organ failure, and death in 30% of cases. StrepTSS occurs sporadically, although minor epidemics have been reported. Most patients present with a viral-like prodrome, history of minor trauma, recent surgery, or varicella infection. The prodrome may be caused by a viral illness that predisposed to strepTSS, or these vague early symptoms may be related to the evolving infection. In cases associated with necrotizing fasciitis, the infection may begin deep in the soft tissue at a site of minor trauma that frequently does not result in a break in the skin. Although surgical procedures and viral infections such as varicella and influenza may provide portals of entry, no portal can be ascertained in 45% of cases. Preceding symptomatic pharyngitis is rare. Shock and organ failure are related to the production of cytokines by monocytes and lymphocytes stimulated with exotoxins, including pyrogenic exotoxins A, B, and C.

### **Clinical Findings**

**A. Signs and Symptoms.** The abrupt onset of severe pain is a common initial symptom of strepTSS. The pain most commonly involves an extremity but may also mimic peritonitis, pelvic inflammatory disease, acute myocardial infarction, or pericarditis. Treatment with nonsteroidal anti-inflammatory agents may mask the presenting symptoms or predispose to more severe complications, such as shock.

Fever is the most common presenting sign, although some patients present with

profound hypothermia secondary to shock. Confusion is present in over half of the patients and may progress to coma or combativeness. On admission, 80% of patients have tachycardia, and over half will have systolic blood pressure of <110 mm Hg. Of those with normal blood pressure on admission, most become hypotensive within 4 hours. Soft-tissue infection evolves to necrotizing fasciitis or myositis in 50-70% of patients, and these require emergent surgical debridement, fasciotomy, or amputation. An ominous sign is progression of soft-tissue swelling to violaceous or bluish vesicles or bullae (see section on necrotizing fasciitis).

Many other clinical presentations may be associated with strepTSS, including endophthalmitis, myositis, perihepatitis, peritonitis, myocarditis, meningitis, septic arthritis, and overwhelming sepsis. Patients with shock and multiorgan failure without signs or symptoms of local infections have a worse prognosis since definitive diagnosis and surgical debridement may be delayed.

**B. Laboratory Findings.** Hemoglobinuria is present and serum creatinine is elevated in most patients at the time of admission. Serum albumin concentrations are moderately low (3.3 grams/dl) on admission and drop progressively over 48-72 hours. Hypocalcemia, including ionized hypocalcemia, is detectable early in the hospital course. The serum creatine kinase level is a useful test to detect deeper soft-tissue infections, such as necrotizing fasciitis or myositis.

The initial hematologic studies demonstrate only mild leukocytosis, but a dramatic left shift (43% of white blood cells may be band forms, metamyelocytes, and myelocytes). The mean platelet count is normal on admission but may drop rapidly by 48 hours, even in the absence of criteria for disseminated intravascular coagulopathy.

Group A streptococcus is isolated from blood in 60% of cases and from deep tissue specimens in 95% of cases. M types 1, 3, 12, and 28 are the most common strains isolated. Pyrogenic exotoxins A and/or B have been found in isolates from the majority of patients with severe infection. Infections in Norway, Sweden, and Great Britain have been primarily caused by M type 1 strains that produce pyrogenic exotoxin B. Other novel pyrogenic exotoxins are being described that may also explain the recent enhanced virulence of Group A streptococcus.

**C. Course.** Shock is apparent early in the course, and fluid management is complicated by profound capillary leak. Adult respiratory distress syndrome occurs frequently (55%), and renal dysfunction, which precedes hypotension in many patients, may progress despite treatment. In patients who survive, serum creatinine levels return to normal within 4-6 weeks, although many will require dialysis. The recommended antibiotic therapy for strepTSS is shown in [Box 48-5](#). Overall, 30% of patients die despite aggressive treatment including IV fluids, colloid, pressors, mechanical ventilation, and surgical interventions, such as fasciotomy, debridement, exploratory laparotomy, intraocular aspiration, amputation, and hysterectomy.

### **Nonsuppurative Complications**

The nonsuppurative complications of *S pyogenes* infection are acute rheumatic fever and acute glomerulonephritis.

**A. Rheumatic Fever.** The prevalence of acute rheumatic fever (ARF) in the Western world decreased dramatically after World War II (0.5-1.88 cases per 100,000 school age children per year). In contrast, in India and Sri Lanka, the prevalence of ARF has remained 140/100,000 for children between 5 and 19 years of age. Socioeconomic factors seem to be important because the highest rates in all countries have been among the impoverished in large cities. Although improved living conditions and the development of penicillin have had important roles in reducing the prevalence of ARF in the United States, the decreases had begun before antibiotics were available.

In addition, a resurgence of ARF has occurred predominantly among U.S. military recruits and white middle-class civilians. A particularly frightening aspect of these recent civilian cases was the low incidence of symptomatic pharyngitis (24-78%). Thus our modern primary prevention strategy (diagnosis of acute GAS pharyngitis with penicillin treatment within 10 days) would not have prevented ARF in these cases ([Box 48-6](#)).

The clinical manifestations of acute rheumatic fever are multiple, and because each is not specific for ARF, several criteria must be met to establish a definitive diagnosis. Simply put, two major manifestations or one major and two minor manifestations plus, in either case, evidence of an antecedent GAS infection are required for definitive diagnosis. The major manifestations and the frequency with which they occur during first attacks of ARF are as follows: arthritis (75%), carditis (40-50%), chorea (15%), and subcutaneous nodules (<10%). The minor manifestations are fever, arthralgia, heart block, presence of acute-phase reactants in the blood (C-reactive protein, leukocytosis, and elevated erythrocyte sedimentation rate), and prior history of ARF or rheumatic heart disease.

Carditis, when present, occurs during the first 3 weeks of illness and may involve pericardium, myocardium, and endocardium. Patients with pericarditis may have chest pain or pericardial effusion, whereas those with myocarditis may have intractable heart failure. Manifestations of acute endocarditis involve the development of new murmurs of mitral regurgitation, or aortic regurgitation, the latter being sometimes associated with a low-pitched apical middiastolic flow murmur (Carey Coombs murmur). Murmurs of mitral stenosis and aortic stenosis are not detected acutely during first attacks of ARF but are chronic manifestations of rheumatic heart disease. Migratory arthritis involves several joints, most frequently the knees, ankles, elbows, and wrists, in more than 50% of patients. Each involved joint has evidence of inflammation that characteristically resolves within 2-3 weeks with no progression to chronic arthritis or articular damage.

Subcutaneous nodules occur several weeks into the course of ARF and are found over bony surfaces or tendons. They last only 1-2 weeks and have in some cases been associated with severe carditis. Erythema marginatum is an evanescent, nonpainful erythematous eruption occurring on the trunk or proximal extremities. Individual lesions can develop and disappear within minutes, but the process may wax and wane over several weeks or months. Sydenham's chorea often occurs later in the course than other manifestations of ARF and is characterized by rapid nonpurposeful choreiform movements of the face, hands, and feet. Attacks usually disappear during sleep but may persist for 2-4 months.

**B. Post-streptococcal Glomerulonephritis.** Acute glomerulonephritis (AGN) can follow either pharyngeal or skin infection and is associated with GAS strains possessing M types 12 and 49, respectively. During epidemics of skin or pharyngeal infection produced by a nephritogenic strain, attack rates of 10-15% have been documented with latent periods of 10 days after pharyngitis and 3 weeks after pyoderma. Nonspecific symptoms include lethargy, malaise, headache, anorexia, and dull back pain. The classic signs of AGN are all related to fluid overload and are manifested initially by edema, both dependent and periorbital. Hypertension develops in most patients and is usually mild. Severe cases may be characterized by ascites, pleural effusion, encephalopathy, and pulmonary edema, although evidence of heart failure per se is lacking.

Evidence of glomerular damage by renal biopsy has been documented in nearly 50% of contacts of siblings with AGN, suggesting that, as in ARF, subclinical disease is not uncommon after infection with certain strains of GAS. Unlike rheumatic fever, but similar to scarlet fever, glomerulonephritis occurs most commonly in children between 2 and 6 years of age. Like ARF and scarlet fever, AGN may affect several members of the same family. Recurrences or secondary attacks occur only rarely, and there is little to suggest that AGN progresses to chronic renal failure.

The differential diagnosis of post-streptococcal AGN must include Henoch-Schonlein disease, polyarteritis nodosa, idiopathic nephrotic syndrome, leptospirosis, hemolytic uremic syndrome (*Escherichia coli* 0157:H7), and malignant hypertension. The diagnosis is simpler if there is a recent history of symptomatic GAS pharyngitis, impetigo, or scarlet fever. Elevated or rising antibody titers to streptococcal antigens such as ASO, anti-DNase A or B, and/or antihyaluronidase are helpful, although ASO concentration may be low in patients with pyoderma. A careful urinalysis to document proteinuria and hematuria should be performed, but it is mandatory to demonstrate red blood cell casts because the latter is the hallmark of glomerular injury. The blood urea nitrogen and creatinine values are elevated and if nephrotic syndrome is present the serum cholesterol level is elevated and serum albumin concentration is low. Twenty-four-hour excretion of protein is usually less than 3 g, and total hemolytic complement and C3 levels are markedly reduced.

### **Treatment of Group A Infections**

During epidemics, particularly when rheumatic fever or a post-streptococcal glomerulonephritis are prevalent, treatment of asymptomatic carriers may be necessary. Studies by the U.S. military have shown that monthly injections of benzathine penicillin greatly reduce the incidence of streptococcal pharyngitis and rheumatic fever in young soldiers living in crowded conditions.

Erythromycin resistance of *S pyogenes* is currently 4% in Western countries; however, in Japan in 1974, the rate reached 72%. Sulfonamide resistance currently is reported in <1% of GAS isolates.

Resistance to penicillin has not been described, yet in some settings there is a lack of in vivo efficacy despite in vitro susceptibility to penicillin. Three mechanisms may explain this lack of efficacy.

Penicillin failure in pharyngitis, tonsillitis, or mixed infections may be caused by inactivation of penicillin in situ by beta lactamases produced by cocolonizing organisms such as *Bacteroides fragilis*, *Haemophilus influenzae*, or *S aureus*. For example, the failure rate of penicillin treatment of GAS pharyngitis may approach 25%, and, if such patients are treated with a second course of penicillin, the failure rate may approach 80%, perhaps owing to selection of beta-lactamase-producing bacteria. In contrast, cures of 90% have been achieved when treatment consisted of amoxicillin plus clavulanate, oral cephalosporin, or clindamycin.

Streptococcal cellulitis responds quickly to penicillin, although, in some cases in which staphylococcus is of concern, nafcillin or oxacillin may be a better choice. For treatment of streptococcal pneumonia, prolonged penicillin therapy, thoracoscopy, and decortication of the pleura may be necessary.

## 49 . Enterococci — Robin Patel, MD

### Essentials of Diagnosis

- Gram stain shows gram-positive cocci that occur in singles, pairs, and short chains; recovery of microorganism from culture of blood or other sterile source.
- Lancefield group D antigen.
- Clinical isolates: *Enterococcus faecalis*, 74%; *E faecium*, 16%; other species, 10%.
- Facultative anaerobes grow in 6.5% NaCl at pH 9.6 and at temperatures ranging from 10 °C to 45 °C, and grow in the presence of 40% bile salts and hydrolyze esculin and L-pyrrolidonyl- $\beta$ -naphthylamide.
- Infections typically of a gastrointestinal or genitourinary origin.
- The most common infections are urinary tract infection, bacteremia, endocarditis, intra-abdominal and pelvic infection, and wound and soft tissue infection.

### General Considerations

**A. Epidemiology.** Enterococci are able to grow and survive under harsh conditions and can be found in soil, food, water, and a wide variety of animals. The major habitat of these organisms is the gastrointestinal tract of humans and other animals, where they make up a significant portion of the normal gut flora. Most enterococci isolated from human stools are *E faecalis*, although *E faecium* are also commonly found in the human gastrointestinal tract. Small numbers of enterococci are occasionally found in oropharyngeal and vaginal secretions and on the skin, especially in the perineal area. Because enterococci are part of the normal gut flora of almost all humans, infections caused by these organisms may be endogenously acquired from the patient's own flora.

Enterococcal infections also occur in hospitalized patients or in patients undergoing peritoneal or hemodialysis, and the organisms causing such infections often appear to be exogenously acquired. There is clear-cut evidence for spread of strains of enterococci between patients and even for dissemination of such strains from one institution to another. Strains of enterococci causing nosocomial infections have been found on the hands of medical personnel and on environmental surfaces in hospitals and in nursing homes. Most likely, enterococci from patients or hospital personnel first colonize the gastrointestinal tract (or occasionally the skin and groin or other contiguous areas) before causing infections in other patients. Devices such as electronic rectal thermometers may also aid in the spread of enterococci, especially antibiotic-resistant enterococci.

Enterococci account for 12% of nosocomial bacterial infections. The most common nosocomial enterococcal infections involve the urinary tract (62% of cases) and are often associated with urinary tract instrumentation or structural abnormalities. Wound

infections are the next most common presentation of nosocomial enterococcal infections, usually involving abdominal or pelvic sites (25% of cases). Bacteremia (10% of cases) is the third most commonly reported nosocomial enterococcal infection.

Risk factors for acquiring nosocomial enterococcal infection or colonization, especially those caused by vancomycin-resistant enterococci (VRE), include being critically ill; having severe underlying disease; being immunosuppressed (especially patients on oncology or transplant wards); having renal insufficiency; undergoing intra-abdominal or cardiothoracic surgical or other invasive procedures; having an indwelling urinary or central venous catheter; having a prolonged hospital or intensive care unit stay; intrahospital transfer between floors; multi-antimicrobial agent, third-generation cephalosporin, anti-anaerobic antimicrobial or vancomycin therapy; proximity to infected patients; care by colonized staff; and the receipt of selective bowel decontamination, sucralfate, or enteral feedings.

**B. Microbiology.** Enterococci are gram-positive cocci that occur in singles, pairs, and short chains. The genus *Enterococcus* contains over a dozen species. *E faecalis* isolates account for ~74% of organisms encountered in the clinical microbiology laboratory. *E faecium* accounts for 16% of such isolates. The other *Enterococcus* species, including *E durans*, *E avium*, *E casseliflavus*, *E gallinarum*, *E raffinosus*, and *E hirae* (among others), are encountered clinically in ~10% of cases. Enterococci are facultative anaerobes that are able to grow in 6.5% NaCl at pH 9.6 and at temperatures ranging from 10 to 45 °C. They carry the Lancefield group D antigen and will grow in the presence of 40% bile salts. They hydrolyze esculin and L-pyrrolidonyl- $\beta$ -naphthylamide.

Enterococci are characterized by intrinsic resistance to many antibiotics (eg, oxacillin, clindamycin, cephalosporins, and aminoglycosides) and the capacity to acquire resistance to many others. The uniformly poor activity of  $\beta$ -lactams, particularly cephalosporins, against enterococci results from reduced affinity of the penicillin-binding proteins. Unlike most streptococci, enterococci are inhibited but not killed by apparently active penicillins (ampicillin, mezlocillin, penicillin, piperacillin), carbapenems (imipenem, meropenem), and glycopeptides (vancomycin or teicoplanin). Cephalosporins are not clinically useful against enterococci.

Enterococci are also naturally resistant to clinically achievable levels of aminoglycosides used alone. For treating serious enterococcal infections, combination therapy is recommended, generally penicillin, ampicillin, or vancomycin with an aminoglycoside, usually gentamicin or streptomycin. The rationale for this approach is to weaken the cell wall with the cell wall-active agent, thereby facilitating entry of the then bactericidal aminoglycoside. Such combinations have been shown to be synergistic, as long as the organism is susceptible to the cell wall-active agent and does not demonstrate high-level resistance to the aminoglycoside (gentamicin minimum inhibitory concentration = 500 ug/mL, streptomycin minimum inhibitory concentration = 2000 ug/mL).

Acquired resistance in enterococci can develop by genetic mutation or by acquiring altered DNA from a resistant organism. Enterococci have been reported to have acquired high-level resistance to aminoglycosides, cell wall-active agents (including penicillins and vancomycin), chloramphenicol, clindamycin, erythromycin, and the newer

quinolones. *E faecium* isolates exhibit more antibiotic resistance than do other species.

Most enterococci with high-level resistance to aminoglycosides contain aminoglycoside-modifying enzymes. When high-level resistance to aminoglycosides is a concern, only gentamicin and streptomycin minimum inhibitory concentrations need to be tested in the clinical microbiology laboratory because the enzyme that neutralizes gentamicin also modifies tobramycin, amikacin, kanamycin, and netilmicin but not streptomycin. In addition to enzymatic resistance, ribosomal modification has been described as a second mechanism for high-level streptomycin resistance.

Acquired resistance to ampicillin and penicillin is generally caused by altered penicillin-binding proteins. This confers higher levels of resistance than the intrinsic resistance present in enterococci. This mechanism confers resistance to all  $\beta$ -lactams (including the carbapenems).  $\beta$ -lactamase production among enterococci is rare and has been reported in a few hospitals.

In the background of increasing resistance of enterococci to penicillins and aminoglycosides, vancomycin resistance emerged in the late 1980s. In vancomycin-resistant cells, an abnormal pentapeptide peptidoglycan precursor, with which vancomycin interacts minimally, is synthesized and incorporated into the cell wall of the organism. Resistance to the glycopeptide antibiotic vancomycin in enterococci, as understood to date, is phenotypically and genotypically heterogeneous. Three glycopeptide resistance phenotypes, VanA, VanB, and VanC, have been described in enterococci; they can be distinguished by the level and inducibility of resistance to vancomycin and teicoplanin. VanA-type glycopeptide resistance is characterized by acquired inducible resistance to both vancomycin and teicoplanin, and it is transferable. VanB-type glycopeptide resistance is characterized by acquired inducible resistance to various concentrations of vancomycin but not to teicoplanin, and it is also transferable. VanC-type glycopeptide resistance is characterized by low-level vancomycin resistance but teicoplanin susceptibility and has been described as an intrinsic property of most isolates of *E gallinarum*, *E casseliflavus*, and *E flavescens*. VanD-, VanE- and VanG-type glycopeptide resistance have been recently described and do not appear to be common.

**C. Pathogenesis.** Little is known about specific pathogenesis and virulence factors of enterococci. Enterococcal bacteremia has, however, been associated with high mortality rates (42-68%). In many cases, enterococci cause infections in severely debilitated hosts and are part of a polymicrobial infection. Thus their independent contribution to mortality and morbidity is difficult to assess. The intrinsic and acquired resistance of enterococci to many antimicrobial agents, as discussed previously, is an important factor that allows these organisms to survive and proliferate in patients receiving antimicrobial therapy. In addition, enterococci are able to adhere to heart valves and renal epithelial cells, properties that likely contribute to their ability to cause endocarditis and urinary tract infections, respectively.

Although enterococci are found in one-fifth of intra-abdominal infections, their exact role in polymicrobial infection is controversial. In cases of intra-abdominal infections, selective therapy against *Escherichia coli* and *Bacteroides fragilis*, which has minimal in vitro activity against enterococci, has been found to be sufficient to reduce enterococcal

counts. Nevertheless, in animal models of experimental polymicrobial intra-abdominal infection, enterococci have been found to enhance abscess formation, weight loss, and mortality. Similarly, clinical reports have indicated the emergence of enterococcal abscesses and bacteremia after treatment of intra-abdominal sepsis with antimicrobial agents that lack significant in vitro enterococcal activity. A recent multicenter study of intra-abdominal infection has found that the presence of enterococci in the initial cultures, in addition to serious underlying disease, independently predicts treatment failure with broad-spectrum antimicrobial regimens that lack specific enterococcal activity.

## **CLINICAL SYNDROMES**

### **URINARY TRACT INFECTION**

Urinary tract infections, including uncomplicated cystitis, pyelonephritis, prostatitis, and perinephric abscess, are the most common type of clinical infections produced by enterococci ([Box 49-1](#)). Most enterococcal urinary tract infections are nosocomial and are associated with urinary catheterization or instrumentation.

### **BACTEREMIA & ENDOCARDITIS**

Nosocomial enterococcal bacteremias are commonly polymicrobial. Portals of entry for enterococcal bacteremia include the urinary tract, intra-abdominal or pelvic sources, wounds (especially burns, decubitus ulcers, and diabetic foot infections), intravascular catheters, and the biliary tree. Metastatic infections other than endocarditis are rare in enterococcal bacteremia.

Enterococci account for ~5-10% of all cases of infective endocarditis (see [Chapter 11](#)). Most cases are caused by *E faecalis*, but *E faecium*, *E casseliflavus*, *E durans*, *E gallinarum*, and *E raffinosus* have also been isolated from patients with endocarditis. Only ~2% of cases of enterococcal bacteremia are associated with endocarditis, and this is much more common in patients whose bacteremia is community acquired versus those with nosocomial enterococcal bacteremia. Enterococcal endocarditis is a disease of older patients, with males outnumbering females in most series. Most cases occur in patients with underlying valvular heart disease or prosthetic valves, although enterococci are capable of causing infections of anatomically normal valves. An association between enterococcal endocarditis and urinary tract infection or urinary instrumentation in older men and abortion or childbirth in younger women has been suggested. Enterococci usually produce left-sided endocarditis with more frequent involvement of the mitral than the aortic valve. The typical clinical course of enterococcal endocarditis is that of subacute bacterial endocarditis. There is a suggestion that the relapse rate is higher in patients who have had symptoms of endocarditis for = 3 months before treatment, which has implications for length of therapy (see below).

### **INTRA-ABDOMINAL & PELVIC INFECTION**

Enterococci are frequently found as part of mixed aerobic and anaerobic flora in intra-abdominal and pelvic infections. As discussed above, the exact role of enterococci

in these mixed aerobic and anaerobic intra-abdominal and pelvic infections is unclear. Enterococci can cause spontaneous peritonitis in patients with nephrotic syndrome or cirrhosis and can cause peritonitis in patients undergoing chronic ambulatory peritoneal dialysis. Monomicrobial enterococcal peritonitis is also occasionally seen as a complication of abdominal surgery or trauma. Enterococci can produce abscesses and bacteremia as a complication of endometritis, Cesarean section, and acute salpingitis.

## **WOUND & SOFT TISSUE INFECTION**

Enterococci may be isolated from mixed cultures with gram-negative bacilli and anaerobes in surgical wound infections, decubitus ulcers, and diabetic foot infections; the significance of enterococci in these settings is difficult to assess. Enterococcal wound colonization and sepsis have been described in burn patients whose wounds have been covered with porcine xenografts presumably contaminated with enterococci. Enterococci occasionally cause chronic osteomyelitis.

## **MENINGITIS**

Enterococci rarely cause meningitis. Most cases occur in patients who have anatomic defects of the central nervous system or who have had previous neurosurgery or head trauma. Rarely, however, meningitis may be a complication of high-grade bacteremia such as that seen in patients with enterococcal endocarditis. Meningitis may also be seen in association with enterococcal bacteremia in patients with human immunodeficiency virus infection and acute leukemia and in neonates and transplant recipients.

## **NEONATAL SEPSIS**

### **Introduction**

Enterococci may cause neonatal sepsis characterized by fever, lethargy, and respiratory difficulty accompanied by bacteremia, meningitis, or both. Early onset bacteremia in otherwise normal neonates may be seen, as well as nosocomial bacteremia, meningitis, or both, which has been described in premature or low-birth-weight neonates who have nasogastric tubes and intravascular devices.

### **Diagnosis**

The diagnosis of enterococcal infection is made by isolating enterococci from typically sterile sites (eg, urine, blood, intra-abdominal or pelvic fluid, or spinal fluid). As discussed above, community acquisition of enterococcal bacteremia suggests the possible presence of endocarditis. The diagnosis of endocarditis, in the appropriate clinical context (see [Chapter 11](#)), may be further confirmed by the presence of clinical findings consistent with endocarditis as well as by the use of echocardiography. The diagnosis of intra-abdominal and pelvic infections, in the appropriate clinical context, can be assisted by the use of ultrasound or computed tomographic imaging with drainage, Gram stain, and culture of any fluid collection(s) present.

The diagnosis of enterococcal meningitis can be confirmed by the isolation of

enterococci from the spinal fluid. Typically, enterococcal meningitis is associated with a low cerebrospinal fluid leukocyte count (< 200/mL), although this is not always the case.

The isolation of enterococci from respiratory secretions is of questionable significance, although there are very rare well-documented cases of enterococcal pneumonia and even lung abscesses in patients with severe and debilitating diseases.

## Treatment

Penicillin or ampicillin remains the antibiotic of choice for treating enterococcal infections such as urinary tract infections, peritonitis, and wound infections (ie, infections that do not require bactericidal treatment) ([Box 49-2](#)). Vancomycin is the alternative agent for patients allergic to penicillin or for organisms with high-level penicillin resistance that are  $\beta$ -lactamase negative and vancomycin susceptible.

Combination therapy with a cell wall-active agent such as penicillin, ampicillin, or vancomycin, along with an aminoglycoside, is essential for the treatment of enterococcal endocarditis and probably for enterococcal meningitis as well. The situation is not as clear-cut for enterococcal bacteremia alone; there is no consensus as to whether combination therapy is required in this setting.

For the treatment of enterococcal endocarditis, combinations of cell wall-active agents such as penicillin, ampicillin, or vancomycin with aminoglycosides (usually streptomycin or gentamicin) are required (see [Chapter 11](#) for specific treatment recommendations). In most cases, 4 weeks of combination therapy appear to be adequate, with a 6-week regimen reserved for patients who have had symptoms for > 3 months before starting treatment, for patients with prosthetic valves, or for patients who have relapsed after previous shorter courses of therapy.

Most strains of enterococci are susceptible to nitrofurantoin, and this agent has been successfully used to treat uncomplicated enterococcal infections limited to the urinary tract. The quinolones such as ciprofloxacin, ofloxacin, levofloxacin, gatifloxacin, enoxacin, and norfloxacin have in vitro activity against enterococci and may be useful for treating some enterococcal urinary tract infections, but their effectiveness for enterococcal infections in general has not been convincingly demonstrated, and increasing resistance has been demonstrated. Tetracyclines and chloramphenicol may exhibit in vitro activity against some strains of enterococci, but they are only bacteriostatic against enterococci, and clinical failures of chloramphenicol and tetracyclines have been reported.

The emergence of multiply resistant enterococci now greatly complicates therapeutic choices. For patients who have endocarditis caused by enterococci with high-level gentamicin resistance, it is useful to test for high-level streptomycin resistance because some highly gentamicin-resistant strains are synergistically killed by cell wall-active agents plus streptomycin. For endocarditis due to strains with both high-level streptomycin and gentamicin resistance, no combination will consistently produce synergism. These patients may be treated with prolonged courses (8-12 weeks) of intravenous ampicillin given by continuous infusion, although this approach should be considered experimental at this time. Surgical excision of infected valves may be

required in such cases.

Infections caused by enterococci with high-level penicillin resistance and  $\beta$ -lactamase negativity should be treated with vancomycin.  $\beta$ -lactamase-producing, penicillin- and ampicillin-resistant enterococci remain susceptible to  $\beta$ -lactam- $\beta$ -lactamase inhibitor combinations such as ampicillin-sulbactam and amoxicillin-clavulanate. VRE that remain susceptible to penicillin or ampicillin may be treated with penicillin or ampicillin. Infections caused by organisms with both high-level penicillin resistance and vancomycin resistance should be treated with either quinupristin-dalfopristin or linezolid. Notably, *E faecium* is more susceptible to quinupristin-dalfopristin than is *E faecalis*. Neither quinupristin-dalfopristin nor linezolid have bactericidal activity against VRE resulting in enormous challenges in the management of VRE endocarditis.

## Prevention & Control

Prophylaxis for Infective Endocarditis. Antimicrobial prophylaxis for enterococcal endocarditis is recommended for patients with certain cardiac lesions predisposing to endocarditis who undergo invasive procedures with an increased risk of enterococcal bacteremia. Details of patients, procedures, and regimens are outlined in [Chapter 11](#).

Prevention of Vancomycin Resistance. From 1989 to 1993, the percentage of nosocomial enterococcal infections reported to the Centers for Disease Control and Prevention's National Nosocomial Infection Surveillance System that were caused by VRE increased from 0.3 to 7.9%. This overall increase primarily reflected the 34-fold increase in the percentage of VRE infections in patients in intensive care units (ie, from 0.4 to 13.6%), although a trend toward an increased percentage of VRE infections in non-intensive care patients was also noted.

Laboratory experiments have achieved the transfer of high-level vancomycin resistance from enterococci to *Staphylococcus aureus*, and reduced susceptibility of *S aureus* to vancomycin has recently been described in clinical *S aureus* isolates, although the mechanism of the latter resistance differs from that in enterococci. Vancomycin resistance has also been transferred by conjugation or transformation from enterococci to *Streptococcus sanguis*, *Lactococcus lactis*, *Streptococcus pyogenes*, and *Listeria monocytogenes*. The *vanA* gene has been found in vancomycin-resistant clinical isolates of *Oerskovia turbata* and *Arcanobacterium haemolyticum* (typically these organisms are vancomycin susceptible) isolated from the stools of two patients during an outbreak of VRE infection in London. The *vanA* gene has been identified in a *Bacillus circulans* clinical isolate. The *vanB* gene has recently been found in a vancomycin-resistant isolate of *Streptococcus bovis* isolated from a stool swab collected from a patient on admission as surveillance for VRE. The potential for emergence of vancomycin resistance in clinical isolates of *Staphylococcus epidermidis*, *Streptococcus pneumoniae*, viridans streptococci, and *Corynebacterium* spp. as a result of transfer of vancomycin resistance genes from enterococci is also a public health concern.

In November 1994, the Hospital Infection Control Practices Advisory Committee of the Centers for Disease Control and Prevention issued the following recommendations for preventing and controlling the spread of vancomycin resistance with a special focus on VRE. It was recommended that each hospital through collaboration of its quality

improvement and infection control programs; pharmacy and therapeutics committee; microbiology laboratory; clinical departments; and nursing, administrative, and housekeeping services, develop a comprehensive institution-specific strategic plan to detect, prevent, and control infection and colonization with VRE. The first aspect of this plan incorporated prudent vancomycin use. (Vancomycin has been reported as a risk factor for infection and colonization with VRE.) ([Table 49-1.](#))

In addition, education programs concerning the epidemiology of VRE and the potential impact of this pathogen on the cost and outcome of patient care were recommended for hospital staff including attending and consulting physicians; medical residents and students; pharmacy, nursing, and laboratory personnel; and other direct patient care providers. Specific recommendations were also issued for the microbiology laboratory regarding the detection, reporting, and control of VRE. In addition, recommendations were given regarding how to proceed when VRE are isolated from a clinical specimen, how to screen for detection of VRE, and how to prevent transmission of VRE once identified ([Box 49-3](#)). Recommendations for screening for roommates found to be infected or colonized with VRE were also issued.

### **BOX 49-3. Prevention of VRE Transmission**

- All patients harboring VRE should be placed in private rooms or the same room as other patients who have VRE.
- Clean, nonsterile gloves should be worn when entering the room of a VRE-infected or -colonized patient.
- When caring for such a patient, a change of gloves is necessary after contact with material that could contain high concentrations of VRE (eg, stool).
- A gown should be worn when entering the room of a VRE patient if (a) substantial contact with the patient or with environmental surfaces in the patient's room is anticipated; (b) the patient is incontinent; or (c) the patient has had an ileostomy or colostomy, has diarrhea, or has a wound drainage not contained by the dressing.
- Gloves and gowns should be removed before leaving the patient's room, and the health care worker's hands should be washed with antiseptic soap or waterless antiseptic agent.
- Dedicated noncritical items such as stethoscopes, sphygmomanometers, and rectal thermometers should be assigned to a single patient or cohort of patients infected or colonized with VRE.
- If such devices are to be used on other patients, they should be adequately cleaned and disinfected first.

## 50 . Other Gram-Positive Cocci — Robin Patel, MD

### VIRIDANS GROUP STREPTOCOCCI, INCLUDING *ABIOTROPHIA DEFECTIVA* & *ABIOTROPHIA ADJACENS*

#### Essentials of Diagnosis

- Facultatively anaerobic gram-positive cocci, catalase negative, coagulase negative.
- a or ? hemolytic on blood agar.
- *Abiotrophia defectiva* and *Abiotrophia adjacens* require pyridoxal or thiol group supplementation.
- *Streptococcus milleri* group organisms often exhibit Lancefield antigens A, C, F, or G and often have a butterscotch odor.

#### General Considerations

**A. Epidemiology.** Viridans streptococci are part of the normal microbial flora of humans and animals and are indigenous to the upper respiratory tract, the female genital tract, all regions of the gastrointestinal tract, and, most significantly, the oral cavity. Clinically significant species that are currently recognized as belonging to the viridans group of streptococci include *Streptococcus anginosus*, *S constellatus*, *S cristatus*, *S gordonii*, *S intermedius*, *S oralis*, *S mitis*, *S mutans*, *S cricettus*, *S rattis*, *S parasanguis*, *S salivarius*, *S thermophilus*, *S sanguinis*, *S sobrinus*, and *S vestibularis*.

Detailed studies of the ecology of strains in the oral cavity and oropharynx have been performed. The buccal mucosa and initial dental plaque are associated with *S sanguis* and *S mitis*, the dorsum of the tongue with *S mitis* and *S salivarius*, mature supragingival plaque with *S gordonii*, and subgingival plaque with *S anginosus*. In healthy individuals, adherence of viridans streptococci may provide "colonization resistance" within the oral cavity preventing the establishment of more pathogenic bacteria. Fibronectin, a complex glycoprotein found on the surface of oral epithelial cells, selectively promotes attachment of *S salivarius*, *S mutans*, and other gram-positive cocci to oral epithelial cells. If fibronectin is lost, as occurs in chronically ill or hospitalized patients, adherence of gram-negative bacilli to oral epithelial cells is increased, predisposing to the development of invasive gram-negative bacillary infections.

Viridans streptococci are strongly associated with bacterial endocarditis (see [Chapter 11](#)). Notably, endocarditis caused by *A defectiva* and *A adjacens* carries a higher mortality rate than that reported for viridans streptococci overall. Relapse is reported more frequently in endocarditis cases caused by *A defectiva* and *A adjacens*. In endocarditis cases caused by other viridans streptococci, members of the *S milleri* group are associated with deep-seated abscesses in visceral organs.

**B. Microbiology.** Viridans group streptococci are facultatively anaerobic gram-positive cocci that do not produce catalase or coagulase and, on blood agar, are typically  $\alpha$  or  $\beta$  hemolytic. Although some isolates react with Lancefield grouping antisera, the species do not conform to the specific serogroups, and many isolates are entirely nongroupable. Resistance to optochin and lack of bile solubility can distinguish viridans streptococci from *Streptococcus pneumoniae* (which also produces a hemolysis on blood agar). Most viridans streptococci grow well on conventional blood culture media. On solid agar, viridans streptococci are usually facultatively anaerobic, but some strains may be capnophilic or microaerophilic. The colonies vary in size and appearance depending on the composition of the medium and the atmosphere of incubation. In broth cultures, viridans streptococci appear as spherical or ovoid cells that form chains or pairs. The organisms are nonmotile and non-spore forming, and they ferment carbohydrates with acid but not gas production.

Viridans streptococci can be distinguished by their biochemical characteristics. *S milleri*, *S constellatus*, and *S anginosus* constitute the *S milleri* group of viridans streptococci. Members of the *S milleri* group of viridans streptococci often require CO<sub>2</sub> for growth and typically grow as tiny colonies that may be  $\alpha$ ,  $\beta$ , or  $\gamma$  hemolytic on sheep blood agar. Members of the *S intermedius* group often exhibit Lancefield antigens A, C, F, or G and often have a butterscotchlike odor.

*A defectiva* and *A adjacens* are defined by their requirement for pyridoxal or thiol group supplementation for growth. These organisms form satellite colonies around *Staphylococcus aureus* and other microbes, and their colonies are typically small.

**C. Pathogenesis.** Viridans streptococci have been considered to be bacteria of low virulence. An exception is those members of the *S milleri* group that have a propensity for producing localized purulent collections. The reasons for this pathogenic characteristic are unknown. Infections with viridans streptococci usually result from spread of organisms outside of their normal habitat, especially in patients at risk for endocarditis or immunocompromised patients. Their most important virulence trait consists of an ability to adhere to and propagate on cardiac valves, leading to endocarditis; the presence of extracellular dextran likely plays a role in this regard. In addition to causing infective endocarditis, certain species of viridans streptococci, notably *S mutans*, have a strong association with the development of dental caries. The high cariogenic potential of *S mutans* is thought to be related to its ability to adhere in large masses to teeth and to produce high concentrations of acid from the fermentation of dietary sugars.

## CLINICAL SYNDROMES

### 1. ENDOCARDITIS

Viridans streptococci have a strong association with bacterial endocarditis (see [Chapter 11](#)) ([Box 50-1](#)). *A defectiva* and *A adjacens* were once an important cause of culture-negative endocarditis. However, current laboratory media and techniques enable these "nutritionally variant streptococci" to be identified more readily.

## 2. BACTEREMIA

Viridans streptococci account for 2.6% of positive blood cultures reported from clinical laboratories; however, of these, only about one-fifth are thought to be clinically significant (the remainder are attributed to contamination or transient bacteremia). Viridans streptococci are, however, one of the leading causes of bacteremia in febrile neutropenic patients. Viridans streptococcal bacteremia in neutropenic patients usually occurs in association with aggressive cytoreductive therapy for acute leukemia or allogeneic bone marrow transplantation. The prophylactic administration of trimethoprim-sulfamethoxazole or the quinolones, the presence of mucositis, and the presence of indwelling central venous catheters are associated with viridans streptococcal bacteremia in these populations.

Patients may present with fever alone; however, neurologic, pulmonary, and cardiovascular manifestations may be seen, and a fulminant shock syndrome characterized by hypotension, rash, palmar desquamation, and the adult respiratory distress syndrome may be present. Notably, clinically apparent endocarditis is seldom present in neutropenic patients with viridans streptococcal bacteremia.

Bacteremia associated with *S milleri* group isolates is often associated with deep-seated abscesses in visceral organs.

## 3. MENINGITIS

When viridans streptococci are recovered from cerebrospinal fluid, they are most often contaminants. Viridans streptococci, however, are rare causes of meningitis, which may occur in patients of all ages, including neonates. Clinical manifestations are typical of acute pyogenic meningitis with evidence of meningeal irritation, neurologic deficits, seizures, and altered sensorium.

## 4. OTHER VIRIDANS STREPTOCOCCI INFECTIONS

### Introduction

Viridans streptococci may be associated with a variety of other infections, including pneumonia, pericarditis, peritonitis, acute bacterial sialadenitis, orofacial and odontogenic infections, endophthalmitis, otitis media, sinusitis, liver abscesses, pelvic abscesses, subphrenic abscesses, appendicitis, abdominal wound infections, cholangitis, mediastinitis, brain abscesses, subcutaneous abscesses, and cellulitis.

### Diagnosis

The diagnosis of viridans streptococcal infection is made by isolating viridans streptococci from typically sterile sites. As mentioned above, community-acquired viridans streptococcal bacteremias are strongly associated with bacterial endocarditis. This diagnosis may be further confirmed by the presence of clinical findings consistent with endocarditis as well as by the use of echocardiography. *A defectiva* and *A adjacens* require pyridoxal or thiol group supplementation for growth. There is sufficient pyridoxal in human blood to support the growth of *A defectiva* and *A adjacens* in most blood

culture media (with the notable exception of unsupplemented tryptic soy broth). For subculture, however, solid media must be supplemented with 0.001% pyridoxal or 0.01% L-cysteine to sustain growth. As an alternative, the culture plate may be cross-streaked with *Staphylococcus aureus* to provide these factors and permit the growth of the streptococci as satellite colonies. In addition, as noted above, members of the *S milleri* group are associated with deep-seated abscesses in visceral organs. Therefore infections caused by these organisms should alert the clinician to initiate an appropriate investigation for the detection of a possible subclinical focus of infection.

## Treatment

Viridans streptococci with a minimum inhibitory concentration (MIC) of = 0.12 ug/mL to penicillin are defined as penicillin susceptible. Those with a penicillin MIC of 0.25 to 2.0 ug/mL are intermediately susceptible to penicillin. Those with a penicillin MIC of > 2 ug/mL are resistant to penicillin. A high frequency of penicillin-resistant viridans streptococcal infections may be noted in febrile neutropenic patients. For serious infections, such as endocarditis, with these resistant or intermediately susceptible organisms, combination therapy consisting of a penicillin plus an aminoglycoside is recommended. Viridans streptococci are usually resistant to aminoglycosides when traditional breakpoint concentrations for these agents are applied. However, in vitro studies in experimental models of endocarditis have demonstrated synergistic bactericidal activity between combinations of penicillin and aminoglycosides.

Many other  $\beta$ -lactam antibiotics have in vitro activity similar to penicillin against streptococci. In particular, ceftriaxone is an alternative agent to penicillin for the outpatient treatment of viridans streptococcal endocarditis. Other agents with consistently good in vitro activity against viridans streptococci are cefazolin, vancomycin, and imipenem. *A defectiva* and *A adjacens* are less susceptible in vitro to penicillin than are most other streptococci. It is recommended that all patients with *A defectiva* and *A adjacens* endocarditis be treated with combination therapy consisting of a penicillin plus an aminoglycoside.

## Prevention & Control

Endocarditis prophylaxis, as discussed in [Chapter 11](#) on bacterial endocarditis, is used to prevent viridans group streptococcal endocarditis.

## GROUP B STREPTOCOCCUS (*S AGALACTIAE*)

### Essentials of Diagnosis

- Group B streptococcus (*S agalactiae*).
- Facultative gram-positive diplococci.
- Grayish white in color on sheep blood agar with a narrow zone of  $\beta$  hemolysis.
- Group B cell wall antigen positive.

- Resistant to bacitracin and trimethoprim-sulfamethoxazole.
- Hydrolyzes sodium hippurate.

## General Considerations

**A. Epidemiology.** Group B streptococci are especially associated with neonatal and puerperal infections but cause infections in nonobstetric, nonneonatal populations as well. The incidence of early onset neonatal group B streptococcal infection (defined as the onset of symptoms during the first 5 days of life) is 1.3/1000 live births and appears to be declining. The attack rate for late onset neonatal infection (defined as onset of symptoms from 6 days to 3 months of age) is 0.5/1000 live births.

Group B streptococci colonize the mucous membrane of newborns via vertical transmission of the organism from the mother. This takes place either in utero via the ascending route or at the time of delivery. The rate of vertical transmission to neonates born to women colonized with group B streptococci at the time of delivery ranges from 20% to 72%. A high genital inoculum at the time of delivery is associated with a higher rate of vertical transmission. In addition, infants born to heavily colonized women are more likely to develop invasive early onset group B streptococcal disease. Heavily colonized infants have significantly increased rates of early and late onset group B streptococcal disease. Nosocomial transmission of group B streptococci may occur and may be influenced by poor hand washing by health care providers and by crowding.

Several factors have been identified that increase the incidence of invasive early onset infection among neonates born to colonized mothers. They include rupture of the membranes > 18 h before delivery; multiple births; premature rupture of the membranes (< 37-week gestation); maternal fever or amnionitis, or both; black race; age < 20 years; history of previous miscarriage; and preterm delivery.

Group B streptococci may be isolated from genital or lower gastrointestinal tract specimens or both of 5-40% of pregnant women. Lower socioeconomic status, having < three pregnancies, the presence of an intrauterine device, sexual activity, age of < 20 years, and the first half of the menstrual cycle are associated with an increased rate of detection of group B streptococcal colonization in the female genital tract, whereas being of Mexican-American heritage is associated with a decreased rate. Group B streptococci may be harbored in the urinary tract during pregnancy in association with asymptomatic bacteriuria; bacteriuria is a marker for high inoculum in the genital tract.

Group B streptococci are associated with postpartum febrile morbidity with or without bacteremia. In addition, adults with diabetes mellitus, chronic hepatic dysfunction, HIV infection, or malignancies requiring immunosuppressive therapy are also susceptible to group B streptococcal infections.

**B. Microbiology.** Group B streptococci are facultative gram-positive diplococci that are easily grown on a variety of bacteriologic media. On sheep blood agar, isolated colonies are 3-4 mm in diameter and grayish white in color. A narrow zone of  $\beta$  hemolysis surrounds the flat, somewhat mucoid colonies, although a small number of strains may be  $\alpha$  hemolytic. Group B-specific cell wall antigen may be detected by counter-current

immunoelectrophoresis, enzyme-linked immunosorbent assay, indirect immunofluorescence, staphylococcal coagglutination, or latex agglutination. Group B streptococci are resistant to bacitracin and trimethoprim-sulfamethoxazole, hydrolyze sodium hippurate, and produce an orange pigment during anaerobic growth on certain media. Group B streptococci produce CAMP (named for Christie, Atkins, and Munch-Petersen) factor, which is a thermostable extracellular protein that results in synergistic hemolysis on sheep blood agar in conjunction with the  $\beta$  hemolysin of *S aureus*.

**C. Pathogenesis.** Preterm labor may be associated with an increased rate of symptomatic group B streptococcal infection in the neonate because ascending infection caused by group B streptococci may be a primary pathogenic event initiating preterm rupture of the membranes. Low levels of antibody to the capsular antigen of group B streptococci may predispose to neonatal infection. In addition, complement and heat-stable opsonins may play a role in the pathogenesis of group B streptococcal infections.

In addition to host factors, bacterial virulence factors contribute to the host-parasite interaction that determines the outcome between exposure and the development of asymptomatic group B streptococcal colonization or symptomatic group B streptococcal infection. Specifically, a high quantity of cell-associated sialic acid, and its elaboration in supernatant fluid at high concentrations, is associated with virulence. The unique capsular structures of group B streptococci might also enhance the invasiveness of one serotype over another.

## **CLINICAL SYNDROMES**

### **1. EARLY-ONSET GROUP B STREPTOCOCCAL NEONATAL INFECTION**

Early-onset group B streptococcal neonatal infection has three major clinical expressions: bacteremia with no identifiable focus of infection, pneumonia, and meningitis ([Box 50-1](#)). Signs and symptoms of early-onset group B streptococcal neonatal infection include lethargy, poor feeding, jaundice, abnormal temperature, grunting respirations, pallor, and hypotension.

In most infants with pneumonia, symptoms of respiratory distress are present at or within a few hours after birth. Signs of respiratory distress associated with pneumonia include apnea, grunting, tachypnea, and cyanosis. The radiographic findings in infants with pneumonia may be indistinguishable from those of hyaline membrane disease.

Infants with meningitis have a clinical presentation that initially cannot be distinguished from that of infants without meningeal invasion. Lumbar puncture is required to identify neonates with meningitis.

The mortality of early-onset group B streptococcal infection is 10-15% but may be higher in infants with lower birth weights. One-half of patients with meningitis develop seizures within 24 hours of onset; if seizures persist, a poor outcome may follow.

### **2. LATE-ONSET GROUP B STREPTOCOCCAL NEONATAL INFECTION**

The mean age of onset of late-onset group B streptococcal neonatal infection is 24 days. Bacteremia with concomitant meningitis is a frequent presentation. Signs and symptoms include poor feeding, irritability, and fever. Some infants present with fulminant infection characterized by progression within a few hours from the absence of symptoms to a morbid state with septic shock and seizures with cerebrospinal fluid Gram stains demonstrating sheets of organisms. This fulminant presentation is associated with an increased risk for mortality or permanent neurologic sequelae. Neutropenia on admission, prolonged seizures, and high concentrations of polysaccharide antigen in admission cerebrospinal fluid specimens are also associated with fatal outcomes or permanent neurologic sequelae.

Of all survivors of early- or late-onset group B streptococcal meningitis, 25% to 50% will have permanent neurologic sequelae. One-third of patients with these complications will have severe blindness, deafness, and/or global developmental delay. In the remainder of patients, the deficits are subtler and may be detectable only when language and cognitive function are adequately tested.

Bacteremia without an apparent focus and bone and joint infections are other clinical presentations of late onset group B streptococcal disease. Infants with bacteremia should be evaluated for foci of infection including cellulitis, adenitis, otitis media, conjunctivitis, peritonitis, endocarditis, or deep abscesses. Group B streptococcal osteomyelitis is characterized by an indolent onset in which diminished movement of the involved extremity is the most common symptom. Septic arthritis is associated with an acute onset of symptoms usually in the context of bacteremia. Fever is uncommon in both bone and joint infections. Lower extremity involvement is most commonly observed in patients with septic arthritis, whereas osteomyelitis has a predilection for involvement of the proximal humerus. However, involvement of the femur, tibia, and flat and small bones may be seen.

### **3. PERIPARTUM INFECTIONS**

Group B streptococci cause symptoms of endometritis including fever, malaise, and moderate uterine tenderness. Pelvic abscesses, septic shock, and septic thrombophlebitis are rarely seen. Group B streptococci also cause peripartum bacteriuria that may be asymptomatic or may be diagnosed in association with cystitis or, less frequently, pyelonephritis.

### **4. GROUP B STREPTOCOCCAL PNEUMONIA**

This may occur in patients with diabetes mellitus or neurologic disease. Chest radiographs may demonstrate bilateral or lobar infiltrates. Infection is frequently polymicrobial, although group B streptococci are usually the predominant organisms. Empyema may be present.

### **5. ENDOCARDITIS (ACUTE OR SUBACUTE ONSET)**

Endocarditis caused by group B streptococci is rare. The mitral valve is more frequently involved than the aortic valve, and tricuspid valve involvement is found mainly in

intravenous drug users. Underlying heart disease is present in more than one-half of cases, and rheumatic heart disease is the most common underlying condition. Valvular disease, atherosclerotic heart disease, and mitral valve prolapse have also been described as predisposing factors. Large friable vegetations are a frequent feature of group B streptococcal endocarditis. Embolization may occur early. Rapid valvular destruction may occur necessitating early valve replacement in some patients.

## **6. ARTHRITIS**

This is typically monoarticular and most commonly affects the knee, hip, or shoulder joints (see [Chapter 14](#)). Diabetes mellitus is a predisposing factor, as are osteoarthritis and the presence of a prosthetic joint. The most common presenting signs are fever and joint pain in a patient with septicemia. Osteomyelitis may occur as a consequence of adjacent arthritis, peripheral vascular disease, orthopedic surgery, or concomitant infections such as frontal sinusitis. Hematogenously acquired osteomyelitis is most likely to involve the vertebrae. Osteomyelitis may complicate foot ulcers in adults with long-standing diabetes mellitus. In patients with prosthetic joints, group B streptococci typically cause acute onset septic arthritis with local pain, erythema, and swelling.

## **7. SKIN & SOFT TISSUE INFECTIONS**

Group B streptococci may cause cellulitis, foot ulcers, abscesses, and infection of decubitus ulcers (see [Chapter 13](#)).

## **8. OTHER GROUP B STREPTOCOCCAL INFECTIONS**

### **Introduction**

Meningitis, keratitis, endophthalmitis, urinary tract infections in nonobstetric populations, and other unusual presentations may also occur.

### **Diagnosis**

The diagnosis of group B streptococcal infection is made by the isolation of the organism from typically sterile sites (eg, blood, cerebrospinal fluid, abscess material). Antigen detection methods may be used to permit a presumptive diagnosis, especially in neonates. Countercurrent immunoelectrophoresis, latex agglutination, staphylococcal coagglutination, and enzyme immunoassays may be used to detect group B streptococcal antigen in various body fluids. A number of selective media enhance the accurate detection by culture of low numbers of group B streptococci from sites such as the genital or gastrointestinal tract of pregnant women. These media usually contain Todd-Hewitt broth with or without sheep red blood cells and antimicrobial agents such as nalidixic acid and gentamicin or colistin. Molecular and antigen detection methods can also be used to detect group B streptococcal genital or gastrointestinal tract colonization in pregnant women.

### **Treatment**

Group B streptococci are uniformly susceptible to penicillin, although less so than S

*pyogenes*. Penicillin G is therefore the drug of choice; however, because of the increased penicillin MIC (as compared with *S pyogenes*), the combination of penicillin plus an aminoglycoside is recommended for the treatment of group B streptococcal endocarditis ([Box 50-2](#)). Penicillin plus an aminoglycoside exhibit in vitro and in vivo synergistic killing of the organism. Group B streptococci are also susceptible to ampicillin, imipenem, vancomycin, and first-, second- (excluding cefoxitin), and third-generation cephalosporins, although degrees of activity vary. Some isolates are resistant to clindamycin, erythromycin, and clarithromycin; tetracycline resistance is frequently seen. Group B streptococci are uniformly resistant to nalidixic acid, trimethoprim-sulfamethoxazole, and aminoglycosides.

Parenteral therapy of a 10-day duration is recommended for treatment of bacteremia, pneumonia, pyelonephritis, and soft tissue infections, whereas a 14-day minimum duration is recommended for treatment of meningitis and a 4-week minimum for treatment of endocarditis or ventriculitis. In adults with endocarditis, cardiac surgery early in the course may be necessary because of rapid left-sided valvular destruction. In practice, many neonates are empirically treated with ampicillin plus gentamicin.

### **Prevention & Control**

Prevention of early onset neonatal sepsis and postpartum maternal febrile morbidity may be achieved by administration of intravenous ampicillin or penicillin during labor. Women colonized with group B streptococci may be identified by obtaining cultures using lower vaginal and anorectal swabs processed in selective broth media or by using rapid antigen or molecular detection methods when patients are admitted to the hospital. The American College of Obstetrics and Gynecology, the American Academy of Pediatrics, and the Centers for Disease Control and Prevention have developed two strategies (a screening approach and a nonscreening approach) for preventing perinatal group B streptococcal disease ([Box 50-3](#)).

To prevent early onset sepsis, maternal chemoprophylaxis should be initiated at least 4 h before delivery and at high doses (see [Box 50-3](#)). This allows time to achieve sufficient concentrations of ampicillin or penicillin in the fetal circulation and in the amniotic fluid. Management of neonates born to women receiving chemoprophylaxis should be based on clinical findings.

## ***STREPTOCOCCUS DYSGALACTIAE* SUBSP. *EQUISILIMIS* & *STREPTOCOCCUS ZOOEPIDEMICUS***

### **Essentials of Diagnosis**

- Associated with domestic animals.
- Formerly known as groups C and G streptococci.
- Pharyngitis, skin and soft tissue infections, and arthritis are common syndromes.

### **General Considerations**

**A. Epidemiology.** *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* have been isolated from the throat, nose, skin, and genital and intestinal tracts of asymptomatic carriers and from the umbilicus of as many as two-thirds of asymptomatic newborns. Domestic animals (eg, horses, cattle, pigs, and chickens) may be infected; epidemic infections have been noted in horses, cattle, sheep, and pigs. Many cases of human infection can be traced to an animal source. Human infection has also been associated with consumption of homemade cheese and unpasteurized cow's milk. Underlying conditions have been noted in most patients with *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* infections. These include cardiopulmonary disease, diabetes mellitus, chronic dermatologic conditions, malignancy, immunosuppression, alcohol abuse, renal or hepatic insufficiency, and injection drug abuse. These streptococci also cause recurrent cellulitis at the saphenous vein donor site in patients who have undergone coronary artery bypass surgery.

**B. Microbiology.** *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* include the organisms formerly known as groups C and G streptococci (*S equisimilis*, *S equi*, *S zooepidemicus*, *S dysgalactiae*, and *S canis*).

## CLINICAL SYNDROMES

### 1. PHARYNGITIS

The symptoms of pharyngitis caused by these organisms mimic those of *S pyogenes* pharyngitis ([Box 50-1](#); see also [Chapter 48](#)). Poststreptococcal glomerulonephritis has been described following *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* pharyngitis. Notably, however, no antistreptolysin O antibody response will be detected as these organisms do not produce streptolysin O. *S dysgalactiae* subspp. *equisimilis* pharyngitis has been associated with sterile reactive arthritis. Acute rheumatic fever, however, has not been described in association with *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* pharyngitis.

### 2. SKIN & SOFT TISSUE INFECTIONS

Cellulitis, wound infections, pyoderma, erysipelas, impetigo, and cutaneous ulcers can be caused by these organisms (see [Chapter 13](#)). Breaches in skin integrity may provide a portal of entry leading to bacteremia. *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* have been isolated in patients with cellulitis after vein harvest for coronary artery bypass grafting and in patients with conditions associated with abnormal venous or lymphatic drainage. Lymphangitis may accompany cellulitis. Bacteremia often occurs as a complication of skin and soft tissue infections.

### 3. ARTHRITIS

The skin is the presumed portal of entry in many patients (see [Chapter 14](#)). Almost any joint may be involved and frequently the arthritis is polyarticular. Prosthetic joint infection may occur. There have been isolated case reports of *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* osteomyelitis.

### 4. OTHER INFECTIONS

## Introduction

*S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* may rarely cause pneumonia or sinusitis. Infective endocarditis caused by *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* is uncommon. Patients may present acutely or subacutely. Destruction of valve leaflets, myocardial abscesses, conduction abnormalities, and severe congestive heart failure may be seen. Major systemic emboli to the spleen, kidneys, myocardium, and central nervous system may occur. Rare reports of *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* meningitis exist. These organisms have been associated with puerperal sepsis and endometritis. Neonatal sepsis with *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* occurs in premature or low birth weight infants and in the setting of premature rupture of the membranes. The onset of disease is typically within the first week of life.

Bacteremia may occur in *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* infections. Other infections caused by *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* include pericarditis, pyomyositis, brain abscess, epiglottitis, cervical lymphadenitis, intra-abdominal infection, subdural empyema, arterial-venous fistula infection, peritonitis in dialysis patients, panophthalmitis, and spinal epidural abscess. A toxic shocklike syndrome has also been reported.

## Diagnosis

The diagnosis of *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* infection is made by isolating these organisms from typically sterile sites.

## Treatment

The antimicrobial agent of choice for *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus* is penicillin G. Other agents with good in vitro activity include cefazolin, vancomycin, the semisynthetic penicillins, and cefotaxime ([Box 50-2](#)). The addition of gentamicin to penicillin, cefotaxime, or vancomycin may result in a better outcome in cases of serious infection such as bacterial endocarditis caused by *S dysgalactiae* subspp. *equisimilis* and *S zooepidemicus*.

## **STREPTOCOCCUS BOVIS**

### Essentials of Diagnosis

- Grow in 40% bile, hydrolyze esculin.
- Do not grow in 6.5% sodium chloride.
- Pyrrolidonyl arylamidase reactivity negative.

### General Considerations

**A. Epidemiology.** *S bovis* is a normal inhabitant of the gastrointestinal tract. *S bovis*

bacteremia is highly associated with bacterial endocarditis as well as with underlying lesions of the colon, including malignancy. In some series, the prevalence of malignancy in patients with *S bovis* bacteremia exceeds 50%. As such, all patients with *S bovis* bacteremia should undergo a careful workup to exclude colonic neoplasms.

**B. Microbiology.** *S bovis* are group D streptococci and share properties in common with enterococci including the ability to grow in the presence of 40% bile and to hydrolyze esculin. A number of other tests, however, including growth in 6.5% sodium chloride and pyrrolidonyl arylamidase reactivity differentiate *S bovis* from enterococci.

## CLINICAL SYNDROMES

### Introduction

*S bovis* causes bacteremia, endocarditis, urinary tract infection, meningitis, and neonatal sepsis ([Box 50-1](#)). The gastrointestinal tract is the usual portal of entry in cases of *S bovis* bacteremia although the hepatobiliary tree, urinary tract, and even dental procedures have been implicated as possible sources.

### Diagnosis

Isolation of *S bovis* from typically sterile sites permits the clinical diagnosis of infection.

### Treatment

*S bovis* is very susceptible to penicillin (MICs range from 0.01 to 0.12 ug/mL) ([Box 50-2](#)). Other effective agents include ampicillin, the antipseudomonal penicillins, ceftriaxone, erythromycin, clindamycin, and vancomycin. Penicillin alone given for 4 weeks is adequate to treat patients with *S bovis* endocarditis. Vancomycin is a reasonable alternative in penicillin-allergic patients. Bacterial endocarditis prophylaxis regimens are given in [Chapter 11](#) and are relevant to *S bovis* endocarditis.

## OTHER GRAM-POSITIVE COCCI

### INTRODUCTION

The following organisms are too rare to merit extensive discussion of clinical syndromes, diagnosis, and treatment (see [Box 50-4](#)).

#### ***STREPTOCOCCUS INIAE***

*S iniae* has recently been described as a cause of cellulitis, bacteremia, endocarditis, meningitis, and septic arthritis associated with the preparation of the aquacultured fresh fish tilapia.

#### ***LEUCONOSTOC SPECIES***

*Leuconostoc* spp. are gram-positive cocci or coccobacilli that grow in pairs and chains; *Leuconostoc* spp. may be morphologically mistaken for streptococci. They are

vancomycin-resistant facultative anaerobes that are commonly found on plants and vegetables and less commonly in dairy products and wine. *Leuconostoc* spp. have been documented to cause bacteremias, intravenous line sepsis with localized exit site infection and/or bacteremia, meningitis, and dental abscess. Many patients with *Leuconostoc* spp. infection are severely ill, immunocompromised, or both.

Despite exhibiting resistance to vancomycin, *Leuconostoc* spp. are susceptible to most other agents with activity against streptococci, including penicillin, ampicillin, clindamycin, minocycline, erythromycin, tobramycin, and gentamicin. Some clinical data suggest that penicillin or ampicillin are the agents of choice for treating infections due to *Leuconostoc* spp.

### **PEDIOCOCCUS SPECIES**

*Pediococcus* spp. are also vancomycin-resistant gram-positive cocci. They may be isolated from blood cultures, typically in immunocompromised patients.

### **STOMATOCOCCUS MUCILAGINOSUS**

*Stomatococcus mucilaginosus* is a gram-positive coccus that may cause endocarditis, bacteremia, intravascular catheter infection, meningitis, and peritonitis. Many patients infected with *S mucilaginosus* have underlying serious diseases, neutropenia, the presence of foreign bodies, cardiac valvular disease, and/or a history of intravenous drug use. Destruction of the oral mucous membranes because of chemotherapy or radiotherapy has been hypothesized to play a role in the dissemination of stomatococci from their normal habitat in the oral cavity. Resistance to penicillin has been documented among some *S mucilaginosus* strains, and susceptibility to other commonly used antimicrobials varies with the isolate. Stomatococci are uniformly susceptible to vancomycin.

### **AEROCOCCUS SPECIES**

Although aerococci may appear as contaminants in clinical cultures, occasional reports of a clinically significant role of these organisms in cases of endocarditis, bacteremia, and urinary tract infection have been noted. Aerococci are susceptible to penicillin and vancomycin.

### **GEMELLA SPECIES**

*Gemella haemolysans* has been isolated (as a pathogen) in cases of endocarditis, meningitis, and prosthetic joint infections. *G morbillorum* has been isolated from blood, respiratory, genitourinary, wound, and abscess cultures and from an infection of an arterial-venous shunt. *Gemella* spp. appear to be susceptible to penicillin and vancomycin.

### **ALLOIOCOCCUS OTITIS**

Alloiococci have been isolated from the middle ear fluid of children with chronic otitis media and a role for these organisms in the pathogenesis of persistent otitis media has

been suggested.

### **MICROCOCCUS SPECIES**

Micrococci are frequently contaminants in clinical cultures but may occasionally cause infections such as infective endocarditis. A review of micrococcal endocarditis in cardiac surgery patients noted that MICs of penicillin ranged from 3.12 to 40.0 ug/mL and those of vancomycin spanned from 1.56 to 10.0 ug/mL. All of the isolates tested were susceptible to cephalothin.

### **LACTOCOCCUS SPECIES**

*Lactococcus* spp. may be associated with bacterial endocarditis. Lactococci are susceptible to vancomycin and moderately susceptible to penicillin.

### **GLOBICATELLA SPECIES**

*Globicatella sanguis*, the sole species in this genus, has been isolated from patients with bacteremia, urinary tract infection, and meningitis.

### **HELCOCOCCUS KUNZII**

*Helcococcus kunzii*, the only member of this newly described genus, has been isolated from wound cultures, notably those from foot ulcers, characteristically as part of a mixture of bacteria. The clinical significance of this organism is not yet defined.

**BOX 50-3.** Prevention and Control of Perinatal Group B Streptococcal Disease

**Screening Approach**

- All pregnant women should be screened at 35- to 37-week gestation for group B streptococcal carriage.
- All identified carriers and women who deliver preterm before a culture result is available should be offered intrapartum antimicrobial prophylaxis (see below).

**Nonscreening Approach**

Intrapartum antimicrobial agents should be offered to women with risk factors (eg, those with elevated intrapartum temperature, membrane rupture = 18 h, premature onset of labor or rupture of membranes at < 37 wks): Ampicillin 2 g IV every 4-6 h (until delivery), or penicillin G 5 million U IV every 8 h (until delivery). In penicillin-allergic patients, use clindamycin IV or erythromycin IV until delivery.

## 51 . Gram-Positive Aerobic Bacilli — Jeffrey Loutit, MB, ChB, & David Relman, MD

### ***LISTERIA MONOCYTOGENES***

#### **Essentials of Diagnosis**

- Incriminated foods include unpasteurized milk, soft cheeses, undercooked poultry, and unwashed raw vegetables.
- Asymptomatic fecal and vaginal carriage can result in sporadic neonatal disease from transplacental and ascending routes of infection.
- Incubation period for foodborne transmission is 21 days.
- Organism causes disease especially in neonates, pregnant women, immunocompromised hosts, and elderly.
- Organism is grown from blood, cerebrospinal fluid (CSF), meconium, gastric washings, placenta, amniotic fluid, and other infected sites.

#### **General Considerations**

**A. Epidemiology.** *L. monocytogenes* is found in soil, fertilizer, sewage, and stream water; on plants; and in the intestinal tracts of many mammals. It is a foodborne pathogen that causes bacteremic illness and meningoen­cephalitis, with few if any gastrointestinal manifestations. Contaminated food appears to be the most common source for both sporadic and outbreak-related cases. An estimated 2500 cases occur each year in the United States. The median incubation period for foodborne transmission is ~ 30 days. Foods that have been linked to outbreaks of listeriosis include Mexican style cheeses, unpasteurized milk, and undercooked chicken. The organisms can multiply at 4°C; therefore, foods refrigerated for prolonged periods are well-recognized sources for microbial transmission. Although the incidence of listeriosis is relatively low, there are several populations at increased risk for disease. These populations include persons older than 70 years, pregnant women, and patients with defects in cell-mediated immunity, including transplant hosts, those receiving high-dose corticosteroids, and patients with AIDS. The case fatality rate associated with listeriosis is ~ 23%; listeriosis is estimated to account for almost one-third of all food-related disease deaths. Asymptomatic vaginal and fecal carriage in pregnant women can result in sporadic neonatal disease, either from transplacental infection or from exposure during delivery.

**B. Microbiology.** *L. monocytogenes* is a facultative anaerobic, non-spore-forming, gram-positive bacillus that can grow in acidic conditions, high salt concentrations, and a wide temperature range, including the temperatures of household refrigerators. There are = 13 serotypes of *L. monocytogenes*, of which types 1B and 4B are the most

commonly associated with disease.

**C. Pathogenesis.** *L. monocytogenes* displays unusual capabilities in its interactions with host cells and its mechanisms of pathogenesis. After entering the small intestine, the organisms induce their uptake into epithelial cells and macrophages. E-cadherin serves as a host cell receptor. Once internalized, the bacteria rupture the phagolysosomal vacuolar membrane, using a pore-forming hemolysin, listeriolysin O, and escape into the host cell cytoplasm. *Listeria* multiplies readily within this environment; it also moves about the cytoplasm by nucleating host cell actin polymerization at one pole of the bacterial cell, using its protein ActA (Figure 51-1). An actin "comet tail" is formed as actin regulatory proteins are recruited, and the process extends. The actin tail itself is fixed, and the bacteria are propelled by polymerization at the proximal end of the tail at speeds of ~ 0.1  $\mu\text{m/s}$ . Many of the bacteria migrate to the periphery of the cytoplasm, pushing against the host cell outer membrane to form elongated protrusions. These protrusions are then ingested by adjacent cells; *Listeria* bacteria then secrete phospholipases and listeriolysin O that rupture the double membrane that separates them from this second cell's cytoplasm. This mechanism allows *Listeria* spp. to spread from cell to cell without directly contacting the extracellular environment. Several other pathogens induce actin polymerization as a means of movement within the host cell cytoplasm, including *Shigella* spp., *Rickettsia* spp., and vaccinia virus.

### Clinical Findings (Box 51-1)

**A. Central Nervous System (CNS) Infection.** Although most cases of listeriosis occur after ingestion of contaminated food, few patients complain of gastrointestinal symptoms or display gastrointestinal signs. The CNS is the site most commonly involved, where disease results in three different clinical presentations: meningitis, meningoencephalitis, and rhomboencephalitis. Meningitis is the most common manifestation of listeriosis in adults and children. *L. monocytogenes*, after *Escherichia coli* and the group B streptococci, is the third most common cause of bacterial meningitis in adults and neonates, and it accounts for 5-15% of cases. The clinical manifestations of *Listeria* meningitis are similar to other forms of bacterial meningitis; however, the proportion of neutrophils among CSF leukocytes is often lower, and Gram stains of CSF are usually negative. In some cases, meningitis is accompanied by clinical signs of encephalitis. This organism, unlike other bacterial causes of meningitis, exhibits a tropism for brain parenchyma and, in particular, the brain stem, resulting in rhomboencephalitis. The latter is often preceded by 4-10 days of nonspecific flulike symptoms, followed by cranial nerve deficits, particularly of the sixth and seventh nerves. Brain stem involvement may lead to hemiparesis, ataxia, and even respiratory compromise. In most cases of meningoencephalitis, the CSF monocyte differential counts may reach 80-90%, but cases with no pleocytosis and normal CSF protein and glucose levels have been reported. Brain abscess is a rare manifestation of CNS listeriosis.

**B. Bacteremia.** Bacteremia or non-CNS focal infection occurs in 5-30% of adult cases. The diagnosis is based on positive blood cultures. *Listeria* causes focal infections in bone, native and prosthetic joints, eyes, spinal cord, pleura, peritoneum, and liver. Endocarditis, myocarditis, and mycotic aneurysms have also been described. Approximately one-third of women who contract *Listeria* infection are pregnant. Women in their third trimester are at greatest risk, but symptoms are usually mild, often

mimicking a flulike illness. Blood cultures, if obtained, may be positive, but symptoms usually resolve spontaneously without therapy.

**C. Neonatal Infection.** Neonatal *Listeria* infection may present as an amnionitis, and infection is associated with premature labor. An uncommon clinical syndrome called granulomatosis infantiseptica has been described. This syndrome is caused by dissemination of *L monocytogenes* in utero. Abscesses and granulomata form within the fetal liver, lung, spleen, kidneys, brain, and skin. The mortality rate is high, ranging from 35% to 55%.

## Diagnosis

*L monocytogenes* can be easily cultivated in the microbiology laboratory from blood, CSF, meconium, gastric washings, placenta, amniotic fluid, and other specimens. A CSF Gram stain with gram-positive or-variable rods should suggest *Listeria* infection, but this organism may be mistaken as a diphtheroid.

## Treatment

There are no clinical trials comparing different antibiotic regimens for the treatment of listeriosis. Ampicillin or penicillin is generally recommended as the treatment of choice ([Box 51-2](#)). Gentamicin is added for severe infections, because the combination of ampicillin and an aminoglycoside is more effective than ampicillin alone in animal models. These agents should be given intravenously. The duration of therapy required to prevent relapse is not known; however, 10-14 days is recommended in patients without meningitis, 2-3 weeks is recommended for those with meningitis, and 3-6 weeks is recommended for immunosuppressed patients. Another effective agent is trimethoprim-sulfamethoxazole, because high intracellular levels are achieved, and it is bactericidal for *Listeria* species.

## Prognosis

*Listeria* infection of the CNS is associated with a high mortality rate. Of patients with meningoencephalitis, 36-51% die. Most of those who survive have persistent neurologic sequelae. Early recognition and rapid institution of antibiotics are critical for improving outcome.

## Prevention

Patients at risk for listeriosis should be advised on how to minimize their exposure to this organism ([Box 51-3](#)). This advice should include cooking well all food from animal sources, washing raw vegetables thoroughly, and keeping uncooked meat separated from vegetables and cooked foods. Patients should also avoid consumption of unpasteurized milk, soft cheeses, or foods made with raw milk, and they should wash hands, knives, and cutting boards after handling uncooked food. An additional recommendation for high-risk persons is to heat all leftovers or ready-to-eat foods until these foods are steaming hot.

## ANTHRAX

## Essentials of Diagnosis

- Contact with infected animals, carcasses, hair, wool, or hides from goats, sheep, cattle, swine, horses, buffalo, or deer.
- Incubation period lasting 1-7 days, usually 2-5 days, after exposure.
- Painless lesion progressing to papule, to vesicle, to necrosis, and to eschar.
- Rapid development of chest pain, dyspnea, and circulatory collapse after brief flulike syndrome.
- Direct gram-stained smear and/or cultures of lesions or discharges.
- Widened mediastinum on chest radiograph in inhalational disease.

## General Considerations

Anthrax is primarily a disease of herbivores, but humans acquire the disease through contact with infected animals or animal products.

**A. Epidemiology.** Historically, anthrax has been an occupational disease of persons who handle animal hair, skin, and other contaminated products. The incidence of this disease in the United States has fallen dramatically; only six cases of anthrax were reported to the Centers for Disease Control and Prevention from 1978 through 1998. The cutaneous form of the disease is most common. Continued concern about this disease stems from the unfortunate development of anthrax spores as biological weapons by a number of nations.

**B. Microbiology.** *Bacillus anthracis*, a sporulating gram-positive rod, is the causative agent of anthrax. *B anthracis* is distinguished from other *Bacillus* species in the laboratory based on its colony morphology and capsule.

**C. Pathogenesis.** *B anthracis* persists in soil as a nonreplicating spore. These spores are highly resistant to temperature extremes, drying, UV light, high pH, high salinity levels, and routine methods of disinfection. The virulence of *B anthracis* is due to the presence of a polysaccharide capsule that prevents phagocytosis and to the production of 2 two-component exotoxins. Each of these toxins is of an A-B structure. They share the same B component, known as protective antigen, which binds each of these binary toxins to host cells and mediates internalization. Lethal toxin causes rapid cell death by the action of its A subunit, a zinc metalloprotease that cleaves a critical intracellular signaling molecule. Edema toxin contains an A subunit that acts as a calmodulin-dependent adenylate cyclase and catalyzes production of cyclic AMP within host cells. This toxin is believed to be responsible for the dramatic tissue edema that characterizes cutaneous anthrax. The genes encoding the three toxin components are located on one plasmid, and the genes encoding the capsule are on a second plasmid. Strains missing either of these plasmids are avirulent. Expression of these toxins takes place upon germination of spores within macrophages and vegetative growth of the

bacilli, after they have been inoculated into an animal host. Subcutaneous inoculation occurs via abrasions or breaks in the skin, and it leads to cutaneous disease with occasional systemic dissemination. Inhaled spores are deposited in the alveoli, phagocytosed by macrophages, and taken to regional lymph nodes where bacterial growth and disease first become manifest. Gastrointestinal anthrax results from ingestion of grossly contaminated or undercooked meat, and it is extremely rare. Only the spore is infectious for humans; hence, human-to-human transmission of disease does not occur.

## Clinical Findings

There are three forms of the disease in humans: cutaneous, inhalational, and gastrointestinal ([Box 51-4](#)).

**A. Cutaneous Anthrax.** Cutaneous disease accounts for > 95% of all cases of anthrax. This disease begins as a small, painless, but often pruritic papule. As the papule enlarges, it becomes vesicular and, within 2 days, ulcerates to form a distinctive black (hence the name of the disease) eschar, with surrounding edema. Gram stain of the vesicular fluid may reveal gram-positive rods and rare polymorphonuclear leukocytes.

**B. Inhalational Anthrax.** Inhalational anthrax is much less frequent and accounts for < 5% of cases; the incubation period is ~ 10 days, but it may be more prolonged in some cases. This form of the disease begins with an upper-respiratory flulike syndrome, and after a few days it takes a fulminant course, manifested by dyspnea, cough and chills, and a high-grade bacteremia. Inhalational anthrax is not a disease of the lung parenchyma, but is rather a hemorrhagic mediastinitis. Nearly all patients with this disease die within several days.

**C. Gastrointestinal Anthrax.** Gastrointestinal disease is accompanied by mucosal ulceration, mesenteric adenitis, and ascites; it is reported in Africa and Asia but has not been described in the United States.

## Diagnosis

An appropriate epidemiologic history involving animal exposure is the cornerstone of the diagnosis of cutaneous anthrax. Other diagnostic features include edema out of proportion to the size of the skin lesion, the lack of pain during the initial phases of the infection, and the rarity of polymorphonuclear leukocytes on Gram stain. The organism can be readily cultivated and forms nonhemolytic gray-white colonies. A critical diagnostic feature of inhalational anthrax is a widened mediastinum on chest radiography. Patients with this disease usually die before organism growth in blood cultures is detected; however, organisms can sometimes be detected in blood with the Gram stain, owing to the high burden of bacteria in the endovascular compartment.

## Treatment ([Box 51-5](#))

Cutaneous anthrax responds well to penicillin G, which should be continued for 7-10 days. Doxycycline is also effective for cutaneous disease. Other antibiotics, such as ciprofloxacin and chloramphenicol, are alternative drugs for penicillin-allergic patients.

The addition of streptomycin to penicillin may offer additional benefit. Penicillin resistance has been reported among some naturally occurring isolates; these strains have remained sensitive to ciprofloxacin. Despite the early use of antibiotics, cutaneous lesions continue to progress through the eschar phase. Surgery or excision of lesions is contraindicated. With appropriate antibiotic therapy, fatalities are rare (< 1%).

Despite the use of antibiotics as described above, inhalational anthrax is almost always fatal, once it becomes clinically manifest. If anthrax is suspected, public health authorities should be notified immediately.

## Prevention

Doxycycline or ciprofloxacin ([Box 51-6](#)) may prevent development of inhalational disease if given to exposed individuals before onset of disease. Either of these antibiotics should be given for at least 6 weeks before or 2 weeks after the third dose of anthrax vaccine. The currently licensed anthrax vaccine contains protective antigen, and it has been shown to be effective in limited studies against inhalational disease in monkeys and cutaneous disease in humans.

## OTHER *BACILLUS* SPECIES

### General Considerations

*Bacillus* species other than *B anthracis* are found in soil, decaying organic matter, and water, but they are rare causes of disease. Risk factors associated with *Bacillus* infection include the presence of intravascular catheters, intravenous drug use, sickle cell disease, and immunosuppression—particularly corticosteroid use, transplantation, AIDS, and neutropenia secondary to chemotherapy. The hardy growth characteristics of *Bacillus* spp. cause them to arise as common laboratory contaminants; however, they are also capable of causing severe invasive illness.

*B cereus* and *B subtilis* are the most frequent *Bacillus* spp. to cause invasive infection. Pneumonia, meningoencephalitis, endocarditis (native and prosthetic valves), and intravascular catheter infection have been well described. High-grade bacteremia with *B cereus* can be seen in the presence of indwelling intravenous catheters and always necessitates the removal of the catheter along with appropriate antimicrobial therapy. *B cereus* also causes soft-tissue and bone infections, including necrotizing fasciitis, particularly after contamination of wounds by soil. The characteristics of diseases associated with *Bacillus* spp. are indistinguishable from those associated with other pyogenic bacteria, and diagnosis depends on culture data.

### Clinical Findings

*B cereus* accounts for 1-3% of all foodborne disease reported in the United States, although 10-14% of humans are colonized by this organism in their intestinal tract. There are two clinical syndromes associated with ingestion of this organism, an emetic and a diarrheal syndrome. The emetic syndrome is characterized by a short incubation period (1-6 h). Patients present with vomiting and abdominal cramping. The emetic syndrome is usually associated with ingestion of contaminated cooked rice and is

caused by a preformed, heat-resistant 5- to 10-kDa emetic toxin. The diarrheal syndrome has a longer incubation period (6-14 h), and it is characterized by watery diarrhea, abdominal cramping, and, less commonly, by vomiting. The diarrheal syndrome is associated with ingestion of contaminated vegetables, sauces, and puddings, and it is attributed to at least two heat-labile enterotoxins produced by *B cereus*. The durations of illness are 2-10 h for the emetic syndrome and 16-48 h for the diarrheal syndrome. The symptoms in both syndromes are self-limited, and supportive care only is necessary. Outbreaks of foodborne illness caused by *B subtilis*, *B licheniformis*, and *B pumilus* have also been reported.

*B cereus* is also a major cause of ocular infections such as endophthalmitis after eye trauma, and it is often associated with intraocular foreign bodies. The onset of infection is rapid, leading to destruction of the vitreous and retinal tissue with subsequent loss of vision within 12-48 h. Panophthalmitis and endophthalmitis with *B cereus* have also been described in injection drug abusers, without ocular trauma.

## Treatment

*B cereus* is resistant to penicillin and other beta-lactam drugs, including cephalosporins. Active antimicrobial agents include vancomycin, clindamycin, aminoglycosides, carbapenems, and ciprofloxacin. Non-*B cereus* spp. are susceptible to penicillin and cephalosporins. Appropriate empiric therapy for suspected *Bacillus* spp. infections (other than anthrax) is vancomycin or clindamycin, with or without an aminoglycoside. Intraocular infections require aggressive therapy with systemic antibiotics plus intravitreal clindamycin or an aminoglycoside. Intravitreal dexamethasone and early vitrectomy are also recommended for sight-threatening *B cereus* ocular infection.

## DIPHTHERIA

### Essentials of Diagnosis

- Mildly painful tonsillitis/pharyngitis with associated membrane, cervical adenopathy, and signs of systemic toxicity; "bull neck" appearance.
- Hoarseness and stridor.
- Palatal paralysis.

### General Considerations

**A. Epidemiology.** Humans are the only known natural hosts for *C diphtheriae*, the organism that causes diphtheria. This organism is usually spread via upper respiratory tract droplets, but it can also be spread by direct contact with skin lesions. Transmission appears to be more common when people are living indoors in crowded conditions. Disease is transmitted by those incubating the disease, those convalescing from infection, and also healthy carriers. The organism itself can survive for = 6 months in dust, which may also serve as the vehicle for transmission. Immunization against diphtheria toxin prevents the serious complications of disease, by blocking the ability of the toxin to enter cells and also by reducing colonization of the nasopharynx by

toxin-producing strains. Diphtheria is a rare disease in the United States; however, this disease can easily spread in populations that lack adequate levels of antitoxin immunity, as dramatically demonstrated in the former Soviet Union in the early 1990s.

**B. Microbiology.** *C diphtheriae* is a gram-positive rod with club-shaped swellings at each end. Most strains produce an exotoxin, diphtheria toxin, which is encoded by a gene carried by a lysogenic bacteriophage and is responsible for the disease.

**C. Pathogenesis.** *C diphtheriae* attaches to the mucosal surfaces of the nasopharynx. There it remains in the superficial layers of the mucosa. When iron concentrations are low, lysogenic diphtheria bacilli produce high concentrations of diphtheria toxin. The conversion of nontoxigenic, nonlysogenic *C diphtheriae* to toxin-producing strains can occur within the nasopharynx after bacterial infection with the beta-corynephage. Diphtheria toxin is composed of A and B fragments. The B fragment is recognized by a specific host cell membrane receptor resulting in endocytosis of the entire molecule. Once the toxin is inside the endosome, acidification results in a conformational change of the B fragment. A membrane channel is formed, allowing passage of fragment A into the host cell cytoplasm. Fragment A blocks protein synthesis by cleaving NAD and covalently attaching ADP-ribose to the essential host protein, elongation factor-2. ADP-ribosylation interferes with the ability of elongation factor-2 to add amino acids to a peptide chain, blocking protein synthesis. Its effects are seen throughout the body but are most prominent in the heart and kidney and on nerves. Local cytotoxic effects lead to production of the characteristic "pseudomembrane." Anti-toxin antibody can neutralize toxin adsorbed to cells, but, once the toxin penetrates, its toxic effects are irreversible.

### Clinical Findings ([Box 51-7](#))

**A. Respiratory Diphtheria.** The incubation period for respiratory diphtheria is generally 2-4 days, but it can last = 7 days. Initial symptoms include a low-grade fever. Sore throat and malaise are the most common manifestations of pharyngeal diphtheria. Unvaccinated patients tend to have more severe disease. The development of cell necrosis, secondary to the exotoxin, is commensurate with the presence of the characteristic membrane ([Figure 51-2A](#)). Initially the membrane is white and smooth, but later it becomes gray with patches of green and black necrosis. As the membrane spreads, it can interfere with airflow. Involvement of the posterior pharynx is often accompanied by cervical adenopathy and swelling, giving rise to a "bull neck" appearance ([Figure 51-2B](#)). With extensive disease there is increased release of exotoxin, resulting in myocardial and neurologic complications, thereby increasing the mortality associated with this disease.

**B. Cutaneous Diphtheria.** Cutaneous diphtheria usually begins with pustules that progress to ulcer formation with a gray-brown membrane at the base. Commonly, *C diphtheriae* will superinfect existing skin lesions such as insect bites, ecthyma, and impetigo. Cutaneous infections induce high levels of antitoxin antibody that prevent progression to systemic disease; therefore, the infections tend to be indolent and are not usually associated with signs of intoxication. Cutaneous infection poses a greater risk of environmental contamination and transmission to others than does pharyngeal infection.

**C. Cardiac Disease.** Myocarditis with clinically-significant cardiac dysfunction is observed in 10-20% of patients with pharyngeal disease. The likelihood and severity of myocarditis are correlated with the extent and severity of respiratory tract compromise. ST segment and T-wave changes and first-degree block are found by electrocardiography in less severe disease, whereas left bundle branch block and atrioventricular block are associated with high mortality. In severe cases, patients usually sustain permanent injury to the myocardium.

**D. Neurologic Disease.** Neurologic complications occur in ~ 10% of respiratory cases and are predicted by the severity of respiratory tract involvement. Symptoms and signs develop 10-28 days after the respiratory complaints and reflect both cranial nerve involvement and a peripheral neuropathy that can lead to complete paralysis. These complications are usually reversible.

## Diagnosis

Prompt recognition and treatment of respiratory diphtheria are critical for preventing complications and mortality. A dark pharyngeal membrane that cannot be removed without bleeding, systemic toxicity, neurologic abnormalities such as 9th and 10th cranial nerve deficits, and/or electrocardiograph changes should alert the clinician to the possibility of diphtheria. The microbiology laboratory should be notified about the possibility of diphtheria, because special media, such as Loeffler's or tellurite selective media, must be used to prevent overgrowth of normal flora.

## Treatment

All patients should be hospitalized and isolated. Rapid institution of antitoxin is critical because it is most effective if given within 4 days of the onset of illness ([Box 51-8](#)). Hyperimmune antiserum produced in horses has been used for > 100 years. The dose of antitoxin is adjusted to the severity of disease. Sensitivity of the patient to horse protein must be assessed (see recommendations in [Box 51-8](#)). An initial scratch test may be performed on the volar forearm with a 1:100 dilution. If negative, this should be followed by an intracutaneous injection of 0.02 mL of a 1:1000 dilution of antitoxin in saline. No additional benefit is provided by repeated doses. Antibiotics should be initiated as soon as possible to kill organisms, stop toxin production, and eliminate the carrier state. Erythromycin for 2 weeks is the treatment of choice and should be given intravenously until the patient is able to handle oral medications. Procaine penicillin for 2 weeks is an alternative. Other measures include airway and cardiac support. If diphtheria is suspected, the patient should be isolated until two cultures from the affected site are negative. Cultures should be taken from all persons who have been in close contact with a diphtheria patient, to determine whether they are pharyngeal carriers. All carriers need to be treated with erythromycin or penicillin for 14 days.

## Prevention

Children 6 weeks to 7 years of age should be immunized with three injections of vaccine containing formalin-inactivated diphtheria toxin ([Box 51-9](#)). Susceptibility to diphtheria correlates inversely with serum levels of anti-toxin antibody. Because these levels wane,

adults should receive booster vaccinations every 10 years.

## ***CORYNEBACTERIUM JEIKEIUM***

Infection with *Corynebacterium jeikeium*, formerly known as *Corynebacterium* CDC group JK, almost invariably occurs in a hospital setting, because these bacteria commonly colonize the skin of hospitalized patients. Patients at highest risk for colonization include those receiving broad-spectrum antibiotics and those with neutropenia. The most common form of disease is bacteremia and is most often seen in neutropenic patients after breaks in the integument of their skin, such as with intravascular catheters. Endocarditis with this organism has been described, but it is rare, as are extravascular infections such as pneumonia, peritonitis, and prosthetic knee infections. The treatment of choice is vancomycin (1 g every 12 h); the length of therapy is dictated by the disease process. Prosthetic valve endocarditis with *C jeikeium* often requires removal of the valve for control of the infection.

## **OTHER *CORYNEBACTERIUM* SPECIES**

*Corynebacterium* species colonize the skin and are therefore frequently recovered as contaminants in blood cultures; however, serious infections can occur. In particular, immunocompromised hosts and those with indwelling vascular catheters have an increased risk of infection with these organisms. *C ulcerans*, *C pseudotuberculosis*, *C bovis*, *C striatum*, and *C pseudodiphtheriticum* rarely cause human disease, but severe upper respiratory tract, cardiac, and CNS diseases have been reported. *Rhodococcus equi* (previously *C equi*) has recently been reported to cause pneumonia and cavitary pulmonary disease in patients with AIDS and renal transplantation. The treatment of choice for this organism is erythromycin or imipenem-cilastatin, plus rifampin.

## ***ERYSIPELOTHRIX RHUSIOPATHIAE***

### **General Considerations**

*Erysipelothrix rhusiopathiae* is a gram-positive bacillus that causes occupationally related skin infections and, rarely, septicemia in humans.

**A. Epidemiology.** *E rhusiopathiae* is ubiquitous in nature and is an uncommon cause of human disease. It can infect mammals, birds, fish, shellfish, and insects, and it may reside in swine, which serve as a reservoir. Disease in humans is most commonly seen in persons with an appropriate exposure, usually including butchers, slaughterhouse workers, and especially fish handlers. Most cases of skin infection ("erysipeloid") occur in the summer and early fall. The organism is often traumatically inoculated and intense inflammation of the dermis follows.

**B. Microbiology and Pathogenesis.** The organism is non-spore forming and nonmotile and is a facultative anaerobe. The organism may appear as a beaded gram-positive rod owing to partial decolorization during the staining process. It grows well on sheep blood agar and exhibits alpha hemolysis. The organism tolerates a high-salt environment and can survive in saltwater. *E rhusiopathiae* is catalase negative, oxidase negative, and

weakly fermentative.

## Clinical Findings

Skin lesions are usually purplish-red with a sharply defined, raised, serpiginous border; they most commonly involve the proximal region of the hands and fingers. Lesions spread slowly, and, over time, the central portion heals leaving a pale center with a surrounding purplish-red border. Proximal lymphadenopathy and systemic symptoms are rare. Acute or subacute endocarditis secondary to *E rhusiopathiae* is uncommon, but is severe when it occurs. The aortic valve is most commonly involved, and 40% of patients will have or just had the characteristic skin lesion of erysipeloid.

## Diagnosis

The diagnosis requires an appropriate epidemiologic history. The skin lesion may resemble erysipelas caused by *Streptococcus pyogenes*, but the rate of progression is slower, and there is a lack of lymphangitis, lymphadenopathy, and systemic symptoms. Full-thickness skin biopsy with appropriate culture will yield the organism in the majority of cases. Blood cultures should also be obtained.

## Treatment

Treatment of choice for *E rhusiopathiae* infection is penicillin. Erysipeloid is usually self-limited and resolves over the course of 3 weeks, but therapy will hasten the resolution of symptoms. Endocarditis should be treated with intravenous penicillin at 12-20 million U/day, in 4-6 divided doses for 4-6 weeks. It is noteworthy that *E rhusiopathiae* is resistant to vancomycin. Despite appropriate therapy, the mortality rate for patients with *E rhusiopathiae* endocarditis is 30-40%.

## **52 . *Neisseria Gonorrhoeae* & *Neisseria Meningitidis* — D. Scott Smith, MD & David A. Relman, MD**

### **INTRODUCTION**

*Neisseria gonorrhoeae* was first described by Albert Neisser in 1879, in the ocular discharge and exudate from newborn infants with conjunctivitis. Descriptions of a condition resembling the disease gonorrhea can be found in the written record as early as 130 AD, when Galen created a descriptor for the malady by using the Greek words *gonos* (seed) and *rhoea* (flow) to characterize what was believed to be the morbid loss of semen. *Neisseria meningitidis* is thought to be responsible for epidemics in the Napoleonic and Persian armies in the early 1800s. The pathogen was first described in 1886 by Weichselbaum, who observed gram-negative diplococci in the cerebrospinal fluid (CSF) of a young patient who died with purulent meningitis.

Within the family *Neisseriaceae*, there are five genera—*Neisseria*, *Branhamella*, *Moraxella*, *Kingella*, and *Acinetobacter*. *N meningitidis* and *N gonorrhoeae* are the organisms that are pathogenic for humans in the *Neisseria* genus ([Table 52-1](#)). Approximately 10 other *Neisseria* species have been isolated from humans, but these usually establish a commensal relationship with their host and usually do not cause disease. They lack virulence factors, such as pili and virulence-associated outer membrane proteins (OMPs).

### **NEISSERIA GONORRHOEAE**

#### **Essentials of Diagnosis**

- Transmission associated with unprotected sex.
- Purulent urethral discharge, dysuria in men.
- Vaginal discharge, dysuria, intermenstrual bleeding in women.
- Dermatitis-arthritis syndrome with disseminated infection.
- Gram-negative diplococci inside neutrophils on stained smears of urethral, cervical, skin, or joint material.
- Fastidious organism requires special media and growth conditions.
- DNA amplification methods (PCR, LCR) offer improved sensitivity and specificity.

#### **General Considerations**

**A. Epidemiology.** *N gonorrhoeae* is found only in humans. It is primarily transmitted sexually by contact with infected secretions. It is the most common reportable infectious

disease in the United States, with 300,000-400,000 cases occurring per year—a rate of ~ 130/100,000 persons per year. *Chlamydia* infections are more common but are not reportable in all states. The incidence of *N gonorrhoeae* rose during the late 1960s in the United States, peaked in the mid 1970s, and has since declined, but it now may be increasing in certain risk groups such as teenagers. The highest incidence is observed in those 20-24 y of age, in African-Americans, and in lower socioeconomic groups. Most cases are reported in men (male to female ratio, 4:3), which may reflect a greater frequency of symptoms in males. Incidence is higher in men, but prevalence is higher in women. The greatest decline in the prevalence of gonorrhea during the last 15 y has been noted in sexually active gay men, with > 10-fold decreases. This is attributable to safer sex practices in the early wake of the HIV epidemic.

The estimated risk of transmission from an infected female to a male by vaginal intercourse is 20% per exposure. The male-to-female transmission risk is less well studied, but is thought to be ~ 50% per contact. Transmission by rectal intercourse is relatively efficient, although it has not been quantified. Infection can also be transmitted perinatally. High rates of promiscuity are required to maintain a high prevalence of gonorrhea in a population. The so-called "core transmitters" of disease are those who frequently have unprotected intercourse with new partners.

**B. Microbiology.** *Neisseria* species are gram-negative cocci, 0.6-1.0  $\mu\text{m}$  in their longest dimension, that usually form pairs (diplococci) with flattened adjacent edges. Their appearance has been likened to kidney beans. Motility is sometimes observed, although they are usually nonmotile. When grown on solid media, gonococci and meningococci form transparent or opaque, mucoid, nonpigmented, nonhemolytic colonies that are 1-5 mm in diameter.

Both *N gonorrhoeae* and *N meningitidis* require specially treated media such as chocolate agar to improve their growth. Chocolate agar is a heme-based growth medium enriched with glucose and other defined supplements; Thayer-Martin medium is chocolate agar with vancomycin, nystatin, and colistin, which inhibit other common commensals, as well as *Neisseria* species other than *gonorrhoeae* and *meningitidis*. Modified Thayer-Martin medium is now commonly used and also contains trimethoprim to inhibit *Proteus* spp. Growth is optimal at 35-37 °C and requires a carbon dioxide-enriched atmosphere. Fatty acids are toxic to *N gonorrhoeae*; hence, untreated cotton from some clinical swabs may prevent subsequent growth. *Neisseria* species are strictly aerobic, but, when nitrate is provided as an electron acceptor, these species can grow anaerobically. *Neisseria* colonies form within ~ 24-48 h on the solid media mentioned above. *Neisseria* species are usually identified by their carbohydrate utilization patterns. The principal distinguishing metabolic difference between *N meningitidis* and *N gonorrhoeae* is that the latter utilizes maltose. Both can generate acid from glucose. The *Neisseria* species are classified within the beta subdivision of the division *Proteobacteria*.

**C. Pathogenesis.** *N gonorrhoeae* has a complex set of molecular mechanisms for invasion and survival in humans. The activation of this complex armamentarium of cellular machinery begins when the pathogen arrives on a mucosal surface. The basic sequence of steps includes (a) long-range attachment by means of pili, (b) close attachment, (c) invasion of mucosal columnar cells, perhaps mediated by porin proteins,

(d) transportation through the cell in phagosomes, and (e) occasional "transcytosis" into the submucosa and then, rarely, invasion into the blood stream. Once established in the host, *N gonorrhoeae* is antigenically heterogeneous, changing its surface structures to avoid host defenses. Several important antigenic structures include pili, porin proteins, opacity (Opa) proteins, reduction-modifiable protein, and lipooligosaccharide (LOS). Pili are the hairlike structures that extend several micrometers from the cell surface and enhance attachment to host cells, as well as help resist phagocytosis. There is great variability in their antigenic structure, through expression of different pilin structural subunit types, as well as variability in expression of different Opa proteins. Gonococci can express several LOS chains simultaneously, but, unlike lipopolysaccharide from other gram-negative bacteria, the gonococcal LOS does not have long O-antigen side chains. The endotoxic effects of LOS are responsible for the systemic toxicity observed in patients with disseminated disease.

Iron acquisition by *N gonorrhoeae* at the mucosal surface is a critical requirement for survival and growth. This organism and *N meningitidis* express receptors on their surface for human lactoferrin and transferrin, to capture iron from the host.

## Clinical Findings

Genital infection with *N gonorrhoeae* most often presents as urethritis in men and cervicitis in women.

**A. Genital Infection in Men.** In men dysuria usually precedes development of a urethral discharge, which is creamy, yellow, profuse, and sometimes blood tinged. The incubation period ranges from 1 to 10 d after exposure, but > 90% of men become symptomatic within 5 d. Most untreated cases resolve spontaneously within several weeks. The most common complication of urethral gonorrhea in men is epididymitis. However, *N gonorrhoeae* causes only 10% of all cases of infectious epididymitis. Other less common complications of genital infection include penile edema, penile lymphangitis, periurethral abscess, and infection of the Cowper's glands. Stricture of the urethra is now uncommon, but was a more frequent complication in the past.

The microbiological differential diagnosis for urethritis includes other infectious agents such as *Chlamydia trachomatis* and *Ureaplasma urealyticum*. Reiter's syndrome should be considered in patients with urethritis, conjunctivitis, and arthritis. Dysuria and an itching sensation characterize chlamydial urethritis and, in contrast to gonococcal urethritis, may not have profuse purulent discharge. Of men with chlamydial urethral infection, ~ 25% are asymptomatic.

**B. Genital Infection in Women.** In women, uncomplicated *N gonorrhoeae* genital infection is manifest as a purulent cervicitis. Although most women who are seen in acute care settings have symptoms with infection, population-based screening efforts identify many infected women who are asymptomatic. The incubation period in women is less well defined but is ~ 10 d. Symptoms include vaginal discharge, dyspareunia, dysuria without increased frequency, and intermenstrual bleeding. On physical exam, there may be mucopurulent cervical discharge, edema of the cervix, and mucosal friability.

Gonococcal infection in women may progress to involve the uterus and fallopian tubes, causing either acute or chronic salpingitis or pelvic inflammatory disease (PID). Bilateral lower abdominal pain is the most common symptom of PID. There are also signs and symptoms of accompanying lower genital tract infection, as well as cervical-motion tenderness. Fever, leukocytosis, and elevated erythrocyte sedimentation rate or C-reactive protein are common. In PID, anaerobes and chlamydiae may accompany the gonococcal infection. Tubal scarring and infertility are the dreaded sequelae. Perihepatitis (Fitz-Hugh-Curtis syndrome) is a rare complication that occurs by extension of the infection from the fallopian tubes to the peritoneum and the liver capsule. It is accompanied by right upper quadrant tenderness. Laparoscopy demonstrates adhesions between the liver and the parietal peritoneum.

The consequences of gonorrhea during pregnancy include an increased risk of spontaneous abortion, inappropriate rupture of membranes, preterm labor, and fetal mortality. The clinical presentation is essentially the same as that described with genital infection, except that, after the first trimester, PID is less commonly observed because the conceptus obstructs the opening of the uterine cavity. It is unclear whether pregnancy alters the risk for disseminated gonococcal infection.

**C. Anorectal Gonorrhea.** Anorectal gonorrhea is observed in ~ 40% of women with genital infection who have receptive anal intercourse and in the same percentage of gay men with genital infection. Only a minority of persons with positive rectal cultures are asymptomatic; in those who are symptomatic, complaints and findings include tenesmus, purulent discharge, pruritus, and rectal bleeding.

**D. Ocular Infection.** Gonococcal conjunctivitis occurs by direct inoculation of gonococci into the eye. In adults, this occurs primarily by self-inoculation in persons with active genital infection. In neonates, infection can occur during delivery or postpartum. In adults and neonates, the conjunctivitis is severe, with copious purulent exudate. Corneal ulceration and even blindness can result, especially in the newborn.

**E. Disseminated Gonococcal Infection.** Disseminated gonococcal infection results from hematogenous spread of gonococci. It occurs in ~ 3% of infected patients. Arthritis and skin lesions, including pustules and hemorrhagic papules, are the most common manifestations of dissemination ("arthritis-dermatitis syndrome") and are mediated in part by immune complexes, as well as other indirect immunologic mechanisms. The arthritis most commonly affects the knees, ankles, and wrists. Fever and leukocytosis with polymorphonuclear leukocyte (PMN) predominance are also observed. Cultures of blood or synovium are positive in only about half of all patients with disseminated gonococcal infection, but cultures of mucosal sites are positive in ~ 80% of cases.

## Diagnosis

The cornerstone of diagnosis is the Gram stain or culture. One is looking for gram-negative diplococci associated with neutrophils. Gram stain of urethral exudate from men has a sensitivity of 90% and specificity of 98% when compared with culture. Staining of endocervical exudates is 50% sensitive and 95% specific in the hands of an experienced microscopist. Stained smears of the throat or rectum are not helpful because there are confounding flora that make specific diagnosis a challenge. Cultures

need not be done for men in the setting of a positive Gram stain, but are indicated for samples from women or in any case in which there is a question of drug resistance. To cultivate the organism, a swab specimen is streaked on enriched selective medium, such as modified Thayer-Martin, and incubated in 5% carbon dioxide at 37 °C. If immediate inoculation with optimal growth conditions is not possible, a transport culture system (ie, JEMBEC) can be used.

In systemic disease, blood culture is necessary. An isolator tube system is preferred. *N gonorrhoeae* can be cultured from the blood in ~ 30% of cases of gonococcal arthritis. Skin pustule cultures are also useful in defining systemic disease, especially if antibiotic therapy has already been started, because blood cultures will be of lower yield.

Other diagnostic modalities may be used when laboratory culture is not practical or there are specimen transport problems. Assays based on the polymerase chain reaction or ligase chain reaction offer a rapid diagnosis and may offer better specificity and sensitivity than culture; they are becoming more widely available in the United States. Serologic detection of antibodies to gonococcal pili and OMPs by using immunoblotting, radioimmunoassay, or enzyme-linked immunosorbent assay are available for epidemiologic or research purposes but are not clinically useful because of antigenic heterogeneity, the delay in the development of antibody in the setting of acute infection, and the cost.

## Treatment

Many antibiotics are safe and effective for the treatment of *N gonorrhoeae* ([Box 52-1](#)). In choosing a regimen, consideration must be given to the site of infection, other concurrent infections, and the possibility of resistance. The treatment of sex partners is also a crucial consideration in treating any patient with *N gonorrhoeae* (see Prevention & Control section below). Ceftriaxone in a single dose is the treatment of choice for uncomplicated gonorrhea at all sites. Ciprofloxacin has the advantages of a single oral dose, less expense than ceftriaxone, and effectiveness in patients who are intolerant of cephalosporins; however, resistance has been observed with ciprofloxacin, and it is not active against *Treponema pallidum*.

Complicated infections or disseminated gonococcal infections, such as arthritis, perihepatitis, or bacteremia resulting in petechial or pustular skin lesions, require a higher dose of antibiotics than uncomplicated gonorrhea infections and a longer duration of therapy. These regimens should be continued for 24-48 h after clinical improvement is noted (ie, they become afebrile, or joint erythema or skin lesions improve) and then switched to an oral regimen for a total of 7 d. Patients with gonococcal meningitis or endocarditis require higher doses and longer duration of therapy. Meningitis is treated with ceftriaxone for 14 d. Endocarditis should be treated for = 4 wk.

Concurrent infection with *C trachomatis* is estimated to occur in 40% of those infected with *N gonorrhoeae*. Therefore doxycycline or azithromycin must be added to the antigonococcal regimen. In pregnant women, for whom doxycycline is contraindicated, an erythromycin base can be used. If erythromycin cannot be tolerated, amoxicillin for 7-10 d is indicated.

Antibiotic resistance has been a major concern, as penicillin resistance has spread and, more recently, fluoroquinolone resistance has been increasingly reported. Beta-lactams remain the drugs of choice in most instances. Antibiotic resistance occurs by one or more mechanisms, including chromosomal mutations leading to decreased penicillin-binding-protein affinity, decreased outer membrane permeability, or beta-lactamase production.

## **Prevention & Control**

The primary measures for prevention of gonorrhea include sexual abstinence and barrier methods with sexual intercourse ("safer sex") ([Box 52-2](#)). Once a case of gonorrhea is identified, treatment of sex partners is an essential element of control of the disease. Epidemiologic treatment refers to the treatment of contacts of patients after a history of exposure to the disease, but without confirmation of infection. This is done in situations in which the risk of unnecessary treatment is outweighed by the risk of developing complications of the infection or the probability of transmission to other contacts. The prevention of gonorrhea must also be considered in sexual assault cases, and antigonococcal medications are included in the recommendations for treatment.

## ***NEISSERIA MENINGITIDIS***

### **Essentials of Diagnosis**

- Transmission in crowded or closed populations.
- Meningitis most common, but bacteremia, pneumonia, and other syndromes can occur in absence of meningitis.
- Disease often associated with petechial or purpuric rash, which may involve palms and soles.
- Neutrophil-predominant cell profile in CSF, with low-glucose and high-protein concentrations.
- Gram-negative diplococci inside neutrophils on stained smears of CSF and aspirated skin lesions.
- Fastidious organism requires special media and growth conditions.
- Blood and CSF most useful specimens for recovery of organism.
- Improved sensitivity of detection with PCR in CSF, but not widely available.

### **General Considerations**

**A. Epidemiology.** *N meningitidis* is found only in humans and is a member of the normal oropharyngeal flora in 5-15% of healthy adults and children. In crowded or closed populations such as in boarding schools or military camps, higher carriage rates

are observed. Transmission is from person to person by the respiratory route through nasopharyngeal secretions. *N meningitidis* is communicable and spreads within families and communities; there is a 500- to 1200-fold increased risk of developing meningococcal disease among household contacts of an index case in the 30-60 d after exposure, compared with the risk of developing disease among the general population.

Meningococcal disease usually occurs as isolated cases, but sporadic small epidemics occasionally take place. Group A strains in particular tend to cause widespread epidemics in 8- to 12-y cycles, especially in sub-Saharan Africa ([Figure 52-1](#)). The case rates in endemic areas of Africa vary widely, but overall the rate is 10-25 cases per 100,000 population per year. In the United States, the average annual incidence is 1-2 cases per 100,000 population per year. Most cases are seen in children and young adults (ages 5-19 y).

Microbiologic characterization of *N meningitidis* has been useful in understanding the epidemiology of this disease. The *N meningitidis* polysaccharide capsule provides the basis for a serogroup typing system. The most important serogroups causing invasive disease are A, B, C, W-135, and Y. These different polysaccharide capsular types are associated with characteristic epidemiological patterns. Group A strains are linked to worldwide epidemics, whereas B and C strains are considered endemic, causing sporadic cases and limited outbreaks. Currently ~ 50% of all cases in the United States are caused by serogroup B and another 20% by serogroup C. The remainder are primarily serogroups Y and W-135. The proportions of disease caused by serogroups C and Y have been rising in recent years. Each serogroup has been further subdivided into serotypes. For example, *N meningitidis* group B has 12 serotypes based on unique OMPs. These further subtypings of serogroups have been important both for epidemiologic studies and for vaccine development.

**B. Microbiology.** See discussion in *N gonorrhoeae* section.

**C. Pathogenesis.** Adherence, colonization, and invasion are the three essential properties of *N meningitidis* that enable infection in the human host. Before attachment can occur, secretory immunoglobulin A (IgA) must be inactivated. This is accomplished by secretion of a protease that cleaves IgA<sub>1</sub>. *N meningitidis* cells attach selectively to nonciliated pharyngeal mucosal cells, leading to colonization of the nasopharynx and upper respiratory tract. The PilC molecule and the OMPs Opa and Opc (opacity proteins) are important for adherence to the nasopharyngeal epithelial cells. The expression of Opa also mediates host cell invasion. The capsular polysaccharide facilitates invasion into the bloodstream and is antiphagocytic. The Opa and Opc groups of proteins have a high variability in their surface expression; this involves variation in promoter activity and frameshifts, which result in reversible on-off switching at the transcriptional and translational levels.

Host genetic factors, as well as other cofactors such as passive smoke and concurrent infection in the upper respiratory tract, appear to play a role in the development of meningococcal disease. Viral infection may increase the development of nasopharyngeal infection with *N meningitidis*, and thus lead to higher carriage rates in households or groups of exposed individuals. It should be noted however that exposure to pathogenic strains of *N meningitidis* most often leads to a carrier state, but not always

to active infection.

The protection provided by the host complement system is demonstrated by the enhanced susceptibility to bacteremic *Neisseria* disease of those patients who are complement deficient. The importance of another protective factor, specific IgG antibody to *N meningitidis*, is demonstrated by the increased incidence of serious *N meningitidis* infection in children between the ages of 6 mo and 2 y. This time interval corresponds to the time between loss of maternal antibodies and the development of natural immunity. Infections in outbreak situations, eg, in young adults, generally represent new infection with a virulent strain in individuals without specific antibodies.

Meningococcal endotoxin, primarily LOS, induces meningococcal sepsis. LOS mediates production of cytokines such as tumor necrosis factor-alpha (TNF-alpha), interleukin (IL)-1, IL-6, and interferon-gamma. The expression of these host inflammatory mediators results in increased endothelial permeability and myocardial depression and hypotension. Damage to the vascular endothelium results in petechial or purpuric skin lesions. These lesions reflect a similar process that occurs in multiple organs, leading to shock. Other inflammatory mediators such as prostaglandins, leukotrienes, and platelet-activating factor enhance granulocytic function and intravascular clotting and thrombosis. This in turn leads to disseminated intravascular coagulation, adrenal hemorrhage, decreased vascular resistance, circulatory collapse, and finally death.

## Clinical Findings

*N meningitidis* causes acute bacterial meningitis with or without meningococcemia. Its potential to progress rapidly mandates early recognition and use of empiric antimicrobial treatment. Pharyngitis precedes meningitis in most patients and is followed by fever with chills and malaise. The classic symptoms of meningitis are headache, nausea and vomiting, and stiff neck. A prominent feature is a petechial rash that starts distally on the extremities and progresses to the trunk. It often involves the palms and soles. Skin lesions evolve over hours and may continue to develop for a day or more despite appropriate antibiotic treatment ([Figure 52-2](#)). Fulminant meningococcemia (Waterhouse-Friderichsen syndrome) occurs in 5-15% of cases. Fulminant disease is associated with vascular collapse, often presaged by apprehension, restlessness, and mental status changes, all developing within a few hours. Acute meningococcemia can occur in the absence of meningitis and presents as the sepsis syndrome.

High fever is usually observed; absence of fever is a poor prognostic sign. Pneumonia from *N meningitidis* is reported in as many as 15-20% of patients with meningococcemia or meningitis and may occur by itself. Case fatality rates vary according to the prevalence of the disease and socioeconomic conditions. The fatality rate in meningococcal meningitis may be as low as 7% in industrialized countries and as high as 70% for meningococcemia in some developing countries.

Chronic meningococcemia is less common than other bacteremic meningococcal syndromes and presents with fever, headache, rash (90%), and joint pains (66%) that occur intermittently or over a period of days or weeks. The skin lesions occur with the febrile episodes. These lesions are maculopapular (47%) or petechial (12%) or erythematous and nodular with a pustular center (13%). Without diagnosis and

treatment, localized infection such as meningitis, endocarditis, or arthritis develops. Chronic meningococcemia is very responsive to antibiotic therapy.

## Diagnosis

The diagnosis of meningococcal infection is made by isolation of the organism or detection of its antigen from blood or cerebrospinal fluid (CSF). If possible, blood, CSF, throat swab, and petechial lesions should be cultured prior to antibiotic use. Collection of these specimens, however, should never delay treatment. Leukocytosis is often as high as 20,000-30,000 cells/mm<sup>3</sup>. Blood cultures are positive in 50% of cases of meningitis before antibiotics and in ~ 5% of cases after antibiotics are given. Gram stains of skin lesions are positive in ~ 70% of cases. This is a useful diagnostic test especially if antibiotics have been given before the culture specimens could be obtained.

The CSF pleocytosis of meningococcal meningitis is typical of most acute bacterial meningitides with a predominance of PMNs. The CSF glucose is low with a normal or high CSF protein. Gram stain of the CSF is positive in ~ 75% of cases. CSF should be inoculated onto chocolate agar as soon as possible (within minutes) because of the fastidious nature of this organism, like *N gonorrhoeae*. A latex agglutination test is available and may be indicated for diagnosis in patients treated with antibiotics. This test is expensive and may not improve diagnostic specificity compared with a Gram stain performed by an experienced microscopist. Positive throat and nasopharyngeal cultures in the setting of meningitis should be interpreted with caution, because there are many coincidental meningococcal carriers.

## Differential Diagnosis

The differential diagnosis is broad, given the clinical presentation of infections caused by *N meningitidis*. The primary considerations in the setting of meningitis with a rash should include the rickettsial diseases such as Rocky Mountain spotted fever, epidemic typhus, and Brill-Zinsser disease. Toxic shock syndrome caused by *Staphylococcus aureus* may mimic meningococcemia, and therefore additional appropriate antimicrobial coverage is required. Other diseases to consider include viral exanthems such as infection with echovirus type 9, typhoid fever, and vasculitis syndromes such as polyarteritis nodosa, Churg-Strauss syndrome, and Henoch-Schonlein purpura.

## Treatment

Treatment should be initiated as soon as the diagnosis is considered ([Box 52-3](#)). Intravenous penicillin G or ceftriaxone is the standard of therapy. The duration of therapy is dependent on the clinical response, but 7 d is considered adequate for both meningitis and chronic meningococcemia.

The clinical importance of isolates found to have altered penicillin-binding proteins with intermediate resistance to penicillin (MIC of 0.1-1.0 ug/ml) is unclear, as patients with these strains respond well to penicillin. For patients who do not respond adequately to therapy, the bacterial isolate should be tested for antibiotic resistance, and the therapy changed to ceftriaxone or cefotaxime if the isolate is resistant to penicillin.

*N meningitidis* has traditionally been exquisitely sensitive to penicillin, but recent reports from Spain, England, South Africa, Argentina, Canada, and the United States indicate an increasing percentage of penicillin-resistant strains. A third-generation cephalosporin such as ceftriaxone should be used if there is resistance in the area or if the microbiologic diagnosis might include *Haemophilus influenzae* or *Streptococcus pneumoniae*.

Chloramphenicol is effective for meningococcal infection, although there are reports of resistance in parts of sub-Saharan Africa. Although it is usually considered bacteriostatic, chloramphenicol is bactericidal against the meningococcus and achieves high CSF levels. It remains an excellent alternative in beta-lactam-allergic patients and in situations in which multiple dosing of parenteral drug is not feasible. Data to support the use of corticosteroids as adjunctive therapy in meningococcal meningitis are limited.

## Prevention & Control

Antimicrobial chemoprophylaxis should be given to close contacts of patients with meningococcal disease, because this is a primary means of prevention of disease ([Box 52-4](#)). Close contacts are defined as household members, day care center contacts, and anyone directly exposed to the patient's oral secretions. Antimicrobial prophylaxis should be administered as soon as possible (ideally within 24 h) after case identification, because the secondary attack rate is highest within the first few days of onset of disease in the primary patient. Chemoprophylaxis given > 14 d after the onset of illness in the primary (index) case is of limited or no value. Nasal and oropharyngeal cultures are of no value in determining the need for chemoprophylaxis.

The three antibiotics used for chemoprophylaxis against meningococcal disease are rifampin, ciprofloxacin, and ceftriaxone. Rifampin is the best studied and may be the most efficacious, but it is not the most convenient. It requires multiple dosing, is not recommended in pregnancy, and may cause gastrointestinal side effects. Ciprofloxacin is given as a single dose and is generally well tolerated, but it is not recommended in pregnancy or for children < 18 y of age. Ceftriaxone is also given as a one-time dose but requires intramuscular injection.

A quadrivalent vaccine for meningococcal serogroups A, C, Y, and W-135 is available in the United States. Efficacy varies by age and serogroup. Protection against disease caused by serogroups A and C is 85-100% in older children and adults. The vaccine polysaccharides elicit bactericidal antibody that is serogroup specific. The serogroup B polysaccharide is poorly immunogenic in humans, and thus no useful vaccine against serogroup B is currently available; however, with the recent determination of the complete serogroup B meningococcus genome sequence, a set of immunogenic outer surface proteins from this organism has been revealed. A candidate vaccine has been created from some of these proteins. Serogroup B is the most common cause of meningococcal disease in Europe, North America, and several countries in Latin America.

Vaccine protection decreases over time and more rapidly in young children. In children older than 4 y, one study documented an efficacy of 67% at 3 y after vaccination. The

current vaccine is useful in controlling serogroup C meningococcal outbreaks. It is also recommended in the following high-risk groups: (1) complement-deficient hosts (C3, C5-C9), (2) asplenic individuals, (3) travelers to endemic areas, (4) research or laboratory personnel, and (5) military recruits.

INTRODUCTION

---

**Table 52-1.** Features of *Neisseria gonorrhoeae* and *Neisseria meningitidis*

	<b><i>Neisseria gonorrhoeae</i></b>	<b><i>Neisseria meningitidis</i></b>
<b>Clinical</b>	Men: purulent urethral discharge, dysuria. Women: usually asymptomatic, vaginal discharge, dysuria without frequency.	Petechial rash (may involve palmar, plantar, and mucosal surfaces), fever, headache, sore neck, vomiting, seizures, confusion.
<b>Laboratory</b>	Gram-stain of cervical or urethral swab shows gram-negative diplococci in association with PMNs. Culture of the affected site demonstrates the organism.	Gram stain: gram-negative intracellular diplococci. CSF: cloudy, purulent, high leukocyte count, PMN predominance, increased protein, decreased glucose. Culture of CSF, blood, or aspirated petechial lesion demonstrates organism. Latex agglutination of CSF or urine may be indicated in treated patients but is similar to Gram stain of CSF for sensitivity.
<b>Epidemiology</b>	Sexual transmission.	Crowded or closed population settings (e.g., boarding schools and military camps). Most cases in children and young adults.

## 53 . Enteritis Caused by *Escherichia coli* & *Shigella* & *Salmonella* Species — Gary W. Procop, MD, & Franklin Cockerill III, MD

### Essentials of Diagnosis

- Enteritis: diarrhea, which may be watery, bloody, or dysenteric; abdominal pain; and fever and/or;
- Systemic disease: highly variable presentations that may include enteric fever, hemolytic uremic syndrome, or bacteremia with infectious foci in distant sites.
- History of exposure, possibly in known endemic areas or associated with an outbreak, through the ingestion of unclean water, unpasteurized juice or milk, undercooked meats, or other possibly contaminated food.
- Microbiologic isolation and identification of enteric pathogens or molecular detection.

### General Considerations

The *Enterobacteriaceae* are a diverse family of bacteria that, in nature, exist in soil, on plant material, and in the intestines of humans and other animals. Another ecological niche in which these organisms thrive is the hospital. Many of these organisms cause a wide variety of extraintestinal diseases that are often nosocomial and commonly present in debilitated or immunocompromised hosts. These manifestations have been examined previously in this volume and include urinary tract infections ([chapter 16](#)), skin and soft tissue infections ([chapter 13](#)), lower respiratory infections and pneumonia ([chapter 10](#)), and infective endocarditis and sepsis syndrome ([chapters 11](#) and [17](#)). The genera most frequently associated with extraintestinal disease are *Escherichia*, *Enterobacter*, *Klebsiella*, *Proteus*, *Citrobacter*, and *Serratia*.

Some members of the *Enterobacteriaceae*, however, cause primarily enteric disease or enteric-associated systemic disease ([Box 53-1](#)). These are *Shigella* and *Salmonella* species and particular strains of *E coli* and *Yersinia enterocolitica*. This chapter is devoted to enteritis and enteric-associated systemic disease caused by diarrheagenic strains of *E coli* and of *Shigella* and *Salmonella* species. Enteritis and associated mesenteric lymphadenitis caused by *Y enterocolitica* are covered separately (see [chapter 60](#)).

The family *Enterobacteriaceae* consists of at least 27 definitive genera and numerous enteric groups. The final classification of the enteric groups has yet to be resolved. Although there is diversity within this group, members have several common, characteristic features. All *Enterobacteriaceae* are gram-negative, facultative anaerobic bacilli that have the ability to reduce nitrate to nitrite. They produce catalase, ferment D-glucose with or without gas production, and do not produce oxidase. This latter characteristic is useful in differentiating this group of organisms from other nosocomial gram-negative pathogens, such as *Pseudomonas aeruginosa*, which is oxidase positive.

Traditionally, phenotypic characterization has been the method of choice for differentiating the members of the *Enterobacteriaceae*, but, with increasing frequency, genotypic methods are being used to detect particular genera and pathogenic varieties. Phenotypic methods, however, remain the standard for routine identification of these organisms in the clinical microbiology laboratory. The characteristics that are most useful for identification include colony morphology (particularly distinctive for some *Proteus* strains), indole production from tryptophan, reactions of the methyl red and Voges-Proskauer tests, motility, the ability to produce hydrogen sulfide, and the ability to use various organic substances. Several pathogenic *Enterobacteriaceae*, particularly many of the diarrheagenic *E coli*, fail to demonstrate unique phenotypic characteristics and continue to pose a challenge for microbiologists.

## **ESCHERICHIA COLI**

### **Essentials of Diagnosis**

- Enteritis caused by *E coli* may be watery (any *E coli* subtype), mucoid [enteroaggregative *E coli* (EAggEC)], hemorrhagic [enterohemorrhagic *E coli* (EHEC)], or dysenteric [enteroinvasive *E coli* (EIEC)] and is associated with fever and abdominal pain.
- Hemolytic uremic syndrome, caused by EHEC, consists of hemolytic anemia, uremia, and systemic symptomatology.
- Risks for *E coli*-induced enteritis include ingestion of fecally contaminated food (EHEC, EIEC) or water [enterotoxigenic *E coli* (ETEC), EIEC, EAggEC, enteropathogenic *E coli* (EPEC), and diffusely adherent *E coli* (DAEC)], especially in endemic areas, or close contact with infected individuals (EIEC, EHEC).
- *E coli*-induced enteritis is also indicated by microbiologic isolation and identification of enteric pathogens or molecular evidence of infection in the appropriate clinical setting.

### **General Considerations**

**A. Epidemiology.** *E coli* is the most common member of the *Enterobacteriaceae* to be isolated in the clinical microbiology laboratory. Most *E coli* isolates are either opportunistic or nosocomial pathogens (ie, causes of urinary tract or wound infections) or normal flora (ie, enteric contaminants of urine cultures or normal stool flora in stool cultures). There are, however, at least six diarrheagenic varieties of *E coli*. Some of these produce enteritis alone, whereas others produce enteritis-associated systemic disease that may be fatal. The six types of diarrheagenic *E coli* are the ETEC, EHEC, EIEC, and three distinct subtypes of enteroadherent *E coli*—the EPEC, EAggEC, and DAEC.

**1. ETEC.** The ETEC are spread by the fecal-oral route and are most common in developing countries that lack appropriate sanitation and drinking-water treatment facilities. Disease may occur at any time of the year, but incidence peaks in the warm, wet seasons that favor environmental bacterial replication. The most important mode of transmission is contaminated, improperly treated drinking water. Fruits and vegetables

that are washed with contaminated water and not cooked before they are eaten also serve as vehicles of transmission. Person-to-person spread is uncommon.

In a normal host, exposure to ETEC leads to the development of mucosal immunity, presumably secondary to secretory immunoglobulin A (IgA) antibodies directed toward the fimbriae-associated colonization factor antigens (CFAs). In endemic areas, natural resistance is usually well developed in adults. These individuals serve as carriers and shed large numbers of toxigenic *E coli* into the environment. Disease occurs in those lacking mucosal immunity, principally neonates and travelers from nonendemic areas.

**2. EHEC.** The EHEC are commensals and pathogens of live stock. Food, water, or unpasteurized beverages that are contaminated with animal feces are the principal modes of spread, but person-to-person transmission is also possible. EHEC commonly colonize cattle. Beef frequently becomes contaminated with bovine feces during the slaughter process. Ground beef that is contaminated is especially hazardous, because grinding distributes the bacteria through the meat. When hamburgers are made from contaminated beef and not cooked thoroughly, the bacteria are able to survive. The EHEC are more acid tolerant than many other bacterial enteric pathogens, with the possible exception of *Shigella* species, and relatively small inocula can survive gastric passage in humans and cause disease. Good cooking practices and food preparation hygiene can significantly reduce the likelihood of EHEC infections (see "Prevention" section).

**3. EIEC.** The EIEC are spread by the fecal/oral route. Contaminated food and water are the usual vehicles of spread and food-borne outbreaks have occurred. Person-to-person transmission is possible but is uncommon. Compared with *Shigella* species, a higher infective dose of EIEC is required to cause disease. Infections by EIEC are thought to be rare, but this is unclear, because EIEC may be mistaken for *Shigella* species.

**4. Enteroadherent *E coli*.** Contaminated food, water, and fomites serve as vehicles for the fecal/oral transmission of the enteroadherent *E coli*. Of the three types of enteroadherent *E coli*, the EPEC primarily cause disease in neonates and young children, with most cases occurring in children < 2 years old and particularly in those < 6 months old. Unlike ETEC, the EPEC are rarely a cause of traveler's diarrhea. Disease, however, may occur in adults if sufficiently high inocula are ingested. This organism has caused outbreaks in pediatric wards, nurseries, and day care centers and in adults that have consumed contaminated food from a buffet. The prevalence of disease in the United States is thought to be much lower than earlier in this century, but is still probably underestimated. In developing countries, the EPEC are highly prevalent and are an important cause of childhood diarrheal disease and dehydration-associated deaths. In some areas, the incidence of EPEC-associated enteritis surpasses the incidence of rotavirus infection and may represent 30%-40% of childhood diarrheal diseases.

The EAaggEC are also a cause of diarrheal disease in both developing and developed countries and have caused serious outbreaks in nurseries. Infants are most commonly affected, and growth retardation may be caused by persistent diarrhea. In the United States, EAaggEC have been shown to cause persistent diarrhea in patients infected by the human immunodeficiency virus (HIV).

Although not extensively studied, the DAEC seem to infect children > 1 year of age, rather than neonates.

**B. Microbiology.** All *E coli* isolates, regardless of subtype, demonstrate a typical morphology on sheep's blood agar and chocolate agar. Colonies are typically gray and flat to slightly raised. On sheep's blood agar, colonies produce a distinctive smell from the metabolism of tryptophan to indole and may be associated with  $\beta$ -hemolysis. Most *E coli* strains, with the notable exception of the EIEC, rapidly ferment lactose and produce typical colonies on MacConkey and eosin methylene blue agars. Like other members of the *Enterobacteriaceae*, these organisms do not produce oxidase. Both the production of indole from tryptophan and the absence of oxidase activity may be detected in the laboratory through the use of rapid "spot" tests.

Many of the diarrheagenic *E coli*, namely the ETEC, EPEC, EAaggEC, DAEC, and non-O157:H7 EHEC, demonstrate colony morphology and biochemical reactions in standard tests (biophysical profile) that are identical to normal-flora *E coli*. For this reason, the identification of these organisms is a problem for clinical microbiologists. If these diarrheagenic varieties are not suspected clinically and additional testing is not performed, they will be erroneously dismissed as normal flora. Fortunately, in most instances, enteritis caused by these agents is self-limited and resolves without antimicrobial therapy. The most commonly encountered EHEC strain, *E coli* O157:H7, and the EIEC have distinctive features that may be used to screen for these organisms.

**1. ETEC.** ETEC strains have been associated with a wide variety of somatic antigens, a few flagellar antigens, and certain CFAs. In the appropriate clinical setting and in the absence of other enteric pathogens, the presence of *E coli* with a particular somatic:flagellar (O:H) antigen profile in the stool is supportive evidence of an ETEC infection. However, the mere presence of a particular O:H profile is not proof that a strain is toxigenic, because these antigens may also be found on nontoxigenic *E coli*. Definitive proof that a strain is toxigenic requires the demonstration of either enterotoxins or the genes that encode them.

Animal models and cell culture assays have been used to detect the heat-labile (LT) and heat-stable (ST) enterotoxins, but those methods have largely been replaced by immunoassays. Commercial immunoassay kits are now available for both the LT and ST toxins. Molecular assays, designed for the detection of the genes that encode for these toxins, are another method of detection. Signal amplification assays with nucleic acid probes have been used directly on stool and on colony blots of suspect isolates. Polymerase chain reaction (PCR)-based assays have also been used to detect these genes. If PCR is attempted directly on stool specimens, a preamplification treatment may be necessary to remove PCR inhibitors that are inherently present in stool. Better results may be obtained if PCR is performed on isolated colonies, rather than stool.

**2. EHEC.** The most common EHEC, *E coli* O157:H7, has a few distinguishing characteristics that make screening for this organism possible. *Escherichia coli* O157:H7, unlike most *E coli*, does not rapidly ferment sorbitol and fails to produce  $\beta$ -glucuronidase. Microbiologic assays that detect these traits have been developed to detect *E coli* O157:H7. A modified MacConkey plate, which contains sorbitol rather than lactose (SMAC), is the screening method most commonly used. Nonfermenting colonies

on a SMAC plate may be further tested for their ability to produce  $\beta$ -glucuronidase.  $\beta$ -Glucuronidase is an enzyme that cleaves 4-methylumbelliferyl- $\beta$ -glucuronide and yields a UV light (366 nm)-excitable end product. Nonfermenting colonies on a SMAC plate and/or isolates that fail to produce  $\beta$ -glucuronidase are then tested for the presence of the O157 antigen, usually by agglutination with type-specific antiserum. Isolates that are O157-positive are then examined for the H7 flagellar antigen by motility inhibition. Specific H7 antiserum, present in a semisolid medium, will inhibit the motility of organisms with the H7 flagellar antigen, whereas the motility of non-H7 strains is unaffected.

In South America and Australia, the non-O157:H7 EHEC serotypes cause more hemorrhagic colitis (HC) and hemolytic-uremic syndrome (HUS) than the O157:H7 serotype. These serotypes are more difficult to detect, because they are able to ferment sorbitol and are therefore phenotypically similar to normal-flora *E coli* on the SMAC screening agar. The identification of these strains is more complicated and relies on methods to detect the shigalike toxin or verotoxin (VT), the *VT* gene, or other markers of pathogenicity.

Cultured Vero or HeLa cells may be used to detect the presence of VT, but this test is costly and labor intensive, and it has largely been replaced by immunoassays. A wide variety of molecular assays have been developed for the detection of EHEC. These methods include PCR-based assays and nucleic acid probes for the detection of the *VT* gene or other markers of pathogenicity, such as the pO157 plasmid and the *eae* gene encoding intimin, which is necessary for attachment to enterocytes.

Although these detection methods are not currently used in most clinical microbiology laboratories, they may be more widely used in the future. Many of these methods offer greater sensitivity than the SMAC agar, and they detect non-O157:H7 serotypes. However, problems with these technologies do exist. Substances present in stool may inhibit PCR. Some non-nucleic acid amplification methods, such as the measurement of free fecal cytotoxin or culture enhancement by using O157 immunomagnetic beads, may have sensitivities that are superior to PCR-based assays. Determining the significance of the detection of either VT or the *VT* gene is another problem. The presence of VT or the *VT* gene is supportive evidence, but not definitive proof, that the isolate is the cause of disease. There are > 200 serotypes of *E coli* that can express VT and only a fraction of these have been associated with HC. The serotypes O26:H11, O111:H-, O103:H2, and O113:H21 are other EHEC that have been associated with HC and/or HUS outbreaks. Therefore, when VT or the *VT* gene is detected in stool or stool isolates, the detection of other virulence factors or particular O:H serotypes would be necessary to further characterize the isolate.

The principal disadvantage of most molecular detection technologies is cost. In many instances, an expensive screening test is not cost effective, especially when the pathogen is infrequently encountered and less expensive screening methods exist. These technologies, however, are attractive in outbreak situations or when the incidence of disease is high.

**3. EIEC.** *E coli* and *Shigella* species are so closely related that they are currently classified in the same biogroup. The EIEC have several phenotypic characteristics that

are more typical of *Shigella* spp. than *E coli*. Like *Shigella* spp. and unlike most *E coli*, the EIEC are nonmotile, do not ferment lactose or ferment it only slowly, and do not decarboxylate lysine. However, complete characterization of EIEC strains discloses the presence of some biochemical features that are typical of the genus *Escherichia*. Nevertheless, the phenotypic differentiation of EIEC from a *Shigella* species is difficult, and many isolates may be misidentified as *Shigella* species. The isolation of an enteritis-associated bacterium that has a mixture of *Shigella*-like and *Escherichia*-like biochemical characteristics is a clue to the presence of this organism. The subsequent detection of EIEC-associated O antigen groups/O:H subtypes is useful to confirm that the organism is an EIEC.

The stool from patients with EIEC enteritis is indistinguishable from the stool of patients with shigellosis and may be watery or dysenteric. *Shigella* antigen testing is of no use in differentiating these bacteria, because EIEC may cross-react with *Shigella* antiserum. In a similar manner, tests of invasiveness, in cell culture or animal model (Sereny test), are positive with both EIEC and *Shigella* spp. Molecular methods, such as enzyme-linked immunosorbent assays, nucleic acid probes, or PCR, have been used for the detection of *Shigella*/EIEC species, but they are less useful for differentiation.

**4. Enteroadherent *E coli*.** The biophysical profiles of the enteroadherent *E coli* subtypes are indistinguishable from normal-flora *E coli* in routine bacteriologic studies. These varieties, which do represent distinct pathogenic subtypes, adhere differently from one another to HEp-2 cells in cell culture. The EPEC adhere to the HEp-2 monolayer in a localized pattern, the EAaggEC produce three-dimensional aggregates, and the DAEC adhere diffusely. Although these adherence patterns are reliably produced, the HEp-2 assay requires cell culture capability and interpretation experience.

The EPEC can also be identified by the production of an attaching and effacing lesion (A/E) and absence of verotoxin (VT) (EHEC produce the A/E lesion, but also produce VT). If the phenotype is used for identification, it is important to demonstrate the absence of VT, because EHEC also produces an A/E lesion. Like the other diarrheagenic *E coli*, the EPEC have been associated with particular somatic antigens. Many of the EPEC possess specific O:H profiles that may be used for organism identification. Antiserum directed against some of these O antigens is commercially available and may be used to screen suspect colonies. A positive screening test then requires confirmation, which may include titration, complete O:H typing, or molecular analysis (see below).

Both direct DNA probes and PCR-based assays may be used for the detection of genes that encode pathogenic factors of the enteroadherent *E coli*. The presence of the *eae* gene, which is associated with the A/E phenotype, and the EAF plasmid, which contains the *bfp* gene cluster, are important for pathogenesis of EPEC; detection of these genes and the absence of the *VT* gene are important for molecular identification of the EPEC. Molecular detection of EAaggEC may be accomplished by identifying a 65-MDa plasmid by either DNA probe or PCR technology. The molecular detection of the DAEC has been accomplished through the detection of a particular fimbria (F1845)-associated gene, but false positive reactions may occur.

All of the ancillary tests, both phenotypic and genotypic, used to identify the

enteroadherent *E coli* subtypes are impractical and cost prohibitive for most clinical microbiology laboratories. These tests are most efficiently and cost-effectively performed by reference or public health laboratories that have expertise in identifying these organisms. In most instances, however, the complete identification of the enteroadherent *E coli* subtype is unwarranted, because most patients have a self-limited course with appropriate supportive therapy. If diarrhea from an infectious etiology becomes persistent, antimicrobial therapy is warranted and should be based on the organism's particular antimicrobial susceptibility profile.

**C. Pathogenesis.** Regardless of the diarrheagenic *E coli* subtype, successful gastric transit is a prerequisite to disease. Generally, the larger the inoculating dose, the greater the likelihood that viable bacteria will survive gastric passage. Foodstuffs contaminated with bacteria buffer gastric acid and thereby facilitate gastric passage. Individuals with achlorhydria or hypochlorhydria are at an increased risk for bacterial enteritis, because the diminished gastric acidity decreases bacterial killing. The bacteria that survive gastric passage enter the small intestine and colonize the epithelium of the small intestine, colon, or both, depending on the infecting diarrheagenic *E coli* subtype.

**1. ETEC.** The ETEC produce LT and/or ST toxins. The plasmid-encoded LT enterotoxin of the ETEC is highly homologous to a toxin of *Vibrio cholerae* and has the same mechanism of action. This toxin consists of two subunits, B and A. The B subunit, which binds to gangliosides on the surface of the enterocytes, facilitates entry of the enzymatic A subunit into the cytosol. The A subunit ribosylates the adenylate cyclase regulatory G protein, G<sub>s</sub>, which results in a massive increase in cytosolic cyclic AMP (cAMP). This, in turn, results in alteration of the chloride ion channels and causes osmotic diarrhea.

One of the *E coli* ST toxins, ST<sub>a</sub>, results in osmotic diarrhea, similar to the LT toxin, but through activation of guanylate cyclase and increased cytologic cyclic GMP (cGMP) levels. The other ST toxin, ST<sub>b</sub>, does not cause alterations in cAMP or cGMP levels, but increases intracellular calcium, promotes the secretion of bicarbonate, and stimulates serotonin and prostaglandin E<sub>2</sub> release. In addition, unlike the other toxins, ST<sub>b</sub> damages enterocytes and causes epithelial cell loss and partial villous atrophy. These changes also contribute to diminished absorption and osmotic diarrhea.

**2. EHEC.** The EHEC represent a variety of organisms possessing a set of virulence factors that cause HC and sometimes HUS. In the United States and Canada, the most common EHEC is *E coli* O157:H7. In some parts of the world, EHEC O:H serotypes other than O157:H7 are more commonly associated with HC/HUS.

The EHEC are a subset of *E coli* that produce disease through the combination of a variety of virulence factors. The most important virulence factor is a lysogenic bacteriophage-encoded toxin that is typical of *Shigella dysenteriae* type 1. This shiga toxin is also known as a VT because of its toxicity to Vero cells. VT binds to G3b, a glycolipid receptor. After binding, a portion of the VT enters the cell and disrupts protein synthesis by enzymatically altering the 28S ribosomal subunit. The high concentration of G3b on intestinal villous tip cells and renal endothelial cells may partially explain the damage to the intestine and kidneys in HC and HUS, respectively.

Although important, the presence of VT alone is probably insufficient for the production of disease, because there are VT-producing *E coli*, which do not produce HC/HUS. Another virulence factor of the EHEC is a chromosomal 35-kilobase locus of enterocyte effacement (LEE), as also found in the EPEC. This locus contains the *eae* gene, which codes for an outer membrane protein, an intimin, that mediates adherence between the EHEC and the enterocyte. This locus also confers the A/E phenotype that is typical of EHEC and EPEC. Finally, plasmid-encoded hemolysins are also probably virulence factors.

**3. EIEC.** The EIEC that reach the small intestine adhere to the cell surface of mucosal enterocytes. The watery-diarrhea phase, which begins next, may be secondary to the elaboration of an enterotoxin. This enterotoxin may be encoded for by the plasmid-based gene *sen*. The adherent bacteria then penetrate into the cell. Cell entry is facilitated by both chromosomal and plasmid-encoded invasive factors. Within the cell, the bacterium moves through the cytoplasm by alterations in cellular actin. The EIEC then infects adjacent enterocytes. Eventually, cell death and mucosal sloughing occur, which evoke the intense inflammatory response and the dysenteric phase of the disease.

**4. Enteroadherent *E coli*.** The enteroadherent *E coli* subtypes, like all other diarrheagenic *E coli*, initiate pathogenesis by colonization of the intestinal mucosa. An intimate attachment occurs between bacterium and enterocyte that is distinctly different from the mucosal colonization seen with the ETEC. The enteroadherent *E coli* cause diarrhea without the production of better described virulence factors such as LT and ST of the ETEC or VT of the EHEC. However, some strains have been shown to produce an enterotoxin. Microbial colonization appears limited to the mucosal surface, and deep-tissue invasion is not seen, but a chromosomally encoded, cell entry gene product has been identified in some strains. Although some of the pathogenic mechanisms of these organisms have been described, to a large extent they have yet to be elucidated.

The EPEC, like the EHEC, contain a chromosomal LEE gene cluster. This locus includes the *eae* gene, which encodes for an intimin outer membrane protein (OMP). This OMP mediates adherence between the bacterium and the enterocyte. The LEE locus also contains the genes responsible for the attaching and effacing lesion (A/E lesion). After attaching, the bacterium causes changes that result in the effacement of the microvilli of the cell membrane, which can only be fully appreciated when viewed by electron microscopy. However, a portion of the A/E lesion, the aggregated intracytoplasmic, filamentous actin, may be detected in cell culture or intestinal biopsy by using immunohistochemical stains. Some strains may produce an enterotoxin and may contain a cell entry gene product. The precise relationship, however, between these products and the production of disease remains to be determined.

The EAggEC adhere to enterocytes via a fimbria designated aggregative adherence fimbria I or AAF/I, a 38-kDa OMP. Another fimbria (AAF/II) has also been implicated in cytoadherence. It is currently thought that, after colonization, the EAggEC promote enhanced mucus secretion. This mucus forms a protective biofilm, which contains the EAggEC and may diminish nutrient absorption. Finally, the production of enterotoxin may cause enterocyte damage and diarrhea.

Enterocyte surface adherence by the DAEC probably also occurs through the fimbriae (F1845) and/or outer membrane proteins. The precise mechanism of disease, however, remains to be determined.

## **CLINICAL SYNDROMES**

### **INTRODUCTION**

The diarrhea produced by these organisms is variable and may be watery, mucoid, dysenteric, or bloody, and it may be associated with serious and even fatal systemic sequelae. The presentation and course of disease are largely dependent on the infecting *E coli* subtype, as well as the age and nutritional status of the patient. Infants and children, especially if malnourished, are particularly susceptible to dehydration and may succumb rapidly. The mechanism of disease production also varies with the *E coli* subtype. The enteritis caused by these organisms results from toxin production, enterocyte invasion, intimate bacterial/enterocyte adherence, or a combination of these mechanisms.

#### **1. ETEC**

##### **Clinical Findings**

Patients with ETEC enteritis usually have an abrupt onset of watery diarrhea that does not contain blood, pus, or mucus (ie, is nondysenteric). The diarrhea is usually mild to moderate in severity, but some patients may have severe fluid loss, like that seen in patients with cholera. A low-grade fever, nausea, and abdominal pain may also be present. Dehydration may become severe and life threatening in neonates and children, necessitating aggressive fluid and electrolyte replacement. A self-limited course, with resolution in 2-5 days, is most common in adult travelers who acquire the disease.

#### **2. EHEC**

##### **Clinical Findings**

Disease caused by the EHEC usually follows the ingestion of contaminated food or beverage. The incubation phase averages 3-4 days, with a range from 1 to 8 days. Individuals remain asymptomatic during the incubation phase. Early in the course of disease, patients develop watery diarrhea that is usually not bloody. Accompanying symptoms may include nausea and vomiting, abdominal cramping, and a low-grade fever. The diarrhea may then become noticeably bloody within a few days. It is interesting that fecal leukocytes are characteristically few and are detected in only ~ 50% of patient's stools. In most patients, the disease is self-limited. However, = 10% of children and a lesser number of adults may develop HUS.

HUS is a severe systemic disease with a significant mortality. It consists of the triad of microangiopathic hemolytic anemia, renal failure, and a thrombocytopenia that may be part of a consumptive coagulopathy. The kidneys are particularly susceptible to damage (see below). In general, the kidneys may have a "flea-bitten" appearance secondary to punctate cortical hemorrhages that result from multifocal occlusion of afferent arterioles.

Biopsies demonstrate microvascular deposition of immunoglobulins, complement components, and fibrin by immunofluorescence. Arteriolar and intimal hyperplasia and subintimal fibrin deposits may be seen in histologic sections. Additional findings may include microinfarcts, acute tubular necrosis, and interstitial edema. Renal failure commonly develops, with resultant oliguria, azotemia, and hematuria. Patients who survive HUS suffer morbidity caused by central nervous system and renal sequelae.

### **3. EIEC**

#### **Clinical Findings**

Volunteer studies and occasional, well-documented outbreaks have helped to establish the EIEC as a cause of enteritis. Patients infected by EIEC have moderate-to-severe diarrhea that begins watery, but may become dysenteric with sheets of leukocytes, blood, and mucus. The watery diarrhea is similar to that produced by ETEC infection, and the dysentery is indistinguishable from that produced by *Shigella* species infection. Fever and abdominal cramping are also frequently present.

### **4. ENTEROADHERENT *E COLI***

#### **Clinical Findings**

The presentation and course of disease caused by the enteroadherent *E coli* (EPEC, EAggEC, and DAEC) are variable and depend to some degree on the infecting *E coli* subtype. The EPEC primarily cause acute, profuse, watery diarrhea, which rarely may become persistent. Stools are typically not bloody, mucoid, or dysenteric. Low-grade fever with nausea and vomiting may be present. Microscopic examination of the stool may disclose rare fecal leukocytes.

The EAggEC produce an acute, secretory diarrhea that is usually watery to mucoid and may also become prolonged. In some instances, gross blood may be present. A low-grade fever is common, but vomiting is infrequent.

The DAEC seem to produce a watery diarrhea, usually without blood or fecal leukocytes, but too few studies have been performed to adequately characterize this disease.

#### **Differential Diagnosis**

The differential diagnosis of diarrheal diseases is extensive and includes infectious etiologies, inflammatory-bowel disease, irritable-bowel syndrome, postsurgical dumping syndromes, and even some neoplasms, such as hypersecretory villous adenomas or vasointestinal peptide-producing neuroendocrine tumors. This extensive differential is successfully narrowed through the examination of the patient (history and physical exam), laboratory studies, and often endoscopy with biopsy

The physical examination of the patient, as well as exposure/travel history, past medical history, and the duration and presentation of current disease, yields clues to the cause of the diarrhea.

Laboratory tests, radiologic studies, and special procedures, such as endoscopy with biopsy are useful in delineating the cause of disease. A colonoscopy with biopsy is often necessary to determine the cause of persistent diarrhea, particularly when microbiologic studies are negative. Inflammatory bowel disease, ischemic colitis, lymphocytic/collagenous colitis, and neoplasia are often suspected clinically and confirmed with histopathologic studies.

The stool of patients with fever and new-onset diarrhea should be cultured for common bacterial enteric pathogens. Fecal leukocyte testing is not useful, because fecal leukocytes may be present in the stool of patients who have enteritis caused by a wide variety of pathogens, as well as in the stool of patients who have noninfectious enteritis. Clinical microbiologists use selective and differential agar media to screen the stool for *Salmonella*, *Shigella*, and *Campylobacter* species and for *E coli* O157:H7. In most laboratories, cost-effective screening for *E coli* O157:H7 is performed only when patients have bloody stools or a history of bloody stools. In a similar manner, the culture for even rarer bacterial enteric pathogens, such as *Y enterocolitica* and *Vibrio* species, is most often performed upon request and usually after exclusion of more typical pathogens. If bacterial agents that resemble normal flora on routine bacterial media are suspected (ETEC, EPEC, EAggEC, DAEC, or EHEC other than O157:H7), the laboratory should be notified so that confirmatory testing may be performed.

Other methods used to detect infectious agents in the stool include the direct examination, immunofluorescence enzyme-linked immunosorbent assays and cell culture-based assays. The microscopic examination of stool, often by using special stains (ie, trichrome or modified acid-fast stain), is used to detect ova and parasites. Immunoassays and ELISAs are available for the detection of *Giardia lamblia*, *Cryptosporidium parvum*, rotavirus, and *Clostridium difficile* toxins. Some laboratories use cell culture-based assays to detect *C difficile* toxin. Similar assays may be used to detect the VT of EHEC and shiga toxin of *Shigella dysenteriae* 1.

Individually, these microbiologic assays may be relatively inexpensive, but when numerous tests are ordered nonjudiciously, costs rapidly accrue. Microbiologic assays, like any laboratory assay, should be used to answer specific clinical questions. In patients with enteritis, the most likely causes of disease should be explored first. Patients who develop diarrhea after 3 d of hospitalization and who have been treated with antimicrobial agents probably do not warrant bacterial stool cultures or a stool examination for ova and parasites. These patients should be tested for *C difficile* toxin, because they are more likely to have pseudomembranous colitis.

## **Complications**

All of the diarrheagenic *E coli* may produce dehydration and electrolyte abnormalities. The EAggEC may cause chronic disease and EIEC, like *Shigella* species, may cause a protein-losing enteropathy if dysentery is produced. Disease secondary to these agents is usually most pronounced in children, who may become dehydrated rapidly.

The most severe complication of EHEC infection is the development of HUS. This devastating disease most commonly occurs in children and has a significant mortality

rate (3%-10%). Patients develop microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. Patients that do not succumb may suffer significant morbidity secondary to renal and central nervous system dysfunction.

## Diagnosis

Enteritis caused by the ETEC, EPEC, EIEC, DAEC, and EAaggEC is usually self-limited and may be associated with travel or a particular outbreak. In most instances, the presence of one of these organisms is assumed, and the diagnosis is based on history, physical examination, and the exclusion of other enteric pathogens. A definitive diagnosis cannot be made, unless specific assays are performed. These confirmatory assays are costly and usually clinically unnecessary. In outbreak situations, however, complete microbiologic characterization of clinical isolates, with strain analysis, may be warranted for public health purposes.

The severe sequelae that may occur secondary to EHEC infections necessitate the identification of suspicious isolates on SMAC screening agar. The diagnosis of EHEC is strongly associated with bloody diarrhea or a history of bloody diarrhea and is often associated with the ingestion of undercooked beef. The presence of *E coli* O157:H7 is determined by culture and serotyping.

## Treatment

Treatment of fluid and electrolyte loss is usually achieved through oral rehydration. The use of the World Health Organization Oral Rehydration Salts (ORS) solution is recommended. Intravenous rehydration may be necessary for infants, individuals with excessive vomiting, or those with severe dehydration.

Bismuth subsalicylate, 1 oz of liquid or two (262.5-mg) tablets taken every 30 min for 4 h, may decrease the amount of diarrhea and the duration of disease. Antimicrobial therapy is generally not indicated, because of the self-limited nature of most of these diseases. Some contend that empiric therapy may decrease symptomatology and shorten the clinical course. It is a concern, however, that the overuse of antimicrobial agents will promote resistant strains. If chronic or persistent diarrhea develops in patients infected by one of the enteroadherent *E coli* strains, specific antimicrobial therapy should be used. If available, the antimicrobial susceptibility profile should be used to guide therapy. If unavailable, a trial of empiric therapy for *E coli* is warranted ([Box 53-2](#)). Antimicrobial therapy has not been shown to decrease the morbidity/mortality of patients with HC/HUS. Antimicrobial therapy may worsen the clinical course, possibly by decreasing competitive enteric flora. A synthetic analog of G3b and diatomaceous earth, SYNSORB-Pk (Synsorb Biotech, Inc.), holds promise as a treatment of HC/HUS. Taken orally, this agent should absorb the VT and, it is hoped, prevent HUS.

As previously noted, disease caused by the EIEC is very much like shigellosis. It is unclear, however, if duration of disease and shedding of viable organisms by patients infected with EIEC are diminished by antimicrobial therapy, as occurs in patients with shigellosis. The diagnosis of EIEC infection requires the isolation of the organism; therefore, an antimicrobial susceptibility profile should be available to guide therapy.

Infections by the EHEC are severe and sometimes fatal. Antimicrobial therapy and antimotility agents may worsen the clinical course. Fluid and electrolyte replacement should be used as needed to treat dehydration. Transfusion, dialysis, and other supportive measures may be required for patients with HUS. Antimotility agents should not be used by patients with severe infectious enteritis regardless of the etiology, but should be especially avoided by patients infected by EHEC. These drugs increase the duration and severity of disease by inhibiting the passage of the pathogenic bacteria and their toxins.

## **Prevention & Control**

The diarrheagenic *E coli*, with the notable exception of EHEC, are transmitted in a human fecal-oral cycle. Most of these organisms thrive in underdeveloped countries secondarily to poor living conditions, ineffective sanitation, and unsafe drinking water. Improvements in sanitation and the quality of drinking water, as well as raising the standards of living, would greatly diminish the prevalence of these diseases ([Box 53-3](#)). In endemic areas, political instability, war, and a weak socioeconomic infrastructure contribute to the persistence of these organisms. Prophylactic antibiotics are not recommended for most travelers, but individuals at high risk for severe disease may benefit from antimicrobial prophylaxis. Travelers should drink bottled water and avoid eating raw, locally washed vegetables. Bismuth subsalicylate, 2 oz or two tablets four times daily, provides some prophylactic benefit, but should not be used as a substitute for other preventive measures. There are currently no vaccines approved for human use against the diarrheagenic *E coli*.

The EHEC inhabit the intestinal tracts of cattle and other animals. Control of this organism in its natural reservoir is currently impractical. Antimicrobial agents should not be used for its suppression in animals, because these practices provide selective pressures that promote antimicrobial resistance. Infections by the EHEC can be diminished by thoroughly cooking food, consuming only clean water and pasteurized juices, using good food preparation techniques, and maintaining good personal hygiene.

A wide variety of foods have served as vehicles for the transmission of EHEC. These include beef and beef products, dried salami, yogurt, and fresh-pressed apple cider. Of these, ground beef is especially prone to contamination and should never be eaten unless thoroughly cooked. When cooking or reheating meats, all parts of the meat should reach at least 70 °C. Children, who are at higher risk for HUS, should never be given undercooked hamburger.

Only pure, clean water should be consumed and used in food preparation. Wells, especially if they are near farms, should be periodically checked for enteric pathogens. Only pasteurized milk and juices should be consumed. Pasteurization is an effective means of eliminating EHEC, but care must be taken to avoid inadvertent postpasteurization contamination.

Good food preparation practices can also diminish the likelihood of EHEC infection. Hands should be washed thoroughly before food preparation and whenever raw meats have been touched. In addition, great care must be taken to avoid cross-contamination

of foods that may not be thoroughly cooked before ingestion. Vegetables and fruits should be rinsed thoroughly under clean, free-flowing water. Cutting boards, knives, and other cooking utensils should be washed after they have been in contact with raw meat.

The infectious dose of *E coli* O157:H7 is so low that person-to-person transmission may occur. Anyone with EHEC HC must thoroughly wash their hands to avoid transmitting the bacteria. Children with a diarrheal disease should be carefully monitored for good hand washing. Finally, children with a diarrheal disease or history of recent diarrheal disease, especially bloody diarrhea, should avoid contact with other children, particularly contact during swimming.

## **SHIGELLA SPECIES**

### **Essentials of Diagnosis**

- Enteritis caused by *Shigella* species may be watery (*Shigella sonnei*, *Shigella boydii*) or dysenteric (*Shigella dysenteriae*, *Shigella flexneri*).
- Risks include ingestion of fecally contaminated food or water and contact with infected individuals.
- Definitive diagnosis requires microbiologic isolation and identification of *Shigella* species or molecular evidence of infection.

### **General Considerations**

**A. Epidemiology.** Dysentery is a disease of antiquity and has been described throughout the ages. It was not until the 19th century that dysentery was recognized to be caused by either parasitic amoebae or certain bacteria. In 1898, Shiga recognized and isolated bacteria from patients with dysentery that would agglutinate when exposed to the patient's serum. Today, the most commonly recognized agents of bacterial dysentery are *Shigella* species and the EIEC (see above).

*Shigella* species are unique among bacterial enteric pathogens in that < 200 and possibly = 10 organisms may transverse the gastric acid barrier and cause disease. For this reason, person-to-person transmission is common. Person-to-person transmission results in increased frequencies of shigellosis in day care centers, schools, and custodial-care facilities. Disease is most common in infants and young children and frequently occurs in family members of patients. Peak incidence occurs in the summertime, and common houseflies are thought to contribute to the spread of disease. Outbreaks have also occurred from fecally contaminated food. Transmission through contaminated water is most common in developing countries that lack adequate sewage and water treatment facilities.

In the United States, *S sonnei* is the most commonly encountered *Shigella* species, whereas *S boydii* has a worldwide distribution. The prevalence of shigellae appears to be cyclic, with replacement of the predominant strain approximately every 20 years. This cycling of prevalence is presumably secondary to slowly acquired herd immunity in a given host population. Epidemic shigellosis, caused by *S dysenteriae* and *S flexneri*, is

prevalent in underdeveloped countries, but may develop anywhere that poverty, overcrowding, or conditions of war exist.

**B. Microbiology.** Shigella are nonmotile, facultative anaerobic, gram-negative bacilli that are closely related to the genus *Escherichia*. At least 40 serotypes compose four groups or species. These are *S dysenteriae* (serogroup A), *S flexneri* (serogroup B), *S boydii* (serogroup C), and *S sonnei* (serogroup D).

The numbers of shigellae present in the stool vary with the course of disease. Early in the watery-diarrhea phase, shigellae are abundant and number  $10^3$ - $10^9$  shigellae/g of feces. During this phase of disease, shigellae are easily recovered on MacConkey or eosin methylene blue (EMB) agar, where they appear as lactose nonfermenting colonies. Later in the course of disease, in the dysentery and postconvalescent phases, bacterial stool counts decline to  $10^2$ - $10^3$  shigellae/g of feces. Furthermore, the recovery of shigellae is inversely proportional to specimen transport time, especially in stool specimens with a low number of shigellae. During the latter phase of disease, culture is best accomplished by rapid specimen transport or bedside medium inoculation, combined with the use of enrichment broth and moderately to highly selective media, such as xylose-lysine-desoxycholate medium and *Shigella-Salmonella* medium.

In many laboratories, suspect colonies, lactose nonfermenters, are screened by using a three-tube set: (i) one tube containing triple sugar iron (TSI) or Kligler iron agar (KIA), (ii) the second containing lysine iron agar (LIA), and (iii) the third containing Christensen's urea agar (CU) (also see the *Salmonella* Microbiology section below). On the TSI and KIA, shigellae characteristically produce an alkaline slant and acid butt without the production of gas. Rare isolates may produce gas. Negative reactions are produced on the LIA and CU, because shigellae do not decarboxylate lysine or hydrolyze urea. In addition, shigellae do not produce hydrogen sulfide, which is detected by the TSI, KIA, and LIA systems. An attempt to agglutinate organisms that are thought to represent *Shigella* species may be performed by using group antisera. Isolates with a suggestive screen profile are further characterized by additional biochemical reactions in either traditional or automated systems.

Useful clues in the identification of shigellae include the following: the majority of shigellae cannot ferment mucate, cannot use acetate, and are negative for indole and *ortho*-nitrophenyl- $\beta$ -galactopyranoside.

**C. Pathogenesis.** Shigellosis may produce either predominantly watery diarrhea or watery diarrhea that progresses to dysentery. The severity of disease is largely determined by the invading organism. *S dysenteriae* and *S flexneri* are the agents most commonly associated with bacillary dysentery, whereas the other *Shigella* species more often produce watery diarrhea.

The pathogenesis of the watery-diarrhea phase of bacillary dysentery is caused by a combination of luminal bacterial replication and superficial mucosal invasion in the small intestine. During this phase of disease, large numbers of shigellae are present in the lumen of the small intestine. This phase of the disease is correlated with the onset of cramping abdominal pain, fever, and toxemia.

Within days, the luminal contents of the small intestine do not contain shigellae, and the site of infection is the colon. The shigellae invade colonic mucosa and occasionally invade to the level of the submucosa. Factors that are important for invasion are present on the bacterial chromosome, as well as on a 140-MDa plasmid. Eventually, epithelial cell death occurs, and the mucosa sloughs, possibly secondarily to shigatoxin production. The loss of mucosa evokes an intense inflammatory response and allows for the introduction of coliform bacteria. Microabscesses, epithelial ulcerations, and pseudomembranes that consist of sloughed epithelial cells, bacteria, fibrin, and inflammatory cells may be seen. This phase of the disease correlates with tenesmus and fractionated stools that contain blood, mucus, and inflammatory debris.

## Clinical Findings

**A. Signs and Symptoms.** Early in the course of disease, when bacteria are present in the small intestine, patients develop acute, watery diarrhea; fever; and abdominal pain. Patients may become toxemic and fever may reach as high as 104 °F. Later in the course of disease, the primary site of infection is the colon. In this phase, fever continues, but is usually less pronounced. The pain that is present is usually in the lower abdominal quadrants. Stools become dysenteric, consisting of a mixture of neutrophils, blood, mucus, and debris. Frequent, small-volume or fractionated stools may occur, and tenesmus is often present. Patients experience pain upon rectal examination. Colonoscopy discloses hyperemic and friable-to-ulcerated colonic mucosa.

**B. Differential Diagnosis.** When watery diarrhea predominates, other bacterial, parasitic, and viral enteric pathogens must be considered. *Entamoeba histolytica* and EIEC must also be considered in patients with dysentery. Infection with *E histolytica* is most commonly associated with travel to or living in endemic locales. These organisms are readily recognized on a microscopic examination of the stool for ova and parasites. Dysentery caused by the EIEC, however, may pose a diagnostic challenge for the clinical microbiologist. The EIEC, unlike other *E coli*, are often nonmotile, may not ferment lactose or may ferment it slowly, are lysine decarboxylase negative, and may cross-react with *Shigella* antisera. Laboratory personnel must recognize this potential pitfall and exclude this organism through additional testing (see above).

Noninfectious causes of diarrhea must also be considered. The differential diagnosis of noninfectious colitis is extensive and includes inflammatory-bowel disease, lymphocytic/collagenous colitis, neoplasia, and numerous other disorders. Patients with inflammatory-bowel disease may also have fecal leukocytes, limiting the usefulness of this test. An accurate diagnosis may be achieved through a thorough history and physical examination, excluding enteric pathogens through appropriate microbiologic studies, and by obtaining and reviewing gastrointestinal biopsies via endoscopy and histopathologic studies.

**C. Complications.** The most common complications of bacillary dysentery include dehydration and a protein-losing enteropathy. In rare instances, a toxic megacolon may occur and may result in perforation, intra-abdominal hemorrhage, peritonitis, and possibly death. Some patients, particularly those with HLA-B27 phenotypes, may develop a postinfectious arthritis or Reiter's syndrome.

## Diagnosis

Patients with acute diarrhea, which may be watery to dysenteric; fever; abdominal pain; and systemic symptomatology/toxemia may have shigellosis. A history of exposure to individuals with shigellosis, travel to endemic areas, and exposure to a high-risk population, such as persons in a custodial-care facility, should raise the index of suspicion. The presence of leukocytes in the stool, although supportive, is by no means definitive for shigellosis. Fecal leukocytes may be present in the stools of patients with other bacterial enteritides, amoebic dysentery, pseudomembranous colitis, and noninfectious disease, such as inflammatory-bowel disease. The definitive diagnosis requires the microbiologic identification of a *Shigella* species.

Shigellae are particularly susceptible to some environmental changes, and they die rapidly in transport. Therefore, it is imperative to rapidly transport the stool of patients suspected of having shigellosis to the laboratory. This is especially important for patients in the latter stages of disease, in whom the number of shigellae in the stool are relatively few.

## Treatment

Fluid and electrolyte replacements are necessary for patients with dehydration. In most instances, this is readily accomplished by oral rehydration. Unlike in many other bacterial enteritides, antibiotic therapy is important in the treatment of shigellosis ([Box 53-4](#)). Antibiotic therapy limits the clinical course of the disease, may decrease the likelihood of intestinal complications, and decreases the fecal excretion of viable pathogenic organisms, which in turn diminishes transmission. Fluoroquinolones are the treatment of choice for adults. TMP/SMX is the treatment of choice for children. Alternatives are ampicillin, chloramphenicol, and nalidixic acid. In areas of known resistance to TMP/SMX, such as parts of Southeast Asia, Africa, and South America, quinolones should be used for adults, and one of the above mentioned alternatives for children with shigellosis. When available, the antimicrobial-susceptibility profile should guide therapy.

Antimotility agents, such as diphenoxylate, should not be used. The inhibition of diarrhea increases the contact between the intestinal mucosa and the pathogenic organisms and their toxins and may cause more fulminant disease.

## Prognosis

The prognosis is generally good for patients with endemic or sporadic shigellosis. Infants and the elderly, especially if malnourished, suffer the highest mortality. Epidemic shigellosis caused by *S dysenteriae*, however, is a severe and often life-threatening disease with mortality rates from 5% to 20%. This disease must be treated aggressively with antimicrobial and rehydration therapies.

## Prevention & Control

The development and refinement of sewage disposal and drinking water treatment systems are important in developing countries. In both developed and developing

countries, personal hygiene, good hand washing practices, and clean living conditions are important preventive measures, particularly in custodial-care facilities (see [Box 53-3](#)). Fly control and hygienic food preparation practices should also diminish the incidence of disease.

## **SALMONELLA SPECIES**

### **Essentials of Diagnosis**

#### **I. Enteric fever.**

- Enteric fever is a systemic disease that may or may not be preceded by a diarrheal illness.
- Key signs and symptoms include possible diarrhea or constipation that precedes constitutional symptoms and possible hepatosplenomegaly; other signs and symptoms may include "rose spots," paroxysmal bradycardia, and mental status changes (so called "typhoid psychosis").
- Enteric fever is usually associated with the ingestion of water that has been contaminated by human feces.
- "*S typhi*," "*S paratyphi*," or rarely other *Salmonella* "species" (see General Considerations section below for clarification of current *Salmonella* taxonomy) from blood or bone marrow are isolated early in the course of disease and/or from the stool later in the course of disease, or there is molecular evidence of infection.

#### **II. *Salmonella* enteritis.**

- Enteritis caused by *Salmonella* species usually results in watery diarrhea that in some instances may become hemorrhagic or dysenteric.
- *Salmonella* enteritis is usually associated with the ingestion of contaminated, undercooked foods, particularly undercooked eggs.
- There is microbiologic isolation and identification of *Salmonella* species or molecular evidence of infection.

### **General Considerations**

For decades, phenotypic studies have been used to identify and categorize the *Salmonella* species. These organisms have been categorized by antisera directed against particular bacterial somatic (O) and flagellar (H) antigens. Serologic stratification has resulted in the identification of > 2000 *Salmonella* serotypes. These serotypes have traditionally been treated as individual species. More recently, molecular analysis has revealed significantly less variability among the salmonellae than serologic studies have implied. Newer taxonomy recognizes two *Salmonella* species, *S enterica* and *S bongori*, and six subspecies of *S enterica*. Although this taxonomy is more precise, many healthcare providers have a greater familiarity with the previous nomenclature. For this

reason, reference to previous nomenclature is appropriate and should avoid confusion, facilitate communication, and ensure optimal patient care. Therefore, for the remainder of this chapter, the *Salmonella* serotypes will be treated traditionally as species.

**A. Epidemiology.** *Salmonella* species cause various clinical manifestations, depending on the infecting serotype, but all commonly begin with oral intake of fecally contaminated food or water. Salmonellosis is usually characterized as enteric fever or enteritis.

**1. Enteric fever.** The agents of enteric fever are maintained in a human fecal-oral cycle. Enteric fever, therefore, is most commonly seen in areas of developing countries that lack adequate waste disposal and drinking water treatment facilities. In endemic areas, children and young adults are most commonly affected, but any age and either sex may contract enteric fever. The Indian subcontinent and parts of Africa, Asia, and Central and South America are endemic for enteric fever. In developed countries, clean drinking water and adequate waste disposal have dramatically diminished the prevalence of enteric fever, and most cases of enteric fever are imported from endemic areas.

Enteric fever is distinguished from enteritis if systemic manifestations predominate and there is bacterial dissemination throughout the body and extensive involvement of the reticuloendothelial system. Classically, the enteric fevers are typhoid fever or paratyphoid fever, caused by *S typhi* or *S paratyphi*, respectively. Infrequently, other strains may cause enteric fever. *S typhi* is found exclusively in humans, and *S paratyphi* is found predominantly in humans. Contraction of disease, therefore, requires the presence of individuals either recovering from enteric fever or harboring the organism. Enteric fever remains a major public health problem in much of the world, and in some areas it ranks among the top five causes of death.

Enteric fever is a severe, life-threatening disease that, despite antimicrobial therapy, still causes significant mortality. Some individuals who have had enteric fever become chronic carriers. These individuals are usually asymptomatic and most frequently harbor the bacteria in the gallbladder, which contains calculi. In areas where *Schistosoma haematobium* is endemic, the bacteria may also be harbored in the bladder, associated with schistosome eggs. Chronic carriers are public health threats, because they continue to shed pathogenic bacteria into the environment over long periods of time and may substantially contaminate local water supplies, particularly in areas lacking appropriate treatment facilities. If carriers are food handlers and poor hand washers, epidemics may occur through contaminated food.

**2. *Salmonella* enteritis.** *Salmonella* enteritis is characterized as enteritis if gastrointestinal disease predominates, without extensive involvement of the systemic reticuloendothelial system. *Salmonella* serotypes, other than *S typhi* or *S paratyphi*, are usually responsible for this disorder. Occasionally bacteremia occurs and there may be extraintestinal manifestations caused by seeding of distant organs. In some instances, the intestinal symptomatology may be minimal, and extraintestinal symptomatology may be the primary manifestation.

Although the number of cases of typhoid fever has diminished dramatically over the past 100 years in the United States, the number of cases of nontyphoid salmonellosis

continues to increase. These organisms colonize the intestinal tracts of a wide variety of animals and are also transmitted by the fecal-oral route, through the ingestion of contaminated meats and animal products. Some *Salmonella* serotypes occur in many different animals, whereas others tend to occur in particular animals. For example, *S typhimurium* and *S enteritidis* are often associated with chickens, whereas *Salmonella arizonae* is associated with reptiles.

Person-to-person transmission of *Salmonella* species among food handlers and healthcare workers is possible but is not a common mode of transmission. Infants and neonates, however, are at an increased risk for infection if exposed to an infected mother or other family members.

**B. Microbiology.** Salmonellae are nonfastidious members of the *Enterobacteriaceae* that will grow on most routine media, including broth-based blood culture systems. Most *Enterobacteriaceae* ferment lactose, but the vast majority of *Salmonella* species (99%) do not. This feature has permitted the use of selective and differential agar media to separate these enteric pathogens from the legions of other bacteria present in the stool. MacConkey and EMB agars are the most common media used for this purpose. These agars contain bile salts and/or dyes that suppress the growth of gram-positive bacteria and lactose and pH indicators for the determination of an organism's ability to ferment lactose. On MacConkey agar, lactose fermenters appear as pink to red colonies, whereas nonlactose fermenters appear clear. On EMB agar, the lactose fermenters appear as blue to violet colonies and may incorporate dyes that are present in the media into the colony, which gives them a green metallic sheen. Bacterial colonies that do not ferment lactose appear light purple to clear.

When plating stool for the detection of *Salmonella* and/or *Shigella* species, a moderately or highly selective agar is often used in conjunction with the MacConkey or EMB plates. Moderately selective agars for the isolation of *Salmonella* and *Shigella* species include Hektoen-enteric and xylose-lysine-desoxycholate agars. Highly selective media, such as *Salmonella-Shigella* agar, brilliant green agar, and bismuth-sulfate agar, are most effectively used in outbreak situations. If used appropriately, an enrichment broth, such as selenite broth, may also be used to increase the recovery of *Salmonella* species from stool.

Bacteria that are suspected to be *Salmonella* or *Shigella* species are often then tested in the three-tube set as described above. In the TSI/KIA system, the majority of salmonellae produce an alkaline slant over an acid butt and produce gas. However, strains of *S paratyphi A* can ferment lactose, which produces an acid over acid reaction. Although most salmonellae produce hydrogen sulfide from sodium thiosulfate metabolism, ~ 90% of *S paratyphi A* and 50% of *S choleraesuis* isolates do not. Hydrogen sulfide production is detected by the TSI, KIA, and LIA systems and, when present, reacts with ferric ammonium citrate to form a black precipitate. It is significant that *S paratyphi A*, which produce an A/A TSI reaction and do not produce hydrogen sulfide, may be discarded as non-*Salmonella Enterobacteriaceae*.

The LIA system detects lysine decarboxylation, deamination, and the production of hydrogen sulfide. The hydrogen sulfide-producing bacteria genera *Morganella*, *Proteus*, and *Providencia* may be differentiated from *Salmonella* by their ability to deaminate

phenylalanine. Except for *S paratyphi A*, the salmonellae generate a positive reaction for the decarboxylation of lysine. *Salmonella* species, like *Shigella* species, do not produce urease and generate no reaction on CU agar. This medium is included in the three-tube set to help differentiate *Salmonella* species from some of the other hydrogen sulfide producers and to detect *Y enterocolitica*.

Isolates with an appropriate biochemical profile in the three-tube set are often serotyped and definitively identified by traditional or automated biochemical testing.

For patients with enteric fever, the percent yield from blood or bone marrow culture vs stool culture varies during the course of disease (see Clinical Findings). Clinicians must be aware of which sites render the highest yield during each phase of the disease and submit appropriate specimens for culture.

### **C. Pathogenesis.**

**1. Enteric fever.** The clinical course of enteric fever may be separated into three phases: an early phase that includes incubation and the onset of symptoms; the middle phase, which is the time of maximal symptomatology; and a late phase that includes diminishing symptoms, recovery, and possible carriage.

The incubation phase begins after ingestion of *S typhi* and usually lasts between 10 and 14 days. The incubation time, however, is variable and to a certain extent is inversely proportional to the size of the inoculum. Normal stomach acid functions as a physiologic barrier to infection, and  $\sim 10^5$  organisms are required to survive gastric passage. A smaller inoculum may cause disease in patients with achlorhydria or decreased gastric acid production.

The next phase of the disease is characterized by bacterial invasion of the mucosa. The salmonellae adhere to the luminal surface of the enterocytes, particularly specialized enterocytes, termed M cells, which overlie the Peyer's patches. The low number of organisms present in the stool at this stage of disease explains the common occurrence of negative stool cultures.

After adhesion, the enterocyte cell membrane becomes ruffled, and there are cytoskeletal alterations. The bacteria are then internalized by endocytosis and transmigrate through the enterocyte. They exit the basilar aspect of the cell through the basement membrane and are free in the lamina propria. The organisms are phagocytosed by mononuclear phagocytes in Peyer's patches and/or are drained by terminal lacteals to regional lymph nodes. This is followed by lymphatic and hematogenous dissemination of the bacteria to organs with fixed tissue histiocytes, such as the liver, spleen, and bone marrow. The salmonellae are able to alter the environment within macrophages and survive phagocytosis. This intracellular location also protects the bacteria from phagocytosis by polymorphonuclear leukocytes, to which they are susceptible, and to aminoglycoside antibiotics, which have poor intracellular penetration. Another virulence factor that these organisms possess is a capsule that has antiphagocytic properties and protects them from complement and antibody-mediated killing.

Bacteria, which involve the liver, may be subsequently passed into the bile. These organisms thrive in bile and may colonize the gallbladder, especially if gallstones are present. A bacterial enterohepatic circulation occurs wherein bacteria that have been shed into the bile pass into the small bowel and again adhere to and invade the small intestinal mucosa.

**2. *Salmonella gastroenteritis.*** Although the pathogenic mechanisms by which *S typhi* causes enteric fever have been well documented, the precise pathophysiology of *Salmonella gastroenteritis* has yet to be ascertained. The salmonellae that survive food processing and gastric acidity probably adhere to the apical portion of enterocytes by specific pili. *Salmonella* species may release an enterotoxin similar to the LT enterotoxin of the ETEC or the enterotoxin of *V cholerae*. Alternatively, these organisms may cause changes in arachidonic acid metabolites and subsequent alterations in cytosolic second messengers other than cyclic AMP. It is known that the invasion of enterocytes by salmonellae causes the production of interleukin-8, a potent neutrophil chemotactic factor. Diarrhea may in part result from disruption of the epithelium through the influx of neutrophils and release of their toxic contents.

*Salmonella* species survive poorly at low pHs and are killed rapidly by stomach acid. Unlike *Shigella* species, a substantial number of salmonellae are required to successfully cross the gastric acid barrier and cause disease. Any decrease in gastric acidity increases the likelihood of *Salmonella* survival. Anyone, such as persons that have had gastric surgery, with hypo- or achlorhydria are at increased risk for salmonellosis. Undercooked foods that are contaminated with salmonellae buffer gastric acid and thereby facilitate the passage of bacteria into the small intestine. Neonates and infants that may be relatively hypochlorhydric are at increased risk for infection. Persons with an impaired immune response are also at risk for nontyphoidal salmonellosis.

## ENTERIC FEVER

### Clinical Findings

**A. Signs and Symptoms.** Patients are asymptomatic during the incubation phase. Early in the course of disease, patients may experience diarrhea or constipation. Patients then develop a variety of nonspecific symptoms, such as fever, chills, weakness, malaise, myalgia, and cough. Signs, that are not always present, such as rose spots, paroxysmal bradycardia in sharp contrast to the clinical presentation and elevated temperature, and hepatosplenomegaly are clues to the diagnosis. Profound mental status changes and picking at bed clothing, termed typhoid psychosis, may develop in some patients with enteric fever. The middle phase of disease is the time of maximal symptomatology. If complications do not intervene (see below), patients begin to feel progressively better through the latter half of the disease course.

**B. Laboratory Findings.** Blood culture is superior to stool culture during the early to mid stages of disease. During the first half of the disease course, bone marrow cultures have the greatest yield but are more difficult to obtain. Peripheral blood findings are variable, and pancytopenia may be seen. During the latter half of the disease course, stool cultures and occasionally urine cultures become positive and provide greater yields than blood cultures.

**C. Differential Diagnosis.** Typhoid fever was so named because of its clinical resemblance to typhus, the louse-borne rickettsial disease. The causative organisms are not closely related and are transmitted by very different mechanisms, but both may cause nonspecific signs, such as fever and rash. In addition, both of these diseases occur in impoverished areas and cause epidemics during war. Because of a better understanding of the microbiology, pathophysiology, and histopathology of these diseases, distinguishing between these diseases today is no longer a problem. An accurate diagnosis is usually made through the combined use of serology, culture, and immunohistochemistry. Other infectious diseases, such as visceral leishmaniasis and malaria, may produce fever and hepatosplenomegaly similar to that seen in typhoid fever. These as well as other infectious and noninfectious causes of hepatosplenomegaly are excluded by history, physical examination, laboratory studies, and, in some instances, liver biopsy.

**D. Complications.** A characteristic of the enteric fevers is extensive Peyer's patch and mesenteric lymphoid hyperplasia. The mucosa overlying the Peyer's patches becomes thinned and often necrotic, which creates a breach in the mucosal barrier and a conduit through which coliform bacteria may invade the bowel wall. Extensive shedding of the necrotic mucosa and underlying lymphoid tissue results in ulceration. Perforation and peritonitis may occur. Massive intraluminal or intra-abdominal hemorrhage may result if ulceration or perforation involves mesenteric blood vessels. These severe complications manifest in ~ 10%-15% of untreated patients with typhoid fever.

Intestinal perforation usually occurs during the latter portion of the middle stage or the early portion of the late stage, when symptoms are beginning to wane. Perforation may present as worsening abdominal pain or rapidly progressive hypotension if hemorrhage occurs. In the absence of rapidly progressing hypotension, abdominal imaging is useful in advanced typhoid fever if perforation is suspected. Emergency surgery is necessary for survival.

The development of a chronic carrier state is a complication of enteric fever and is of more importance to the public health system than to the patient. Chronic carriers shed viable, pathogenic organisms into the environment and serve as sources for subsequent outbreaks. *S typhi* is the serotype that is most often associated with the chronic carrier state. Much more rarely, patients infected with other serotypes may develop a chronic carrier state. Most often, chronic carriers harbor *S typhi* in the gallbladder in association with calculi. Urinary tract carriage is associated with *Schistosoma haematobium* infection or urinary tract calculi. Chronic carriers require long-term therapy, follow-up cultures, and occasionally surgery for the eradication of these organisms.

## Diagnosis

In the appropriate clinical setting, the definitive diagnosis of enteric fever requires isolation and biochemical characterization of the etiologic agent. Febrile patients who have visited endemic areas may have enteric fever. Some patients with enteric fever may have an insidious onset, but eventually become severely ill. The Widal antigen/antibody agglutination is a presumptive test that is still used for the diagnosis of typhoid fever. This test, however, lacks both sensitivity and specificity. Blood and/or

bone marrow culture, followed by empiric therapy, is a more reliable method of diagnosing enteric fever. Early in the course of disease, blood and bone marrow cultures yield the highest recovery of organisms, while later in the course of disease, stool and sometimes urine cultures are more likely to become positive. The submission of appropriate specimens for culture is important, so that rapid isolation of the causative agent and susceptibility testing can be performed. Antimicrobial susceptibility testing is necessary to optimally direct therapy, because of possible antimicrobial resistance.

## Treatment

Chloramphenicol, TMP/SMX, ampicillin, third-generation cephalosporins, and quinolones have been used successfully for the treatment of enteric fever ([Box 53-5](#)). Unfortunately, antimicrobial resistance has emerged to each of these agents. Some *Salmonella* isolates are multidrug resistant. For this reason, whenever possible, antimicrobial therapy should be based on an individual isolate's susceptibility profile, obtained by standard methods. Until such data are available, empiric therapy should be used, based on known antimicrobial-resistance profiles.

Chloramphenicol was the first drug used for the treatment of typhoid fever. However, increasing resistance, high relapse rates, bone marrow toxicity, and the promotion of a chronic carrier state have limited its usefulness. If isolates are susceptible to chloramphenicol, advantages include its high efficacy, low cost, and oral administration.

Ampicillin and TMP/SMX were used to treat enteric fever after chloramphenicol resistance emerged. For susceptible isolates, these drugs are effective, easily administered, and do not have the high rate of relapse associated with chloramphenicol.

The third-generation cephalosporin, ceftriaxone, is highly effective for the treatment of typhoid fever in adults and children. Third-generation cephalosporins are especially useful as empiric therapy in areas in which multiple-drug resistance has been reported. When the susceptibility profile of a particular isolate is known, the antimicrobial agent may be changed to a drug with a narrower spectrum of activity. Hopefully, this will also diminish the selection of organisms with resistance to third-generation cephalosporins.

Currently, ciprofloxacin is the drug of choice for adults from India, Asia, or the Middle East. In these areas, *S typhi* strains that are resistant to chloramphenicol, ampicillin, and/or TMP/SMX have been reported. Chromosomally mediated quinolone resistance has emerged, however, but it is hoped that it will not spread as rapidly as the plasmid-mediated resistance to chloramphenicol, ampicillin, and TMP/SMX. First- and second-generation cephalosporins and aminoglycosides should not be used to treat *S typhi* infections, regardless of the in vitro susceptibility profile. Patients with typhoid fever who develop mental status changes may benefit from a short course of dexamethasone.

## **SALMONELLA ENTERITIS**

### **Clinical Findings**

**A. Signs and Symptoms.** *Salmonella* enteritis, frequently caused by *S enteritidis*, *S choleraesuis*, or *S typhimurium*, occurs between 12 and 48 h after the consumption of

contaminated food. Patients experience fever, abdominal cramping, and diarrhea that may be accompanied by nausea and vomiting. The diarrhea varies in consistency from watery to dysenteric.

**B. Laboratory Findings.** Microscopic examination of the stool usually discloses nonspecific neutrophils.

**C. Differential Diagnosis.** The differential diagnosis of infectious diarrhea includes parasitic, viral, and bacterial etiologies. Noninfectious causes of diarrhea, such as inflammatory-bowel disease, lymphocytic/collagenous colitis, neoplasia, and numerous other disorders, must be considered. Patients with inflammatory-bowel disease may also have fecal leukocytes, further limiting the usefulness of this test. An accurate diagnosis can be achieved with a thorough history and physical examination, excluding enteric pathogens by appropriate microbiologic studies, and obtaining and reviewing gastrointestinal biopsies by using endoscopy and histopathologic studies.

**D. Complications.** In immunocompetent individuals, the disease usually lasts = 1 week and resolves without specific antimicrobial therapy. Neonates and young children, the elderly, and pregnant women are at increased risk for severe disease. In addition, immunocompromised individuals and patients with sickle cell disease or other hemoglobinopathies are at increased risk for bacteremia and the establishment of metastatic foci of infection. The complications of *Salmonella* infections may be separated into four categories: (i) dehydration and electrolyte abnormalities, (ii) local inflammatory response, (iii) bacteremia with the spread of organisms to distant sites, and (iv) postinfectious arthritis.

**1. Extensive diarrhea.** Regardless of the cause, extensive diarrhea may lead to fluid and electrolyte abnormalities. Dehydration and electrolyte imbalance may cause tissue ischemia, central nervous system changes, and fatal dysrhythmias. Young children and the elderly, especially if malnourished, often suffer the greatest morbidity and mortality.

**2. Mesenteric lymphoid hypertrophy.** Mesenteric lymphoid hypertrophy is associated with enteric fever, but patients with *Salmonella* enteritis may develop mesenteric lymphadenitis. These patients develop severe abdominal pain that may mimic acute appendicitis. Although mesenteric lymphadenitis is most commonly associated with *Y enterocolitica*, it may also occur in patients with bacterial enteritis of other etiologies.

**3. Bacteremia.** By definition, bacteremia is a part of the disease process in enteric fever, but patients with *Salmonella* enteritis also occasionally develop bacteremia. *Salmonella* bacteremia may result in dissemination of bacteria and foci of infection into virtually any organ. The spread of bacteria to distant sites has resulted in a wide variety of diseases, including abscesses of the liver and spleen, acute and chronic cholecystitis, soft-tissue infections, urogenital infections, pneumonia and empyema, meningoenzephalitis, and osteomyelitis. Osteomyelitis may be associated with areas of prior trauma or underlying bony abnormalities or, classically, has been associated with sickle cell anemia or other hemoglobinopathies.

Atherosclerotic plaques may also become infected during *Salmonella* bacteremia. These are serious infections, because infected plaque material is almost impossible to

sterilize with antibiotics alone. These plaques become an intravascular focus of infection and continually seed the bloodstream. In the laboratory, intravascular infections, including plaque infections, are detected as high-grade bacteremia, wherein > 50% of three or more blood cultures are positive. The abdominal aorta is a common site for atherosclerotic disease and is the vessel most commonly infected. Abdominal aortic plaque infections may result in a life-threatening aortoduodenal fistula or in mycotic aneurysms. Intravascular infections usually require combined medical and surgical therapy. If the patients are not surgical candidates, they may require long-term, suppressive antimicrobial therapy.

Endocarditis is not common in either *Salmonella* enteritis-associated bacteremia or typhoid fever. Patients with structural cardiac anomalies, such as previous rheumatic heart disease or ventricular aneurysm, are at higher risk for developing endocarditis, regardless of the etiologic agent.

**4. Post-infectious arthritis.** As with other bacterial etiologies, patients with salmonellosis may develop a post-infectious arthritis. The joint pain usually begins about 2 weeks after the diarrheal illness, and multiple joints are affected. This reactive, immune-mediated arthritis may last for months. Like patients with Reiter's syndrome, individuals with an HLA-B27 phenotype are at increased risk for developing this complication.

## Diagnosis

Patients with *Salmonella* enteritis have positive stool cultures and occasionally positive blood cultures. Apart from the agents of enteric fever, *Salmonella choleraesuis* is more likely to result in bacteremia than other *Salmonella* species. After isolation, *Salmonella* species are rapidly grouped by using antisera and are differentiated by various biochemical reactions.

Over the past decade, several molecular methods have been explored for the rapid detection of *Salmonella* species, including enzyme-linked immunosorbent assays, indirect immunofluorescence, and polymerase chain reactions. Advances in molecular diagnostics should permit the rapid detection of antigens or nucleic acids that are unique to these organisms. Many of these tests, however, are not commercially available and may be cost prohibitive compared with culture.

## Treatment

Uncomplicated enteritis caused by *Salmonella* species should not be treated with antimicrobial agents. Antimicrobial agents may prolong bacteria shedding and promote antimicrobial resistance. Fluid and electrolyte replacement should be used to treat dehydration. In most instances, oral rehydration is sufficient, but, if severe electrolyte anomalies exist, intravenous rehydration may be necessary. Antimotility agents should not be used, because these agents inhibit the clearance of pathogenic bacteria and their toxins. Patients at risk for or with systemic disease/complications should be treated. A third-generation cephalosporin, such as ceftriaxone, may be used for patients with severe disease, until antimicrobial susceptibility data are available (see [Box 53-5](#)). Prophylactic therapy is appropriate for individuals at increased risk for severe disease

([Box 53-6](#)). In the absence of an antimicrobial-susceptibility profile, empiric therapy should be used.

Systemic infections should be treated with antimicrobial agents based on the particular isolate's susceptibility profile. Intravascular infections and osteomyelitis may require long-term antimicrobial therapy, possibly combined with surgery to effect a cure.

## Prevention & Control

The prevention of all *Salmonella* infections requires an interruption of the fecal-oral cycle (see [Box 53-3](#)). Developed countries with adequate sewage disposal, clean drinking water, and an effective public health service have dramatically lowered the prevalence and incidence of enteric fever. Infections by *S typhi* have been particularly affected, because humans are the only known reservoir for this organism. Diminishing infections caused by other *Salmonella* strains are more difficult, because these organisms are commensals in the intestinal tracts of a wide variety of animals. Infections by these organisms are usually associated with contaminated or incompletely cooked foods. The control of these infections may be effected through education and efforts that stress the importance of rinsing meats when appropriate, avoiding cross-contamination of food preparation utensils, avoiding raw-egg-containing products, and thoroughly cooking meats.

Of particular public health interest is the association of *S enteritidis* with chicken eggs. Ovarian infections in chickens may result in the transovarial passage of *Salmonella* species. Therefore, even thoroughly washed eggs with intact shells may transmit *S enteritidis*. Foods that require uncooked egg whites and/or yolks should be prepared by using pasteurized egg products. For this reason, raw eggs and foods or beverages that contain raw eggs should not be ingested. Additionally, cracked eggs should never be consumed, because these are even more likely to be contaminated with *Salmonella* species. The thorough cooking of eggs renders them safe for consumption.

Beef and poultry may become contaminated with feces during the slaughter process. If possible, these products should be washed with free-flowing water and cooked thoroughly before consumption. Knives, cutting boards, and other utensils become contaminated during contact with uncooked foods. These fomites may cross-contaminate other foods and thereby transmit *Salmonella* species. Utensils and food preparation surfaces that have been used to process uncooked food should be washed thoroughly before they are used to process other foods. The thorough cooking of food and pasteurization of milk and other liquids substantially reduce the risk of *Salmonella* enteritis.

Vaccinations are available for individuals at risk for typhoid fever; prophylactic antimicrobial agents are not recommended. Current recommended candidates for vaccination include travelers to endemic areas and people who are household contacts of infected persons. In the United States, the traditional vaccine consists of heat-killed, phenol-treated organisms. This vaccine offers 55%-77% protection, but its usefulness is limited by side effects. The minor side effects include fever, headache, and local pain at the site of injection and may last from hours to several days, but more severe reactions may occur. This vaccine requires two injections 4 weeks apart. The minimum age for

vaccination is 6 months, and a booster is required every 3 years.

A newer, capsular polysaccharide vaccine, ViCPS, appears to offer similar protection after a single injection and has fewer side effects. This vaccine has a minimum age requirement of 2 years and requires a booster every 2 years.

An attenuated, live-bacteria, oral vaccine has been licensed in the United States and may rapidly become the vaccine of choice for many individuals. This vaccine, Ty21a, appears to be safe and effective, with no serious side effects. It relies on the development of natural immunity by using an attenuated *S typhi* strain. Therefore, patients on antimicrobial therapy should not be given this vaccine concomitantly. As with other "live" vaccines, this vaccine should not be given to persons that are immunocompromised. It is not recommended for children < 6 years old. Because of these limitations, the oral vaccine will not completely replace the injectable vaccines. A booster dose is needed every 5 years.

None of the typhoid vaccines offer long lasting protection, and booster doses are required to maintain protective antibody levels. In addition, none of the vaccines are 100% effective and should be used in conjunction with other preventive measures. Information regarding typhoid fever prevention and the prevention of other travel-associated diseases is available from the Centers for Disease Control and Prevention toll free at 1-888-232-3228 or on the internet at <http://www.cdc.gov/travel>.

Future directions for vaccine development include vaccines that elicit longer lasting immunity and confer immunity to more than one enteric pathogen. Such vaccines have been created, using molecular techniques. The insertion into *Salmonella* strains of genetic material that encodes for the somatic antigens of *S sonnei* and *V cholera* has allowed for the genetic construction of bacteria with multiple somatic antigens. It is hoped that vaccination with these genetically engineered bacteria will confer protection to several enteric pathogens.

**BOX 53-3. Prevention & Control of Bacterial Gastroenteritis/Enteric Fever**

**Prophylactic Measures**

- Appropriate sewage disposal and waste treatment
- Treatment of drinking water (ie, chlorination)
- Good personal hygiene
- Thorough cooking of food, especially eggs and hamburger
- Good food preparation skills (ie, avoid cross-contamination)
- Bismuth subsalicylate for travelers may aid other prophylactic measures

**Isolation Precautions**

- Good handwashing necessary, especially if the infecting organism is *Salmonella typhi*, *Salmonella paratyphi*, *Shigella* spp., or *E coli* O157:H7.
- Patients recovering from enteric fever (*S typhi* or *S paratyphi*) should not work as food preparers until stool cultures are negative.

## 54 . *Pseudomonas aeruginosa* — David Dockrell, MD, & Walter Wilson, MD

### Essentials of Diagnosis

- Nosocomial acquisition.
- Predisposing factors include immunosuppression (neutropenia, cystic fibrosis [CF], AIDS, corticosteroid use, diabetes mellitus); presence of a foreign body, prosthesis, or instrumentation; prolonged hospitalization and antibiotic use; intravenous drug use.
- Most common infections include pneumonia, bacteremia, urinary tract infection, otitis media, skin and skin structure infections, including ecthyma gangrenosa.
- Gram stain shows gram-negative bacilli; recovery of microorganism from culture of blood or other tissue.

### General Considerations

**A. Epidemiology.** The genus *Pseudomonas* consists of a number of human pathogens, the most important of which is *Pseudomonas aeruginosa*. *P. aeruginosa* is an opportunistic pathogen found widely in soil, water, and organic material, reflecting its limited nutritional requirements. A moist environment is favored. Human colonization in the community is rare, and, when it occurs, the skin, gut, and upper or lower airway are colonized. Carriage of *P. aeruginosa* in the community is associated with predisposing medical conditions, which allow the organism to bridge normal host defenses such as loss of the normal mechanical barrier provided by skin encountered in burn patients or abnormalities in pulmonary physiology encountered in patients with bronchiectasis or CF. In addition, prolonged antibiotic use by eliminating the normal host flora predisposes to *P. aeruginosa* colonization.

Nosocomial colonization is much more frequent and most often occurs in patients with predisposing conditions leading to impaired immunity, especially neutropenia, the presence of instrumentation disrupting host defenses, the prolonged use of extended spectrum antibiotics, and the existence of hospital reservoirs of infection. Hospital epidemics have been investigated by a variety of epidemiologic tools including serotyping, antibiogram patterns, and phage typing, but increasingly DNA fingerprinting is used. Potential sources of infection in the hospital environment include infected respiratory equipment, endoscopes, infusion solutions, intravascular catheters, whirlpools, sinks, drains, and indoor plants.

**B. Microbiology.** On the basis of ribosomal RNA and DNA sequence homology, the *Pseudomonas* genus is divided into five groups. Group I contains *P. aeruginosa* in addition to *P. fluorescens* and *P. alcaligenes*; Group II contains *P. mallei*, *P. pseudomallei*, and *Burkholderia cepacia*; Group III contains the *Comamonas* species; Group IV contains *P. diminuta*; and Group V contains *Stenotrophomonas maltophilia* (formerly *Xanthomonas maltophilia*). *Pseudomonas* spp. are gram-negative, straight or slightly

curved rods that are motile by means of flagella. They are nonsporing and facultative aerobes. [Table 54-1](#) outlines the essential microbiological features of *P aeruginosa* by which it can be distinguished from other non-*Pseudomonas* gram-negative bacteria. Differentiation from other *Pseudomonas* spp. is more difficult and uses differences in sugar oxidation, growth characteristics at 42 °C, and flagella stains. The production of the pigment pyocyanin by approximately half of *P aeruginosa* strains is specific, and a sweet grapelike odor is often said to be characteristic of *P aeruginosa*.

**C. Pathogenesis.** The pathogenicity of *P aeruginosa* is a function of host and microbial factors. *P aeruginosa* is an opportunistic pathogen. Host defects may result from alterations in the normal physical barriers to infection. These may be breached by physical alterations such as occur to the skin in burn patients or by prosthetic materials such as catheters that bypass these mechanical barriers. The presence of an effective immune response to *P aeruginosa* requires functional neutrophils in adequate number, the presence of specific immunoglobulin G (IgG) antibodies, and complement activation by both classical and alternative pathways. The production of high titers of antibody to exoenzyme A early on in *P aeruginosa* septicemia results in an improved outcome as compared with a less favorable outcome in those patients with low titers of antibody to exoenzyme A. Immunological defects contribute to infection and may consist of neutropenia, hypogammaglobulinemia, complement defects, or more subtly, age, prolonged hospitalization, or diabetes. Bronchiectasis and CF are lung diseases associated with pathological changes that predispose to colonization and often infection with *P aeruginosa*.

Bacterial factors also contribute. Colonization often precedes infection. Colonization is aided by the bacterial pili and production of mucoid exopolysaccharide. Pili or fimbriae are of particular importance in pulmonary colonization. The alginate capsule is a feature of mucoid strains and has an important role in CF pathogenesis (see below). It protects the organism from antibodies, complement, and phagocytosis. In addition, mucoid strains are associated with decreased susceptibility to antibiotics, especially aminoglycosides. Enzymes that contribute to invasiveness are produced, including alkaline protease, hemolysins, and elastase. Alkaline protease induces necrosis in tissues, possesses strong anticoagulant activity, and inactivates a variety of cytokines including tumor necrosis factor (TNF). Elastase has a variety of pathogenic effects including the degradation of IgG and IgA, complement cleavage, inactivation of TNF, and interferon gamma, and is linked to the pathogenesis of the characteristic skin lesions of *Pseudomonas* septicemia referred to as ecthyma gangrenosum.

Hemolysins aid tissue invasion by degrading lipids and lecithin. One hemolysin, phospholipase c, degrades phosphatidylcholine, a component of lung surfactant, resulting in atelectasis. Cytotoxin, formerly called leukocidin, inhibits neutrophil function and is linked to the pathogenesis of *Pseudomonas*-induced acute lung injury in adult respiratory distress syndrome. Pyocyanin alters the function of ciliated respiratory epithelium and enhances tissue damage by means of the generation of toxic free radicals.

As with other gram-negative bacteria, lipopolysaccharide plays a key role in the manifestations of septic shock. It stimulates the production of TNF and other cytokines, prostaglandins, leukotrienes,  $\beta$ -endorphins, kinins, complement activation, and the

activation of the coagulation and fibrinolytic cascades. Exotoxin A acts by a method similar to diphtheria toxin to inhibit protein synthesis. This toxin plays a significant role in the necrosis observed in animal models of *Pseudomonas* corneal or lung injury. Mutant strains of bacteria that do not produce exotoxin A produce less severe injury than strains expressing exotoxin. Exotoxin A may also be immunosuppressive to both T and B lymphocytes. Exoenzyme S ribosylates proteins of the *ras* gene superfamily and alters local host defense mechanisms.

## Clinical Syndromes

[Box 54-1](#) summarizes the principal clinical symptoms associated with *P aeruginosa* infection.

## PULMONARY INFECTIONS

*Pseudomonas* lung infections occur in patients with chronic lung disease or impaired immunity, usually in association with nosocomial factors such as endotracheal intubation, respiratory therapy, prolonged hospitalization, antibiotic use, and neutropenia. Pneumonia takes two forms: primary and bacteremic. Primary pneumonia arises in predisposed patients following nosocomial colonization and aspiration of *P aeruginosa*. Pneumonia is characterized by fever, tachypnea, cough with purulent sputum, shortness of breath, cyanosis, and often signs of sepsis.

The diagnosis of pneumonia caused by *P aeruginosa* is established by the chest x-ray findings of bilateral bronchopneumonia often with radiolucencies resembling *Staphylococcus aureus* pneumonia ([Figure 54-1](#)) and recovery of *P aeruginosa* from pulmonary secretions or blood culture. *P aeruginosa* frequently colonizes hospitalized patients, especially those with chronic pulmonary disease or those with endotracheal intubation and mechanical ventilation. Colonization, especially in ventilated patients, is often difficult to differentiate from infection, and the diagnosis of infection requires the presence of signs and symptoms of infection together with recovery of *P aeruginosa* from expectorated sputum, blood cultures, bronchoalveolar lavage, or a protected brushing sample obtained at bronchoscopy. *P aeruginosa* is particularly common in patients with ventilator-associated pneumonia. One study found it caused 27% of cases of ventilator-associated pneumonia and identified risk factors such as chronic obstructive pulmonary disease, mechanical ventilation for more than 8 days, and prior antibiotic use. In the rare instances in which community acquired pneumonia is found, it occurs primarily in patients with chronic obstructive airways disease and history of prior antibiotic use.

Bacteremic pneumonia is caused by septic embolization of the lung. Neutropenia complicating chemotherapy, underlying hematologic malignancy, or AIDS are the usual settings for this type of pneumonia. This is usually a rapidly fatal disease. Pathologically, two characteristic pulmonary lesions are encountered. One type is hemorrhagic nodules, which are primarily subpleural and surround pulmonary vessels without inflammatory infiltrates. The second type is umbilicated nodules with liquefactive necrosis and leukocyte infiltration or more frequently with coagulative necrosis. These lesions are the pulmonary form of cutaneous ecthyma gangrenosum. The radiologic appearance of bacteremic pneumonia evolves over 1 to 3 days and is initially

manifested by pulmonary congestion and edema with subsequent alveolar infiltrates, pulmonary hemorrhage, and finally cavitation.

## **INFECTIONS IN PATIENTS WITH CYSTIC FIBROSIS**

Patients with CF demonstrate particularly complex host-parasite interactions involving *P aeruginosa*. CF is characterized by mutations in the CF transmembrane conductance regulator resulting in abnormal chloride ion secretion and cellular dehydration. A continuous cycle of cellular inflammation with increased numbers of neutrophils in bronchoalveolar lavage fluid, increased interleukin 8 secretion, viscous mucus, mucus plugging of airways, and infection results. Whether *P aeruginosa* infections play a role in the pathogenesis of the disease is still a matter of debate, but research has established a complex interaction.

Colonization rates for *P aeruginosa* increase with age and reach 60-80% for adult CF patients. One of the effects of the genetic mutation causing CF is an increase in levels of the receptor,  $\alpha$ -sialo GM<sub>1</sub>, on respiratory epithelium. *P aeruginosa* isolates from CF patients who are colonized demonstrate the mucoid phenotype discussed above and form a biofilm that protects the bacteria from antibiotics, immunoglobulin, complement, and oxygen-free radicals. Conversely, strains lose the polysaccharide O side chains of lipopolysaccharide and become susceptible to complement, which prevents invasive infection and bacteremia. Motility is lost, and loss of flagella correlates with decreased nonopsonic phagocytosis. Immuno-evasion is accomplished with the aid of a variety of bacterial products, especially elastase (which proteolyzes immunoglobulin, complement, and cytokines) and cytotoxin (which induces T-lymphocyte, macrophage, and neutrophil cytotoxicity).

Colonization is facilitated by prior antimicrobial treatment of respiratory infections, which eradicates existing respiratory flora. Acute exacerbations with productive cough caused by bronchitis or pneumonia occur and are associated with further reduction of respiratory reserve. Fever is usually absent. Antimicrobial treatment of acute exacerbations is necessary, although eradication of the carrier state does not usually occur. Prophylactic or suppressive antimicrobial therapy has not been demonstrated to be efficacious; however, intermittent antipseudomonal therapy, including the use of nebulized antimicrobial agents, in particular, tobramycin, improves pulmonary function and decreases exacerbation of infection. Chest physiotherapy is essential in limiting infections. Ultimately, respiratory failure may lead to heart-lung or double lung transplantation, and *P aeruginosa* infection contributes to the high morbidity and mortality associated with transplantation in this population.

## **BACTEREMIA**

*P aeruginosa* is a common cause of nosocomial bacteremia, which may be either primary (no identifiable source) or secondary (recognizable extravascular source). Community-acquired *P aeruginosa* bacteremia is very rare. Host factors contributing to nosocomially acquired *P aeruginosa* bacteremia include neutropenia caused by hematological malignancy or chemotherapy, hypogammaglobulinemia, AIDS, organ transplantation, insulin-dependent diabetes mellitus, burns, premature births or advanced age, instrumentation or catheterization, high-dose corticosteroid use, and

prolonged antibiotic therapy. *P aeruginosa* bacteremia is associated with higher mortality than bacteremia caused by other gram-negative microorganisms, although this observation may reflect the host's underlying immunosuppression.

A poor prognosis is associated with an absolute neutrophil count of  $< 100$  cells/mL<sup>3</sup>, septic shock, renal failure, or a serious underlying illness. Primary bacteremia or bacteremia-complicating pneumonia or skin infections are also associated with a poor prognosis. Clinical signs of *P aeruginosa* bacteremia are those of gram-negative sepsis and include fever, tachycardia, respiratory distress, hypotension, obtundation, and renal failure. *P aeruginosa* bacteremia has a particular propensity to cause jaundice. Disseminated intravascular coagulation is less frequently encountered with *P aeruginosa* bacteremia than other gram-negative bacteremias.

The classic skin lesion of *P aeruginosa* bacteremia is ecthyma gangrenosum, which is characterized by the presence of a small vesicle with a rim of surrounding erythema that undergoes necrosis and ulcerates with localized gangrene and black discoloration ([Figure 54-2](#)). Histopathology reveals the invasion of small arteries and veins by bacteria and is characterized by the absence of a significant inflammatory infiltrate. Lesions occur most frequently on the extremities, buttocks, perineum, or axilla, although they may occur anywhere including within the oral cavity. Although occasionally reported in infections with other organisms including *Escherichia coli* and *Candida* spp., these lesions are highly suggestive of *Pseudomonas* infection. However, only a minority of bacteremic infections develop this lesion. Other skin lesions encountered include vesiculopustular or maculopapular lesions and cellulitis. The diagnosis is made by the characteristic appearance of gram-negative microorganisms on Gram stain and recovery of *P aeruginosa* from blood or tissue cultures.

## SKIN & SOFT TISSUE INFECTIONS

Infections caused by *P aeruginosa* involving the skin may be primary or secondary. Secondary infections have been described above and include ecthyma gangrenosum, subcutaneous nodules, vesicles, bullae, cellulitis, deep abscesses, and necrotizing fasciitis. Primary skin lesions are noted as complications of neutropenia, burns, decubitus ulcers, prematurity, exposure to a moist environment, and hydrotherapy. Burn wound sepsis is a serious complication that may be caused by *P aeruginosa*. Colonization of the burn may lead to invasive disease. The signs are black, brown, or violet discoloration of the burn eschar; destruction of granulation tissue leading to rapid eschar separation and subcutaneous hemorrhage; erythematous nodules; edema or hemorrhage of adjacent uninfected tissue; black neoeschar formation; or signs of septicemia. This complication of burns has a high associated mortality. Diagnosis is by skin biopsy of both burn tissue and adjacent viable tissue. The presence of  $> 10^5$  organisms per gram of tissue cultured, the presence of *P aeruginosa* in adjacent healthy tissue, vasculitis, or inflammation at the burn margin are diagnostic.

Other skin and soft tissue infections caused by *P aeruginosa* include the following: hot tub- or hydrotherapy-associated folliculitis, which is usually self-limited ([Figure 54-3](#)); web space infection of the toe associated with humid climates or tinea pedis infection and characterized by maceration and scaling with purulent discharge, which may be green in color; green nail syndrome, which is characterized by paronychia occurring in

association with a history of frequent submersion of the hands in water and nail discoloration caused by incorporation of pigment in the nail; green foot syndrome resulting from *P aeruginosa* colonization of rubber-soled shoes producing pigment that stains the feet, but in which *P aeruginosa* does not cause direct infection; diving suit dermatitis; necrotizing fasciitis after Cesarean section, and noma neonatorum, a complication of premature infants in developing countries where necrotizing hemorrhagic lesions of mucosal surfaces or the groin result in fulminant infection and often death.

## **URINARY TRACT INFECTION**

Urinary tract infection (UTI) with *P aeruginosa* occurs primarily in two settings: nosocomial infection or complicated urinary tract infection. Nosocomial infections involve patients with urinary catheterization, instrumentation, or surgery. Renal transplant recipients have a high risk of *P aeruginosa* urinary tract infection. Complicated urinary tract infections are often nosocomially acquired and occur in association with renal stones, chronic prostatitis, or urinary tract malformations. Rarely community-acquired *P aeruginosa* cystitis occurs in young patients as the result of transient colonization.

The clinical presentation of *P aeruginosa* UTI includes dysuria, increased frequency of micturition, and hematuria. Fever and flank pain occur in cases of pyelonephritis. Diagnosis is made by the recovery of *P aeruginosa* from cultures of a midstream or catheterized urine sample in association with pyuria or hematuria. Urinary tract infections contribute significantly to the total number of patients with *P aeruginosa* bacteremia and are associated with a better outcome than bacteremia associated with other sources.

Rare complications of *Pseudomonas* UTI include the sloughing of bladder mucosa associated with ulceration of the urinary bladder or renal infarcts caused by invasion of small blood vessels representing a form of ecthyma gangrenosum in the kidney. Treatment of UTI infection is complicated by the tenacity with which *P aeruginosa* adheres to urinary epithelium predisposing to chronic infection and relapse.

## **EAR, NOSE & THROAT INFECTIONS**

*P aeruginosa* infection of the external auditory canal may be acute or may be a chronic serious infection called malignant otitis externa. Acute diffuse otitis externa is often referred to as swimmer's ear. *P aeruginosa* may be part of the normal flora of the external auditory canal or may colonize the canal as a result of exposure to water. Swimming, a humid climate, and local trauma result in inflammation, desquamation, and bacterial proliferation. The clinical signs and symptoms are erythema, discharge, pain, and pruritus. An aggressive hemorrhagic form has been associated with hot tub use. Topical antibiotics, topical corticosteroids, and drying agents are usually effective therapy, although relapse is frequent.

Malignant otitis externa is the contiguous spread of necrotizing *P aeruginosa* infection from beyond the external auditory canal to the adjacent soft tissue and bone and is a serious infection usually occurring in elderly diabetics with microvascular disease but

may also occur in elderly nondiabetics, or in association with systemic corticosteroid treatment, AIDS, or rarely in infants. Irrigation of the ear with water in these patients may represent a risk factor. Infection spreads from the external auditory canal through adjacent cartilage and soft tissue to the parotid space, the temporal bone, and mastoid air cells and then to the base of the skull.

Symptoms include severe pain and discharge sometimes associated with decreased hearing, but systemic symptoms are rare. On examination the external auditory canal is erythematous and edematous, and granulation tissue may be observed. The middle ear is usually spared. Ipsilateral facial nerve palsy is a common early finding. Potential complications include parotid swelling and trismus, palsies of the 9th through 12th cranial nerves, cavernous venous thrombosis, and rarely, brain abscess or meningitis. An elevated erythrocyte sedimentation rate (ESR) in the absence of significant elevation of white blood cell count is common. For the radiologic diagnosis, magnetic resonance imaging may be more sensitive than computed tomography scans, and radionuclide scans, such as indium-labeled white blood cell scans, are useful to detect early bone involvement.

*P aeruginosa* is usually recovered from cultures of the external auditory canal or from debrided tissue. Antimicrobial therapy should be combined with local debridement, and in more severe cases, extensive debridement is warranted. Cure is also dependent on successful management of underlying conditions such as diabetes mellitus or reduction of corticosteroid therapy. Early diagnosis improves the outcome, and an adequate response to therapy may be assessed by documenting decreased otalgia, a decrease in erythrocyte sedimentation rate, and improved radiologic appearance.

*P aeruginosa* is the most frequent pathogen identified in chronic suppurative otitis externa infections in all ages and is also a recognized pathogen in mastoiditis in diabetics, sinusitis in patients with AIDS, and perichondritis of the auricle following ear piercing or other traumatic procedures performed on the pinna.

## **ORTHOPEDIC INFECTIONS**

Bone and joint infections caused by *P aeruginosa* may result as complications of surgery, in particular the implantation of joint prostheses, or pelvic or genitourinary surgery, in association with intravenous (IV) drug abuse, trauma resulting in open fractures such as motor vehicle or farm related accidents, complicated UTIs, diabetic foot ulcers, or puncture wounds of the foot. *P aeruginosa* has a predilection to infect fibrocartilaginous structures. *P aeruginosa* prosthetic joint infections may occur as a result of contamination during implantation, aspiration, or injection of the joint with corticosteroids.

In addition, *P aeruginosa* prosthetic joint infections may occur as a result of repeated surgical manipulation of the joint, joint revision, or reimplantation of the prosthesis. Polymicrobial osteomyelitis with *P aeruginosa* and other microorganisms is commonly associated with farm or motor vehicle accidents when open fractures become contaminated with water, soil, or vegetative materials. Vertebral osteomyelitis occurs in IV drug abusers or as a complication of UTI or genitourinary surgery. The lumbosacral spine is principally involved, although cervical involvement occurs in IV drug abusers.

Sternoarticular pyarthrosis may occur in IV drug abusers or occasionally as a complication of infective endocarditis. Infection of the symphysis pubis may occur after pelvic or genitourinary surgery and must be differentiated from nonpyogenic osteitis pubis.

Puncture wound infections of the foot occur at all ages and have a particular association with punctures through rubber-soled sneakers. These infections occur as a result of the growth of *P aeruginosa* in the moist inner sole layer of the shoes, and puncture wounds through the shoe inoculate *P aeruginosa* directly into the bones of the foot and surrounding soft tissue.

Chronic osteomyelitis may occur as a result of contiguous infection following trauma, surgery, or as a complication of diabetic foot ulcers due to direct inoculation or local expansion of the organism. These infections tend to be indolent with pain and decreased range of movement in the absence of fever or leukocytosis. An elevated erythrocyte sedimentation rate, abnormalities on CT scanning or MRI or a positive radionuclide scan suggest the diagnosis, but confirmation requires demonstration of the organism on a Gram stain and recovery of *P aeruginosa* from cultures. Puncture wounds of the foot may be more acute in presentation, and typically the initial pain after the injury resolves and recurs a few days later with pain and swelling over the site of inoculation. Osteomyelitis of any of the bones of the foot may result ([Figure 54-4](#)).

Effective treatment requires antimicrobial therapy combined with surgical debridement. Successful treatment of *P aeruginosa* prosthetic joint infection requires resection of the prosthesis and other foreign material together with debridement and antimicrobial therapy.

## ENDOCARDITIS

*P aeruginosa* endocarditis occurs predominantly in two settings: in association with IV drug use (IVDU) or with prosthetic valve endocarditis (PVE). The majority of cases of native valve endocarditis caused by *P aeruginosa* occur in association with IVDU. Risk factors for endocarditis associated with IVDU include the use of substances that are not boiled after mixing before injection, the injection of drugs at shooting galleries, and the use of pentazocine and tripeleminam. Intravenous drug users often have a combination of these factors. Despite the strong association of IVDU with *P aeruginosa* endocarditis, *S aureus* and streptococci more frequently cause endocarditis in IVDU.

The tricuspid valve is most frequently infected in intravenous drug users, occurring in over two-thirds of cases. Infection of the mitral, aortic, or pulmonic valves may also occur, and infection of multiple valves is common. Evidence of prior valvular pathology is usually absent, although foreign materials in injected substances may predispose by causing endothelial damage and fibrosis. The infection is usually subacute with fever and cardiac murmur occurring in the absence of other classic stigmata of infective endocarditis, such as Osler nodes, Janeway lesions, or Roth spots.

Presentation may be due to complications arising from septic pulmonary embolization characterized by cough, sputum production, pleuritic chest pain, or new infiltrates on chest x-ray. Left-sided valvular disease is less frequently encountered, and embolic

complications and cardiogenic shock are frequent sequelae. Ecthyma gangrenosum is rarely encountered in patients with endocarditis.

PVE caused by *P aeruginosa* is often highly aggressive. Diagnosis is based upon clinical illness compatible with infective endocarditis and blood cultures positive for *P aeruginosa*. Definitive diagnosis is made by recovery of *P aeruginosa* from blood cultures or tissue obtained at surgery or autopsy.

In addition to antibiotic therapy, surgical intervention is often necessary especially in left-sided valvular infections. Successful treatment of *P aeruginosa* PVE requires surgical intervention together with antimicrobial therapy. Infection of the tricuspid valve may also require surgery if bacteremia persists after 2 weeks of effective antimicrobial therapy or recurs after a 6-week course of antibiotics. The procedure of choice is tricuspid valvectomy. In cases without a history of IVDU, a tricuspid valve replacement can be performed ~6-8 weeks after valvectomy. Poor prognostic factors in *P aeruginosa* endocarditis are an age > 30 years, fever lasting > 2 weeks on appropriate antimicrobial-agent therapy, embolization, mural vegetation, left-sided infection, PVE, and mixed infection, particularly with *S aureus* as the copathogen.

## **OPHTHALMOLOGIC INFECTION**

*P aeruginosa* infections involving the eye take two predominant forms: keratitis and endophthalmitis. Keratitis often results from corneal ulceration induced by trauma. Risk factors include the use of contact lenses, especially extended wear soft contact lenses; topical ophthalmic steroid use; contaminated ophthalmic solutions; burn patients; prolonged coma; tracheostomy; ocular irradiation; or AIDS. In intensive care units, tracheal colonization, corneal drying, corneal abrasion, and a decrease in the bactericidal effect of lacrimal secretions contribute to the increased risk of infection.

Symptoms include pain, erythema, photophobia, purulent discharge, and blurred vision. On exam, a necrotic pale corneal ulcer is observed with adherent mucopurulent discharge and hypopyon formation (pus in the anterior chamber). Loss of vision may be rapid, and this condition is an ophthalmologic emergency necessitating prompt diagnosis and treatment. Diagnosis is made by ophthalmologic examination, scrapings from the ulcer, demonstration of organism presence on Gram stain, and organism recovery from culture. Treatment requires the application of antibiotic-containing ophthalmic solution combined with subconjunctival injection of antibiotics.

Endophthalmitis may result from keratitis, hematogenous spread, direct trauma, or surgery. The clinical signs and symptoms include a painful red eye with chemosis, hypopyon, anterior uveitis, decreased visual acuity, and in severe cases panophthalmitis. Therapy consists of combined topical, subconjunctival, intraocular and systemic treatment often combined with vitrectomy.

## **CENTRAL NERVOUS SYSTEM INFECTION**

Infection of the central nervous system (CNS) with *P aeruginosa* occurs as a result of immunosuppression and altered local defenses. Spread to the CNS may be from a local source, such as malignant otitis externa or sinusitis, direct inoculation at the time of

head trauma, or surgery (including the placement of external or internal shunts or dural grafts), or by hematogenous spread from a remote focus such as endocarditis. Infection may result in either meningitis or brain abscess.

Signs and symptoms of infection depend on whether bacteremia is associated with the infection. Bacteremic cases are usually acute with fever and signs of sepsis in addition to headache, nuchal rigidity, and photophobia characteristic of meningitis. Spinal fluid analysis demonstrates elevated protein and gram-negative bacteria on Gram stain, and in nonneutropenic patients an elevation in neutrophils is usual. Cases linked to direct inoculation resulting from head trauma, surgery, or neurosurgical procedure may occur with a more indolent course of fever, headache, and nonspecific signs of CNS infection. Spinal fluid analysis may establish the diagnosis. Cases complicated by abscess formation require aspiration or biopsy to confirm the diagnosis. Successful treatment requires correction of structural defects, removal of foreign materials, and drainage of abscesses when possible, in addition to antimicrobial treatment.

## **GASTROINTESTINAL INFECTIONS**

The gastrointestinal tract is the principal portal of entry for *Pseudomonas* bacteremia in neutropenic patients receiving chemotherapy. In addition, these patients may develop localized gastrointestinal infection. Although infection may involve any part of the gastrointestinal tract, it particularly involves the cecum and rectum. Localized areas of necrosis and gangrene in the cecum are termed typhilitis. *Pseudomonas* infection of the cecum is characterized by hemorrhagic, necrotic ulcers with bacterial invasion of the submucosal blood vessels and an absence of inflammatory cells. Patients present with abdominal pain, and peritonitis may occur. The abdominal radiograph may reveal signs of perforation of a viscus. The rectum is also a source of bacterial abscesses in neutropenic patients, and *P aeruginosa* is most frequently the cause. Rectal abscesses may be the source of bacteremia or may result in localized spread causing gangrene. These lesions must be carefully searched for because the absence of inflammation in neutropenic patients may delay diagnosis. Rectal abscesses require prompt surgical drainage.

The second group of patients with ulcerative intestinal lesions due to *P aeruginosa* is young infants who develop necrotizing enterocolitis. Risk factors include prematurity, comorbid illness, and admission to the neonatal intensive care unit. Clinical signs are fever, irritability, vomiting, bloody diarrhea, dehydration, and abdominal distension. An abdominal radiograph may demonstrate pneumatosis intestinalis, portal air, or free peritoneal air.

## **INFECTION IN PATIENTS WITH AIDS**

### **Introduction**

*P aeruginosa* infections may occur in patients with AIDS. Risk factors for infection include a CD4 count of  $< 100$  cells/mL<sup>3</sup>, neutropenia or functional neutrophil defects, intravascular catheterization, hospitalization, and prior use of antibiotics including ciprofloxacin or trimethoprim-sulfamethoxazole. Many cases are community acquired. Bacteremia is common, and the lung or an intravenous catheter is the most frequent

portal of entry. An impaired ability to mount immunotype-specific antibodies to *Pseudomonas* lipopolysaccharide antigen has been noted in HIV-positive individuals with bacteremia. Relapse is frequent, and mortality is high, 40%. Pneumonia is usually associated with cavitation and a high relapse rate. Bacterial sinusitis is an important and frequently undetected illness in HIV-positive individuals, and *P aeruginosa* is a frequent cause. Fluoroquinolone resistance may result from its use for the treatment of *Mycobacterium avium* complex.

Other infections caused by *P aeruginosa* described in patients with AIDS include malignant otitis externa, corneoscleritis, corneal ulceration and orbital cellulitis, meningitis, peritonitis, soft tissue infections, and osteomyelitis including osteitis pubis.

## Diagnosis

The diagnosis of a *P aeruginosa* infection requires the identification of the clinical syndrome by history, physical examination, and laboratory testing. The specific syndrome influences the duration of antimicrobial therapy and the need for surgical intervention. In patients with positive blood cultures, it is critical to determine the source of bacteremia. Microbiological diagnosis requires the recovery of *P aeruginosa* from culture. Gram-negative bacilli in culture should be screened for the presence of oxidase. Oxidase production excludes most gram-negative bacilli other than *Pseudomonas* spp. Definitive diagnosis requires the use of specific microbiological tests to distinguish *P aeruginosa* from other *Pseudomonas* spp.

## Treatment

Antimicrobial therapy of *P aeruginosa* infections is outlined in [Box 54-2](#). Resistance of *P aeruginosa* in vitro to many antimicrobial agents is widespread and is increasing in frequency. Susceptibility testing should be performed on all clinically significant isolates to guide the selection of appropriate antimicrobial therapy. In addition, the following principles should be considered:

- Antibiotics active in vitro against *P aeruginosa* often include extended spectrum penicillins with or without the combination of a  $\beta$ -lactamase inhibitor; some third-generation cephalosporins (ceftazidime, cefoperazone); fourth-generation cephalosporins (cefepime); carbapenems (imipenem, meropenem); monobactam (aztreonam); aminoglycosides (gentamicin, tobramycin, amikacin, netilmicin); and fluoroquinolones (for example ciprofloxacin).
- In general, therapy with a  $\beta$ -lactam antibiotic should not be used as monotherapy. In severe infections a  $\beta$ -lactam should be combined with an aminoglycoside or a fluoroquinolone. Successfully used in the treatment of other gram-negative infections, once-daily dosing of aminoglycosides can be considered in *P aeruginosa* infections.
- A fluoroquinolone is the only effective antimicrobial that may be administered orally.
- Patients with a history of major  $\beta$ -lactam allergy may be treated with a fluoroquinolone, aztreonam, or, cautiously, a carbapenem often combined with an aminoglycoside in severe infections.

- Optimal therapy often requires surgical intervention. Examples include left-sided endocarditis, PVE, necrotizing enterocolitis, malignant otitis externa, osteomyelitis, and prosthetic joint infection.
- Modifications of antimicrobial therapy may be necessary when antimicrobial susceptibility data are available.

CF patients represent a particular challenge to therapy. Altered pharmacokinetics frequently necessitate higher doses of antimicrobial agents than in other patients. Colonization with resistant strains is common in patients with CF. The administration of intermittent antimicrobial therapy to CF patients with chronic pseudomonal infections and the use of nebulized antimicrobial agents may reduce the frequency of *Pseudomonas* infection in CF patients. Despite theoretical concerns about fluoroquinolone incorporation into developing cartilage in pediatric patients, ciprofloxacin has been used successfully and safely in these patients.

Antimicrobial resistance is increasing worldwide among strains of *P. aeruginosa*.  $\beta$ -Lactam resistance may be due to mutational derepression of the *ampC* chromosomal  $\beta$ -lactamase, the acquisition of plasmid- or transposon-mediated  $\beta$ -lactamases, reduced permeability of *P. aeruginosa* to antimicrobial agents, multidrug efflux pump systems, and, in the case of carbapenems, loss of the D2 porin. Zinc-containing  $\beta$ -lactamases confer resistance to carbapenems. Many strains produce inducible cephalosporinases that account for the rapid emergence of resistance during therapy. Aminoglycoside resistance may be caused by decreased uptake owing to overproduction of the major outer membrane protein H1, aminoglycoside modifying enzymes, or modification of ribosomal targets. Mutations in the *gyrA* gene may cause resistance to ciprofloxacin and other fluoroquinolones.

## **Prevention & Control**

*P. aeruginosa* is primarily a nosocomial pathogen, and control measures should be focused on hospital infection control. Appropriate sterilization of all equipment and prompt recognition of hospital outbreaks are essential. Hand washing after patient examination and additional measures such as wound and contact isolation for multiply resistant *P. aeruginosa* should be performed. In particular, measures to decrease the spread of *P. aeruginosa* between patients at CF clinics are necessary.

## **OTHER PSEUDOMONAS SPECIES OF MEDICAL IMPORTANCE**

### ***P. PSEUDOMALLEI* MELIOIDOSIS**

This organism is endemic in Southeast Asia with the highest prevalence in Thailand. The organism is a saprophyte living in the soil. Infection may be subclinical, acute, subacute, or chronic. Pulmonary infection is most common. Histologically, the acute illness is represented by lung abscesses and the subacute form by caseation necrosis. Upper lobe cavities must be distinguished from those caused by tuberculosis. Debilitated patients may develop hematogenous spread of the organism to other organs. Skin lesions from direct inoculation cause suppurative lesions often in

association with nodular lymphangitis and regional lymphadenopathy.

Diagnosis is made in a patient from an endemic area with a compatible clinical illness who has a positive *P pseudomallei* culture or a fourfold increase or decrease in antibody titer. Appropriate therapy requires a combination of antimicrobial agents and surgical drainage. Ceftazidime alone or in combination with either trimethoprim-sulfamethoxazole or amoxicillin clavulanate is the therapy of choice. The duration of therapy ranges from 3 to 12 months with the longest duration of treatment necessary in chronic extrapulmonary disease. Imipenem, piperacillin-tazobactam, chloramphenicol, and tetracycline are alternative agents; the microorganism is resistant to ciprofloxacin and aztreonam.

### ***P MALLEI* (GLANDERS)**

Infection with *P mallei* (glanders) is the result of contact with an infected equine source such as horses, donkeys, or mules. The disease is confined to Africa, Asia, and South America. Human disease takes the following forms: acute suppurative infection with localized nodules and lymphangitis, mucocutaneous granuloma and ulcer, acute pulmonary infection with nodules and lymphadenopathy, acute septicemia, or a chronic suppurative form. Seroconversion or recovery of *P mallei* from culture confirms the diagnosis. Antimicrobial therapy is usually with the same agents effective for melioidosis administered for a period of 1-2 months often combined with surgical drainage.

### ***STENOTROPHOMONAS MALTOPHILIA***

This organism is a free-living microorganism that causes nosocomial infection in debilitated patients particularly in the intensive care or chronic ventilatory units. Infections encountered include pneumonia, UTI, wound infection, bacteremia, and, rarely, peritonitis, cholangitis, or endovascular infections. The emergence of this bacterium as a serious pathogen is caused by its antibiotic resistance pattern. It produces inducible  $\beta$ -lactamases and has low outer membrane permeability but is often susceptible to trimethoprim-sulfamethoxazole or ticarcillin-clavulanate. Alternative agents include ciprofloxacin, minocycline, doxycycline, and occasionally third-generation cephalosporins, but the microorganism is usually resistant to carbapenem or aminoglycosides.

### ***BURKHOLDERIA CEPACIA***

This microorganism is a cause of nosocomial infections similar to those caused by *Stenotrophomonas maltophilia*. It is also an important pathogen in patients with CF, and infection is associated with progressive lung disease and high mortality. CF patients who are colonized with *B cepacia* preoperatively and undergo lung transplantation have higher post-transplantation mortality than those who are not colonized. In CF clinics, colonization rates are high. *B cepacia* is resistant to aminoglycosides and most  $\beta$ -lactam agents. Some strains are variably susceptible to third-generation cephalosporins, ciprofloxacin, trimethoprim-sulfamethoxazole, ampicillin-sulbactam, chloramphenicol, or meropenem.

## **55 . *Helicobacter pylori* — Jay V. Solnick, MD, PhD, & Javeed Siddiqui, MD, MPH**

### **Essentials of Diagnosis**

- Positive serum immunoglobulin G usually indicates active infection.
- Serology is generally not helpful for documentation of cure.
- Urea breath test and stool antigen test are useful to document cure.
- Acid suppression therapy decreases the sensitivity of the urea breath test.
- Culture and susceptibility testing may be useful in refractory cases.

### **General Considerations**

Pathologists have noted spiral bacteria in biopsies and autopsy specimens of gastric mucosa for over 100 years. Their significance was alternately debated and ignored until 1982, when Barry Marshall and Robin Warren cultivated the organism for the first time and suggested that it might be a cause of chronic gastritis and peptic ulcer disease. Although initially called *Campylobacter pylori*, subsequent taxonomic studies showed that the bacterium was not a true *Campylobacter* species, and it was renamed *Helicobacter pylori*. Despite initial skepticism, Marshall and Warren's early proposal that *H pylori* caused gastritis and peptic ulcer disease proved correct. Furthermore, there is now overwhelming evidence that *H pylori* is linked to adenocarcinoma and non-Hodgkin's lymphoma of the stomach. The clinical significance of this organism has been emphasized by a National Institutes of Health consensus panel that recommended antibiotic therapy for the large majority of peptic ulcer patients who are infected with *H pylori* and by the classification of *H pylori* as a carcinogen by the World Health Organization.

### **A. Epidemiology.**

**1. Prevalence of infection.** *H pylori* is one of the most prevalent bacterial disease agents of humans and has been isolated from human stomachs in all parts of the world. In developing countries the prevalence is 70-90%, and most persons acquire *H pylori* infection before the age of 10 years. In the United States and other developed countries, approximately one-third of the population is infected. The prevalence of infection is greater among African-Americans and Hispanics than non-Hispanic whites, which seems to be explained only partially by socioeconomic factors. Prevalence also increases with age, from ~ 10% in children to ~ 50% by 50 years of age. In part, this is because, with each year of life, there is an incremental increase in chances of acquiring *H pylori* infection. However, probably more important is the "cohort effect"; because infection is typically acquired in childhood and the overall prevalence of *H pylori* in developed countries is declining, individuals born 50 years ago (when *H pylori* was more common) are found more often to be infected than persons born more recently. Once

acquired, infection is persistent, usually for the lifetime of the patient.

**2. Transmission.** There are no well-documented environmental reservoirs of *H pylori*. Only humans and some nonhuman primates are infected. While it is known that infection is transmitted from person to person, the exact mechanism is unclear. *H pylori* cannot generally be cultivated from stools of infected patients, although some evidence suggests that cultures may be positive if patients have diarrhea. Recent cultivation of *H pylori* from vomitus raises the intriguing possibility that transmission occurs during episodes of gastroenteritis by the gastro-oral route.

**3. Prevalence of disease.** Although all persons infected with *H pylori* will have histologic evidence of gastritis, only ~ 15-20% will have clinical disease at some point in their lifetime that is associated with *H pylori* infection ([Table 55-1](#)). Thus, although it clearly is a pathogen (recall that only ~ 20% of patients infected with *Mycobacterium tuberculosis* will have disease at some point in their lives), most people infected with *H pylori* will never have clinical sequelae of infection.

**B. Microbiology.** *H pylori* is a microaerophilic gram-negative rod that has a gently curved or S-shaped morphology that resembles *Campylobacter* spp. The organism displays a unique "corkscrew" motility produced by its four to eight unipolar flagella. Optimal growth occurs at 37 °C under microaerobic conditions on brucella agar or other rich medium supplemented with blood or serum. Since cultivation of *H pylori* from gastric biopsy requires 4-7 days, agar plates are typically supplemented with antibiotics (trimethoprim, vancomycin, polymyxin-B, and amphotericin B) to suppress overgrowth by fungi and other bacteria. *H pylori* is identified by the formation of pinpoint translucent colonies, its gram-negative staining characteristics, and positive tests for oxidase, catalase, and urease. Urease is produced in abundance by *H pylori* and is the basis for two tests commonly used to diagnose *H pylori* infection. Analysis of the complete *H pylori* genome reveals a large number of genes that are predicted to encode ion pumps, but few genes that encode regulatory factors; these findings are consistent with the notion of an organism that has adapted to a highly acidic environment. "*Helicobacter heilmannii*" is a related uncultivated bacterium that is uncommon but appears also to be associated with gastritis, peptic ulcer disease, and gastric malignancy. Several other species of *Helicobacter* can occasionally infect the large intestines and perhaps the hepatobiliary system, and they are sometimes associated with diarrheal disease.

## C. Pathogenesis.

**1. Histopathology.** All persons infected with *H pylori* have a chronic gastritis characterized by mononuclear inflammatory cells as well as an associated neutrophilic infiltration. Both the organism and the gastritis tend to be located preferentially in the gastric antrum. The role of *H pylori* in causing this chronic gastritis, previously thought to be a natural result of aging, has been clearly demonstrated by the finding that eradication of *H pylori* eliminates the gastritis and by two experimental self-inoculation studies in which physicians have voluntarily ingested *H pylori*. The organism can be found predominantly in the mucus gel layer, although a minority of bacteria will be adherent to the gastric epithelium. *H pylori* exhibits a profound tissue tropism, and it attaches only to gastric epithelium in the stomach or to epithelium in the proximal duodenum that has undergone gastric metaplasia.

**2. Mechanisms of tissue injury.** Polar flagella and a spiral morphology permit *H pylori* to move within gastric mucus and, on occasion, attach to gastric epithelium. Because the majority of bacterial cells are not attached to the epithelium, soluble factors are thought to play a role in generating the inflammatory response. About 60% of strains isolated from patients in the United States produce a vacuolating cytotoxin called VacA, which induces acidic vacuoles in the cytoplasm of eukaryotic cells. Although the exact role of VacA in disease is unknown, patients infected with strains that produce VacA are more likely to develop peptic ulcer disease and gastric adenocarcinoma than patients infected with strains that do not produce VacA. Interestingly, all *H pylori* strains have the gene for VacA, but cytotoxin activity is, for the most part, found only in those strains that also contain a 40-kilobase pathogenicity island called CagA. These strains also have the ability to induce interleukin-8, which serves to recruit and activate neutrophils. Like all gram-negative bacteria, *H pylori* produces lipopolysaccharide, which can disrupt gastric mucus. Interestingly, the *H pylori* lipopolysaccharide has a relatively low proinflammatory activity compared with that from enteric gram-negative bacteria such as *Escherichia coli*. This probably reflects its ability to coexist with the host over decades, usually causing little overt disease. The histologic gastritis may also reflect autoimmune mechanisms, because portions of the *H pylori* lipopolysaccharide side chains mimic host Lewis antigens expressed on gastric epithelium. *H pylori* also induces gastric mucosal injury by provoking apoptosis.

*H pylori* urease hydrolyzes urea into ammonia and carbon dioxide, which is then converted to bicarbonate. Urease is essential for *H pylori* colonization probably in part because the bicarbonate protects the bacterium from the effects of gastric acid. Urease also has toxic effects on gastric epithelial cells, so it functions both as colonization and virulence factor.

**3. Altered gastric homeostasis.** *H pylori* infection induces the expression of gastrin, an acid-stimulating peptide, and suppresses expression of the acid-inhibiting somatostatin. However, gastric acid production is not always increased in patients infected with *H pylori*. During the first few weeks to months of infection, there is thought to be a transient hypochlorhydria. After this stage, there may be increased or eventually decreased gastric acid, depending on a variety of factors. In general, gastric acid is increased in patients who develop duodenal ulcers but decreased in patients who develop gastric cancer.

## Clinical Findings

**A. Acute Infection.** Limited human inoculation studies suggest that acute *H pylori* infection may be associated with nausea, vomiting, upper abdominal pain, and bloating. It seems likely that some patients diagnosed with "gastroenteritis" have acute *H pylori* infection, particularly children, in whom most infections occur. Symptoms last several days and resolve spontaneously. There are no currently available methods for detection of acute *H pylori* infection, so the diagnosis is virtually never made. Because the acute illness is transient and most patients will not develop clinical sequelae of infection, there is little reason to look for *H pylori* infection in patients with a syndrome of gastroenteritis. Like many infectious diseases, *H pylori* acquisition may be asymptomatic.

**B. Chronic Active Gastritis.** Most if not all patients who acquire *H pylori* infection will remain persistently colonized and will develop chronic active gastritis. This is a pathologic and not a clinical diagnosis, which should not be confused with erosive or other forms of gastritis that can be diagnosed by gross visual examination with an endoscope.

**C. Peptic Ulcer Disease.** Approximately 15-20% of *H pylori*-infected persons will develop peptic ulcer disease at some point in their lifetimes. If one excludes ulcers due to nonsteroidal anti-inflammatory drugs (NSAIDs), > 80% of peptic ulcers can be attributed to *H pylori* infection. This conclusion is based on the observation that *H pylori*-associated ulcers treated with acid suppression alone will commonly recur when therapy is stopped after initial healing, while those treated with antibiotics that eradicate *H pylori* recur much less often. Since ulcers related to NSAIDs are more often gastric than duodenal, the association between *H pylori* infection and duodenal ulcer is stronger than that with gastric ulcer. In the absence of NSAIDs or other conditions such as Zollinger-Ellison syndrome or Crohn's disease, physicians should presume that ulcers in patients infected with *H pylori* are caused by the infection.

**D. Gastric Malignancy.** Although uncommon in the United States and other developed countries, gastric adenocarcinoma is the second leading cause of cancer worldwide and the second leading cause of cancer death. Persons infected with *H pylori* have approximately a sixfold increased risk of developing gastric cancer compared with those that are uninfected. Although the incidence of gastric cancer in the United States is declining, it remains relatively common among Hispanics, African-Americans, and Asians. These populations, like those in developing countries, have a higher prevalence of *H pylori* infection and are typically infected at a younger age than non-Hispanic whites. Overall, < 1% of infected persons in developed countries will develop gastric cancer, but, in developing countries, particularly in Asia, the risk may be as high as 10%.

Gastric cancer and duodenal ulcer disease are almost mutually exclusive outcomes of *H pylori* infection. Persons in developed countries are more likely to develop duodenal ulcer, while those in developing countries more commonly develop gastric cancer. It is thought that the difference lies in whether infection produces high gastric acid, which may lead to duodenal ulcer, or low gastric acid with atrophic gastritis, which is the histologic precursor to gastric adenocarcinoma. The factors that determine whether one progresses down one path or the other are largely unknown.

Gastric mucosa-associated lymphoid tissue (MALT) lymphoma is a rare disease that is strongly associated with *H pylori* infection. If identified early, the tumor can be cured with effective *H pylori* therapy in > 75% of patients. Therefore, antibiotic therapy is considered the standard of care for treatment of patients with *H pylori* infection and gastric MALT lymphoma.

**E. Nonulcer Dyspepsia.** Nonulcer dyspepsia is a poorly defined entity whose etiology is not well understood. Several large randomized clinical trials have now evaluated the effects of antibiotics for *H pylori* on nonulcer dyspepsia. In general, antibiotic therapy produces symptomatic improvement in 20-25% of patients; however, these results are similar in placebo-treated controls.

**F. Other Diseases and Syndromes.** There are multiple reports of associations between *H pylori* infection and cardiovascular disease, as well as several rheumatologic diseases. Since *H pylori* infection is so common, a causal relationship is difficult to demonstrate, and none has yet been established.

## Diagnosis

Several methods for diagnosis of *H pylori* are available, both noninvasive and endoscopic ([Table 55-2](#)).

**A. Serology.** Serum enzyme-linked immunosorbent assay for immunoglobulin G is sensitive and specific for detection of *H pylori* infection. Presuming that the patient has not been recently treated for *H pylori*, in which case an antibody test may be falsely positive because seroreversion has not yet occurred, a positive serum immunoglobulin G for *H pylori* indicates that there is active infection in the gastric mucosa. *H pylori* serum immunoglobulin M measurements are reported by some commercial laboratories, but the methods have not been well standardized and they are currently of no clinical value. Assays based on whole blood are generally less accurate and offer no significant advantages over those based on serum.

**B. Urea Breath Test.** Two urea breath tests have been approved by the U.S. Food and Drug Administration. The patient ingests either [<sup>14</sup>C]-urea or [<sup>13</sup>C]-urea. If *H pylori* is present in the stomach, these substrates are hydrolyzed and either [<sup>14</sup>C]- or [<sup>13</sup>C]-labeled CO<sub>2</sub> can be measured in a sample of expired air. Both tests are highly sensitive and specific for active *H pylori* infection. <sup>13</sup>C is a naturally occurring radioisotope of carbon and involves no ionizing radiation exposure to the patient. The radiation exposure from a [<sup>14</sup>C]-urea breath test is negligible, amounting to approximately the excess radiation dose accumulated by a transcontinental airline flight. Patients should avoid taking H<sub>2</sub> receptor antagonists or proton pump inhibitors for 1-2 weeks before a urea breath test, because these agents increase the likelihood of a false-negative test.

**C. Endoscopy.** Histologic examination of an endoscopic biopsy is a sensitive test for *H pylori* when performed by an experienced pathologist, and the specificity is nearly 100%. Organisms are most easily seen with silver stains such as Warthin-Starry or Genta, but routine hematoxylin and eosin or Giemsa stains are usually sufficient. Multiple biopsies should be obtained because the infection is not uniformly distributed. A rapid urease test may also be performed on gastric biopsies by placing the sample in a vial containing urea and a pH-sensitive dye, which will change color in the presence of bacterial urease activity. This test is inexpensive and accurate, and the results may be available in as soon as a few hours. Cultivation of *H pylori* from gastric biopsies is not commonly performed because it requires special media, and laboratories are often not experienced with growing this fastidious organism. However, cultivation offers the unique advantage over other techniques that the isolate is available for antibiotic susceptibility testing. This may be particularly important in patients who have failed initial attempts at therapy. If a local laboratory cannot cultivate *H pylori*, samples can be placed directly in a sterile tube, frozen (preferably at -70 °C, but -20 °C will usually

suffice), and shipped on dry ice to a reference laboratory.

**D. Stool Antigen Test.** A recently developed stool antigen test is approved by the U.S. Food and Drug Administration for evaluation of *H pylori* infection. It is > 90% sensitive and specific for detection of chronic infection, as well as for confirming eradication of *H pylori* when performed 4 weeks after completion of antibiotic therapy.

## Treatment

**A. Indications for Antibiotic Therapy.** All patients with peptic ulcer disease and *H pylori* infection should be treated with antibiotics, unless an alternative cause such as NSAIDs can be clearly demonstrated. This includes patients newly presenting with ulcer disease as well as those with a well-documented history of ulcer. Often these latter patients will be intermittently taking H2 blockers or proton pump inhibitors, which can be stopped after effective antibiotic therapy. Patients with MALT lymphoma should also receive antibiotic treatment for *H pylori*. Cost-benefit analyses have suggested that it may be economical to treat empirically patients who have dyspepsia and *H pylori* infection. However, the now documented failure of *H pylori* therapy to ameliorate the symptoms of nonulcer dyspepsia, together with growing problems with antibiotic resistance, renders this strategy less attractive. Furthermore, controversial data suggest that eradication of *H pylori* may be associated with an increased incidence of gastroesophageal reflux disease (GERD) and carcinoma of the gastroesophageal junction. Preventive antibiotic therapy may also be considered in a patient with *H pylori* infection and a family history of gastric adenocarcinoma. Because long-term therapy with acid suppression in *H pylori*-infected patients with GERD has sometimes been associated with increased risk of atrophic gastritis, some have suggested that these patients receive therapy for *H pylori* to prevent gastric cancer. This remains controversial, particularly in light of the evidence that *H pylori* eradication may exacerbate symptoms of GERD. *H pylori* screening and treatment in patients with no symptoms and no risk factors for gastric cancer are not indicated based on current data.

**B. Antibiotic Regimens.** Several general guidelines are helpful to identify a proper treatment regimen. First, results for all proton pump inhibitors studied to date are essentially equivalent, so the choice should be guided primarily by cost. Second, related antibiotics in a class should not be substituted for those that are recommended. For example, amoxicillin and tetracycline should not be replaced with ampicillin and doxycycline, respectively, nor should any macrolide be used other than clarithromycin, until further studies are done. Third, all effective regimens include at least two antibiotics in addition to acid suppression. Finally, antibiotic therapy should be continued for a minimum of 1 week, although 2 weeks is preferable. In ulcer disease the acid suppression therapy should be administered for 2 additional weeks.

Many treatment regimens are available that yield cure rates of = 80-90% and differ primarily in cost, convenience, and side effects rather than in efficacy ([Box 55-1](#)). The initial regimen developed for *H pylori* treatment was a combination of an H2 blocker twice daily, tetracycline four times daily, bismuth subsalicylate four times daily, and metronidazole three times daily. Amoxicillin can be substituted for tetracycline, although there may be some marginal loss of efficacy. A proton pump inhibitor is now commonly substituted for the H2 blocker. An effective alternative is a proton pump inhibitor or

ranitidine bismuth citrate (a combination of ranitidine and bismuth) each given twice daily together with two of the following: amoxicillin, clarithromycin, or metronidazole, each given twice daily. The latter approach is significantly more expensive than the bismuth-containing regimen, but twice-daily dosing may promote adherence.

**C. Follow-up Testing.** In the past, follow-up testing has not been routinely recommended, in part because noninvasive methods were not available. Serology is generally not useful for follow-up because a prolonged period is required for seroreversion after effective therapy. Currently, both the urea breath test and the stool antigen test are noninvasive methods that accurately detect *H pylori* eradication when performed = 4 weeks after completion of antibiotic therapy. Patients with gastric ulcer, particularly those in whom the clinical history raises concern about gastric cancer, and patients with MALT lymphoma, should undergo follow-up endoscopy after completion of therapy. Patients who are still infected with *H pylori* after therapy are likely never to have cleared the organism or are likely to have recrudescence rather than reinfection. The reinfection rate in adults after successful therapy documented = 4 weeks after treatment is < 1% per year.

**D. Antibiotic Resistance.** Antibiotic resistance to metronidazole is present in ~ 30% of *H pylori* strains in the United States, but can be as high as 90% in some populations, depending on the frequency of metronidazole use. A clear relationship between in vitro resistance and clinical efficacy has not been consistently demonstrated; this probably reflects heterogeneous mechanisms of resistance. Clarithromycin resistance occurs in 5-15% of strains. It is associated with mutations in the 23S rRNA gene and results in marked loss of efficacy. Because clarithromycin and metronidazole are the two agents for which resistance most commonly develops, it may be prudent not to use them together as initial therapy, to avoid development of resistance to both agents. Resistance to amoxicillin, bismuth, and tetracycline in *H pylori* strains is rare.

**E. Therapy in Treatment Failures.** The patient in whom the initial regimen fails to eradicate adherent *H pylori* should be treated with an alternative combination ([Table 55-3](#)). If metronidazole or clarithromycin was part of the original treatment, it is reasonable to presume that resistance has developed and to substitute clarithromycin or metronidazole, respectively, or to use amoxicillin. Resistance to metronidazole may sometimes be overcome by increasing the dose to 500 mg three times daily or even four times daily if tolerated. One may also consider sending a gastric biopsy for culture and susceptibility testing to a research lab if such testing is not locally available. Susceptibility testing should be performed against clarithromycin, metronidazole, amoxicillin, and tetracycline by the agar dilution method. This method has replaced the epsilometer agar diffusion gradient (E-Test, AB Biodisk) for *H pylori* antibiotic resistance testing.

**F. Treatment of *H pylori* Infection in Children.** *H pylori* infection is uncommon among children in the United States and other developed countries, as are peptic ulcer disease and gastric malignancy. Although the same agents that are used to treat *H pylori* in adults appear to be effective in children, there are no standard guidelines on when or how children should be treated. *H pylori* therapy in children with gastrointestinal symptoms should not be undertaken without consultation from a pediatric gastroenterologist.

## Prevention & Control

There are no available guidelines regarding prevention of infection. However, persons infected with *H pylori* who have diarrhea or vomiting should probably be considered contagious. Oral and parenteral vaccines, primarily based on *H pylori* urease, have been studied extensively in animal models, although none has proven effective at providing sterilizing immunity. Therapeutic-vaccination studies in animals and preliminary studies in humans are also ongoing.

## **56 . *Haemophilus*, *Bordetella*, & *Branhamella* Species — Joseph W. St. Geme III, MD**

### **HAEMOPHILUS INFLUENZAE & OTHER HAEMOPHILUS SPECIES**

#### **Essentials of Diagnosis**

- *Haemophilus influenzae* is generally acquired via the aerosol route or by direct contact with respiratory secretions.
- The most common associated syndromes include otitis media, sinusitis, conjunctivitis, bronchitis, pneumonia, and, to a lesser extent, meningitis, epiglottitis, arthritis, and cellulitis.
- Gram stain shows pleomorphic gram-negative coccobacilli.
- In cases of meningitis, epiglottitis, arthritis, and cellulitis, organisms are typically recovered from blood, and type-b polysaccharide capsular material may be detected in the urine.
- Organisms and type-b polysaccharide capsule may also be present in other appropriate sterile body fluids, such as cerebrospinal fluid (CSF) in meningitis and joint fluid in arthritis.

#### **General Considerations**

**A. Epidemiology.** Before 1990, strains of *Haemophilus influenzae* type b were found in the upper respiratory tract of 3-5% of children and a small percentage of adults. Colonization rates with type-b strains are even lower now, reflecting routine immunization of infants against *H influenzae* type b. Non-type-b encapsulated *H influenzae* are present in the nasopharynx of < 2% of individuals, whereas nonencapsulated (nontypable [see below]) strains colonize the respiratory tract of 40-80% of children and adults.

Historically, *H influenzae* type b was the leading cause of bacterial meningitis and epiglottitis in children < 5 years old and a major cause of septic arthritis, pneumonia, pericarditis, and facial cellulitis in this same age group. In the United States, ~ 1 in 200 children experienced invasive (bacteremic) disease with this organism before the age of 5 years, with a peak incidence of disease at 6-7 months of age. Invasive disease was more frequent in boys, children of African descent, Alaskan Eskimos, Apache and Navajo Indians, child care center attendees, and children living in overcrowded conditions. Other factors predisposing to invasive disease included sickle cell disease, asplenia, human immunodeficiency virus (HIV) infection, certain immunodeficiency syndromes, and malignancies. The introduction of efficacious vaccines and their routine use in infants, beginning in 1991, resulted in a marked decrease in the incidence of *H influenzae* type-b infections, which now are quite rare. The Immunization Practices

Advisory Committee of the Centers for Disease Control and Prevention and the Committee on Infectious Diseases of the American Academy of Pediatrics currently recommend administration of a licensed conjugate vaccine to all children starting at 2 months of age. Invasive disease in this country now occurs primarily in undervaccinated children.

Nonencapsulated strains of *H influenzae* are a common cause of localized respiratory tract disease in both children and adults. In children, these organisms are the most common cause of purulent conjunctivitis, the second most common cause of otitis media (after *Streptococcus pneumoniae*), and a frequent cause of sinusitis. Among children in developing countries, they are a frequent cause of pneumonia and an important source of mortality. In adults they are especially common as a cause of community-acquired pneumonia and exacerbations of underlying lung disease and also account for ~ 30% of cases of otitis media and sinusitis. Beyond producing localized disease, nontypable *H influenzae* is an occasional cause of serious systemic disease, such as sepsis, meningitis, and pyogenic arthritis, particularly in neonates and individuals with compromised immunity.

In the mid-1980s, *H influenzae* biogroup *aegyptius* was recognized as the etiology of Brazilian purpuric fever (BPF), a septicemic illness occurring in young children and associated with a case fatality rate of ~ 60%. In most cases, disease is preceded by purulent conjunctivitis. Both epidemics and sporadic cases have been reported, primarily in the neighboring Brazilian states of Sao Paulo and Parana and in the more distant state of Mato Grosso. Almost all cases of BPF occurring in Brazil have been caused by the same bacterial clone, referred to as the BPF clone.

Disease resulting from non-type-b encapsulated *H influenzae* occurs on occasion and is most common in patients living in underdeveloped countries. For example, among children in Papua, New Guinea, ~ 25% of *H influenzae* isolates associated with acute lower respiratory tract infection and roughly 15% of *H influenzae* isolates recovered from CSF are non-type-b encapsulated strains. In the United States, as the incidence of invasive disease from *H influenzae* type b has declined, serotype f strains have grown in importance as an etiology of *H influenzae* sepsis, meningitis, and pneumonia.

*H ducreyi* is the causative agent of chancroid, a sexually transmitted disease characterized by genital ulceration and inguinal lymphadenitis. Chancroid is a common cause of genital ulcers in developing countries. In contrast, it is relatively uncommon in the United States. Nevertheless, a number of large outbreaks have been identified in the United States since 1981. After a peak of 5000 cases in 1988 and a gradual decline since then, 243 cases of chancroid were reported in 1997 in the United States. These outbreaks have generally resulted from prostitution and its relationship to illicit drug use. Most cases have involved heterosexual transmission, and affected individuals have been primarily black or Hispanic. There is recent evidence that chancroid, like other forms of genital ulcer disease, is an important cofactor in the transmission of HIV. In addition, as many as 10% of patients with chancroid may be coinfecting with *Treponema pallidum* or herpes simplex virus.

*Haemophilus* spp. other than *H influenzae* and *H ducreyi* are members of the normal flora in the upper respiratory tract and occasionally the genital area. These organisms

have been reported in association with a number of local and systemic infections. Together, *H parainfluenzae*, *H aphrophilus*, and *H paraphrophilus* account for ~ 5% of cases of infective endocarditis.

**B. Microbiology.** *H influenzae* is a nonmotile, non-spore-forming, gram-negative bacterium. Microscopic examination reveals pleomorphic coccobacilli with an average size of 1 × 0.3 μm. *H influenzae* is capable of growing both aerobically and anaerobically. It requires supplements known as factors X and V under aerobic conditions and factor X alone in an anaerobic environment. These factors have not been precisely identified. Factor X can be supplied by heat-stable, iron-containing pigments, including hemin and hemoglobin, whereas factor V can be supplied by nicotinamide adenine dinucleotide (NAD), nicotinamide adenine dinucleotide phosphate (NADP), or nicotinamide nucleoside. Factor V is present in red blood cells but must be released to support growth. Consequently, growth media such as Fildes, which contains erythrocytes that have been disrupted by peptic digestion, and chocolate agar, which contains 1% hemoglobin, are required for optimal growth. Incubation in the presence of 5-10% carbon dioxide facilitates primary isolation of some strains.

Isolates of *H influenzae* are classified by their polysaccharide capsule, with six known capsular types (serotypes a-f). In addition, strains can be nonencapsulated; these strains are defined by their failure to react with typing antisera against capsular serotypes a-f and are referred to as nontypable. Based on the results of biochemical reactions that determine the production of indole and the presence of ornithine decarboxylase and urease, isolates can be separated into eight different subgroups called biotypes. Most type-b isolates are biotype I, whereas nontypable strains are usually biotype II or III. Clinical isolates that are biotypes IV through VIII are relatively uncommon and are almost always nontypable. In recent years, the use of multilocus enzyme electrophoresis has demonstrated that the population structure of *H influenzae* is clonal and that most nontypable strains are not recent capsule-deficient variants of extant encapsulated clones. Nontypable strains are genetically distinct and are more heterogeneous than encapsulated *H influenzae*.

*H influenzae* biogroup *aegyptius* represents a distinct subgroup of *H influenzae* biotype III with a predilection for causing purulent conjunctivitis. Historically, this organism was referred to as *H aegyptius* and was considered distinct from *H influenzae*. However, no single phenotypic characteristic consistently distinguishes one organism from the other. Moreover, DNA hybridization studies indicate that these two organisms belong to the same species. To account for the fact that these organisms cannot be phylogenetically separated but appear to differ clinically, the name *H influenzae* biogroup *aegyptius* has been used instead of *H aegyptius*.

*H ducreyi* also has fastidious growth requirements, including a need for factor X, thus resulting in placement in the genus *Haemophilus*. However, recent studies of DNA homology and ribosomal RNA gene sequences indicate major differences between *H ducreyi* and other *Haemophilus* species.

A variety of other *Haemophilus* species have occasionally been implicated in human disease, including *H parainfluenzae*, *H aphrophilus*, *H paraphrophilus*, *H haemolyticus*, *H parahaemolyticus*, and *H segnis*. Like *H influenzae* and *H ducreyi*, these species are

small, pleomorphic, gram-negative coccobacilli. Growth requirements include factor X, factor V, or both ([Table 56-1](#)). For some species, growth requires incubation in the presence of carbon dioxide.

**C. Pathogenesis.** *H influenzae* is transmitted by airborne droplets or by direct contact with respiratory tract secretions. Colonization with a particular strain can persist for weeks to months, and most individuals remain asymptomatic throughout this period. A variety of bacterial factors appear to influence the process of respiratory tract colonization. The lipid A component of *H influenzae* lipopolysaccharide (also called lipo-oligosaccharide) and possibly low-molecular-weight glycopeptides cause ciliostasis and thereby interfere with mucociliary clearance. In addition, both pilus and nonpilus adherence factors facilitate direct bacterial binding to respiratory epithelium. Like several other mucosal pathogens, *H influenzae* produces an immunoglobulin A1 (IgA1) protease, an enzyme that cleaves human IgA1 and likely facilitates evasion of the local immune response. Bacterial antigenic variation may also promote evasion of local immunity.

In certain circumstances, colonization is followed by contiguous spread within the respiratory tract, resulting in local disease in the middle ear, sinuses, conjunctiva, or lungs. Anatomic factors, deficiencies in local immune function, viral respiratory infection, exposure to cigarette smoke, and allergies predispose to localized respiratory tract disease. On occasion, bacteria penetrate the nasopharyngeal epithelial barrier and enter the bloodstream. The determinants of this event remain poorly defined but may include bacterial lipo-oligosaccharide. In most cases, bacteremia probably is transient. However, in nonimmune hosts, intravascular bacteria, especially those that express the type-b capsule, are sometimes able to survive, replicate, and disseminate to distant sites. In the absence of specific antibody, the type-b polysaccharide capsule promotes resistance to serum bactericidal activity and to phagocytosis.

The pathogenesis of disease caused by *H ducreyi* begins with intradermal inoculation, generally during sexual intercourse. Although the mechanisms of virulence remain poorly defined, several putative virulence factors have recently been identified and characterized. Most isolates express fine flexible pili, which by analogy with other pathogens may be important in initiating infection. More recent data indicate that *H ducreyi* lipo-oligosaccharide is important for adherence to keratinocytes and is capable of causing ulcers in rabbits and mice. In addition, *H ducreyi* elaborates at least two toxins, including a cell-associated cytotoxin that kills cultured human foreskin fibroblasts and a secreted toxin that kills epithelial cells (cytolethal distending toxin). Both toxins presumably contribute to the pathology associated with chancroid. *H ducreyi* also expresses a protein that confers resistance to serum killing.

## CLINICAL SYNDROMES

### INTRODUCTION

*H influenzae* was first isolated during the 1892 influenza pandemic and was originally believed to be the causative agent of influenza. Although subsequent studies revealed the fallacy of this idea, *H influenzae* has proved to be a common cause of localized respiratory tract and systemic disease, including meningitis, epiglottitis, pneumonia,

pyogenic arthritis, cellulitis, otitis media, and sinusitis, among others ([Box 56-1](#)).

## 1. MENINGITIS

### Introduction

Meningitis is the most common and serious form of invasive *H influenzae* type-b disease. In the mid-1980s, before the introduction of effective vaccines, ~ 10,000-12,000 cases of *H influenzae* type-b meningitis occurred in the United States each year, and 95% of cases involved children < 5 years old. Nowadays, there are < 200 cases/year, with most episodes occurring after 5 years of age.

### Clinical Findings

**A. Signs and Symptoms.** Symptoms usually include fever, irritability, lethargy, and vomiting. Antecedent symptoms of an upper respiratory infection are common. Occasionally, the course is fulminant, with rapid neurologic deterioration leading to respiratory arrest. Shock is present in 20% of cases of meningitis and can be associated with coagulopathy and purpura.

**B. Laboratory Findings.** Bacteria can almost always be recovered from CSF. In roughly 70% of patients with *H influenzae* meningitis, Gram stain of the CSF is positive for gram-negative coccobacilli. In cases of culture-proven meningitis, capsular antigen can be detected ~ 90% of the time in CSF and even more frequently in concentrated urine. False-positive reactions are uncommon, but occasionally occur owing to cross-reactivity with *E coli*, *S pneumoniae*, *Staphylococcus* spp., or *Neisseria meningitidis*.

**C. Complications.** Complications of *H influenzae* type-b meningitis include subdural effusion or empyema, ischemic or hemorrhagic cortical infarction, cerebritis, ventriculitis, intracerebral abscess, and hydrocephalus. The overall mortality rate is ~ 5%. Among survivors, between 5% and 10% have permanent sensorineural hearing loss, and ~ 30% have some other significant handicap. Tests for more subtle neurologic deficits reveal sequelae in up to one-half of survivors. Meningitis caused by nontypable *H influenzae* is usually associated with sinusitis, otitis media, or an anatomic communication between the upper respiratory tract and the central nervous system, and results from direct extension from the contiguous focus of infection.

## 2. EPIGLOTTITIS

### Introduction

Epiglottitis is a life-threatening infection involving cellulitis of the epiglottis and the aryepiglottic folds. Complete obliteration of the vallecular and pyriform sinuses is typical, and acute airway obstruction can occur.

### Clinical Findings

**A. Signs and Symptoms.** Symptoms are often sudden in onset and usually include

high fever, sore throat, and dyspnea, with rapid progression to dysphagia, pooling of secretions, and drooling. In children < 2 years old, fever may be low grade, dysphagia and drooling may be minimal, and a croup-like cough may be present. Regardless of age, the patient is usually restless and anxious and adopts a sitting position with the neck extended and the chin protruding to reduce airway obstruction. Abrupt deterioration can occur within a few hours, resulting in death unless an artificial airway is established.

**B. Laboratory Findings.** Cultures of the epiglottis usually are positive but should be obtained only after establishment of an artificial airway.

**C. Imaging.** Direct laryngoscopy at the time of controlled placement of an endotracheal tube reveals a red and swollen epiglottis and swollen aryepiglottic folds. On lateral neck radiograph, the swollen epiglottis produces the "thumb sign."

### 3. PNEUMONIA

#### Clinical Findings

**A. Signs and Symptoms.** Generally, *H influenzae* pneumonia is more insidious in onset than is pneumonia caused by *Staphylococcus aureus* or *Streptococcus pneumoniae*. Productive cough, fever, pleuritic chest pain, and dyspnea dominate the clinical presentation.

**B. Imaging.** Pneumonia caused by *H influenzae* is usually associated with a consolidative pulmonary infiltrate. In 50% of cases caused by *H influenzae* type b, there is evidence of pleural involvement on initial chest radiograph, and up to 90% of these patients have pleural fluid recoverable by thoracentesis.

**C. Complications.** An important complication is contiguous spread to the pericardium, resulting in purulent pericarditis, which is manifest by severe dyspnea (grunting in infants), tachycardia, and cardiac failure. Although patients with *H influenzae* type-b pneumonia often have persistent pleural reaction with secondary restrictive lung function at the time of hospital discharge, long-term abnormalities are rare.

### 4. PYOGENIC ARTHRITIS

#### Introduction

In the pre-*Haemophilus* vaccine era, *H influenzae* type b was the most common cause of pyogenic arthritis in children < 2 years of age.

#### Clinical Findings

In most cases a single large, weight-bearing joint (hip, knee, or ankle) is involved, and in 10-20% of patients, contiguous osteomyelitis develops. Response to systemic antibiotics in combination with prompt drainage of the joint is dramatic, but long-term follow-up is important because residual joint dysfunction can occur. On occasion, culture-negative arthritis develops during treatment of *H influenzae* type-b meningitis,

presumably as a result of immune complex deposition in the joint. In 75% of patients with reactive arthritis, signs of joint inflammation begin after a week or more of therapy.

## 5. CELLULITIS

### Introduction

Cellulitis is the result of metastatic spread of blood-borne *H influenzae* type b.

### Clinical Findings

**A. Signs and Symptoms.** Typically, the patient presents with fever and a warm, tender area of erythema or violaceous discoloration on the cheek or in the periorbital area. Cheek (buccal) cellulitis invariably occurs in children < 1 year of age. The age of the child, the location of the cellulitis, and the occasional distinctive violaceous color should suggest the etiology.

**B. Laboratory Findings.** Aspirate cultures, either from the center of the lesion or the leading edge, usually yield the organism.

**C. Complications.** Related to the fact that bacteremia is generally present, ~ 10% of children develop another focus of infection, for example, meningitis. *H influenzae* is not associated with cellulitis that occurs as a complication of trauma to the skin.

## 6. OTITIS MEDIA

### Introduction

Among *H influenzae* isolates from patients with acute otitis media, > 90% are nontypable. Based on studies reported from the United States and Scandinavia, the peak age-specific incidence of *H influenzae* acute otitis media is between 6 and 15 months.

### Clinical Findings

Characteristic manifestations include ear pain, fever, irritability, sleep disturbance, and otorrhea. On examination, the tympanic membrane is usually red or yellow and bulging with distorted landmarks. Pneumatic otoscopy reveals decreased mobility, indicative of middle ear fluid.

In addition to producing acute otitis media, nontypable *H influenzae* is the most common bacterial etiology of otitis media with effusion, which is typically asymptomatic and is characterized by a minimally discolored and often retracted tympanic membrane. Nontypable *H influenzae* is also associated with dual infection of the conjunctiva and the middle ear, referred to as the "conjunctivitis-otitis syndrome."

## 7. SINUSITIS

*H influenzae* accounts for ~ 30% of all cases of acute sinusitis. The majority of patients

with sinusitis have nasal discharge or cough that persists without improvement for > 10 days. Other patients present acutely with high fever and purulent nasal discharge. Physical examination often reveals tenderness over the involved paranasal sinuses.

## 8. EXACERBATIONS OF UNDERLYING LUNG DISEASE

Because sputum frequently is contaminated by pharyngeal bacterial flora, the interpretation of *H influenzae* growth from sputum cultures is difficult. Nevertheless, there is reasonable evidence that *H influenzae* plays a role in exacerbations of chronic bronchitis, bronchiectasis, and cystic fibrosis. Most isolates in these patients are nontypable. The clinical presentation is characterized by increases in dyspnea, sputum production, and sputum purulence, sometimes associated with fever.

## 9. NEONATAL SEPSIS

### Introduction

During the past 2 decades, nontypable *H influenzae* has become recognized as a cause of early onset neonatal sepsis similar to that caused by group B streptococcus. Disease occurs primarily in premature neonates and is associated with a mortality rate of nearly 50%.

### Clinical Findings

**A. Signs and Symptoms.** Most infants develop symptoms within the first few hours of life, with pneumonia and respiratory distress dominating the clinical presentation. Meningitis occurs infrequently.

**B. Laboratory Findings.** *H influenzae* usually can be cultured from the genitourinary tract of mothers of infected infants, often in association with maternal postpartum endometritis. At least one study indicates that a large percentage of these isolates are biotype IV, a subgroup of nontypable *H influenzae* found uncommonly at other sites of infection. Genotypic analysis of these biotype IV strains suggests that they represent a distinct *Haemophilus* species.

## 10. BRAZILIAN PURPURIC FEVER

### Clinical Findings

**A. Signs and Symptoms.** Brazilian purpuric fever is characterized by high fever, abdominal pain, and vomiting. In most patients, purpura and vascular collapse develop within 12 h of fever onset. Patients range in age between 3 months and 10 years, and ~90% have a recent history of conjunctivitis, which in most cases begins 1-2 weeks before the onset of fever.

**B. Laboratory Findings.** Aside from blood cultures, laboratory studies are nonspecific. Leukocyte counts are often elevated, with a preponderance of neutrophils and band forms, and thrombocytopenia and prolonged coagulation times are also seen.

## 11. CHANCROID

### Clinical Findings

**A. Signs and Symptoms.** Chancroid usually begins with a papule on the genitalia that develops after an incubation period of 4-7 days. The papule is typically surrounded by erythema and evolves over 2-3 days to a pustule, which spontaneously ruptures to form a sharply circumscribed ulcer. The ulcer is characterized by tenderness and a tendency to bleed. The surrounding skin generally lacks evidence of inflammation. Roughly 50% of patients develop inflamed inguinal lymph nodes, which often become fluctuant and rupture spontaneously. On occasion, chancroid presents with multiple ulcers that coalesce. In addition, ulcers can appear and then resolve spontaneously, with the development of suppurative inguinal adenitis 1-3 weeks later.

**B. Laboratory Findings.** Gram stain of material obtained by swabbing a lesion can show gram-negative bacteria in a "school of fish" configuration.

### Diagnosis

Consideration of the diagnosis of meningitis, epiglottitis, pneumonia, pyogenic arthritis, or cellulitis is usually prompted by the history and physical examination ([Table 56-2](#)). In most cases of invasive *H influenzae* type-b disease, blood cultures are positive. *H influenzae* is often cultivated from samples of pleural fluid, joint fluid, or pericardial fluid in affected patients.

The type-b capsular polysaccharide is secreted during bacterial growth, and detection of capsular antigen in serum, CSF, urine, and other normally sterile body fluids can help establish the diagnosis. Antigen detection techniques are most valuable in patients who have received prior antibiotic therapy and have sterile cultures. In addition, they may be useful in confirming a diagnosis before bacterial growth is appreciated in the clinical laboratory, thus allowing for earlier chemoprophylaxis of contacts (see below). Of note, *H influenzae* type-b conjugate vaccines can produce positive reactions in urine and CSF for days to weeks after vaccination.

Because *H influenzae* is a common commensal organism in the upper respiratory tract, establishing *H influenzae* as an etiology of localized respiratory tract disease is challenging. Procedures such as tympanocentesis, sinus aspiration, tracheal or lung aspiration, bronchoscopy, and bronchoalveolar lavage can provide a definitive diagnosis, but generally are reserved for patients with persistent or recurrent infection or an underlying immunodeficiency. Several studies have examined the predictive value of surface cultures of the nose, throat, or nasopharynx in patients with acute or chronic sinusitis. Although the organisms isolated from direct aspiration of infected sinuses are generally recovered from surface cultures, they are not consistently the predominant organisms. As a result, surface cultures are of minimal value in establishing an etiologic diagnosis; nevertheless, they may be useful to exclude a particular cause.

In patients with chancroid, an accurate diagnosis relies on cultivation of *H ducreyi* from the lesion. Selective and supplemental media are necessary for isolation. Although a variety of media have been used, the highest rates of recovery from clinical samples

have been obtained with chocolate agar containing Isovitale X and 3 ug/mL of vancomycin; GC agar base containing 1-2% hemoglobin, 5% fetal bovine serum, and 3 ug/mL of vancomycin; and Mueller-Hinton agar supplemented with horse blood, Isovitale X, and vancomycin. For optimal recovery, cultures are incubated at 33 °C in a humid CO<sub>2</sub>-enriched environment. Colonies are of pinpoint size at 24 h and increase to 1-2 mm in diameter at 48 h.

In blood culture, *Haemophilus* species other than *H influenzae* and *H ducreyi* have a tendency to grow in small colonies along the sides of the bottle or in the red blood cell mass, leaving the broth clear. As a result, recovery of these organisms from the blood of patients with endocarditis is enhanced by routine subculture of blood cultures to chocolate agar, use of a biphasic system, or use of a system that detects growth radiometrically.

## Treatment

Empiric therapy for invasive disease caused by *H influenzae* generally includes either a third-generation cephalosporin, such as cefotaxime or ceftriaxone, or the combination of ampicillin and chloramphenicol ([Box 56-2](#)). In the United States, ~ 30% of *H influenzae* isolates are resistant to ampicillin, and thus ampicillin should never be used alone as empiric therapy. Ampicillin resistance usually is related to plasmid-mediated production of β-lactamase, but occasionally is caused by decreased affinity of certain penicillin-binding proteins. To distinguish one form of resistance from the other, both disk susceptibility testing and a β-lactamase assay should be performed. Chloramphenicol is bactericidal for *H influenzae* and reliably penetrates into the CSF. Although resistance to chloramphenicol has been reported, it remains rare in the United States, especially among invasive isolates.

In recent years, the third-generation cephalosporins have become the treatment of choice for *H influenzae* meningitis. Both cefotaxime and ceftriaxone have potent activity against *H influenzae* (including ampicillin-resistant isolates) and achieve high levels in the CSF. For patients with uncomplicated meningitis, therapy for 7-10 days is adequate. For patients who fail to respond promptly or develop complications, therapy for > 10 days may be necessary. Based on empiric experience, most experts recommend that other invasive infections caused by *H influenzae* also be treated with an appropriate parenteral antibiotic for 7-10 days.

Among patients with invasive *H influenzae* disease, antibiotic therapy represents only one component of management. In patients with meningitis, optimal ventilation and judicious fluid administration are important. In addition, dexamethasone should be administered with the first dose or before initiation of antibiotic therapy, whenever possible (without delaying institution of treatment). Dexamethasone serves to diminish production of tumor necrosis factor and other cytokines that contribute to development of cerebral edema and neurologic sequelae. Patients with epiglottitis require placement of an artificial airway, and children with pneumonia often require treatment with supplemental oxygen. When pleural empyema, purulent pericarditis, or pyogenic arthritis is present, prompt drainage is essential to good outcome.

Otitis media, sinusitis, pneumonia, and exacerbations of underlying lung disease are

often treated effectively with oral amoxicillin, but amoxicillin-clavulanate, trimethoprim-sulfamethoxazole, an oral second- or third-generation cephalosporin, erythromycin-sulfisoxazole, azithromycin, and clarithromycin are acceptable alternatives ([Box 56-3](#)). Historically, treatment of otitis media and sinusitis was continued for 7-14 days, but recent evidence suggests that shorter courses of therapy are equally efficacious. Treatment for 7-10 days is usually adequate for pneumonia and bronchitis.

Several antibiotic regimens are effective in the treatment of chancroid. These include ceftriaxone, 250 mg IM as a single dose, azithromycin, 1 g orally as a single dose, and erythromycin, 500 mg orally four times daily for 7 days. Alternative regimens that have not been evaluated as thoroughly include ciprofloxacin, 500 mg orally twice daily for 3 days, and amoxicillin-clavulanate, 500 mg-125 mg, orally three times daily for 7 days. If therapy is successful, ulcers begin to improve within 3 days and usually resolve after 7 days of treatment. Clinical isolates often have plasmid-mediated resistance to ampicillin, chloramphenicol, tetracyclines, and sulfonamide and may be resistant to other antibiotics as well. Thus, when patients do not respond to treatment promptly, susceptibility testing should be performed. Short courses of therapy may be ineffective in patients with HIV infection.

Traditionally, uncomplicated infections from other *Haemophilus* species have been treated with ampicillin. *Haemophilus* endocarditis has been treated with high-dose ampicillin, often in combination with an aminoglycoside. However, resistance to ampicillin, usually related to  $\beta$ -lactamase production, is being recognized with increasing frequency. Consequently, a second- or third-generation cephalosporin (eg, ceftriaxone) should be used until antibiotic susceptibility results are available (see [Box 56-2](#)).

## Prevention & Control

Antibody to the *H influenzae* type-b capsule is bactericidal for type-b organisms and confers protection against invasive disease ([Box 56-4](#)). Accordingly, the existing vaccines against *H influenzae* type b contain some derivative of type-b polysaccharide, also called polyribosylribitol phosphate (PRP). To enhance the immunogenicity of these vaccines in young infants, the polysaccharide is conjugated to an immunogenic carrier protein. There are currently four licensed conjugate vaccines, all differing to some extent in the size of the polysaccharide, the chemical linkage between the polysaccharide and the carrier, or the type of protein (see [Table 56-3](#)). In addition, these vaccines differ in immunologic characteristics. As a result of differences in immunogenicity, three of the four (HbOC, PRP-T, and PRP-OMP) are licensed for use in infants, and the fourth (PRP-D) is approved only for children  $\geq$  12 months of age. For HbOC and PRP-T, the primary series of infancy consists of three doses (at 2, 4, and 6 months of age), whereas for PRP-OMP the primary series includes two doses (at 2 and 4 months). In all cases, a booster dose is required between 12 and 15 months of age.

All four of the conjugate vaccines are well tolerated, with the most common adverse effect being transient redness and swelling at the site of injection. Conjugate vaccines can be administered at the same time as other vaccines, including diphtheria-tetanus-whole-cell pertussis (DTP) or diphtheria-tetanus-acellular pertussis (DTaP), polio, hepatitis B, mumps-measles-rubella (MMR), varicella, pneumococcal vaccines, and meningococcal vaccine, and in some cases have been combined during

production with DTP, DTaP, or hepatitis B. Postlicensing studies indicate that the available conjugate vaccines are highly effective against *H influenzae* type b and have decreased the incidence of invasive *H influenzae* type-b disease by > 95%; however, these vaccines provide no protection against non-type-b strains.

There are currently no vaccines available for prevention of disease caused by nontypable *H influenzae* or other *Haemophilus* species. However, work is underway to identify nontypable *H influenzae* and *H ducreyi* antigens that are surface exposed and elicit protective antibody, and several promising candidates exist.

Chemoprophylaxis is another important intervention for preventing invasive disease caused by *H influenzae* type b. The intent is to eradicate nasopharyngeal colonization and thereby prevent subsequent invasion of the bloodstream in individuals at increased risk for invasive disease. Eradication of colonization will also interrupt transmission to other susceptible hosts. In households with a child < 12 months old, the index case and all members of the household should receive rifampin prophylaxis. The same is true in households with at least one contact < 48 months old who is incompletely immunized against *H influenzae* type b and in families with a fully immunized but immunocompromised child, regardless of age. When two or more cases of invasive disease occur within a 60-day period among attendees of a child care center and incompletely vaccinated children attend the facility, rifampin is recommended for all attendees and supervisors. Management of a single case at a child care center is controversial and depends on the age and immunization status of attendees and the duration of daily contact between attendees and the index patient. Because most secondary cases in households occur during the first week after hospitalization of the index case, chemoprophylaxis should be initiated as soon as possible.

Chemoprophylaxis is also a consideration in children who have recurrent otitis media caused by nontypable *H influenzae* (or other typical pathogens). In this situation, chronic prophylaxis with either amoxicillin or sulfisoxazole may be effective in reducing infectious episodes, an effect that must be balanced against the possibility of selecting for resistant organisms. According to a recent report, among patients who develop conjunctivitis caused by the BPF clone of *H influenzae* biogroup *aegyptius*, oral rifampin may be effective in preventing BPF.

## **BORDETELLA SPECIES**

### **Essentials of Diagnosis**

- Key signs and symptoms of whooping cough include sudden attacks of severe, repetitive coughing, the presence of an inspiratory whoop at the end of an episode of coughing, and post-tussive vomiting.
- Predisposing factors include the lack of adequate immunization with a pertussis vaccine and exposure to an adult with a coughing illness of > 14 days.
- *Bordetella pertussis* is acquired by the respiratory route via exposure to aerosol droplets.

- Definitive diagnosis is established by recovery of organisms from nasopharyngeal mucus or detection of *B pertussis* antigens by direct immunofluorescent assay of nasopharyngeal secretions.

## General Considerations

**A. Epidemiology.** *Bordetella pertussis* is a respiratory pathogen with a tropism for ciliated respiratory epithelial cells and is the usual cause of an acute respiratory infection called pertussis or whooping cough, which was described as far back as 1500. *B parapertussis* accounts for ~ 5% of cases of pertussis in the United States and typically produces more mild disease. The term pertussis means "intense cough," reflecting the most striking feature of the illness.

Pertussis is a common disease worldwide, with ~60 million cases and > 500,000 deaths each year. During the prevaccine era in the United States, pertussis was the leading cause of death from a communicable disease among children < 14 years, and in 1945, pertussis caused more deaths in infants in the United States than did diphtheria, polio, measles, and scarlet fever combined. The introduction of a pertussis vaccine in the late 1940s resulted in a more than 100-fold decrease in the incidence of pertussis by 1970. However, in recent years there has been a steady increase in the incidence of disease, with epidemics in a number of states. In 1996, 7796 cases were reported to the Centers for Disease Control and Prevention, representing the highest number since 1967. Of note, it is estimated that only 10% of actual cases are reported.

Pertussis is transmitted person-to-person by the respiratory route and is highly contagious, with attack rates of > 90% in unimmunized populations exposed to aerosol droplets at close range (eg, nonimmune household contacts). Asymptomatic infection has been demonstrated but is considered unlikely to be a major factor in transmission. Adolescents and adults have been recently recognized as a major reservoir for *B pertussis* and account for nearly 25% of reported cases, usually with mild or atypical symptoms. They are the usual source for infection in infants and children. Patients are most contagious during the first stage of illness, before the onset of paroxysms (see Clinical Findings, below); communicability then diminishes rapidly but may persist for 3 weeks or more after the onset of cough.

Pertussis is endemic, with superimposed periodic outbreaks that usually occur every 3-4 years. The majority of cases are diagnosed between July and October. Approximately 35% of reported cases occur in infants < 6 months, and ~ 60% occur in children < 5 years. Infants born prematurely are at increased risk for severe pertussis, with higher frequencies of hospitalization and death. The incubation period ranges between 6 and 20 days and is usually 7-10 days.

**B. Microbiology.** *B pertussis* is a small, gram-negative organism that grows as coccobacilli or short rods ranging in size from 0.2 × 0.5 μm to 0.5 × 2.0 μm. It is a fastidious obligate aerobe with an optimum growth temperature of 35-37 °C. Some evidence suggests that growth is impaired in an environment containing 5 to 10% CO<sub>2</sub>. A number of substances, including fatty acids, heavy metal ions, sulfides, and peroxides, inhibit growth. Media for primary isolation include Bordet-Gengou, modified Stainer-Scholte, Jones-Kendrick charcoal, and Regan-Lowe charcoal-horse blood agar,

which contain substances such as starch, charcoal, ion-exchange resins, or a high percentage of blood to inactivate the inhibitory substances.

Other *Bordetella* species associated with human disease include *B parapertussis*, *B bronchiseptica*, *B hinzii*, and *B holmesii* ([Table 56-4](#)). *B pertussis* and *B parapertussis* are obligate human pathogens, whereas *B bronchiseptica* causes disease predominantly in animals. *B hinzii* and *B holmesii* have been recently recognized as rare causes of bacteremia in immunocompromised patients and infect avian or canine hosts as well. All *Bordetella* species possess DNA with a high mole percent of guanine plus cytosine (66 to 70%). Interestingly, based on DNA hybridization and multilocus enzyme electrophoresis studies, *B pertussis*, *B parapertussis*, and *B bronchiseptica* are not sufficiently diverse to be classified as separate species. Nevertheless, they are associated with distinct clinical syndromes and continue to be considered individual species.

**C. Pathogenesis.** *B pertussis* produces a number of molecules that have been implicated in the pathogenesis of disease, including filamentous hemagglutinin (FHA), fimbriae (types 2 and 3), pertactin, pertussis toxin, adenylate cyclase toxin, dermonecrotic toxin, tracheal cytotoxin, and lipo-oligosaccharide. Among these factors, all but tracheal cytotoxin and lipo-oligosaccharide are activated by a regulatory locus referred to as the *Bordetella* virulence gene (Bvg) system. The roles for these factors can be considered in the context of the sequence of events involved in the pathogenesis of disease, namely entry into the host and attachment to a target tissue, persistence in the respiratory tract, and production of local damage. *B pertussis* does not invade beyond the respiratory mucosa. Thus systemic manifestations presumably result from dissemination of bacterial components, such as pertussis toxin.

FHA, types 2 and 3 fimbriae, pertactin, and pertussis toxin facilitate attachment to respiratory epithelium. Tracheal cytotoxin is derived from the bacterial cell wall and causes ciliostasis and sloughing of ciliated cells, thus allowing the organism to overcome mucociliary clearance. Adenylate cyclase toxin, a pore-forming cytotoxin that belongs to the RTX family, inhibits phagocyte functions, including chemotaxis, phagocytosis, oxidative burst, and bactericidal activity, and presumably enables the organism to evade local immunity. Pertussis toxin also impairs phagocyte functions, including neutrophil chemotaxis and phagocytosis. Tracheal cytotoxin, adenylate cyclase toxin, dermonecrotic toxin, and lipo-oligosaccharide may contribute to local damage to the respiratory mucosa.

## CLINICAL SYNDROME

### Introduction

Classical pertussis occurs in three clinical stages: catarrhal, paroxysmal, and convalescent ([Box 56-5](#)).

### Clinical Findings

**A. Signs and Symptoms.** The catarrhal stage is characterized by nonspecific upper respiratory symptoms, including rhinorrhea, mild cough, and low-grade fever. During this

stage, which typically lasts 1-2 weeks, the disease is highly communicable. The paroxysmal stage is marked by sudden attacks or paroxysms of severe, repetitive coughing, often culminating with the characteristic whoop and frequently followed by vomiting. A marked lymphocytosis usually accompanies this stage of the disease, with lymphocyte counts sometimes exceeding  $50,000/\text{mm}^3$  and usually representing 70% or more of total circulating leukocytes. The paroxysmal stage typically lasts 1-4 weeks and can be associated with a variety of complications, including secondary bacterial infections such as pneumonia and otitis media, toxic central nervous system manifestations such as seizures and encephalopathy, and effects of increased intrathoracic and intra-abdominal pressure such as pneumothorax, hernia, and rectal prolapse. The beginning of the convalescent (recovery) stage is marked by a reduction in frequency and intensity of coughing spells. After clinical pertussis, immunity to disease is lifelong.

Although most cases of pertussis follow a characteristic course, exceptions exist. In infants < 3 months, the catarrhal stage is usually no longer than a few days, and the paroxysmal and convalescent stages are extremely protracted, with coughing spells that continue throughout the first year of life. In infants < 6 months, apnea is a common manifestation, and the whoop is often absent. Paradoxically, in infants, cough and whoop may become louder and more classic during convalescence, reflecting growth in body mass and increased strength. In immunized children, all three stages are shortened, and in adults, only a protracted cough may be present. Post-tussive vomiting is common in pertussis at all ages and is a major clue to the diagnosis in adolescents and adults. With subsequent respiratory illnesses over the next several months, paroxysmal coughing may recur, though not because of recurrence of active *Bordetella* infection.

**B. Laboratory Findings.** During the catarrhal stage, organisms are most readily isolated from cultures of the posterior nasopharynx. During the paroxysmal stage, it is increasingly difficult to recover the organism from the respiratory tract.

**C. Imaging.** The chest radiograph is mildly abnormal in the majority of hospitalized infants, showing perihilar infiltrates or interstitial edema and patchy atelectasis. Pneumothorax, pneumomediastinum, and soft tissue air are sometimes seen.

**D. Complications.** Surveillance data on pertussis in the United States from 1980 to 1989 demonstrated that the clinical course in infants was complicated by pneumonia in 21.7% of cases, by seizures in 3.0% of cases, and by encephalopathy in 0.9% of cases. The mortality rate was 1.3% in infants < 1 month and 0.3% in infants 2-11 months of age. Considering all individuals with pertussis, pneumonia develops in ~ 10%, seizures in ~ 2%, and encephalopathy in 0.5% to 1%.

## Diagnosis

The traditional approach for diagnosing pertussis involves culturing *B. pertussis* or *B. parapertussis* from nasopharyngeal mucus (see [Table 56-2](#)). Mucus should be collected by aspiration or by swabbing the nasopharynx with a dacron or calcium alginate swab. After plating on an appropriate medium, *B. pertussis* is usually detected in 3-5 days, and *B. parapertussis* is visible in 2-4 days. Regan-Lowe agar or a related charcoal-horse

blood agar containing 40 ug/mL cephalexin is the preferred medium for primary isolation.

The organism is rarely found after the fourth week of illness, and culture is less likely to be positive in immunized individuals and in those who have received antibiotics. Examination of nasopharyngeal secretions by direct immunofluorescent assay is considered an alternative approach to diagnosis. However, direct immunofluorescent assay has low sensitivity and variable specificity and requires experienced personnel for interpretation. Polymerase chain reaction has been used on an investigational basis and is more rapid than culture but is variably sensitive.

*B pertussis* infections stimulate a heterogeneous antibody response that differs among individuals, depending on age, previous exposure to the organism, and immunization status, and thus no single serologic test is diagnostic. Nevertheless, in experienced research laboratories, the serologic diagnosis of pertussis has excellent sensitivity and specificity when acute serum is collected early in the illness and paired acute and convalescent sera are tested for antibodies to a number of antigens.

Absolute lymphocytosis is often present in patients with classic pertussis but represents a nonspecific finding, especially in infants. The degree of lymphocytosis usually parallels the severity of the patient's cough. The lymphocytes include both T cells and B cells and are normal small cells rather than large atypical lymphocytes. Adults and partially immunized children have less marked increases in lymphocyte count.

Because laboratory confirmation of pertussis can be difficult, clinicians often need to make the diagnosis on the basis of characteristic manifestations, including a prolonged paroxysmal cough, an inspiratory whoop, post-tussive emesis, and lymphocytosis. For sporadic cases, cough of > 14 days duration in combination with either paroxysms, whoop, or post-tussive vomiting has a sensitivity of 81% and a specificity of 58% for culture confirmation. In a study of university students, 25% of subjects with a coughing illness for 7 or more days had pertussis.

## Treatment

Infants < 6 months and other patients with potentially severe disease often require hospitalization for supportive care to manage coughing paroxysms, apnea, cyanosis, feeding difficulties, and other complications. Antibiotic therapy initiated during the catarrhal stage promotes more rapid clinical improvement ([Box 56-6](#)). However, after the onset of paroxysms, antimicrobial agents usually have little discernible effect on the course of illness. Nevertheless, they are recommended to limit the spread of the organism to others. The drug of choice is erythromycin. Currently, the recommended duration of therapy is 14 days, although recent evidence suggests that a 7-day course is also efficacious. Azithromycin and clarithromycin are alternatives based on clinical studies demonstrating the ability of these drugs to eradicate the organism.

Trimethoprim/sulfamethoxazole is another possible alternative, but its efficacy is unproven. In *in vitro* studies, *B pertussis* is also susceptible to fluoroquinolones and to a lesser extent ampicillin and rifampin. *B parapertussis* is less susceptible *in vitro* to all agents except erythromycin.

Among patients with pertussis who are treated with erythromycin, nasopharyngeal cultures almost always become negative within 5 days after initiating therapy. In order to prevent secondary transmission effectively, antibiotic treatment also should be prescribed for all household and other close contacts, including those who have been immunized against *B pertussis*, since vaccine-induced immunity is not absolute and may not prevent infection. Individuals exposed to a patient with pertussis should be closely monitored for respiratory symptoms over the ensuing 2-3 weeks.

Corticosteroids, albuterol, and pertussis-specific immunoglobulin may be effective in reducing paroxysms of coughing but require further evaluation before they can be recommended.

## Prevention & Control

Universal immunization with pertussis vaccine is critical for control of pertussis ([Box 56-7](#)). Whole-cell and acellular pertussis vaccines in combination with diphtheria and tetanus toxoids (DTP and DTaP, respectively) are available in the United States and should be administered to all children < 7 years. The primary series includes doses at 2, 4, 6, and 15-18 months of age, followed by a booster at 4-6 years of age. Whole-cell vaccines are prepared from a suspension of inactivated *B pertussis* cells, whereas acellular vaccines contain one or more antigens derived from *B pertussis* and lack endotoxin. These antigens include pertussis toxin, filamentous hemagglutinin, fimbriae type 2, fimbriae type 3, and pertactin. All acellular vaccines contain pertussis toxin, in an inactivated form.

Based on household studies of children in the United States exposed to pertussis, the efficacy of whole-cell vaccines for children who received at least three doses is estimated to be 50 to 90%, depending on the case definition. Protection is greatest against culture-confirmed, more severe cases. Vaccine-induced immunity persists for at least 3 years and then diminishes. Although whole-cell vaccines have been highly effective in reducing the burden of disease and deaths due to *B pertussis*, they are associated with a number of troublesome adverse effects, including redness, induration, and tenderness at the injection site, low-grade fever, drowsiness, irritability, and anorexia. Less common serious adverse reactions include seizures, hypotonic-hyporesponsive episodes, fever > 40 °C, and persistent, severe, inconsolable crying lasting 3 or more hours. Encephalopathy, other neurologic conditions, and sudden infant death syndrome have been attributed to vaccination with whole-cell pertussis vaccines, but evidence for a causal association is lacking.

Acellular pertussis vaccines were first demonstrated to be efficacious in studies in Japan involving children 2 years of age and older, and in 1991, two different formulations were licensed in the United States for use as the fourth and fifth (booster) doses in the routine series. More recent studies in Europe compared acellular and whole-cell vaccines in infants and found them to be associated with similar levels of protective efficacy. Concentrations of serum antibody to PT, FHA, fimbriae, and pertactin were at least as high after immunization with the acellular vaccines as they were after vaccination with a whole-cell vaccine. Furthermore, adverse reactions were significantly less frequent among recipients of the acellular vaccines. With this

information in mind, five acellular vaccines are now approved in the United States for use during infancy, and licensure of additional products is anticipated. Given their efficacy and safety profile, acellular vaccines are preferred over whole cell vaccines in the United States.

Once a case of pertussis has been diagnosed, all contacts should be identified. Close contacts < 7 years who have received fewer than four doses of pertussis vaccine (DTP or DTaP) should have pertussis immunization initiated or continued. As mentioned above, contacts should also receive chemoprophylaxis with erythromycin or a suitable alternative.

For the hospitalized patient, droplet precautions are recommended for 5 days after initiation of effective therapy. Similarly, outpatients should be excluded from day care or school until 5 days of treatment are completed. If antibiotic therapy is not administered, precautions should be continued until 3 weeks after the onset of paroxysms.

## **BRANHAMELLA CATARRHALIS**

### **Essentials of Diagnosis**

- *Branhamella catarrhalis* is presumed to be acquired by direct contact with contaminated respiratory tract secretions or by droplet spread.
- The most common infections include otitis media, sinusitis, and, to a lesser extent, exacerbations of underlying lung disease.
- Gram stain of infected fluid shows gram-negative diplococci. Culture of infected fluids when indicated is also useful.

### **General Considerations**

**A. Epidemiology.** *B. catarrhalis* was previously thought to be a harmless commensal organism, but it is now clear that this organism is an important cause of human disease. *B. catarrhalis* colonizes the nasopharynx of 5 to 10% of adults and ~ 30% of children. Colonization rates may be even higher during the winter months. *B. catarrhalis* accounts for ~ 15% of all cases of otitis media. Evidence that *B. catarrhalis* is a true middle ear pathogen comes from the observation that antibodies specific for this organism develop after otitis media in which a pure culture of *B. catarrhalis* is obtained from middle ear fluid. *B. catarrhalis* also causes sinusitis and can be recovered alone or in combination with other bacteria from direct sinus aspirates of patients with clinical and radiographic evidence of acute bacterial sinusitis.

**B. Microbiology.** The taxonomic position of *B. catarrhalis* remains controversial. There are conflicting proposals to classify this organism as a member of the genus *Moraxella*, subgenus *Branhamella*, or to leave it as the only species in the genus *Branhamella*. The genera *Branhamella* and *Moraxella* are classified along with the genera *Neisseria*, *Kingella*, and *Acinetobacter* in the family *Neisseriaceae*. In contrast to *Moraxella* spp., which are rod-shaped, *B. catarrhalis* appears as gram-negative diplococci with kidney-shaped cells and thus is morphologically indistinguishable from *Neisseria*. It

grows well on blood agar and chocolate agar, forming small, opaque, gray-white colonies, 1-3 mm in diameter, which are circular and firm. Nevertheless, recovery from mucosal surfaces is facilitated by the use of selective media such as Thayer-Martin or TV broth (Mueller-Hinton broth supplemented with trimethoprim and vancomycin). Isolates typically produce cytochrome oxidase, catalase, and DNase. They are unable to ferment maltose, glucose, lactose, or sucrose, thus distinguishing them from *N gonorrhoeae* and *N meningitidis*. *B catarrhalis* lipopolysaccharide molecules lack long O-polysaccharide side chains and are referred to as lipo-oligosaccharide. These organisms are nonencapsulated.

**C. Pathogenesis.** The pathogenesis of localized respiratory tract disease due to *B catarrhalis* begins with colonization of the upper respiratory tract mucosa. Subsequently, the organism spreads contiguously to produce disease in the middle ear, the sinuses, or the lower respiratory tract. Factors that increase the likelihood of spread to the tracheobronchial tree include smoking, intercurrent viral infection, corticosteroid use, and other forms of immunosuppression. The determinants of colonization remain poorly defined but may include pili, which are present on most isolates, and a nonpilus protein called UspA1. Persistence on the respiratory mucosa may relate to the ability of the organism to resist complement-dependent bactericidal activity, which is mediated by a high-molecular-weight protein referred to as UspA2 (antigenically related to UspA1 and also called HMW-OMP). In animal models of *B catarrhalis* lower respiratory infection, the organism appears to release a potent chemotactic factor and elicits a striking neutrophil response in the lung.

## CLINICAL SYNDROMES

### Introduction

*B catarrhalis* causes bronchitis and pneumonia in patients with underlying lung disease, especially chronic obstructive pulmonary disease. It is also a rare cause of invasive disease, including meningitis, endocarditis, bacteremia without a focus, septic arthritis, and cellulitis. In addition, it is a recognized cause of acute conjunctivitis and is periodically mistaken as *Neisseria gonorrhoeae* in newborn infants with conjunctivitis. *B catarrhalis* occasionally colonizes the genital mucosa and has been reported as a cause of urethritis.

### Clinical Findings

**A. Signs and Symptoms.** The signs and symptoms of *B catarrhalis* acute otitis media and sinusitis are indistinguishable from those present when acute otitis media and sinusitis are caused by other pathogens ([Box 56-8](#)). However, episodes of *B catarrhalis* otitis media are more likely to resolve spontaneously than are those caused by *Streptococcus pneumoniae* or *H influenzae*. The clinical manifestations of lower respiratory tract infection caused by *B catarrhalis* also are similar to those caused by other bacteria. Episodes of bronchitis in patients with chronic obstructive pulmonary disease are characterized by increased cough, purulent sputum, shortness of breath, and sometimes low-grade fever. Pneumonia due to *B catarrhalis* occurs almost exclusively in elderly persons and in patients with chronic obstructive pulmonary disease and is characterized by fever as high as 39.4 °C, cough, purulent sputum, and

shortness of breath.

**B. Laboratory Findings.** Nasopharyngeal and throat cultures are not helpful in establishing a microbiological diagnosis but can be useful in excluding certain organisms.

## Diagnosis

Tympanocentesis is necessary to establish the etiology of otitis media, and sinus aspiration is required to confirm the cause of sinusitis (see [Table 56-2](#)). However, these procedures are rarely performed. In patients with pneumonia, auscultation sometimes reveals evidence of consolidation, and chest radiograph sometimes shows patchy or lobar infiltrates. Pleural effusion and empyema are uncommon. The most practical approach to establish the diagnosis of *B catarrhalis* pneumonia or bronchitis is to examine a gram-stained sputum sample, which will show a predominance of intracellular and extracellular gram-negative diplococci.

## Treatment

Approximately 80% of isolates produce  $\beta$ -lactamase, and at least three different *B catarrhalis*  $\beta$ -lactamases have been identified, including BRO-1, BRO-2, and BRO-3. The activity of these  $\beta$ -lactamases can be inhibited by  $\beta$ -lactamase inhibitors such as clavulanate and sulbactam. Most *B catarrhalis* infections can be treated with oral agents, including Augmentin (amoxicillin plus clavulanate), erythromycin, trimethoprim-sulfamethoxazole, and tetracycline ([Box 56-9](#)). *B catarrhalis* is also uniformly susceptible to ticarcillin, piperacillin, mezlocillin, azlocillin, most second- and third-generation cephalosporins, chloramphenicol, newer macrolides, and aminoglycosides. *B catarrhalis* is resistant to penicillin, ampicillin, vancomycin, clindamycin, and methicillin. Approximately 1-2% of isolates are resistant in vitro to tetracycline or erythromycin. Isolates producing  $\beta$ -lactamase may be reported by the clinical laboratory as susceptible to penicillin and ampicillin, because of the low activity of the BRO- $\beta$ -lactamases. However, clinical treatment failures with such organisms suggest they should be considered resistant to these antibiotics. Similarly, cefaclor and possibly other cephalosporins may be inactivated by the BRO- $\beta$ -lactamases.

## Prevention & Control

Currently, there are no measures for prevention and control of *B catarrhalis* infection. However, a number of laboratories are characterizing *B catarrhalis* surface antigens, hoping to develop a vaccine effective against this organism.

### **VIBRIO INFECTIONS**

#### ***VIBRIO CHOLERAE* INFECTIONS**

##### **Essentials of Diagnosis**

- History of exposure, particularly travel to endemic or epidemic locales.
- Acute onset of voluminous, watery diarrhea, with low-grade fever and mild abdominal pain, which are disproportionate to the amount of diarrhea.
- During outbreaks, the presence of straight-to-curved gram-negative bacilli, with a single polar flagellum, in the stool of infected patients.
- In wet preparations, these organisms demonstrate a characteristic darting or "shooting star" motility. The identification may be confirmed by motility inhibition with specific antisera.
- Cultures of *V cholerae* from stool with differential media, such as thiosulfate-citrate-bile salts-sucrose (TCBS) medium.
- Bacterial growth in nutrient broth, without 1% NaCl supplementation. This characteristic is useful for separating *V cholerae* from most other *Vibrio* species.
- Detection of *V cholerae* toxin by latex agglutination or enzyme-linked immunosorbent assay (ELISA) or the detection of *V cholerae*-specific nucleic acid sequences by polymerase chain reaction (PCR)-based methods.

##### **General Considerations**

**A. Epidemiology.** Cholera is a disease of antiquity and probably represents some of the diarrheal illnesses described by Hippocrates and other early physicians. Robert Koch discovered *V cholerae* in 1884. Since the 17th century, at least eight epidemics of cholera have swept the globe. At least seven of the eight pandemics originated from the Ganges River delta, where cholera is endemic. *V cholerae* is transmitted by the fecal-oral route, often by way of contaminated water supplies.

The areas where cholera remains endemic lack adequate sewage disposal systems and water treatment facilities. Cholera epidemics often occur during war, when basic human needs are not met. Throughout the past 30 years, cholera epidemics have repeatedly occurred in overcrowded refugee camps. In the 1994 Rwandan refugee camps, a significant proportion of the deaths were caused by cholera. During this time, 600,000 people are believed to have been infected with *V cholerae* 01, which resulted in ~

45,000 deaths.

**B. Microbiology.** The *Vibrionaceae* share many characteristics with the *Pseudomonadaceae* and the *Enterobacteriaceae*. Genera in this family that cause human disease include *Vibrio*, *Aeromonas*, and *Plesiomonas*. The genus *Vibrio* consists of gram-negative bacilli that are straight or curved and are motile usually by means of a single polar flagellum. Most species are oxidase producers, have the ability to ferment glucose, and can grow in the presence or absence of oxygen.

During cholera outbreaks, the clinical diagnosis may be supported by examination of the stool. In cholera, a preponderance of straight-to-curved gram-negative bacilli with a single polar flagellum may be seen. In wet preparations, these exhibit a characteristic darting or "shooting star" motility. Motility inhibition, after exposure to type-specific antiserum, confirms the identity of these organisms.

The culturing of *V cholerae* from stool is most effectively achieved with TCBS agar. The colonies of *V cholerae* are able to ferment the sucrose in TCBS and appear yellow. Suspicious colonies should be subcultured to a nonselective agar, such as blood or chocolate agar, and after sufficient growth is present, oxidase testing and agglutination testing with polyvalent *V cholerae* antiserum can be performed.

*V cholerae* and a closely related species, *V mimicus*, unlike other *Vibrio* species, are able to grow in nutrient broth without 1% NaCl supplementation. Additional biochemical features, such as the ability to decarboxylate lysine and ornithine and the inability to hydrolyze arginine, are characteristics that may help to separate *V cholerae* and *V mimicus* from other vibrios. *V cholerae* and *V mimicus* may be easily separated, since *V cholerae* ferments sucrose, while *V mimicus* does not.

## CLINICAL SYNDROMES

### Introduction

Cholera is a fulminant diarrheal disease caused by *V cholerae* ([Box 57-1](#)). Patients with cholera develop frequent, watery stools, which may reach volumes =1 L/h. If these patients are untreated, they will develop rapid dehydration and electrolyte abnormalities, which may result in death within hours from the onset of disease. Therefore cholera is a medical emergency.

*V cholerae* is noninvasive and produces diarrhea by the elaboration of a potent enterotoxin. This enterotoxin consists of two subunits that have been well characterized. The circular, pentameric B-subunit binds monosialosyl ganglioside residues on the surface of the intestinal epithelial cell and introduces the enzymatic A-subunit into the cytoplasm. The A-subunit functions as an adenosine diphosphate (ADP) ribosylase and transfers an ADP-ribose moiety from cytoplasmic nicotinamide adenine dinucleotide (NAD) to the cell-membrane-associated adenylate cyclase. ADP-ribosylation renders adenylate cyclase unresponsive to feedback inhibition. The result is dramatically increased intracellular cyclic adenosine monophosphate (cAMP) levels. Elevated cytoplasmic cAMP levels cause massive fluid and electrolyte transit into the bowel lumen, resulting in the characteristic "rice water" stool of cholera.

## Clinical Findings

**A. Signs and Symptoms.** Patients with cholera initially develop increased peristalsis, a feeling of fullness, and occasionally vomiting. Diarrhea develops rapidly and soon becomes watery. Abdominal pain and high fever are usually minimal or absent and distinctly disproportionate to the amount of diarrhea. Fever, when present, is usually caused by dehydration. Electrolyte abnormalities, from voluminous diarrhea, may manifest as muscle weakness, intestinal ileus, or even cardiac dysrhythmia. The clinical manifestations of infection and the possibility of severe complications correlate with the patient's hydration and electrolyte abnormalities. Mental status changes secondary to hypoglycemia may also occur. Without urgent fluid and electrolyte replacement therapy, hypovolemic shock and death may occur rapidly.

**B. Laboratory Findings.** The stool from patients with cholera tends to lose its fecal odor as the disease progresses and may develop a sweet odor. Also, as the disease progresses and normal fecal material is passed, the stool becomes watery, turbid, and gray. Small flecks of mucus in this gray water give these stools their "rice water" appearance. Blood and neutrophils are generally not present in choleric stools. In the appropriate clinical and epidemiological context (eg, during outbreaks of cholera), a direct examination of stool can be useful for the presumptive identification of *V cholerae*. A microscopic examination of stool that discloses straight or curved bacilli with rapid, darting, or "shooting star" motility is suggestive of *V cholerae*. Inhibition of the motility of the organism by *V cholerae* O1 antiserum further supports the diagnosis of cholera.

Stool from patients with diarrheal disease suspected to be caused by *V cholerae* should be cultured on a selective and differential media, such as TCBS. Latex agglutination and ELISA-based methods to detect the presence of cholera toxin have been developed. These methods are rapid and may be useful in rapidly detecting patients with cholera in the early phases of disease. Polymerase chain reaction based methods of organism detection have been used successfully to detect *V cholerae* nucleic acids from choleric stools.

**C. Imaging.** Rarely, patients with cholera may develop an ileus as an early manifestation of disease. Abdominal imaging techniques are especially important in such patients since excessive fluid accumulation and visceral rupture may occur.

**D. Differential Diagnosis.** *Salmonella* species, *Shigella* species, *Yersinia enterocolitica*, *Campylobacter* species, and the enteric pathogenic *E coli*; viruses such as rotavirus and Norwalk agent; and parasites, such as *Giardia lamblia* and species of *Cyclospora* and *Cryptosporidium* are common pathogens that should be considered in the differential diagnosis of diarrheal disease. The diagnosis of these pathogens is achieved by a careful history combined with laboratory testing.

**E. Complications.** Profound dehydration and hypoglycemia may result in altered mental status, unconsciousness, seizures, and renal failure. Electrolyte abnormalities may manifest as muscle weakness, intestinal ileus, or sudden death caused by cardiac arrhythmia. Vomiting exacerbates the dehydration, makes oral rehydration difficult, and may lead to aspiration pneumonia. During pregnancy the fluid and electrolyte

imbalances may result in fetal death.

Rarely, patients with cholera may develop an intestinal ileus. These patients may accumulate large amounts of fluid in the lumen of the intestine. When this occurs at the onset of disease, the patient may be suspected to have an acute abdomen and cholera may not be suspected. If an ileus develops later in the course of disease and stool volume is used as a basis of fluid replacement, these patients may be inadequately rehydrated and viscus rupture could occur.

## Treatment

**A. Primary Therapy.** Primary therapy of cholera consists of fluid and electrolyte replacement. Published guidelines for fluid and electrolyte replacement in cholera are available. Either a citrate (10 mmol/L)- or bicarbonate (30 mmol/L)-based solution may be used for oral rehydration. These should contain sodium (90 mmol/L), potassium (20 mmol/L), chloride (80 mmol/L), and glucose (111 mmol/L). The glucose is actively transported into enterocytes. This osmotically drives water from the lumen and into the body. In developing countries, the water residua from boiled rice may be used for rehydration. This is an inexpensive and excellent source of oligosaccharides, which like glucose, aid in the osmotic shifting of water from the lumen to the body.

Intravenous fluid replacement therapy is necessary for patients with severe dehydration (=10% of their body weight) and acidosis (pH <7.2). These patients should be rehydrated with 50% normal saline with 44 mmol/L of bicarbonate. Potassium replacement may be given as needed.

If vomiting is not prominent, oral replacement is usually adequate. If mental status changes are present, hypoglycemia should be treated with intravenous glucose infusion (bolus 3-4 mL/kg of a 25% glucose solution, followed by continuous infusion of 10 mg/kg/h).

**B. Antimicrobial Therapy.** Treatment with tetracycline will shorten the duration of cholera ([Box 57-2](#)). Pregnant women and children who develop cholera should be treated with ampicillin. If allergies to penicillin exist, trimethoprim-sulfamethoxazole and furazolidone are also effective.

## Prognosis

The prognosis for patients infected during cholera epidemics is often poor. This directly parallels the lack of basic medical care, such as fluid and electrolyte replacement, which exists in the situations that foster epidemic cholera. If patients with cholera are given appropriate fluid, electrolyte, and glucose replacements, the prognosis is good. In many instances, the fluid replacement is roughly based on the volume lost. Patients who are not recognized to have an intestinal ileus may fare poorly. These patients may initially be misdiagnosed or if recognized to have cholera may not receive adequate fluid and electrolyte replacement.

## Prevention & Control

A clean water supply and effective sanitation are essential for preventing epidemic cholera. The economic means for effective waste disposal and preventive healthcare are not available to the impoverished; therefore cholera persists. In sporadic cases, patient isolation with appropriate waste disposal and hand washing are important means of preventing the spread of disease.

Two vaccines are currently being studied for high-risk individuals to use. These are a B-subunit, killed whole-cell vaccine (BC-WC) and a live, recombinant attenuated, orally administered vaccine (CVD 103-HgR). These vaccines may offer some protection, but they are not an alternative for clean water. In refugee-type settings, in conjunction with preventive measures, these vaccines may help to diminish the spread and mortality of cholera.

## OTHER *VIBRIO* INFECTIONS

### Essentials of Diagnosis

- History of ingestion of raw or possibly undercooked shellfish and/or exposure to seawater.
- Enteritis: acute onset of predominantly watery diarrhea, which may contain blood and/or neutrophils.
- Extraintestinal: cellulitis, wound infections, or septicemia, which may be associated with multiple bullous to ulcerative skin lesions, especially in patients with liver cirrhosis.
- Culture of etiologic agent, with enhanced growth of most species after NaCl supplementation.

### General Considerations

**A. Epidemiology.** In the United States and other developed countries, *Vibrio*-associated disease is caused almost exclusively by species other than *V cholerae*. These vibrios are normal inhabitants of marine environments and are transmitted to humans through the ingestion of raw or undercooked shellfish, through the contamination of foods by seawater, or through exposure to seawater. These organisms may cause gastroenteritis, soft tissue infections, or both. Diseases caused by these organisms usually occur during summer or early fall. The warmer summer waters may enhance the growth of vibrios and water-associated recreational activities increase the risk of exposure.

**B. Microbiology.** As may be expected, the vast majority of these marine vibrios require NaCl for optimal growth. In many instances, these organisms may grow suboptimally on general agar media, unless they are supplemented with NaCl. They grow better on media that contain salt, such as MacConkey and TCBS agar. On MacConkey agar, most of these organisms do not ferment lactose and would be considered possible enteric pathogens. Notable exceptions are *Vibrio mimicus* and *Vibrio vulnificus*, which are lactose positive and may be overlooked as normal enteric flora. *V mimicus* has many biochemical characteristics similar to *V cholerae* and also grows readily without

additional NaCl. *V mimicus* is readily differentiated from *V cholerae* on TCBS agar, by its inability to ferment sucrose. The most common vibrio enteric pathogen in the United States, *V parahaemolyticus*, also is sucrose negative.

If a vibrio infection is suspected, TCBS agar should be used for the detection of possible pathogens. This selective and differential medium inhibits growth of many commensal organisms by the presence of bile (oxygall), sodium cholate, and sodium citrate, while the presence of sucrose and the indicator bromthymol blue allow for the differentiation of sucrose fermenters and nonfermenters. *V cholerae*, *V alginolyticus*, and a few other less commonly encountered vibrios are sucrose positive, whereas *V parahaemolyticus*, *V vulnificus*, and most of the remaining clinically significant isolates are sucrose negative.

Vibrios are facultative anaerobic gram-negative bacilli, which may appear pleomorphic in Gram stains. The clinically relevant *Vibrio* species may be subcategorized into six groups based on their growth requirements and ability to perform certain biochemical tests. The key biochemical reactions necessary to separate the vibrios into these six groups include the following: (1) the requirement of NaCl for growth in nutrient broth; (2) oxidase production; (3) nitrate reductive capacity; (4) *myo*-inositol fermentation; and (5) the presence or absence of arginine dehydrolase, lysine decarboxylase, and ornithine decarboxylase. Additional biochemical reactions may be used for complete speciation.

These tests are used in the microbiology laboratory to exclude certain diagnostic possibilities. Most vibrios are oxidase positive, with the exception of *V metschnikovii*. With the exception of *V cholerae* and *V mimicus*, isolates require 1% NaCl supplementation to adequately perform biochemical tests. The six groups are as follows:

- Group 1 consists of *V cholerae* and *V mimicus*. These are readily distinguished from the other vibrios by their ability to grow in nutrient broth, without NaCl supplementation.
- Group 2 consists of *V metschnikovii*, which is differentiated from other vibrios by its inability to produce oxidase and reduce nitrate to nitrite.
- Group 3 consists of *V cincinnatiensis*, which is differentiated from other vibrios by its ability to ferment *myo*-inositol.
- Group 4 consists of *V hollisae*, which is differentiated from other vibrios by its inability to hydrolyze arginine and to decarboxylate lysine and ornithine.
- Group 5 consists of *V damsela*, *V fluvialis*, and *V furnissii*. Unlike some of the other vibrios, this group produces arginine dihydrolase.
- Group 6 consists of *V alginolyticus*, *V parahaemolyticus*, *V vulnificus*, and *V carchariae*. These organisms are differentiated from other vibrios by a combination of their ability to produce lysine decarboxylase and their inability to hydrolyze arginine.

## **CLINICAL SYNDROMES**

Noncholera vibrios cause both enteritis and extraintestinal disease ([Box 57-3](#)). In the United States, *Vibrio* species other than *V cholerae* are far more common causes of *Vibrio*-associated gastroenteritis. These agents include *V parahaemolyticus*, *V mimicus*, *V hollisae*, and others. The enteritis caused by these organisms is characterized by fever, mild-to-moderate abdominal pain and cramping, and diarrhea, which may be either watery or bloody. Many of the pathogenic, noncholera vibrios are also halophilic (NaCl enhances growth) and have been associated with the consumption of raw or undercooked shellfish. *V parahaemolyticus* is the most common cause of shellfish-associated gastroenteritis in the United States. In most instances, the enteritis is self-limited, but complications may occur. Septicemia with severe morbidity and death has occurred following noncholera *Vibrio* gastroenteritis.

Extraintestinal disease may be caused by *V vulnificus* or *V alginolyticus*. These organisms are also halophilic and are associated with shellfish ingestion and saltwater exposure. Manifestations of extraintestinal disease may include wound infections, cellulitis, bullous skin lesions, or septicemia. Patients with cellulitis and wound infections caused by these organisms often report exposure to saltwater. In immunocompromised patients, such as those with cirrhosis or diabetes mellitus, fatal septicemia may occur. If these organisms are suspected clinically, the clinician should notify the laboratory, since NaCl supplementation is required for optimal growth.

## NONCHOLERA GASTROENTERITIS

### Clinical Findings

**A. Signs and Symptoms.** Noncholera gastroenteritis is often associated with recent ingestion of raw or undercooked shellfish and often occurs in the summer or early fall in the United States. A typical presentation includes explosive diarrhea, low-grade fever and chills, and mild-to-moderate abdominal pain with cramping. The diarrhea is usually watery but may contain blood and neutrophils.

Dehydration is not as severe as that seen with *Vibrio cholerae* infections, but deaths may occur in children and the elderly. The incubation period is ~ 1 day but ranges from 5 h to 4 days. The diarrhea produced is probably secondary to a combination of exotoxin production and superficial invasion. The patients in which exotoxin production predominates may demonstrate a more watery stool. When mucosal invasion occurs, a dysenteric stool similar to that present in shigellosis may be seen. Secondary spread of these organisms is rare.

**B. Laboratory Findings.** Dehydration and electrolyte abnormalities are usually less severe than those present in cholera but may become profound in children and the elderly. Culture and biochemical identification of the isolate is the standard method of establishing the etiologic agent of disease. The key biochemical reactions for rapidly subcategorizing *Vibrio* species are listed in the Microbiology section. Many of the group characteristics are based on an organism's ability to perform particular biochemical tests. Therefore it is important to remember that 1% NaCl supplementation is required for some organisms to adequately perform biochemical reactions. NaCl enrichment broths or tellurite-taurocholate-peptone broth may be used for enhanced recovery of these organisms.

**C. Differential Diagnosis.** See differential diagnosis for *V cholerae* infection.

## EXTRAIESTINAL DISEASE

### Clinical Findings

**A. Signs and Symptoms.** Patients with septicemia, wound infections, or ear infections caused by a *Vibrio* species frequently have a history of shellfish ingestion or saltwater exposure. Clinical manifestations vary depending on the site of infection. Healing wounds, in appropriately exposed individuals, may become secondarily infected by marine vibrios. Suppuration may occur, and subcutaneous abscesses may form. A spreading, violaceous appearance around the wound, which is warm to the touch is indicative of cellulitis. The clinical findings of *V alginolyticus*-associated otitis media are nonspecific. Findings in *V alginolyticus*-associated otitis externa include a reddened, often painful external auditory canal.

In immunocompromised and debilitated patients, especially those with liver cirrhosis, a septicemia syndrome, with multiple bullous skin lesions may occur. This is usually caused by *V vulnificus* and is often fatal. *V vulnificus*, which may be introduced by the ingestion of raw or undercooked shellfish, may transmigrate the intestinal mucosa and invade the bloodstream with little or no gastrointestinal symptomatology. Infected patients often develop signs and symptoms of septic shock, such as fever, chills, and hypotension. Shortly thereafter, erythematous skin lesions occur, which develop into hemorrhagic vesicles-bullae and finally ulcerate. Although this syndrome is rare, it is important to recognize it, since its mortality rate is ~ 50%.

**B. Laboratory Findings.** Hematopoietic findings are variable and may demonstrate either leukocytosis or leukopenia with left-shifted hematopoiesis. The isolation of vibrios from patients with extraintestinal disease is usually not difficult. The selective and differential agars are not required since the sites of culture are normally sterile. Vibrios causing extraintestinal disease are usually isolated on routine 5% sheep's blood agar. If an extraintestinal *Vibrio* infection is suspected, the microbiology laboratory should be notified. The supplementation of media with 1% NaCl may aid in the more rapid identification of the *Vibrio* species.

**C. Imaging.** Ultrasound or computerized tomography guidance may be useful for identifying and assisting in drainage of deep abscesses.

**D. Differential Diagnosis.** Improperly cared for wounds may be colonized and infected by a variety of bacteria. When these wounds have been exposed to salt water or the patient has recently eaten raw or undercooked shellfish, a vibrio infection should be considered.

Although immunocompromised patients may be infected by a variety of microbes, an extraintestinal vibrio infection should be considered when skin lesions and a sepsislike syndrome are present in association with the recent ingestion of raw or undercooked shellfish.

**E. Complications.** The diarrhea that results from noncholera vibrio infections rarely results in significant dehydration, except in children and the elderly. The hydration status of pregnant women should be carefully monitored to prevent severe dehydration and possible fetal loss.

Extraintestinal vibrio infections may result from septicemia following ingestion of raw shellfish or from direct inoculation of marine vibrios. If septicemia occurs, metastatic foci of infection may be present in virtually any organ. The consequences of extraintestinal vibrio infections during pregnancy are unclear because of the paucity of cases.

## Treatment

**A. Primary Therapy.** Enteritis caused by *V parahaemolyticus* is usually self-limited and requires no therapy. In severe cases of noncholera *Vibrio* gastroenteritis, the principles of cholera therapy should be followed. Patients with extraintestinal disease due to *V vulnificus*, and *V alginolyticus* should undergo appropriate wound debridement and abscess drainage as indicated and should be treated with antimicrobial agents ([Box 57-4](#)). Patients with systemic symptomatology may also require extensive supportive measures for survival.

**B. Antimicrobial Therapy.** Antimicrobial therapy does not shorten the duration of noncholera enteritis and is not recommended in uncomplicated cases. If enteritis is complicated by septicemia, specific antimicrobial therapy should be determined based on the antimicrobial susceptibility profile.

Extraintestinal vibrio infections may be treated with tetracycline, cefotaxime, or possibly ciprofloxacin until the antimicrobial susceptibility profile becomes available.

## Prognosis

The prognosis for noncholera gastroenteritis is usually excellent. The prognosis may become guarded in children, the elderly, and pregnant women with severe dehydration.

If appropriate surgical and medical therapy is given, the prognosis for extraintestinal *Vibrio* infections is usually good in the immunocompetent host. In immunocompromised patients, especially those with cirrhosis or diabetes mellitus, the prognosis is guarded to poor.

## Prevention & Control

Noncholera vibrio enteritis and many cases of extraintestinal vibrio infections may easily be avoided by abstinence from raw shellfish ([Box 57-5](#)). The thorough cooking of shellfish renders it safe for consumption. Regardless of the hazards, raw oysters and clams remain popular in many parts of the world. Warnings concerning the possible health hazards should be posted in plain view in restaurants that serve these dishes, and additional caution should be directed specifically to individuals with liver disease or other immunocompromising conditions. Individuals with healing wounds should avoid exposing the wounds to seawater.

Large-scale commercial oyster and clam farming is becoming more established. In the future, this may present additional hazards. The colonization of an entire mollusk bed by pathogenic vibrios could occur if abundant shellfish are present in close proximity. Additionally, the spread of pathogenic vibrios among mollusk beds could result if numerous beds are located in close proximity. This could result in large numbers of contaminated shellfish being present in the same harvest and could result in epidemics. Therefore, in the future, adequate monitoring systems may be needed more than ever before to prevent possible outbreak situations.

## CAMPYLOBACTER INFECTIONS

### Essentials of Diagnosis

- History of ingestion of appropriate foodstuffs.
- Causes enteritis, characterized by rapid onset of watery to bloody diarrhea with low-grade to moderate fever and moderate-to-severe abdominal cramping.
- Extraintestinal infections include sepsis, thrombophlebitis, endocarditis, and infection of aortic aneurysm.
- Laboratory isolation of a gram-negative "seagull" shaped bacteria, which becomes coccoid as the culture ages.
- These bacteria grow optimally in a microaerophilic, 5-10% oxygen environment; the growth of some species is enhanced by culture at 42 °C.

### General Considerations

**A. Epidemiology.** *Campylobacter* species are intestinal commensals in many animals, including cattle, pigs, sheep, chickens, and turkeys. Contamination of foodstuffs during meat and dairy processing is thought to significantly contribute to the spread of disease. Unpasteurized dairy products, undercooked meats, and contaminated water serve as the vehicles for *Campylobacter* and other bacterial pathogens. Human-to-human transmission by way of a fecal-oral route or through contaminated blood is also possible.

In developing countries where overcrowding and poor sanitation conditions exist, the carriage rate of *Campylobacter jejuni* from healthy individuals is much higher and human-to-human transmission may be greater. *Campylobacter* is one of the etiologic agents of the infantile and childhood diarrhea diseases in developing countries. Although carrier rates are elevated in adults, symptomatic disease is less common; this is presumably because of enhanced immunity. In tropical climates, the incidence is higher during the rainy season and may be related to the corresponding overcrowding and contamination of local water supplies.

In developed countries, the carriage rate is very low (< 1%). This may result from more effective treatment of human waste, requisite pasteurization of dairy products, and educational efforts regarding the thorough cooking of meat products. In developed

countries, campylobacteriosis tends to occur sporadically and year round, with peak incidence in months of the spring or fall. In many instances, infections can be linked to the ingestion of undercooked meats, contaminated milk, or contaminated water supplies.

**B. Microbiology.** *Campylobacter* are weakly gram-negative, curved or "seagull" shaped bacteria, with single polar flagella ([Figure 57-1](#)). Although usually bacillary, many *Campylobacter* species become coccoid as the culture ages. Special culture conditions, including selective media, a microaerophilic environment (5-10% oxygen), and for some species, culture at 42 °C (vs 35-37 °C), are required for optimal recovery of *Campylobacter* species.

Several *Campylobacter* species cause human disease ([Box 57-6](#)). *C jejuni* and *C fetus* are the prototypic etiologic agents for enteric and extraintestinal disease, respectively. [Table 57-1](#) shows the principal biochemical reactions used to separate these and other *Campylobacter* species.

**C. Pathogenesis.** Establishment of infection in the small bowel and colon requires that an adequate inoculum is ingested and sufficient organisms survive after passage through the stomach and that the organisms attach and possibly invade enterocytes. Studies with volunteers have shown that as few as 500-1000 organisms may cause disease. Approximately 9000 organisms reportedly provide the highest illness-to-infection ratio; however, strain variation occurs.

Like *Salmonella*, *Campylobacter* organisms are susceptible to hydrochloric acid. Entry with foods that buffer stomach acid is important for gastric passage of viable organisms. *C jejuni* thrives in the small intestine and colon and is able to replicate in human bile. Infection is initiated by adhesion and colonization. Bacterial proteins that are important for this phase of infection include the superficial bacterial antigen PEB1, and possibly the newly characterized periplasmic binding protein P29. Peritrichous, piluslike structures that are present only when the organism is grown in the presence of bile, may also aid in adhesion.

Motility and the adhesion properties of the flagellar protein flagellin are additional virulence factors important for bacterial infection. The pathologic changes in the bowel wall and the occasional detection of *C jejuni* bacteremia are highly suggestive of bacterial invasion. Mild infections may show only an increased cellularity of the lamina propria due to neutrophils, lymphocytes, plasma cells, and histiocytes. Severe cases may disclose exudative enteritis with ulceration and crypt abscesses.

Extracellular toxins that cause cytopathic changes have been demonstrated. Additionally, a choleralike exotoxin has been suggested as a mechanism of diarrhea. The importance of these toxins remains to be elucidated, since non-toxin-producing strains have also been shown to cause disease.

*C fetus* is the *Campylobacter* species most frequently isolated from blood and is an important agent of extraintestinal disease. Enhanced invasion in a mouse model has been associated with the presence of a surface S protein. The S protein serves as a capsule and imparts an antiphagocytic property to the bacterium. This antiphagocytic

property is due in part to the inhibition of the opsonizing complement component C3b. The S protein is antigenically variable as a result of rearrangements between highly homologous protein-encoding genes.

## CAMPYLOBACTER ENTERITIS

### Clinical Findings

**A. Signs and Symptoms.** The incubation period for *Campylobacter* enteritis is between 1 and 7 days. The rapidity of onset and the severity of disease appear to be related to the inoculating dose. Prodromal fever, headache, malaise, and myalgias are often present 1-2 days before the onset of diarrhea. *Campylobacter*-induced diarrhea is variable in consistency and ranges from watery to bloody. The diarrhea is often accompanied by a low-grade to moderate fever and moderate-to-severe abdominal cramping, which is relieved by defecation. The disease is usually self-limited over several days; however, relapses can occur in 5-10% of untreated patients.

**B. Laboratory Findings.** Direct examination of stool specimens often demonstrate curved, vibriolike rods with a characteristic darting motility. Leukocytes are present in 75% of patients with *Campylobacter* enteritis. Culture on selective media with incubation at 42 °C, in a microaerophilic environment, is used for the enhanced detection of most of the enteropathic *Campylobacter* species ([Figure 57-2](#)). The most common causes of *Campylobacter* enteritis, *C jejuni* and *C coli*, both grow well at 42 °C in a microaerophilic environment and are resistant to cephalothin. Therefore a selective antibiotic media containing cephalothin is often used. Under these conditions, colonies appear gray and spreading and are oxidase positive. Gram stain reveals gram-negative, curved organisms. The differentiation of *C jejuni* from *C coli* depends principally on the ability of the isolate to hydrolyze hippurate (*C jejuni* subspecies *jejuni* hydrolyzes hippurate and *C coli* do not). These techniques, however, will not identify the far rarer cases of enteritis caused by *C fetus* and some other *Campylobacter* species, which do not grow well at 42 °C and are inhibited by cephalothin.

## EXTRAIESTINAL CAMPYLOBACTERIOSIS

### Clinical Findings

**A. Signs and Symptoms.** *Campylobacter fetus*, a less frequent cause of enteritis, is the most common cause of extraintestinal disease; other *Campylobacter* species that may also cause extraintestinal disease include *C jejuni*, *C coli*, *C laridis*, *C sputorum*, and *C hyointestinalis*.

*C fetus* infection may manifest as fever, chills, and myalgias, without definitive localization; additionally, this organism displays a propensity to infect vascular structures. Endocarditis, intravascular infection of abdominal aortic aneurysms, and septic thrombophlebitis with vessel necrosis have been reported. Fetal death, even with appropriate antibiotic therapy, may occur. Fetal complications most commonly occur during the second trimester of pregnancy. Additional manifestations may include pericarditis, meningoencephalitis, septic arthritis and osteomyelitis, spontaneous bacterial peritonitis, salpingitis, empyema, and cellulitis.

**B. Laboratory Findings.** In cases of suspected extraintestinal campylobacteriosis, cultures should be plated on nonselective 5% sheep's blood agar and incubated at 37 °C in a microaerophilic environment. Subcultures from blood culture broth systems should be handled in a similar fashion. Identification of *C fetus* may be accomplished by testing susceptibility to cephalothin (susceptible), growth inhibition at 42 °C, positive catalase reaction, and characteristic Gram stain morphology.

### Differential Diagnosis

The differential diagnosis for *Campylobacter* enteritis includes all enteric bacterial, viral, and parasitic pathogens. This differential is usually resolved by clinical history, stool culture, ova and parasite examination, and, if necessary, viral testing (ELISA, culture, or electron microscopy).

The differential diagnosis for extraintestinal campylobacteriosis varies according to the site involved. Although *C fetus* may be identified by routine blood culture methods, the incubation conditions used are not optimal for isolation. A high index of suspicion must be maintained since special bacterial culturing techniques may be necessary for optimal recovery of the organism.

### Complications

Like other bacterial enteritides, complications of *Campylobacter* enteritis include volume depletion and electrolyte imbalances. Patients with an HLA-B27 phenotype may develop postinfectious arthropathies (Reiter's syndrome) similar to that produced by other bacterial enteric pathogens. Guillain-Barre syndrome rarely occurs following *Campylobacter* enteritis. Guillain-Barre syndrome has been associated with autoantibodies directed to *N*-acetylgalactosaminyl GD1a, GD1b or similar epitopes. Similar epitopes have been shown to occur in the lipopolysaccharides of *C jejuni* and may represent the immunogenic stimulus.

Extraintestinal disease may occur as the result of septicemia and include septic thrombophlebitis, abscess formation, and endocarditis.

### Treatment

Fluid and electrolyte replacement therapy is of principal importance ([Box 57-7](#)). The benefit of antibiotic therapy for enteric campylobacteriosis remains to be determined. Antibiotic treatment is indicated in patients with high fever, bloody stools, worsening clinical symptoms, or greater than eight stools per day. Erythromycin is the drug of choice for children. Ciprofloxacin is an alternative therapy for adults. Point mutations in the DNA gyrase gene, *gyrA*, have been shown to confer quinolone resistance. This may occur during therapy; therefore both antimicrobial susceptibility data and close clinical follow-up are required.

Parenteral antibiotics should be administered for extraintestinal disease based on the results of antimicrobial susceptibility testing. Endocarditis requires at least 4 weeks of therapy. Depending on susceptibility, central nervous system infections should be

treated with ampicillin, a third-generation cephalosporin, or chloramphenicol.

## Prognosis

Severe dehydration and electrolyte imbalances may cause death. This most frequently occurs in children, particularly in underdeveloped and impoverished areas that lack adequate healthcare. Long-term sequelae such as Reiter's syndrome or Guillain-Barre syndrome, although infrequent, may be disabling.

Extraintestinal disease caused by *C fetus* may contribute significantly to morbidity and mortality in immunocompromised patients. These patients may be at increased risk for bacterial enteric infections and associated extraintestinal disease. Infections may be persistent and more severe than in normal hosts. In these patients, the time to initiation of appropriate antibiotic therapy is an important prognostic indicator.

## Prevention

Pasteurization, washing foods when feasible, thorough cooking, and hand washing are useful preventive measures ([Box 57-8](#)).

## 58 . *Legionella* — Michael Bell, MD

### Essentials of Diagnosis

- Key signs and symptoms may include minimally productive cough, low-grade fever, headache, and altered mental status.
- Risk factors include smoking, advanced age, history of cardiac or pulmonary disease, male gender, and cell-mediated immune suppression.
- Common infections include pneumonia with multisystem involvement (Legionnaires' disease) and nonspecific febrile illness without pulmonary involvement (Pontiac fever).
- Gram stain of respiratory secretions may reveal numerous neutrophils without evident organisms.
- Aerobic, pleomorphic, faintly staining gram-negative rods are non-spore forming and unencapsulated.

### General Considerations

**A. Epidemiology.** More than 25 species and 48 serogroups of *Legionella* have been identified. *Legionella pneumophila* (especially serogroup 1) causes ~ 70-80% of cases of legionellosis, but *L micdadei*, *L bozemanii*, *L dumoffi*, *L feelei*, *L longbeacheii*, and other species are also pathogenic. The true incidence of legionellosis, which includes Legionnaires' disease and Pontiac fever, is difficult to establish. Although most developed countries conduct surveillance for infection, underdetection is common, in part because laboratory tests are often not performed or, when performed, lack sensitivity. Between 500 and 1500 cases in the United States are reported annually to the Centers for Disease Control and Prevention (CDC), but the true incidence is believed to be between 13,000 and 20,000 cases a year. Few population-based incidence studies have been conducted. Among members of a prepaid health plan in Seattle, Washington, the annual incidence was 12 cases per 100,000 between 1963 and 1975. In Nottingham, England, 1.4 cases per 100,000 population occurred annually between 1977 and 1991.

*Legionella* species have been detected in virtually all sources of fresh water, including lakes, ponds, rivers, and soil runoff, especially in areas where there is thermal pollution. However these natural water supplies are rarely identified as sources of human infection. Aerosols from artificial reservoirs of water, including cooling towers, evaporative condensers, air conditioners, humidifiers, fountains, and whirlpool spas, are most often implicated in outbreaks. Cooling towers and evaporation condensers are especially prone to *Legionella* colonization because they recycle warm, unfiltered water and accumulate organic debris and biofilm over time. This milieu supports the growth of other microflora, including amoebae. Amoebae may be essential to the life cycle of *Legionella* species; the organism appears to multiply intracellularly in these protozoa in the same way it multiplies in human monocytes. Removal of amoebae by filtration will

also eliminate viable *Legionella* species from water reservoirs.

Potable-water (especially hot-water) distribution systems are also important reservoirs supporting growth of *Legionella* species. Environmental sampling in hospitals, hotels, and homes has demonstrated colonization in 10-50% of hot-water faucets or water heaters, even at sites where no cases of legionellosis have occurred. Electric water heaters are especially prone to colonization because, unlike gas systems that apply heat to the bottom of the tank, electrical heating elements are in the sides of the tank. The temperature of the sediment deposited in the bottom of the tank is thus cool enough to support growth of the organism. Temperature appears to influence the risk of *Legionella* colonization in all water systems. Growth is promoted between 35 °C and 45 °C, and organisms may remain viable at temperatures = 66 °C.

*Legionella* species are transmitted to humans through aspiration, inhalation, or instillation of infected water. There is no evidence to support person-to-person transmission. Cooling-tower exhausts proximate to air conditioning intake vents are an important cause of large outbreaks among occupants of hospitals, hotels, and other buildings. Transmission to persons residing as far as 1-2 miles from the cooling towers has also been suggested. Residential air conditioners that do not use water for cooling do not promote *Legionella* transmission, but home air humidifiers probably do. Showers, faucets, and respiratory therapy equipment have also been sources of outbreaks. One major outbreak of Legionnaires' disease on a cruise ship, involving at least nine separate week-long cruises, was associated with contamination of a whirlpool spa. The water taken aboard the ship probably contained *L pneumophila*, but the potable water supply was properly disinfected (chlorinated) before consumption. However, the water reserved for the spa was not adequately decontaminated by the brominator. *L pneumophila* colonized the organic debris trapped in the sand filter of the spa, creating the potential for infectious aerosols that caused exposure and infection among passengers. In another important outbreak, the humidification mist used to preserve vegetables in a grocery store was linked to transmission of legionellosis to several shoppers.

The sources of sporadic cases of *Legionella* infection are not clear, although > 65% of known cases are not associated with outbreaks. Given the enormous number of potential water sources, it is not surprising that establishing a source of exposure is difficult in the absence of an obvious outbreak. As mentioned above, persons residing near cooling towers may be at increased risk. Tobacco use, alcohol abuse, and conditions that affect pulmonary defense mechanisms are risk factors for legionellosis. Some experts believe that aspiration of infected potable water may be an important source of sporadic and also epidemic legionellosis.

Nosocomially acquired Legionnaires' disease accounts for ~ 23% of all cases reported to CDC. After one case of nosocomial infection is identified, subsequent cases are usually detected. Hence, the CDC recommends that identification of one definite or two possible cases of nosocomial Legionnaires' disease within 6 months should prompt an epidemiologic investigation and intensified surveillance. The capacity of *Legionella* species to colonize hospital plumbing systems for prolonged periods provides an ongoing source for transmission to patients. In older facilities or in those in which renovation results in areas of water stagnation and build-up of organic and inorganic

sediments, *Legionella* colonization is not uncommon. In one recent investigation, the hospital water distribution system was associated with cases of Legionnaires' disease among immunosuppressed patients over a period of 17 years. Mortality from nosocomially acquired Legionnaires' disease in the United States is ~ 40%, compared with 20% for community-acquired cases.

**B. Microbiology.** *Legionella* species are slender, aerobic gram-negative bacilli that may appear as coccobacilli measuring 1-2  $\mu\text{m}$  in clinical specimens. *Legionella* species are fastidious; visible colonies appear on agar only after 2-7 days of culturing at 35 °C. Buffered charcoal yeast extract agar is the preferred culture medium. *Legionella* species are not encapsulated and do not form spores. They are catalase positive and oxidase negative.

**C. Pathogenesis.** *Legionella* species reach the lower respiratory tract via aspiration, inhalation, or instillation of infected water. They are facultative intracellular bacteria that infect host alveolar macrophages and reside within ribosome-lined phagocytic vacuoles. Much as the organism evades the lysosomal defenses of host amoebae, it interferes with macrophage lysosomal fusion and multiplies within that cell's phagosome. New bacilli are released when the infected macrophage ruptures. This process initiates the inflammatory response and pulmonary infiltrates that are the hallmark of Legionnaires' disease. Humoral antibodies develop in infected persons as well as those with subclinical exposures, but they do not appear to be protective. However, cell-mediated responses may confer resistance to subsequent infections. Cytokine production, which activates macrophages and enhances intracellular killing of *Legionella* species, may also be an important host defense.

## CLINICAL SYNDROMES

### INTRODUCTION

*Legionella* species are associated with outbreaks of either Pontiac fever, a self-limited influenzalike condition in otherwise healthy people, or Legionnaires' disease, a severe pneumonic disease more common among elderly and immunocompromised individuals ([Box 58-1](#)). The spectrum of illness is much broader than these two clinical entities suggest, ranging from completely asymptomatic infection to fulminant respiratory failure and death.

#### 1. PONTIAC FEVER

In 1968, the first documented outbreak of Pontiac fever syndrome affected people in a health department building in Pontiac, Michigan. Epidemiologic investigation demonstrated that the infection was airborne and implicated water aerosols that were produced by a faulty air conditioning system as the source of exposure. Sentinel guinea pigs exposed to air in the building developed bronchopneumonia, and lung tissue cultures grew *L pneumophila* (serogroup 1). Paired acute and convalescent serum specimens from 37 patients were tested by the indirect fluorescent antibody technique, using *L pneumophila* serogroup 1 antigen, and 31 (84%) had rises in titer from < 32 to = 64. Since that time, numerous outbreaks of Pontiac fever, almost always attributable to an obvious source of contaminated water, have been detected in communities across

the country.

Pontiac fever is a self-limited infection characterized by fever, chills, headache, myalgia, fatigue, and upper respiratory tract symptoms. It is not associated with a pneumonia or pulmonary infiltrates, although some patients do have a mild nonproductive cough. The incubation period is short, usually 36 h, and the attack rate is high (= 95%), even among individuals with no underlying illness. Patients recover spontaneously, usually within 1 week of symptom onset.

## 2. LEGIONNAIRES' DISEASE

### Introduction

*Legionella* species cause both community-acquired and nosocomial pneumonia among normal individuals, as well among those with depressed cell-mediated immunity (transplant recipients, patients treated with corticosteroids, and those with AIDS). Immunosuppressed patients, those who smoke tobacco, elderly persons, and patients with underlying cardiovascular and pulmonary illnesses are at increased risk. Men are two- to threefold more likely than women to acquire this infection.

Unlike Pontiac fever, for which the incubation period is short (1-2 days), the onset of Legionnaires' disease may occur = 14 days after exposure, although onset usually occurs within 2-10 days. The attack rate is also relatively low (< 8%), when compared with Pontiac fever.

**A. Signs and Symptoms.** The clinical severity of Legionnaires' disease is highly variable. In mild cases, dry cough and low-grade fever are predominant symptoms. Severe cases, especially among immunosuppressed patients, are complicated by multisystem organ failure and adult respiratory distress syndrome.

Early symptoms are nonspecific and do not distinguish Legionnaires' disease from other causes of pneumonia. Common symptoms include fever, headache, malaise, myalgia, nausea, anorexia, and a minimally productive cough. Neurologic symptoms in addition to headache include changes in mental status that range from lethargy to encephalopathy. Chest pain, which may be pleuritic, and modest hemoptysis are sometimes associated with this infection. Nausea, vomiting, and abdominal pain occur in a minority of patients.

**B. Laboratory Findings.** Laboratory abnormalities are nonspecific, although hyponatremia ( $\text{Na} < 130 \text{ mEq/L}$ ) is more likely in legionellosis than in other causes of pneumonia.

**C. Imaging.** Chest x-ray findings are almost always present by the third day of illness and tend to begin as a unilateral lower-lobe infiltrate. The infiltrate may progress despite antibiotic treatment, but the degree of radiographic abnormality does not correlate with severity of clinical illness. In one recent report, cardiac disease, diabetes mellitus, creatinine (= 1.8 mg/dL), septic shock, progressive infiltrates, mechanical ventilation, hyponatremia, and blood urea levels (= 30 mg/dL) were factors related to poor outcome, but appropriate antibiotic treatment and improvement in chest radiographic appearance

were favorable prognostic factors. Multivariate analysis showed that an Acute Physiology and Chronic Health Evaluation (APACHE II [see Rutledge et al, 1991]) score of = 15 at admission and severe hyponatremia were independent predictors of mortality.

**D. Differential Diagnosis.** The differential diagnosis includes pulmonary embolus as well as the usual bacterial and viral causes of pneumonia. A prospective study designed to identify factors that distinguished Legionnaires' disease from other causes of community-acquired pneumonia in the emergency department of a university hospital was recently published. Epidemiologic and demographic data and clinical, laboratory, and radiologic features of patients with Legionnaires' disease were compared with those of patients with community-acquired pneumonia caused by other bacterial pathogens. Legionnaires' disease was more frequent in middle-aged, healthy alcohol-drinking male patients than other causes of pneumonia. Lack of response to initial treatment with  $\beta$ -lactam antibiotic and headache, diarrhea, severe hyponatremia, and elevation in serum creatine kinase levels on presentation were also more common among patients with Legionnaires' disease. In contrast, cough, sputum production, and thoracic pain were less common in Legionnaires' patients than in other pneumonia patients. Multivariate analysis demonstrated that underlying disease, diarrhea, and elevation in the creatine kinase were independent predictors of Legionnaire's disease.

**E. Complications.** In the increasingly large population of immunocompromised individuals, *Legionella* species have been documented to cause extrapulmonary disease that can include cellulitis, wound infection, perirectal abscess, pancreatitis, pyelonephritis, peritonitis, hemodialysis fistula infection, pericarditis, myocarditis, and prosthetic valve endocarditis.

## Diagnosis

Diagnosis of *Legionella* infection depends on a high index of suspicion and special laboratory tests. Definitive diagnosis of legionellosis is based on recovery of the organism from respiratory secretions or tissues. Cultures of sputum, transtracheal aspirates, and blood are each 100% specific, although the sensitivities are 80%, 90%, and 20%, respectively. Pretreating respiratory specimens with acid and use of selective media can improve culture sensitivity. In special cases, coculture with amoebae or intraperitoneal inoculation of guinea pigs will increase the diagnostic yield.

Serologic comparison of acute and convalescent serum specimens demonstrating a fourfold rise in titer (= 128) of immunoglobulin G antibody (indirect fluorescent antibody assay) is > 95% specific when the *L pneumophila* serogroup 1 antigen is used (but less specific with other *Legionella* antigens) and demonstrates a sensitivity of ~ 50%. Clinical utility of serologic diagnosis is limited, however, because 4-12 weeks are required for the human body to mount a full antibody response. This test is therefore mainly useful as an epidemiologic tool.

Direct fluorescent antibody tests can identify *Legionella* antigens in respiratory specimens and tissue with a high degree of specificity, but, as with other tests, the direct fluorescent antibody test is not sensitive (< 60%). Commercially available tests for excreted urinary antigen detect only infections caused by *L pneumophila* serogroup 1, but because this serogroup accounts for > 70% of *Legionella* infections, they are useful

rapid tests in many clinical settings.

Finally, tests using polymerase chain reaction amplification of ribosomal RNA and DNA sequences specific to *L pneumophila* are now available and have been demonstrated to be sensitive and specific for confirming the presence of the organism in cultures. However, the sensitivity of these tests when performed on respiratory tract samples may not be better than that of direct fluorescent antibody tests, and their specificity is worse.

## Treatment

Erythromycin is the recommended treatment for Legionnaires' disease and other serious *Legionella* infections; however, failures have occurred, and adverse effects are common ([Box 58-2](#)). Erythromycins, intravenous azithromycin, and levofloxacin are currently approved by the US Food and Drug Administration for treatment of Legionnaires' disease. Although prospective controlled comparisons have not been performed, clarithromycin and quinolone antibiotics are also effective. Other agents with activity against *Legionellaceae* include doxycycline, minocycline, rifampin, and trimethoprim-sulfamethoxazole. For severe illness and for treatment of immunosuppressed patients, combination treatment either with rifampin plus a macrolide or quinolone or with a quinolone plus a macrolide (eg, levofloxacin plus azithromycin) is recommended.

## Prevention & Control

Isolation of patients with known or suspected *Legionella* infection is not required, because direct person-to-person transmission has not been observed ([Box 58-3](#)). Epidemiologic investigation of sporadic community-acquired cases of *Legionella* infection is not usually productive because of the large number of exposures to potential water sources. When a community outbreak is suspected, conventional epidemiologic methods (ie, case definition, hypothesis generation, and case control study) should be used to confirm the presence of an outbreak and identify the source of exposure. Samples from suspicious water reservoirs should be cultured, and in some cases the potential for these sources to produce aerosol particles in the respirable size range should be evaluated with an air particle-size sampler. Smoke or other tracer materials can be used to evaluate the movement of aerosols and routes of access to ventilation systems, air intake passages, or other modes of dispersion.

In cases of known or suspected nosocomial infection, a detailed environmental investigation of all sources of water exposure is often indicated, especially when two or more unexplained cases have occurred. In addition to evaluating water reservoirs in the facility (eg, cooling towers and evaporative condensers), respiratory-therapy equipment should be checked and procedures should be reviewed to identify occult sources of exposure to potable water. In addition, samples from the water distribution system (eg, showers, faucets, and taps) should be cultured for *Legionella* species.

It is very difficult if not impossible to decontaminate water supplies. Cooling towers and evaporative condensers must be drained, scoured to remove organic debris and sediment, and then disinfected with chlorine. Follow-up maintenance must include periodic chlorination or treatment with alternate disinfectants. Similarly, contaminated

water heaters should be drained, cleaned, and then disinfected. Superheating (> 60 °C) is also recommended for water heaters and distal water distribution systems. However, this procedure can result in severe scalding and must be used with caution. Hyperchlorination has also been used, but can result in high levels of trihalomethanes, which are putative carcinogens. Over time, hyperchlorination corrodes the plumbing system, leading to enhanced opportunities for sediments that promote the growth of *Legionella* species.

Metal ionization procedures are advocated by some, but are not known to work better than conventional methods. One copper-silver ionization system was sequentially installed onto the hot-water recirculation lines of two hospital buildings colonized with *L pneumophila* serogroup 1. A third building with the same water supply, also colonized with *L pneumophila*, served as a control. Within 4-12 weeks of application, the levels of detectable *L pneumophila* in the two treated systems dropped to zero, but remained positive in the untreated system. However, concentrations of copper and silver in excess of Environmental Protection Agency standards can accumulate at the bottoms of hot-water tanks subjected to this type of treatment. Its long-term effectiveness has not been determined.

In cases in which water treatments fail, the entire current and past water distribution system engineering and structural design should be reviewed to identify old pipes that may bypass the part of the system undergoing disinfection. These pipes may introduce contaminated water downstream if they are not disinfected.

Detailed guidelines for preventing nosocomial legionellosis and for decontaminating water reservoirs and distribution systems are available from CDC at [http://www.cdc.gov.ncidod/diseases/hip/pneumonia/pneu\\_mmw.htm](http://www.cdc.gov.ncidod/diseases/hip/pneumonia/pneu_mmw.htm).

## 59 . Important Anaerobes — Jorge Villacian, MD, & James Steckelberg, MD

### Essentials of Diagnosis

- Foul odor of draining purulence.
- Presence of gas in tissues.
- No organism growth on aerobic culture media.
- Infection localized in the proximity of mucosal surface.
- Presence of septic thrombophlebitis.
- Tissue necrosis and abscess formation.
- Association with malignancies (especially intestinal).
- Mixed organism morphologies on Gram stain.

### General Considerations

**A. Epidemiology and Ecology.** Anaerobic bacteria are the predominant component of the normal microbial flora of the human body. The following sites harbor the vast majority of them:

- Skin: Mostly gram-positive bacilli such as *Propionibacterium acnes*
- Gastrointestinal tract: In the oral cavity *Prevotella* spp., *Porphyromonas* spp., *Peptostreptococcus* spp., microaerophilic streptococci, and *Fusobacterium* spp. are the most important anaerobes found; they significantly outnumber aerobic bacteria (1000:1 ratio). On the colonic lumen, *Bacteroides fragilis*, other *Bacteroides* spp., clostridia, and the previously mentioned oral flora are by far the predominant colonizing organisms (1000:1 ratio to aerobes) and play a crucial role in maintaining the delicate balance of local microflora as well as in metabolizing bile acids and cholesterol and absorbing vitamin K.
- Respiratory tract: *Fusobacterium nucleatum*, *B fragilis*, *Prevotella melaninogenica*, and *Peptostreptococcus* spp. are the most common anaerobic organisms in this site.
- Female genital tract: *Lactobacillus* spp., the predominant species in this location, protect against bacterial vaginosis.
- Exogenous infectious sources: In nature, species of the *Clostridium* genus are found in decaying vegetation, soil, ocean sediment, and in human and animal gastrointestinal tracts. Tetanus and botulism (caused by the toxins of *C tetani* and *C botulinum*) are

examples of exogenously acquired anaerobic infections. The facultative gram-negative anaerobic bacillus *Capnocytophaga canimorsus* is part of the normal oral flora of canine species, but in susceptible hosts such as immunocompromised individuals, it may cause septic shock and disseminated intravascular coagulation, an example of an animal-to-human transmission of infection.

**B. Microbiology.** Anaerobes are defined as bacteria that cannot grow on the surface of solid media in an atmosphere containing = 18%-20% of oxygen even when this atmosphere is enriched with = 10% of CO<sub>2</sub>. The degree of oxygen tolerance differs among these microorganisms; a facultative anaerobe is a bacterium that can grow in either the presence or absence of oxygen, and a strict anaerobe is one that requires < 0.5% oxygen to grow on an agar surface. Microaerophilic is a term used for bacteria that grow poorly aerobically but distinctly better under 10% CO<sub>2</sub>.

Anaerobic bacterial species are numerous; taxonomic data are sometimes confusing and have undergone recent changes. For the purpose of this chapter, we have focused on the most representative pathogens ([Table 59-1](#)).

**C. Pathogenesis.** The pathogenic role of anaerobic bacteria was well established at the beginning of the 1900s. Most infections that involve anaerobes arise from the host's normal indigenous flora, as these bacteria are widely distributed among humans and other animal species. Organisms that are most important are those present in significant numbers at the sites of infection as well as those with high virulence or greater antimicrobial resistance.

The characteristic pathologic features of anaerobic infections are suppuration, abscess formation, and tissue destruction. Several factors contribute to the survival and spread of these organisms:

#### **Microbial Factors:**

- Anaerobic environment causes defective neutrophil killing and microbial growth is slower; therefore antibiotic susceptibility decreases.
- Bacterial enzymes such as collagenase and hyaluronidase promote tissue destruction.
- Organisms such as *B fragilis* have a polysaccharide capsule that impairs phagocytosis.
- Toxin-mediated effects are important in the pathogenicity of most of the genus *Clostridium*. This occurs in the form of absorption of preformed toxin such as in cases of botulism or as a result of bacterial overgrowth and toxin production, which is the mechanism of antibiotic-associated *C difficile* colitis.
- Synergism plays a crucial role in anaerobic pathogenesis, especially in the context of mixed infections because the presence of other aerobic bacteria helps create the optimal environmental conditions for the proliferation and virulence of anaerobes.

**Host Factors:** Normal anaerobic flora become pathogenic under circumstances in

which natural barriers that prevent it from gaining access to sterile sites are disrupted. This might happen by a variety of different mechanisms and depends on the site in which the flora occur.

- In pleuropulmonary infections, the usual precipitating factor is an alteration of the level of alertness that may impair the gag and cough reflexes. General anesthesia, cerebrovascular accidents, a variety of drug overdoses, and alcohol intoxication are examples of situations in which normal oropharyngeal flora gains access to the "sterile" lower respiratory tract; dysphagia, and esophageal or gastric outlet obstruction may also lead to aspiration of large amounts of anaerobes.
- Trauma and tissue ischemia are two important mechanisms that predispose to anaerobic infection: seriously contaminated wounds are an example in which poor blood flow and tissue necrosis provide an ideal environment for *C perfringens* to grow and produce significant amounts of toxin eventually leading to gas gangrene.
- Systemic diseases, such as diabetes mellitus in which the immune response is impaired and vascular compromise might be present, predispose to soft tissue infections of the lower extremities in which anaerobic organisms are commonly found. The presence of foreign devices in different sites may be associated with certain anaerobic infections. Classically, women with intrauterine devices may develop actinomycosis. Central nervous system shunts can become infected with skin colonizing *Propionibacterium* spp.

### **Iatrogenic Factors:**

- In postsurgical abdominal infections, manipulation of bowel causes translocation of bacteria into the peritoneal cavity: anaerobes are universally present as copathogens in a polymicrobial flora.
- Administration of broad-spectrum antimicrobial agents alters the normal colonic flora and allows *C difficile* to proliferate uninhibited; toxin production by this organism leads to the development of antibiotic-associated pseudomembranous colitis.

## **CLINICAL SYNDROMES**

### **INTRODUCTION**

[Box 59-1](#) summarizes different clinical syndromes associated with anaerobic bacteria. The sections that follow describe the various syndromes, including clinical findings. For some syndromes, specific diagnosis and treatment information is included as well. For other syndromes, see summary diagnosis and treatment sections at the end of the chapter.

### **HEAD & NECK**

#### **1. EAR & PARANASAL SINUSES**

The flora in as many as two-thirds of chronic sinusitis and otitis cases includes *B fragilis*,

*Prevotella* spp., *Peptostreptococcus* spp., and *Porphyromonas* spp. It is not surprising that ~50% of patients with chronic otitis media are infected with anaerobic bacteria, *B fragilis* being the most common. Mastoiditis may arise as a complication in some of these cases. Clinical findings related to these infections are found in [Chapter 9](#).

## 2. ORAL CAVITY

### Introduction

This site is heavily colonized with anaerobes. Consequently, many infections involving oral cavity structures as well as the pharyngeal spaces involve anaerobic bacteria.

### Clinical Findings

Odontogenic infections including endodontal processes and periapical and dental abscesses may become more serious by spreading to the perimandibular space; here they present with pain and swelling and require surgical intervention. Gingivitis, pyorrhea, and periodontitis involve anaerobes as well; an extreme of this type of process is necrotizing ulcerative gingivitis (Vincent's angina or trench mouth), which manifests as severe tissue destruction, pain, and malodorous discharge. AIDS and Down's syndrome are conditions that predispose to periodontal disease and subsequently to odontogenic infections.

## 3. PHARYNGEAL SPACES

### Clinical Findings

Ludwig's angina is a bilateral infection of the sublingual and submandibular spaces that commonly involves anaerobic bacteria and causes swelling of the oral tissues, especially at the base of the tongue, where it may lead to respiratory compromise. It manifests as indurated cellulitis and begins on the mouth. A dental source of infection can be found in 50-90% of cases. Lemiere's syndrome is a life-threatening complication of *Fusobacterium necrophorum* infection in the posterior compartment of the lateral pharyngeal space, which consists of suppurative thrombophlebitis of the internal jugular vein often accompanied by bacteremia and metastatic abscesses to the lungs and liver. Surgical intervention is almost always necessary in conjunction with intravenous antibiotics.

**A. Signs and Symptoms.** Clinical features of infection of the pharyngeal spaces are dysphagia, hoarseness, nuchal rigidity, fever, and trismus. In Ludwig's angina, a brawny, boardlike swelling of the submandibular spaces, which does not pit on pressure, is present when the mouth is held open and the tongue is pushed up to the roof of the mouth.

**B. Imaging.** Once the diagnosis is made (see below), imaging studies help delineate the extent of the process. Soft tissue x-ray of the neck may show widening of the different pharyngeal spaces involved. Ultrasonography, radionuclide scanning, and computerized tomography (CT) are useful for localizing infections of the head and neck.

## CENTRAL NERVOUS SYSTEM

### Introduction

Oral anaerobes are commonly involved in brain abscesses, occasionally in epidural and subdural empyemas, and very rarely in meningitis. These infections usually arise in the setting of chronic otitis media, sinusitis, or odontogenic processes. Less frequently, brain abscesses can be secondary to hematogenous spread from distant sites in which case they tend to be multiple. Anaerobic infections can also be found as a complication of neurosurgical procedures.

### Clinical Findings

**A. Signs and Symptoms.** Clinical features are those of a space-occupying lesion, including headache, vomiting, altered mental status, focal neurologic symptoms, and seizures. Fever is present in only half of cases; depending on the location of the lesion, corresponding neurologic deficits can be seen. Funduscopic examination may reveal papilledema.

**B. Laboratory Findings.** Microbiology findings may include *B fragilis*, *Peptostreptococcus*, *Fusobacterium*, *Prevotella* spp., *Actinomyces*, *Propionibacterium*, or microaerophilic streptococci in conjunction with aerobic organisms such as staphylococci, streptococci, and gram-negative bacilli.

Invasive procedures such as lumbar puncture should only be performed after careful physical exam to evaluate for increased intracranial pressure or impending herniation. Cerebrospinal fluid examination may show a moderate pleocytosis, high protein concentration, and normal glucose level suggestive of parameningeal inflammatory foci.

**C. Imaging.** The diagnosis is confirmed by contrast-enhanced CT or magnetic resonance imaging.

## RESPIRATORY TRACT

### Introduction

Aspiration of oral and dental flora results in anaerobic pleuropulmonary infections. Predisposing conditions are alterations in mental status, gingivitis, and periodontal disease.

### Clinical Findings

**A. Signs and Symptoms.** Pulmonary abscesses of anaerobic origin usually have an indolent subacute or chronic presentation with symptoms such as malaise, weight loss, pleuritic chest pain, and cough that may be accompanied by foul smelling sputum and can be mistaken for malignancy; a febrile response depends on the patient's age and immune status.

Pathologically, early in the course, pneumonitis is present and then may evolve to form

an abscess causing significant tissue destruction. The pleural cavity is frequently involved, and this results in empyema. Commonly affected anatomical sites are dependent regions such as the posterior segments of the upper lobes and the superior segments of the lower lobes (see Imaging section below).

**B. Laboratory Findings.** Organisms of the *B fragilis* group, other *Bacteroides* spp., *Prevotella melaninogenica*, *Fusobacterium* spp., peptostreptococci, *Peptococcus* spp., gram-negative bacilli such as *Clostridium* spp., or occasionally gram-positive cocci of the *Veillonella* spp. are found. In most cases, aerobic organisms are also present, and successful treatment needs to cover such pathogens as well.

For microbiologic diagnosis, expectorated sputum is not useful as a result of the presence of abundant normal anaerobic flora of the upper airways and oropharyngeal cavities; therefore, invasive procedures including bronchoscopy with bronchoalveolar lavage is important in identifying the causative organisms. Empyema fluid should always be inoculated into appropriate anaerobic vials and sent for anaerobic culture.

**C. Imaging.** Initial findings on chest x-ray are those of a pneumonic infiltrate. This may evolve to form abscesses in which air-fluid levels can be detected. For optimal delineation of extent of involvement, CT of the chest should be performed.

## INTRA-ABDOMINAL

### INTRODUCTION

The gastrointestinal tract harbors a rich microbial flora, and any process that involves perforation or manipulation of a hollow viscus could potentially result in the translocation of bacteria into normally sterile sites. In the oral cavity, there are  $10^7$ - $10^8$  anaerobes/mL of oral contents; the proportion is 10-1000/mL in the stomach,  $10^4$ - $10^6$  anaerobes/mL in the terminal ileum, and  $10^{11}$ /g of stool in the colon.

#### 1. BOWEL

Upper-gastrointestinal-tract processes such as perforated peptic ulcer tend to involve gram-positive anaerobic and aerobic bacteria, whereas lower-tract diseases like appendicitis and colonic perforations are associated with coliforms and anaerobic gram-negative species including *B fragilis*, *Bacteroides* spp., and *Fusobacterium* spp. Therefore, peritonitis (secondary to perforated viscus) and intra-abdominal abscesses always involve anaerobes as a component of a mixed flora. Postsurgical infections may have an anaerobic component as well. See [Chapter 12](#) for clinical findings related to these infections.

Colonic malignancies are commonly associated with members of the *Clostridium* species—*septicum*, *tertium*, and *perfringens*, all of which may cause bacteremia and gas gangrene of the bowel. Enteritis necroticans (caused by *C perfringens*) and neutropenic enterocolitis or typhlitis (caused by *C septicum*) are two representative severe clostridial bowel infections.

## 2. LIVER & BILIARY TREE

Biliary tract infections in nonobstructed biliary systems seldom involve anaerobes, but in patients with obstruction caused by tumors, *B fragilis* or *C perfringens* can be present. Bacterial liver abscesses are usually polymicrobial, and anaerobes constitute part of the flora.

The diagnosis of hepatic or intra-abdominal anaerobic abscesses is made with imaging studies such as CT. If large abscesses are present, drainage is a component of successful therapy and can be achieved either surgically or in some cases by percutaneous CT or ultrasound-guided techniques. See [Chapter 12](#) for clinical findings related to these infections.

## FEMALE GENITAL TRACT

### Introduction

Alteration of the normal microbial flora of the female genital tract causes bacterial vaginosis, which predisposes to different infections in which anaerobes are frequently encountered. These are usually mixed and include endometritis, pelvic inflammatory disease, and tubo-ovarian abscesses, as well as obstetric infections such as amnionitis, septic abortions, septic pelvic thrombophlebitis, and postsurgical wound infections.

Pelvic inflammatory disease is associated in 30-40% of cases with anaerobes; these infections and their sequelae result in high rates of infertility, ectopic pregnancy, and premature delivery.

Anaerobic pathogens encountered are *Peptostreptococcus* spp., *Prevotella* spp., *Porphyromonas* spp., and members of the clostridia family. *B fragilis* is not usually involved in gynecologic-obstetric infections but, when present, carries a poor prognosis. *Actinomyces* spp. and *Eubacterium nodatum* are associated with infections in women with intra-uterine contraceptive devices. In addition to targeting anaerobes, antimicrobial treatment should cover aerobic bacteria as well as atypical organisms such as chlamydia.

### Clinical Findings

**A. Signs and Symptoms.** Clues to anaerobic pelvic infection are foul smelling discharge, presence of gas in tissues, and septic thrombophlebitis.

**B. Laboratory Findings.** The diagnosis of bacterial vaginosis is suggested by secretions with a pH of > 4.5, a "fishy" odor when treated with 10% hydrogen peroxide, and visualization of "clue" cells.

## SKIN, SOFT TISSUE, & BONE INFECTIONS

### Introduction

A wide variety of infections at these sites involve anaerobic bacteria. Specific pathogens

depend on the mechanism of injury disrupting normal skin barrier defenses as well as on the state of the host's immune system. Infections can be localized or widespread and life threatening and may invade deep structures such as bone.

Bite wounds and clenched fist injuries often involve anaerobes, but antibiotic coverage must also include oral aerobic organisms, in particular, *Eikenella corrodens* in human bites and *Pasteurella multocida* in animal bites. Infected decubitus ulcers, pilonidal and sebaceous cysts, diabetic foot and burn wound infections, breast abscesses, and paronychia (mainly in children who suck their thumbs) have a polymicrobial flora in which anaerobes are present.

Involvement of the fascia leads to serious infections including necrotizing fasciitis and soft tissue gas gangrene (associated with *C perfringens*). When the perineal and scrotal regions are affected, this syndrome is known as Fournier's gangrene.

## Clinical Findings

**A. Signs and Symptoms.** Signs and symptoms in general range from pain, erythema, swelling, and suppuration at the site of infection to bacteremia, sepsis syndrome, and tissue crepitation in the most serious cases. The absence of fever may reflect overwhelming infection.

**B. Laboratory Findings.** Microbiologic diagnosis is difficult and superficial swabs are usually not helpful. Deep tissue specimens obtained surgically are preferred in severe cases or when prolonged therapy is anticipated. The organisms that are most frequently encountered in diabetic foot and decubitus ulcer infections include *B fragilis*, *Fusobacterium* spp., *Prevotella melaninogenica*, *Porphyromonas*, *Peptostreptococcus*, and members of the *Clostridium* genus. Gas gangrene is associated with *C perfringens* and *C septicum*. Necrotizing fasciitis involves *Bacteroides* spp. as well as clostridia.

## BACTEREMIA

### Introduction

Anaerobes cause from 5 to 10% of all bacteremias. *B fragilis* and related species account for 60-80% of all cases, followed by clostridia and peptostreptococci. Organisms such as *Propionibacterium* usually represent contamination of blood cultures by skin organisms. For true bacteremias, the common portals of entry are the gastrointestinal tract, female genital tract, lower respiratory tract, head and neck, and skin. Fewer than 5% of neutropenic bacteremias are secondary to anaerobes.

### Clinical Findings

**A. Signs and Symptoms.** Clinical presentation will depend on the site of primary infection and can include fever, chills, and malaise. As previously mentioned, clostridial bacteremias should prompt the search for colonic malignancies.

## OSTEOMYELITIS

It is not uncommon to find anaerobes in cases in which the predisposing factor is vascular insufficiency as in diabetic foot ulcers. Other examples are skull or facial bone infections arising from chronic otitis media, sinusitis, or mastoiditis. Clinically, these infections tend to run indolent courses and may occasionally present with foul smelling drainage through sinus tracts. Gram-negative bacilli and peptostreptococci are frequently involved.

## TOXIN-MEDIATED INFECTIONS

### 1. TETANUS

#### Introduction

Tetanus is a disease of global incidence produced by the toxin of *Clostridium tetani*. The risk of acquiring it increases in people > 60 years of age and in neonates, especially in Third World countries where poor sanitary conditions predispose to umbilical stump contamination. Immunization campaigns have played a crucial role in bringing about the observed decreasing incidence in the United States.

The pathogenesis of tetanus involves the absorption of preformed toxin, or, less commonly, invasion of toxin-producing organisms from contaminated wounds; it may complicate surgical wounds colonized with *C tetani*. Incubation periods vary depending on the portal of entry. The toxin tetanospasmin blocks the transmission of inhibitory neurons, which results in flexor and extensor muscle spasms that are triggered by sensory stimuli.

Most cases progress over 2 weeks. With adequate supportive therapy ([Box 59-2](#)), complete recovery may be seen in 1 month. Autonomic dysfunction and respiratory compromise are potential complications. Mortality rates are 1:100,000 in North America and 28:100,000 in Third World countries.

#### Clinical Findings

**A. Signs and Symptoms.** Muscle spasms are accompanied by pain and manifest as decorticate posturing with intact sensorium. "Risus sardonicus" is the term used to describe the facial expression produced by increased tone of the orbicularis oris. Trismus (or "lockjaw") is often present as a heralding manifestation of generalized disease.

#### Diagnosis

Diagnosis of tetanus is made clinically; conditions that might have similar features are strychnine poisoning and dystonic reactions.

#### Treatment

Treatment should be supportive. Sedation is important: benzodiazepines, propofol, and in severe cases, paralyzing agents can be used; the role of antibiotics is controversial (see [Box 59-2](#)). When autonomic dysfunction is present, alpha and beta adrenergic

blocking agents are recommended.

## 2. BOTULISM

### Introduction

This clinical syndrome is caused by the neurotoxin of *C botulinum*. There are seven types (A-G) of neurotoxin, all of which inhibit the release of acetylcholine at the level of peripheral neuromuscular junctions. In the majority of cases, the disease is acquired by ingestion of preformed toxin in home-canned vegetables, fruits, and fish. In Japan, the former Soviet Union, Scandinavia, and the Great Lakes region of the United States, type E toxin causes disease in people who consume raw or lightly smoked fish. There are four categories of botulism:

- Food borne (most common)
- Wound botulism caused by the absorption of toxin from a wound contaminated by *C botulinum* (the rarest form)
- Infant botulism resulting from in vivo elaboration of toxin by colonizing organisms in the bowel
- Undetermined, which refers to cases that occur in individuals > 1 year old in whom no food or wound source is identified

### Clinical Findings

**Signs and Symptoms.** Symptoms and signs arise 12-36 h after food ingestion and consist of acute onset and progressive flaccid paralysis involving the facial musculature and the cranial nerves bilaterally, then descending symmetrically to the pharynx, thoracic region, and the upper and lower extremities. This evolves into respiratory failure without impairment of consciousness. Fever is classically absent.

In cases of infant botulism, which is found in children 6 days to 11 months old, constipation is the initial symptom, followed by lethargy, feeding difficulties, altered cry, floppiness, ophthalmoplegia, and respiratory failure.

**B. Laboratory Findings.** Besides clinical findings and careful history, stool and serum toxin assays help establish the diagnosis.

**C. Differential Diagnosis.** Differential diagnosis of botulism includes myasthenia gravis, Lambert-Eaton paraneoplastic syndrome, and Guillain-Barre syndrome.

### Treatment

Treatment is mainly supportive; antitoxin made from equine serum can be used. In the United States, it is obtained through state health departments or the Centers for Disease Control. The standard dose is one vial intravenously and one vial intermittently. It may be repeated every 4 h in severe progressive cases. Clinical trials evaluating its

efficacy are lacking. Full recovery takes from 3 months to 1 year. Risk of death ranges from 4 to 25%, depending on the promptness with which the diagnosis is made.

### 3. ANTIBIOTIC-ASSOCIATED COLITIS

#### Introduction

*Clostridium difficile* is the principal causative agent of antibiotic-associated colitis. Two types of toxin are produced by *C difficile*: (1) an enterotoxin (the most important in its pathogenesis) and (2) an enterotoxin that is cytophatic. This organism is present in the bowel flora of = 50% of neonates. This rate declines to 4% by age 2 years. However, antibiotic treatment and hospitalization have been proven to increase the carriage rate = 46%. Chemotherapeutic agents (for malignancies) and antibiotics (most commonly ampicillin, clindamycin, and the cephalosporins) are associated with *C difficile* pseudomembranous colitis. Bowel stasis and surgery predispose to this disease as well, although, in some cases, no identifiable risk factor is found.

#### Clinical Findings

**A. Signs and Symptoms.** Clinical presentation ranges from mild diarrhea to toxic megacolon. Fever is present frequently, and pseudomembrane formation is characteristic.

**B. Laboratory Findings.** The diagnosis is confirmed by toxin assays and cell culture cytotoxicity assays that neutralize with antisera to toxin B. Colonoscopy may provide helpful information by enabling direct observation of the classical pseudomembranes in the colonic mucosal surface. Stool cultures are not diagnostic because of the considerable rates of asymptomatic carrier states.

#### Treatment

In treating patients who have *C difficile*-associated pseudomembranous colitis, if possible, an attempt to stop or narrow broad-spectrum antibiotic therapy (if the patient is receiving it for other reasons) should be made. Oral metronidazole is the first choice for treatment ([Box 59-2](#)). Oral vancomycin should be avoided to prevent further selection of vancomycin-resistant enterococci but can be used in cases of relapse or as a second choice in patients unable to tolerate metronidazole.

#### Diagnosis of Anaerobic Bacterial Infections

The likelihood of anaerobes being part of the infecting flora should be carefully considered when obtaining cultures. In general, anaerobic cultures are needed in complicated infections, in debilitated hosts (those with underlying chronic illnesses or malignancies as well as elderly individuals), in cases where prolonged therapy is anticipated, and in infections where empiric therapy is failing.

Specimens from the oral cavity, upper respiratory tract, or vagina are rich in indigenous anaerobic flora and therefore not useful for diagnostic purposes. Fluid obtained from normally sterile sites, as well as pus or tissue samples are preferred. Fluid or pus from

these sites should be inoculated into special anaerobic vials for transport to the microbiology laboratory, and in the case of tissues, an airtight bag might be used.

Cultures are grown in both selective (directed at specific pathogens) and nonselective media; this approach increases the diagnostic yield. An anaerobic environment must be maintained.

Newer diagnostic techniques include detecting the metabolic end products of carbohydrate fermentation by gas-liquid chromatography. Toxin assays are available for the diagnosis of botulism and *C difficile*-associated colitis.

### **Treatment of Anaerobic Bacterial Infections**

The first principle of treatment for anaerobic bacterial infections is to keep in mind that in most cases, other pathogens coexist as part of a polymicrobial flora; therefore, adequate antibiotic coverage for those should be provided as well ([Box 59-2](#)). Drainage of abscesses and surgical debridement of wounds to remove devitalized tissue are of great importance to achieve therapeutic success.

Historically, penicillin has been one of the most useful antibiotics against anaerobic bacteria, but the increasing frequency of  $\beta$ -lactamase-producing strains of *B fragilis*, *Prevotella melaninogenica*, and *Porphyromonas* spp. has limited its value. Penicillin G is still the drug of choice for clostridia, but *C perfringens*, *C ramosum*, *C clostridiforme*, and *C butyricum* exhibit some degree of resistance.

Cephalosporins in general should not be considered drugs of choice for gram-negative anaerobic coverage, but cefoxitin and ceftizoxime exhibit some activity against these bacteria. Cefoxitin has been used as monotherapy in uncomplicated intra-abdominal infections. First-generation cephalosporins (eg, cefazolin) are active against gram-positive anaerobic cocci.

Tetracycline and its derivatives, frequently administered in the past, are now mostly inactive. Quinolones such as ciprofloxacin and ofloxacin have very poor coverage, but newer compounds with increased anaerobic activity are being developed.

Chloramphenicol has good anaerobic coverage, although occasional resistance may be seen with *B fragilis* and certain clostridia. Penetration to the central nervous system is adequate. The main limiting factor preventing widespread use of chloramphenicol is toxicity (risk of bone marrow suppression, mainly with oral formulations).

Clindamycin is one of the drugs of choice when anaerobes are suspected, however, its spectrum against aerobic gram-negative bacilli is limited; in the setting of polymicrobial infections, the addition of an aminoglycoside, second- or third-generation cephalosporin, or aztreonam is recommended. The central nervous system penetration of clindamycin is very poor. About 30% of *Bacteroides gracilis* and some organisms in the *B fragilis* group can be resistant to clindamycin.

Metronidazole is another potent antianaerobic drug with even less activity against aerobes than clindamycin. It should not be used as monotherapy if aerobes are

suspected. Central nervous system penetration is good.

The combination of  $\beta$ -lactams with  $\beta$ -lactamase inhibitors is active against most anaerobes as well as against many aerobes. These agents include amoxicillin-clavulanic acid (oral) the intravenous ampicillin-sulbactam, ticarcillin-clavulanic acid, and piperacillin-tazobactam.

The carbapenems (imipenem and meropenem) have excellent anaerobic activity as well as broad gram-positive and gram-negative aerobic coverage. Both the  $\beta$ -lactam and  $\beta$ -lactamase inhibitor combinations and the carbapenems are typically more expensive than combination regimens using older agents.

## Prevention

Preventive measures are aimed at minimizing contamination of sterile sites with fluids that contain high amounts of normal microbial flora (as is the case with intra-abdominal postsurgical infections) ([Box 59-3](#)). Preventing aspiration of oropharyngeal contents into the lower airways is important to control anaerobic pneumonitis and empyemas. For obstetrical infections, reducing the duration of labor (if possible) can help. Good cleansing and debridement of wounds decreases the risk of soft tissue infections. Ensuring adequate vascular supply is also important in these situations.

In *C tetani* infections, active, and in some cases passive, immunization are important ([Table 59-2](#)). Avoiding the unnecessary use of broad-spectrum antibiotics for prolonged periods of time is one of the cornerstones for preventing *C difficile*-associated colitis.

**Table 59-2.** Tetanus immunization.

**Active Immunization**

- DTP (diphtheria, pertussis, tetanus): Recommended doses (IM) should be given at 2, 4, 6, and 15-18 mo, and at 4-6 years of age.
- DT (diphtheria, tetanus): Recommended for patients above 7 years old; 2 doses (IM) 4-8 weeks apart and a third dose 6-12 mo later confer immunity for at least 5 years; boosters should be given to *all* patients every 10 years and more frequently if high-risk activities have occurred

**Passive Immunization**

Human tetanus immunoglobulin (500 IU IM) may shorten the duration and lessen the severity of tetanus cases; should be administered prophylactically to patients not immunized during the previous 5 years who have a tetanus-prone wound or if immunodeficiency is suspected; active immunization should also be initiated at the time the immunoglobulin is given

<b>Group</b>	<b>First Choice</b>	<b>Alternatives</b>
<b>Anaerobic Gram-Negative Bacilli</b>	Metronidazole, 500 mg IV every 6 h	Clindamycin, 900 mg IV every 8 h
<b>Anaerobic Gram-Negative Cocci (Veillonella spp.)</b>	Penicillin G, 10-24 million U IV, continuous infusion or every 4-6 h interval dosing	Clindamycin, 900 mg IV every 8 h
<b>Anaerobic Gram-Positive Nonspore-Forming Bacilli</b>	Penicillin G, 10-24 million U IV, continuous infusion or every 4-6 h interval dosing	Clindamycin, 900 mg IV every 8 h
<b>Anaerobic Gram-Positive Spore-Forming Bacilli (Clostridium spp.)</b>	Penicillin G, 10-24 million U IV, continuous infusion or every 4-6 h interval dosing	Metronidazole, 500 mg IV every 6 h
<b>Anaerobic Gram-Positive Cocci</b>	Penicillin G, 10-24 million U IV, continuous infusion or every 4-6 h interval dosing	Clindamycin, 900 mg IV every 8 h
<b>Antibiotic-Associated Colitis</b>	Metronidazole, 250 mg orally three times a day (7-14 days)	Vancomycin, 125 mg orally four times a day (7-10 days)

<sup>1</sup>Combination therapy directed against concomitant aerobic pathogens is of paramount importance in anaerobic infections; other agents used will depend on specific infection sites and resistance patterns information is for adult patients with normal renal and hepatic functions. Pediatric dosing: penicillin G, 30 mg/kg/d; clindamycin, 25 mg/kg/d (in patients with normal renal and hepatic functions).

<sup>2</sup>Imipenem, 500 mg IV every 6 h, or meropenem, 1 g IV every 8 h if resistance to other first-line agent

<sup>3</sup>Ticarcillin-clavulanic acid, 3.1 g IV every 6 h; piperacillin-tazobactam, 3.375 g IV every 6 h; ampicillin 3 g IV every 6 h; amoxicillin-clavulanic acid, 500 mg orally every 8 h.

## **60 . *Brucella, Francisella, Pasteurella, Yersinia, & HACEK* — Elie F. Berbari, MD, & Walter R. Wilson, MD**

### **BRUCELLOSIS**

#### **Essentials of Diagnosis**

- Suspected in patients with chronic fever of unknown etiology who have a history of occupational exposure or come from a high prevalence area.
- Leukopenia.
- Blood culture or bone marrow cultures on appropriate media.
- Serum antibody titer = 1:160.
- Polymerase chain reaction.

#### **General Considerations**

Brucellosis (also called undulant fever, Mediterranean fever, Malta fever) is an infection that causes abortion in domestic animals. It is caused by one of six species of *Brucella* coccobacilli. It may occasionally be transmitted to humans, in whom the disease could be acute or chronic with ongoing fever and constitutional symptoms without localized findings.

**A. Epidemiology.** Brucellosis is transmitted to humans by either direct contact with infected cattle, goat, or sheep (eg, through milk, urine, and products of pregnancy) or indirectly by ingesting contaminated animal products (eg, unpasteurized dairy products). Human-to-human transmission does not occur. The natural reservoir of brucellosis in the United States is domestic animals, especially cattle, bison, sheep, goats, and swine.

The disease exists worldwide, mainly in the Mediterranean basin, the Arabian peninsula, the Indian subcontinent, Mexico, and Central and South America. In the United States, the incidence of brucellosis fell from 4.5 cases/100,000 population annually in the late 1940s to < 0.5 cases/100,000 by the 1990s. Most reported cases in the United States are due to ingestion of unpasteurized goat milk product imported from Mexico or to occupational exposure involving meat-packing plant employees, veterinarians, laboratory personnel, farmers, and ranchers. Recently, bison herds in the Rocky Mountain plains of the United States have become infected with brucellae and could potentially infect domestic cattle in the United States.

**B. Microbiology.** Sir David Bruce, a British microbiologist, isolated the microorganisms responsible for brucellosis in 1886. Brucellae are nonspore-forming, noncapsulated, small gram-negative coccobacilli. They grow best aerobically in high-peptone media at 37 °C and at pH 6.7. Incubation time could take = 30 days for visible growth on solid media. Colonies are small, smooth, translucent, and amber colored. Of the six known

*Brucella* species, only four are reported to cause human disease: *B abortus* (cattle), *B melitensis* (goats), *B suis* (pigs), and *B canis* (dogs). Brucellae may be distinguished from each other by their requirements for carbon dioxide atmosphere for growth, growth in the presence of dyes, production of hydrogen sulfide and urease, and specific agglutination in antisera.

**C. Pathogenesis.** Routes of infection include ingestion of the contaminated food or dairy products by way of the gastrointestinal tract, direct inoculation through skin cuts or mucus membrane contact, or inhalation of the organisms via the respiratory tract. Subsequently, the microorganisms enter the lymphatics and replicate intracellularly in the regional lymph nodes and from there disseminate hematogenously and localize in the reticuloendothelial system (ie, spleen, liver, other lymph nodes, and bone marrow). The bacilli multiply intracellularly within the phagocytic cell where they may be killed rapidly, or the organisms may replicate and destroy the phagocytic cell. This results in proliferation within the reticuloendothelial system and the formation of noncaseating granulomas in affected tissue. In most instances, the granulomas undergo a process of healing, with fibrosis, death of the organisms, and frequently calcification.

## Clinical Findings

**A. Signs and Symptoms.** After a 2- to 8-week incubation period, affected patients present with a spectrum of disease that varies from an asymptomatic form to a severe illness with bacteremia ([Box 60-1](#)). Affected patients typically present with fever, sweats, headaches, malaise, and weight loss. If undiagnosed, these symptoms may persist for months to a year. When symptoms last for more than 12 months without any localization, the disease is classified as chronic. Physical examination, though normal in most cases, may reveal bilateral diffuse lymphadenopathy, splenomegaly, and hepatomegaly in 20%-30% of patients.

In the localized form, the infection may affect virtually any organ system. The osteoarticular, gastrointestinal, genitourinary, and cardiovascular are among the more common affected systems. These forms have signs and symptoms related to the affected organ system. An infectious discitis with adjacent vertebral bony osteomyelitis typically in the lumbar area, is the most common manifestation of localized osteoarticular disease. Sacroilitis is also characteristic of the musculoskeletal form of the infection. Infective endocarditis occurs in < 2% of brucellosis cases.

Patients with chronic brucellosis may have long periods of no symptoms followed by the intermittent recurrence of fever, chills, myalgias, and nonspecific symptoms. This form of relapsing brucellosis may persist for decades and is often refractory to antimicrobial therapy and is frequently associated with multiple or large calcific lesions in the liver and spleen. Many other common illnesses can mimic the most common clinical presentation of brucellosis.

**B. Laboratory Findings.** Patients typically have a mild anemia, neutropenia, and rarely thrombocytopenia. The diagnosis of brucellosis is made with certainty when *Brucella* spp. are recovered from cultures of the blood, bone marrow, or other site. Bone marrow cultures are more often positive than are blood cultures. Blood cultures are often negative in chronic or localized forms. The standard *Brucella* serum agglutination test is

the most widely used serologic test for the diagnosis of *Brucella*. The antibodies measured are directed against the lipopolysaccharide. A titer of at least 1:160 is representative of a past or present infection. A fourfold increase or decrease over a 2- to 4-week period represents acute infection.

The current serum agglutination test does not detect antibodies directed against *Brucella canis*, and diagnosis requires a special serologic test or a positive culture. After successful therapy, the antibody titer may become negative in approximately a year but may remain positive in low titer throughout the patient's life. Persistence of an elevated titer indicates ongoing infection. The prozone phenomena could lead to a false negative test.

Polymerase chain reaction may be used for diagnosis. Primers are directed at different sites of the genomic bacterial DNA. The specificity and sensitivity of this technique may provide a valuable tool for the diagnosis of brucellosis; however, the test is not widely available.

### **Differential Diagnosis**

The differential diagnosis is one of a fever of unknown origin and includes typhoid fever, infectious mononucleosis, Q-fever, hepatitis, and a host of noninfectious syndromes including lymphoma and systemic lupus erythematosus. Infection with *Vibrio cholerae*, *Francisella tularensis*, or *Yersinia enterocolitica* may give a falsely elevated serum agglutination test since antigen of these microorganisms can cross-react with antigen of *Brucella* spp.

### **Treatment**

Several antimicrobial agents are active against *Brucella* spp. ([Box 60-2](#)). Combination therapy of two or more active antimicrobial agents is superior to monotherapy as evidenced by a reduction in relapse rates. Antimicrobial therapy shortens the duration of symptoms and reduces the incidence of complications. Tetracyclines are considered the cornerstone of therapy. Several possible combinations have been used: The World Health Organization recommends a 6-week combination regimen of doxycycline and rifampin. Doxycycline and streptomycin are considered equally efficacious.

The optimum therapy for endocarditis is unclear. Most patients will require a prolonged period (6 months) of combination antimicrobial therapy, and valvular replacement surgery is often necessary. Although rare, infective endocarditis represents 80% of human brucellosis-related deaths.

### **Prognosis**

With appropriate antimicrobial therapy, the mortality rate of brucellosis is < 1%, although the mortality rate is 3%-5% in untreated cases. It appears that the humoral antibodies play a role in the protection against subsequent infection. Thus patients with brucellosis might be less susceptible to acquire a new infection.

### **Prevention & Control**

The prevention of brucellosis requires the eradication or the control of the infection in animals ([Box 60-3](#)). The use of *Brucella* vaccines (*B abortus* strain 19, *B melitensis* strain Rev-1) has resulted in the elimination of the disease in some animals. The use of effective barriers such as gloves, masks, and goggles can protect individuals at risk from potentially infected animals. Pasteurization of milk will effectively kill *Brucella* spp. in dairy products.

## TULAREMIA

### Essentials of Diagnosis

- Suspected in patients with fever, lymphadenopathy, and skin lesions who have a history of animal exposure (including to wild animals, ticks, or deerflies) or are coming from a high prevalence area or in laboratory personnel who work with *Francisella* spp.
- Blood culture or other biologic specimen cultures on appropriate culture media.
- Serum antibody titer = 1:160 or a fourfold increase or decrease in titer.

### General Considerations

*Francisella tularensis* is the causative agent of tularemia (also called rabbit fever or deerfly fever), an infectious disease that occurs primarily in animals. It may occasionally cause human disease, which most often manifests itself by one or more skin lesions, regional lymphadenopathy, fever, and constitutional symptoms.

**A. Epidemiology.** Tularemia is widely distributed, with a higher prevalence in the northern hemisphere. Once common before World War II in the United States, the incidence of tularemia has declined steadily since the 1950s. Currently, the incidence is 0.05-0.15 cases/100,000 population. More than one-half of the cases in the United States occur in Missouri, Arkansas, Oklahoma, Texas, and Illinois. The incidence is higher during the summer months because of the increase in tick-acquired disease.

Transmission of *F tularensis* to humans occurs through dermal or mucosal contact with infected animals, mainly wild mammals, amphibians, fish, birds, or as the result of an insect bite (eg, ticks, deerflies, and mosquitoes). In the United States, the most common reservoirs are rabbits and ticks. Occasionally, the infection is acquired through inhalation of aerosolized organisms. The organism is highly infectious for laboratory personnel.

**B. Microbiology.** *F tularensis* is a small aerobic, nonmotile, catalase-positive pleomorphic gram-negative coccobacilli. The cell wall of *F tularensis* is high in fatty acids. Some strains contain a lipid-rich capsule that increases virulence. *F tularensis* requires a sulphhydryl-containing medium for growth and, therefore, does not grow on most routine commercially available media. Growth requires 2-4 days and produces small, smooth, opaque colonies. The organism may be identified on the basis of its morphology, growth requirements, fluorescent staining, and agglutinins with specific antisera. Most strains are  $\beta$ -lactamase producers.

**C. Pathogenesis.** After contact with the microorganisms, penetration occurs through sites of inapparent skin disruption. Subsequently, *F tularensis* multiplies locally and in the skin produces papules that ulcerate, become encrusted, and form an eschar. The microorganisms then reach regional lymph nodes where they replicate and disseminate to the blood. The organisms are engulfed by cells of the reticuloendothelial system in which they may survive intracellularly for prolonged periods. Occasionally, the microorganisms are inhaled, and a pneumonic form of the disease occurs. Rarely, ingestion of the microorganisms can cause pharyngitis, cervical, and mesenteric lymphadenopathy. Early lesions are characterized histopathologically by focal necrosis occurring in organs of the reticuloendothelial system that subsequently undergo granulomatous reaction. Healing is associated with fibrosis and calcification of the granulomata.

## Clinical Findings

**A. Signs and Symptoms.** The clinical manifestations of tularemia are protean and depend on the portal of entry of the microorganism, virulence of the microorganism, and the immune status of the human host. It can vary from a subclinical illness to a fulminant disease with sepsis and death. Five different clinical syndromes have been described ([Box 60-4](#)). The incubation period is 3-5 days.

In the most common form of infection, the ulceroglandular type, a red, tender cutaneous papule is noted at the site of an insect bite or dermal penetration with ulceration on the affected limb and concomitant tender regional adenopathy. The ulcer becomes crusted and black-colored, forming an eschar, which is a characteristic feature of the cutaneous site of entry. Symptoms include fever (39-40.6 °C), chills, headaches, and generalized malaise. Patients often are acutely ill with severe prostration and occasionally hypotension, septicemia, and death. If untreated, fever may persist for a month or longer. On physical examination, the temperature elevation is often associated with a paradoxically relative bradycardia. Hepatosplenomegaly is common, especially in untreated cases.

Tularemia should be suspected in febrile patients with skin lesions and lymphadenopathy especially when a history of contact with wild animals, ticks, or deerflies is present.

**B. Laboratory Findings.** Organisms are rarely seen on Gram stain of affected tissue. Blood cultures or other biologic specimens need special culture media for growth. Serologic studies using the microagglutination test, or the enzyme immunoassay test, are reliable and widely available. A fourfold increase or decrease in the titers is diagnostic of infection. A titer of = 1:160 may represent recent or acute infection. As many as 50% of cases will have positive titers by the second week of the illness. Titers may remain elevated for months to years after an acute infection.

**C. Imaging.** In 30% of cases, a chest roentgenogram will show infiltrates, despite normal clinical findings. Typical chest roentgenogram findings in the pneumonic form would include lobar or subsegmental infiltrates, hilar adenopathy, or diffuse infiltrates.

## Differential Diagnosis

The differential diagnosis of the ulceroglandular form is one of other diseases that are associated with skin ulcer and lymphadenopathy, such as pyoderma caused by streptococci or staphylococcus, sporotrichosis (*Sporothrix schenckii*), cat-scratch disease, rat-bite fever, plague, anthrax, brucellosis, typhoid fever, infectious mononucleosis, and hematologic malignancies.

## Complications

The most common complication is suppuration of an involved lymph node. Other complications such as meningitis, osteomyelitis, endocarditis, and peritonitis occur rarely.

## Treatment

Aminoglycosides, mainly streptomycin or gentamicin, are considered the drugs of choice for all forms of tularemia ([Box 60-5](#)). Other antimicrobial agents such as tetracyclines and chloramphenicol have been used in patients who cannot tolerate aminoglycosides. Their bacteriostatic effect against *F tularensis* may account for the high relapse rates. Relapse is not caused by resistant microorganisms and may be treated with another course of the same antimicrobial regimen.

## Prognosis

Immunity after infection with *F tularensis* is lifelong. The mortality rate is 5-15% in untreated cases and 1% in treated cases. The typhoidal form is associated with a high mortality rate.

## Prevention & Control

Avoidance of exposure to contact with potential sources of infection is the best means of prevention ([Box 60-6](#)). Gloves, masks, and goggles should be worn when handling potentially infected animals. A live attenuated vaccine is available for individuals at high risk such as veterinarians and meatpacking plant employees.

## PLAGUE

### Essentials of Diagnosis

- Suspected in patients living in or traveling from an endemic area who have acute onset of fever, prostration, and tender adenopathy.
- *Yersinia pestis* may be recovered from blood cultures or cultures of an aspirate from buboes or sputum in the pneumonic form in 80%-100% of cases.
- Gram stains of bubo aspirate or sputum demonstrate the characteristic bipolar "safety pin" gram-negative microorganisms.

- *Y pestis* grows aerobically on most culture media after 48-72 h of incubation.

## General Considerations

The genus *Yersinia*, named after Alexander Yersin (1863-1943), includes *Y pestis*, *Y enterocolitica*, and *Y pseudotuberculosis*. *Y pestis* is the cause of plague, a disease that has left its mark on human history since the medieval time. *Y enterocolitica* and *Y pseudotuberculosis* also cause mesenteric lymphadenitis.

**A. Epidemiology.** Plague occurs worldwide. The most important reservoir for this enzootic disease is rodents: *Rattus rattus* and *Rattus sylvaticus*. The ectoparasite *Xenopsylla cheopsis* (oriental rat flea) represents the most important and efficient vector of transmission to humans. Humans acquire the disease by a fleabite.

Most cases currently occur in developing countries in Africa and Asia. In the United States, most cases occur in the southwestern states during the months of May to October when individuals are outdoors and in contact with rodents and fleas.

**B. Microbiology.** *Y Pestis*, a member of the *Enterobacteriaceae* family, is a nonmotile gram-negative bacilli with bipolar Gram staining. This microorganism grows aerobically on most culture media after 48-72 h of incubation. It produces V and W antigens that play a role in the virulence of the organism.

**C. Pathogenesis.** After inoculation by an infested flea, *Y pestis* cells are phagocytized quickly by leukocytes and macrophages, where they replicate rapidly and produce the virulence antigens. The microorganisms are resistant to intracellular killing and they multiply in the regional lymph nodes and disseminate to the blood and other viscera causing profound toxemia. A severe bleeding diathesis may occur as a result of the effect of plague toxin on blood vessel walls or as a consequence of disseminated intravascular coagulation.

## Clinical Findings

**A. Signs and Symptoms.** After an incubation period of 2-8 days following the bite of an infected flea, patients present with sudden onset of fever, chills, weakness, and headaches ([Box 60-7](#)). The bubonic form of plague is characterized by the appearance of buboes, which are swollen, painful regional lymphadenopathy (typically inguinal or axillary), appearing after a few hours or on the next day. On physical examination, patients are toxic, lethargic, and agitated. The temperature is usually elevated to 41 °C. Buboes are matted, extremely tender and are 2-10 cm in diameter. Rarely, a vesiculopapular lesion from the fleabite is present. Bleeding from the gastrointestinal tract, respiratory tract, or the genitourinary tract is common (so-called red death). Petechiae and large ecchymoses occur along with gangrene of the distal extremities, nose, or penis (so-called Black Death).

The septicemic form of plague is characterized by high-grade bacteremia without palpable lymphadenopathy. Signs and symptoms are otherwise similar to the bubonic form. In this form of the disease, death occurs in 3-5 days in ~ 50% of cases. *Y pestis* reaches the lungs by way of the hematogenous route or less commonly via the airborne

route and causes pneumonia. The pneumonic form is highly contagious and is spread by inhalation of droplet nuclei from a patient with pneumonic plague.

**B. Laboratory Findings.** *Y pestis* may be recovered from blood cultures or cultures of an aspirate from buboes or sputum in the pneumonic form in 80-100% of cases. Gram stains of bubo aspirate or sputum demonstrate the characteristic bipolar "safety pin" gram-negative microorganisms.

### Differential Diagnosis

The differential diagnosis includes tularemia, lymphogranuloma venereum, cat-scratch disease, or severe staphylococcal and streptococcal infections.

### Complications

See Signs and Symptoms.

### Treatment

Streptomycin, the drug of choice for the treatment of plague, reduces the case fatality rate from > 50% in untreated cases to 10% in treated cases ([Box 60-8](#)). For patients who are allergic to or unable to tolerate streptomycin, tetracycline is a satisfactory alternative agent. In meningitis, the use of an antimicrobial agent with good penetration into the cerebrospinal fluid is essential. Chloramphenicol is administered at a loading dose of 25 mg/kg followed by 15 mg/kg intravenously every 6 h for a 10-day course.

### Prevention & Control

**A. Primary prevention.** Patients with suspected pulmonic plague should be placed in strict respiratory isolation until the sputum culture is negative ([Box 60-9](#)). Chemoprophylaxis with tetracyclines or sulfonamides should be administered to individuals who have had close contact with patients with plague pneumonia and for household contacts of flea-borne plague cases.

**B. Secondary Prevention.** For persons at high risk of exposure, two forms of vaccines are available: a live attenuated and a formalin-killed plague vaccine.

## YERSINIOSIS

### Essentials of Diagnosis

- Suspected in a child living in or traveling from a high-prevalence area who has fever, abdominal pain, and diarrhea followed by a reactive polyarthritis.
- *Yersinia* spp. are recovered from cultures of specimens of stool, mesenteric lymph nodes, blood, or abscess material.
- Inoculation of duplicate sets of cultures for incubation at 37 and 25 °C, respectively, enhances recovery of the microorganisms.

## General Considerations

**A. Epidemiology.** Conditions that are associated with increased risk for *Yersinia* spp. infections (yersiniosis) include iron overload states (such as in patients who receive chronic blood transfusions or those with hemochromatosis) and the use of desferrioxamine, a bacterial siderophore. Infections caused by *Y enterocolitica* are more common in children than adults. The disease is more prevalent in northern Europe than in the United States. It is acquired by ingestion of contaminated food or water or by direct contact with an infected animal. The organism has been recovered from a variety of wild and domestic animals including pigs, rodents, rabbits, dogs, and horses, as well as from water and dairy products. The ability of the microorganism to grow at 4 °C allows it to survive in refrigerated food and dairy products.

*Y pseudotuberculosis* infection occurs rarely. The microorganism has been recovered from many species of wild and domestic animals and from food, water, and other environmental sources. The disease is thought to be acquired by contact with infected animals or by ingestion of contaminated food. The disease is more common in Europe and typically affects children and adults during the winter months.

**B. Microbiology.** *Y enterocolitica* or *Y pseudotuberculosis* are the pathogens of the nonplague yersiniosis. They cause a gastrointestinal infection that may manifest itself by diarrhea or fever and abdominal pain that mimics acute appendicitis. These microorganisms are gram-negative bipolar stained bacilli, nonlactose fermenting and urease positive. They are motile at 25 °C but not at 37 °C. They are iron dependent and grow well on conventional culture media at 37 °C and in normal saline at 4 °C. *Y enterocolitica* produces a heat-stable enterotoxin and lipopolysaccharide endotoxin similar to that produced by other enteric gram-negative bacilli. The virulence of *Y pseudotuberculosis* appears to be related to the production of a lipopolysaccharide endotoxin and to the ability to survive intracellularly. *Yersinia* spp. lack siderophores and are dependent on siderophores produced by other bacteria for growth.

**C. Pathogenesis.** The portal of entry of *Y enterocolitica* and *Y pseudotuberculosis* is the gastrointestinal tract. These microorganisms cause terminal ileitis and adenitis. Pathogenic strains of *Y enterocolitica* cause mucosal ulceration and necrosis of Peyer's patches and therefore diarrhea. Bacteremia occurs rarely and is associated with suppurative lesions in the liver, spleen, and other organs. Reiter's syndrome is a reactive polyarthritis and occurs in 20%-30% of patients following infection with *Y enterocolitica*. Cross-reactions between the HLA-B27 antigen and the *Yersinia* antigen are postulated to be the underlying mechanism of arthritis.

## Clinical Findings

The spectrum of disease caused by *Y enterocolitica* and *Y pseudotuberculosis* is wide and may be divided into two categories: infectious (intestinal and extraintestinal) and postinfectious ([Box 60-10](#)).

**A. Signs and Symptoms.** An intestinal infection is the most common manifestation. Typically, patients present with fever, abdominal pain, and diarrhea that is occasionally

bloody for a 1- to 3-week duration. A clinical syndrome indistinguishable from acute appendicitis may occur in older children and adolescents. On laparotomy, thickening of the terminal ileum and cecal wall is present. The appendix is normal. Perforation of the intestine or dilatation of the colon with marked systemic toxicity (toxic megacolon) occurs rarely.

Extraintestinal infections are rare. A septicemic syndrome preceding enterocolitis or associated with transfusions of contaminated blood has a mortality rate of 50%. The iron present in blood and storage at 4 °C are favorable conditions for the growth of *Yersinia* spp. Other extraintestinal manifestations include cutaneous lesions such as cellulitis, vesicobullous lesions, and other manifestations including diffuse lymphadenopathy, splenomegaly, and acute pharyngitis.

Hepatic involvement is common in adults and can be present in two different forms. The acute form mostly occurring in patients with iron overload states is the result of involvement of the liver and sometimes the spleen with abscesses. The chronic form is characterized by a granulomatous inflammation in the liver and can be associated with a positive rheumatoid factor or a positive antinuclear antibody in the serum. The chronic form is thought to be secondary to an immunological phenomenon.

Postinfectious manifestations include polyarthritis involving the weight-bearing joints and occurs in 10%-30% of Scandinavian adults with *Y enterocolitica* infection. Of patients with arthritis, 70% have the histocompatibility antigen HLA-B27. Arthritis begins a few days to a month following the onset of diarrhea and can persist = 4 months. Erythema nodosum occurs in 20%-30% of cases with arthritis. Other postinfectious manifestations include uveitis, glomerulonephritis, Guillain-Barre syndrome and the hemolytic-uremic syndrome.

**B. Laboratory Findings.** Laboratory findings are nonspecific and might include leukocytosis, anemia, and elevated erythrocyte sedimentation rates.

## Differential Diagnosis

The differential diagnosis of polyarthritis is wide and includes acute rheumatic fever, juvenile rheumatoid arthritis, Kawasaki disease, and other postinfectious arthritides.

## Complications

See Signs and Symptoms.

## Treatment

Diarrhea and mesenteric adenitis are usually self-limited, and antimicrobial therapy has not been demonstrated to affect the course of the infection. Immunocompromised hosts and patients with extraintestinal infections should be treated with antimicrobial therapy ([Box 60-11](#)). The optimal therapy is unclear. *Yersinia* spp. are susceptible in vitro to gentamicin, fluoroquinolones, trimethoprim-sulfamethoxazole, third-generation cephalosporins, tetracycline, and chloramphenicol. Empirical therapy with an aminoglycoside alone or in combination with trimethoprim-sulfamethoxazole, or a

third-generation cephalosporin, or chloramphenicol is recommended.

## Prognosis

Mortality is rare, except in the septicemic form, where yersiniosis is associated with 50% mortality.

## Prevention & Control

Hospitalized patients with *Yersinia* spp. infections should be placed in enteric isolation ([Box 60-12](#)). Pasteurization of dairy products and proper cooking of meat or boiling water kills the microorganism in contaminated food. Contact with potentially infected animals in endemic areas should be minimized.

## PASTEURELLA

### Essentials of Diagnosis

- History of a cat or dog bite or other exposure.
- Pain, erythema, swelling, and drainage at the bite site.
- Gram-negative bipolar bacilli on Gram stain of the drainage.
- Culture of the organism confirms the diagnosis.

### General Considerations

*Pasteurella multocida* infection, a disease that primarily affects animals, may occasionally affect humans, causing a wide variety of infections ranging from soft tissue infection to bacteremia and endocarditis.

**A. Epidemiology.** *Pasteurella multocida* has been recovered from cultures of specimens from the nasopharynx and the gastrointestinal tract of a large number of asymptomatic wild and domestic animals. The highest carriage rates occur in cats (50%-90%), dogs or swine (50%), and rats (15%). Infections are usually preceded by a cat or dog bite or scratch on an extremity. Occasionally, infection may occur without a bite or scratch in persons who have frequent contact with animals. Fifteen percent of cases have no history of animal exposure.

**B. Microbiology.** *Pasteurella* spp. are small, nonmotile, non-spore-forming, bipolar staining gram-negative coccobacilli. Growth occurs aerobically at 37 °C in ordinary culture media and is enhanced by using blood- or serum-enriched agar under increased carbon dioxide tension. Among the *Pasteurella* spp. that can cause disease in humans, *P. multocida* is the most common. Different species of *Pasteurella* may be distinguished by their biochemical reactions and their requirements for V factor.

**C. Pathogenesis.** A localized infection occurs after inoculation of the microorganism in soft tissue or a joint space. It is characterized by polymorphonuclear leukocyte infiltrates

followed by necrosis and, in some cases, by abscess formation. When bacteremia occurs, microabscesses may develop in multiple organs.

## Clinical Findings

**A. Signs and Symptoms.** Hours to days after direct contact with an animal (usually by way of a dog or cat bite), a soft tissue infection develops ([Box 60-13](#)). Patients complain of an acute onset of pain, erythema, and swelling at the site of inoculation, usually on the hand, leg, arm, or head and neck. Serosanguineous drainage occurs 1-2 days later. A low-grade fever and regional lymphadenopathy are commonly seen. Abscess formation and septic arthritis or osteomyelitis rarely complicate local infection of the extremity.

**B. Laboratory Findings.** Gram-negative bipolar bacilli appear on Gram stain of the drainage. Cultures of the organism confirm the diagnosis.

## Differential Diagnosis

After an animal bite, the differential diagnosis should include infection caused by anaerobes, staphylococci, streptococci, tularemia, and cat-scratch disease.

## Complications

Occasionally, *P multocida* may affect the respiratory system. These infections occur in persons who have frequent contact with animals. *P multocida* has been recovered from the sputum cultures of asymptomatic patients with chronic obstructive pulmonary disease and in these patients may cause pneumonia. Occasionally, pharyngitis occurs in patients with close contact with infected animals, especially cats. Rarely, *P multocida* may cause meningitis, sinusitis, pharyngeal abscess, otitis, empyema, peritonitis, pyelonephritis, surgical wound infection, and endocarditis. Associated bacteremia can occur with any organ infection.

## Treatment

Animal bites need to be carefully assessed. Examination of the joints, tendons, and neurovascular axis of a limb is mandatory. Bite wounds should be cleaned with normal saline, and devitalized tissue should be debrided. If necessary, the tetanus toxoid vaccine should be administered, and potential exposure to rabies should be assessed.

The microbiology of animal bites is polymicrobial and includes *Pasteurella* spp., staphylococci, streptococci, and anaerobes. Antimicrobial therapy should be active against these microorganisms ([Box 60-14](#)). Amoxicillin-clavulanic acid, cefuroxime, or doxycycline are effective therapy. Ciprofloxacin is effective against *P multocida*; however, it lacks activity against anaerobes, streptococci, and staphylococci. In patients unable to tolerate  $\beta$ -lactams, doxycycline or combination therapy with ciprofloxacin and clindamycin is an effective alternative therapy for animal bites. In monomicrobial infection with *P multocida*, penicillin is the treatment of choice.

## Prevention & Control

Avoidance of contact with wild or domestic animals is probably the only means of preventing human *P multocida* infections ([Box 60-15](#)).

## HACEK INFECTION

### Essentials of Diagnosis

- Suspected in patients with periodontal disease with signs and symptoms suggestive of infective endocarditis.
- Large valvular heart vegetation on echocardiography.
- Small, pleomorphic gram-negative coccobacilli that grow best in enriched media and increased CO<sub>2</sub> tension.

### General Considerations

The fastidious bacteria of the HACEK group include *Haemophilus aphrophilus* and *H paraphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*. These organisms may be considered part of the normal flora of the upper respiratory tract. Because they share common clinical and microbiological properties, they will be reviewed together.

All HACEK microorganisms produce a similar clinical syndrome including infective endocarditis, periodontal disease, and bacteremia ([Box 60-16](#)). Rarely, these microorganisms may cause brain abscess, meningitis, pneumonia, intra-abdominal infections, gynecologic infections, arthritis, osteomyelitis, and human bite wound infection (*E corrodens*).

**A. Epidemiology.** The most common infectious disease caused by these microorganisms is infective endocarditis. These microorganisms account for 3% of infective endocarditis cases. The incidence of HACEK endocarditis is ~ 0.32/100,000 person years of life. HACEK microorganisms are part of the usual microflora of the oral cavity, and this serves as the portal of entry for bacteremia, which may result in infective endocarditis or, very rarely, infections in other organ systems.

**B. Microbiology.** Microorganisms of the HACEK group are small, pleomorphic gram-negative coccobacilli that grow best in enriched media (such as sheep blood agar or chocolate agar) and increased CO<sub>2</sub> tension. Cultures often require prolonged incubation times (average 5-7 days) for growth. They are distinguished among each other by their biochemical reactions.

### Clinical Findings

**A. Signs and Symptoms.** The presentation of endocarditis is often insidious in onset and includes fever, splenomegaly, embolic phenomena, and a new or changing cardiac murmur. More than half of patients with endocarditis will have had a dental procedure

within the 6 months before onset of symptoms or poor dentition at the time of diagnosis. Valvular or congenital structural heart disease or the presence of a prosthetic heart valve was present in 60% and 27% of cases, respectively. Cardiac valvular vegetation observed by echocardiography is characteristically large. This finding probably reflects the chronicity of infection before diagnosis. Signs and symptoms of other HACEK infections are related to the affected site of infection.

**B. Laboratory Findings.** The diagnosis of HACEK infections requires the cultivation of the bacteria from sterile sites. Biological specimens need to be incubated in enriched media under increased CO<sub>2</sub> tension for 5-7 days.

**C. Imaging.** Echocardiography can reveal large endocardial or valvular vegetation.

### **Differential Diagnosis**

The differential diagnosis includes infective endocarditis caused by other microorganisms, such as staphylococci, enterococci, and fungi.

### **Treatment**

With the emergence of  $\beta$ -lactamase-producing HACEK organisms, third-generation cephalosporins (eg, cefotaxime or ceftriaxone) are now considered the treatment of choice (see [Box 60-17](#)). The treatment of infections other than infective endocarditis caused by HACEK organisms requires the same antimicrobial therapy used in infective endocarditis; however, the length of therapy might be shorter, depending on the site of infection. With susceptible microorganisms, combination therapy using penicillin or ampicillin and aminoglycoside is satisfactory. The American Heart Association recommends that native valve and prosthetic valve endocarditis be treated for 4 and 6 weeks, respectively.

### **Prognosis**

Native or prosthetic valve endocarditis caused by HACEK organisms may be cured in 82%-87% of the cases by medical or medical and surgical therapies.

### **Prevention & Control**

Follow American Heart Association guidelines for prevention of infective endocarditis, after dental and other procedures in patients at high risk. See [Chapter 11](#) for cardiovascular-intravascular infection guidelines for subacute bacterial endocarditis prophylaxis.

## 61 . Tuberculosis — *Julie Brahmer, MD, & Merle A. Sande, MD*

### Essentials of Diagnosis

- The cardinal symptoms of tuberculosis (TB) are fatigue, weight loss, fever, and night sweats.
- The most commonly infected populations include the homeless, institutionalized patients, and HIV-positive patients.
- In most cases, a TB skin test (PPD) is positive.
- To establish presence of infection, an acid-fast bacilli (AFB) smear demonstrates the acid-fast bacillus.
- In primary pulmonary TB, an infiltrate in the lower lobes of the lung is usually seen on chest x-ray. In contrast, apical lung infiltrates are commonly seen in the reactivation of pulmonary TB.

### General Considerations

*Mycobacterium tuberculosis* is still an important pathogen. Approximately one-third of the world's population is infected with *M tuberculosis*, according to World Health Organization estimates, resulting in 2.9 million annual deaths. In the United States, tuberculosis is on the rise, after several decades of steady decline.

The disease develops in a subset of those who are infected. In most patients, the reason disease develops is unclear unless they are immunosuppressed by either HIV infection or other immunocompromising diseases. HIV has played a major role in the resurgence of tuberculosis in the United States and in the emergence of multidrug-resistant disease. Prompt diagnosis and treatment of active disease is important in all patients to prevent severe disease and infection of the surrounding population. In those infected with the tuberculosis bacillus, the prevention of active tuberculosis disease is also important.

**A. Epidemiology.** In the United States, tuberculosis had been on the decline until 1985, when the number of cases began to increase. This increase was undoubtedly a result of the HIV epidemic. Cases continued to increase until 1995, when the 22,813 new cases documented in the United States constituted a 6.4% drop from 1994. This drop resulted from a decreased incidence in the U.S.-born population. The overall incidence of tuberculosis in the United States is quite low, but case rates are high among specific groups such as HIV-infected patients, the homeless, recent immigrants from countries that have a high prevalence of tuberculosis, intravenous drug users, inner-city dwellers, and minorities.

In the late 1980s, tuberculosis caused by organisms resistant to antimicrobial agents increased sharply, especially in New York City, where, in 1991, one-third of all cases

were resistant to at least one agent. The rates of resistance in the United States began to decrease in 1995. Of cases reported, the isoniazid (INH) resistance rate was 7.6%, and the INH-rifampin resistance rate was 1.4%. The decrease in resistance rates was most likely caused by the introduction of directly observed therapy and intensive case management.

One lesson learned from the resurgence of tuberculosis and multidrug-resistant tuberculosis is the importance of tuberculosis control strategies and the importance of making sure patients adhere to the medication regimens. The Centers for Disease Control recommends that all tuberculosis patients be observed taking their medications by health care providers ("directly observed therapy," [DOT]). The decrease in U.S. case rates has been attributed to the institution of DOT. Other factors thought to have decreased the case and resistance rates are improved laboratory methods for identifying tuberculosis, broader use of drug-susceptibility testing, expanded use of preventive therapy in high-risk groups, decreased transmission of tuberculosis in congregative settings, improved follow-up of persons with TB, and increased federal resources for state and local TB control efforts.

*M tuberculosis* is transmitted in the air. The bacillus is packaged in a droplet nucleus and coughed out into the surrounding air by one person and inhaled by another. Patients with bronchopulmonary TB with a productive cough are particularly infectious. Other factors that increase the infectivity of a person are the extent of cavitory disease of the lung, presence of AFB on the sputum smear, unprotected coughing, and crowding in a household. Generally, patients with extrapulmonary TB are not infectious.

**B. Microbiology.** *M tuberculosis* is an AFB that is curved or straight and nonmotile. It is slow growing, taking = 18 h for one replication. Typically, it may take 2-6 weeks to grow a significant colony. The bacillus is non-pigment producing, which can be used to differentiate it from some other atypical mycobacteria.

**C. Pathogenesis.** A person is infected with *M tuberculosis* by inhaling bacilli in droplet nuclei. The particles must be retained in the lung. Thus the inhaled particles, which are < 5 um in size, travel to the alveolus during inspiration and are retained in the lung. Larger particles are filtered out before they reach the alveoli. In the alveolus, the bacillus activates the immune system. The first line of defense is the alveolar macrophage. These macrophages engulf the bacilli. Some macrophages are capable of killing the bacillus, whereas others cannot. The bacilli multiply within the cells. The factors controlling the macrophages' ability to kill *M tuberculosis* are not all known and may be genetic. At any rate, T cells are then attracted to these macrophages and recognize the *M tuberculosis* protein presented by the macrophage. The T cell lyses the infected macrophage. Memory T cells then develop which are thought to contribute to the delayed hypersensitivity reaction relied on by the purified protein derivative (PPD) skin test. These memory T cells also enable patients previously infected with TB to resist reinfection. Other factors that influence the progression of infection to disease include the intensity of exposure, interval since infection, age, and other coexisting or comorbid diseases. Extrapulmonary disease develops when the bacillus is not contained in the lungs and travels to other organs by way of the bloodstream.

Infection by *M tuberculosis* is reflected by a positive skin test reaction, although, in some

immunocompromised patients, a PPD test result may be negative even though these patients are infected. Those who are immunosuppressed have an increased chance of developing illness, which may be caused by an ineffective cell-mediated response ([Box 61-1](#)). Cell-mediated immunity is thought to be the mechanism by which a contained TB infection is kept quiescent. Patients who are HIV positive (who have ineffective cell-mediated immunity) and are infected with TB have a 7% chance per year of developing active tuberculosis.

Active tuberculosis disease is defined as tissue involvement by the *M tuberculosis* bacillus that progresses to produce clinical symptoms and signs. On average, illness develops in 3-5% of infected patients. Of the other 95-97% of infected patients, 5% develop active tuberculosis in their lifetime. *M tuberculosis* infection can cause several clinical syndromes.

## CLINICAL SYNDROMES

### PULMONARY TUBERCULOSIS

#### Introduction

The most common syndrome in adults is pulmonary TB, which accounts for ~ 80% of cases of active disease.

#### Clinical Findings

**A. Signs and Symptoms.** Symptoms of infection consist of fatigue, weight loss, fever, night sweats, and a productive cough. Most children who are infected with TB usually have no symptoms. Early symptoms can also include hemoptysis, which also occurs later in the disease when there is significant necrosis of lung parenchyma or if previous cavitations erode into arterioles. Patients with subpleural parenchymal inflammation with pleural membrane involvement or with TB pleuritis without parenchymal disease can experience pleuritic chest pain. Severe shortness of breath is not common. However, extensive pulmonary tuberculosis can cause respiratory failure.

**B. Laboratory Findings.** Routine laboratory test abnormalities are not common. Hyponatremia due to the syndrome of inappropriate secretion of antidiuretic hormone can be seen in some patients with pulmonary TB. However, adrenal involvement with TB can cause adrenal insufficiency, which may also be present with hyponatremia. Anemia secondary to this chronic disease is common.

**C. Imaging.** Pulmonary TB usually produces infiltrates observable on chest x-rays, but occasionally, chest x-rays are normal. Primary TB is the disease that develops before the development of an immune response to the bacillus. Primary TB has different characteristics than secondary reactivation of a pulmonary TB disease. Primary TB usually involves the lower lobes. Five percent of cases show a lobar or segmental infiltrate associated with ipsilateral hilar adenopathy. Fifteen percent of cases may have bilateral hilar adenopathy, but this is more commonly unilateral. A pleural effusion may also be present.

Children with primary pulmonary TB often have hilar adenopathy and occasionally a lower-lobe infiltrate that can be seen on chest x-ray. Secondary or reactivation TB, which is by far the most common presentation, characteristically involves the lung apices (posterior apical segments) or, rarely, the superior segments of the lower lobes. This is seen in 95% of patients with localized pulmonary TB. The typical parenchymal pattern is cavitary lesions with associated air space consolidation of a patchy or confluent nature.

Old, healed pulmonary TB lesions can produce fibrosis or calcific lesions on chest x-ray. These lesions can cause volume loss or contraction of the involved lobe. Cavities also may persist. New infiltrates or masses in areas of old tuberculosis infections may represent carcinoma, bacterial infection, hemorrhage, mycetoma, or recurrence of TB.

**D. Differential Diagnosis.** Differential diagnosis of pulmonary TB includes other atypical mycobacterium infections (*Mycobacterium avium* complex or *M kansasii*) and viral infections (see [Chapter 62](#)).

**E. Complications.** Complications of pulmonary TB include lung bulla formation, poor lung function, overwhelming infection, and death.

## EXTRAPULMONARY TUBERCULOSIS

Extrapulmonary TB accounts for ~ 20% of cases of active tuberculosis. Extrapulmonary TB is more common in immunocompromised patients and in infants and young children. Of these extrapulmonary sites, meningeal and lymphatic locations for disease are more common in infants and young children. In adolescents, the extrapulmonary sites tend to be the pleura, genitourinary tract, or peritoneum. Overall, the most common extrapulmonary site of TB in children is in the lymphatic system.

Other sites of infection in adults can include pleura, genitourinary tract, gastrointestinal tract, bone, meninges, peritoneum, and adrenals. When the *M tuberculosis* bacillus infects the lung, it often disseminates and involves multiple organs, including the bone marrow. This is called disseminated or miliary tuberculosis, but it may be asymptomatic. Extrapulmonary TB develops when the bacillus overwhelms the immune system and disseminates by way of the lymphatics, the bloodstream, or both. In these cases, disease is documented by biopsy, positive blood cultures, or both.

Signs and symptoms of extrapulmonary TB depend on the organ system involved. Weight loss, night sweats, and fever are the classic but nonspecific signs of tuberculosis. Clinicians should do blood cultures as well as biopsy and culture of the suspected tissue.

## TUBERCULOSIS IN PATIENTS WITH HIV INFECTION

### Introduction

HIV patients can have a wide variety of organ system involvement. In early HIV infection, pulmonary TB can be a presenting infection and an AIDS-defining illness. In advanced HIV infection, dissemination is common. A variety of unusual sites of infection

have been documented, including brain, pericardium, and other more common extrapulmonary sites such as those for peritoneal and gastric TB. Overall, the most common site of TB disease in an HIV-positive patient is pulmonary; however, these patients are at increased risk for developing disseminated disease ([Box 61-2](#)).

## Diagnosis

Diagnoses of extrapulmonary and pulmonary TB are the same. A skin test (PPD) is used to prove infection: 0.1 mL of PPD is placed intradermally on the volar surface of the forearm by means of a 26-gauge needle. At 48-72 h after injection, the diameter of induration, not erythema, is measured. A positive skin test reaction is caused by a delayed-type hypersensitivity response, which is directed at the TB protein antigens. Other tests include demonstration of the bacillus by means of culture or AFB smear of affected organs or blood culture in disseminated disease.

**A. Interpreting Tuberculin Skin Tests.** The criteria vary for interpreting a PPD test as positive. An induration = 5 mm is considered positive in patients who are at high risk of infection and developing disease; these include patients with known or suspected HIV infection, which includes all injection drug users. This group also includes close contacts of patients with active disease and patients with a chest x-ray suggestive of previously inactive tuberculosis. An induration of = 10 mm is considered positive in patients who are at intermediate risk of infection and developing TB. This group includes known HIV-negative injection drug users, immigrants from high-prevalence countries (such as Asia and Mexico), residents of long-term care or correctional facilities, locally identified high-prevalence groups (migrant workers, the homeless, and high-risk racial or ethnic groups), and children = 4 years old. Patients also at intermediate risk of TB include those with an immunosuppressive illness other than HIV or those receiving immunosuppressive therapy. These include patients with diabetes, renal failure, or hematologic malignancies or those receiving steroids on a long-term basis (> 15 mg of prednisone/d). Finally, an induration of = 15 mm is considered positive in patients with no known risk of developing TB or being infected with TB.

**B. False-positive PPDs.** False-positive results can occur in two situations. Patients who are infected with atypical mycobacteria such as *M avium* or *M kansasii* may have false-positive PPD results. Bacillus Calmette-Guerin (BCG) vaccination can also cause a positive result. However, a history of prior BCG vaccination should be ignored when one is interpreting skin test results in individuals with a high likelihood of being infected with *M tuberculosis*.

**C. False-negative PPDs.** False-negative results are much more common. In patients with distant infection, reactivity to a PPD test can decrease over time. These patients may require a "boost" PPD given 2 weeks after the first injection. There are multiple other factors to consider that cause a false-negative reaction ([Table 61-1](#)). Patients with coexisting diseases can also have false-negative reactions. In these patients, administration of other antigens such as those for *Candida* infection and mumps may be used to rule out anergy. However, some patients can have selective PPD nonreactivity.

**D. Bacteriologic Evaluation.** Smears and cultures of sputum are the most reliable ways to diagnose active pulmonary tuberculosis. Three separate early-morning sputum

samples should be collected for AFB staining. Cultures should be performed on all specimens of patients suspected of having tuberculosis. Because *M tuberculosis* grows so slowly, it may take = 6 weeks to identify the organism by culture. Drug susceptibility testing should be done on all positive cultures. In extrapulmonary TB, AFB stains and cultures are done on the infected tissue.

**E. Polymerase Chain Reaction (PCR) Technique.** Rapid diagnosis by the PCR technique is another option for the diagnosis of TB. It is commercially available and recently received approval by the U.S. Food and Drug Administration. PCR is approved only for testing AFB-positive sputum smears. In a research setting, PCR's specificity and sensitivity are > 95%. It does not take the place of acid-fast smears or mycobacterial cultures. Many more studies must be performed to better define the utility of PCR in the clinical setting.

## Treatment

Treatments of active extrapulmonary and pulmonary TB are the same. Treatment should be started presumptively before diagnosis in patients with severe disease thought to be TB. Treatment usually does not reduce the isolation rate of AFB in the first several days. In patients with less severe disease or those who present diagnostic dilemmas, therapy can be withheld until a diagnosis is made or until several specimens have been collected.

Patients should be started initially on a four-drug regimen until drug susceptibility tests are finalized, unless the patient is from an area where drug resistance is very low. Most communities in the United States have a > 4% incidence of cases resistant to at least one drug. However, if a community has a < 4% resistance rate, an initial three-drug regimen is acceptable.

**A. Choice of Treatment Regimen.** There are several available regimens for treatment ([Box 61-3](#)). Several considerations should be made when deciding on a particular regimen. These include the probability of primary resistance, previous treatment for tuberculosis, patient compliance, other coexisting illnesses, drug susceptibility of the organism, and history of hypersensitivity to or side effects of antituberculosis drugs. The risk factors for drug resistance include > 4% of INH resistance in the community, prior treatment with INH, exposure to a known drug-resistant case, immigration from countries with a high incidence of drug resistance (countries in Asia, Africa, or Central or South America), HIV coinfection, and intravenous drug use. These patients should be placed on an initial four-drug regimen ([Table 61-2](#)).

Tuberculosis treatment is based on three basic principles. Regimens for treatment of the disease must contain multiple drugs to which the organism is susceptible. The medications must be taken regularly. Finally, drug therapy must continue for an extended period because of the slow growing nature of the *M tuberculosis* bacillus.

If patients do not take their medications regularly, many adverse consequences can result. *M tuberculosis* can develop resistance. It can take a long time for the patient to become noninfective or for the disease to be contained. These factors are why DOT was introduced. Some experts advocate that DOT should be used in all patients.

However, this would be an expensive burden on the public health system. Most physicians use DOT for patients who have a history of noncompliance, risk factors for noncompliance such as substance abuse, and multidrug-resistant TB.

**B. Monitoring During Treatment.** While treating patients for tuberculosis, clinicians should monitor for clearing of the organism and for side effects of the medication. Before treatment is begun, laboratory tests of liver and renal functions should be performed and a baseline blood count obtained. If a patient is starting on pyrazinamide, a baseline uric acid level should be established. If a patient is to be treated with ethambutol, visual acuity and red-green color perception should be checked because this drug is known to produce optic neuritis. Ethambutol should not be used in children who are too young to report vision changes ([Table 61-3](#)).

**C. Follow-up.** Monthly follow-up should be done to check for symptoms of toxicity or disease progression. The patient with TB (pulmonary or extrapulmonary) should have a follow-up sputum monthly until the *M tuberculosis* culture is negative. Successful drug therapy using a combination regimen should eradicate the TB bacillus from the sputum of ~ 85% of patients in 2 months and ~ 100% of patients within 6 months. It is therefore important to obtain a sputum TB culture after the first 2-3 months of treatment and again after 6 months of treatment to document the negative cultures. If organisms are still present in the sputum after 3 months of treatment, patients should be evaluated for noncompliance, poor absorption of medications, or resistance of organisms. These patients should be referred to a tuberculosis specialist, as should patients for whom therapy has failed, patients with known drug-resistant organisms, and patients with complicated drug toxicities secondary to the treatment regimen.

## Prevention & Control

The key to prevention and control of TB centers on preventing exposure and, if infection occurs, preventing disease progression ([Box 61-4](#)). It is important to prevent exposure of the surrounding population to a patient with active tuberculosis. Thus isolation of patients with suspected TB is critical. Isolation can be achieved at home, if the patient lives alone, or in a special room in the hospital. Isolation rooms should have negative pressure and have six exchanges of air per hour with no recirculation of that air within the hospital. These rooms also should have ultraviolet lights to kill the bacilli in that room. Any patient with a cough and an infiltrate consistent with TB on a chest x-ray should always be isolated. Before a patient can be removed from isolation, three negative sputum AFB smears should be obtained. If the patient's disease is TB, the patient can be removed from isolation when the sputum AFB smear quantification decreases significantly (ie, 4+ to 1+). Masks have been a mainstay in preventing infection in health care workers, but efficacy remains unproven. The bacillus is spread from an infected patient by way of airborne droplets with active pulmonary disease only. Extrapulmonary TB is not contagious except when health care workers directly handle infected specimens (see below).

Prevention of disease in patients exposed to tuberculosis is important. It is accomplished by preventive therapy with INH. Patients who are at risk of infection have either a positive PPD, a history of exposure such as household contacts with a patient who has active TB, or both. A patient with a positive PPD test should have a screening

chest x-ray. If signs of active disease are present, a screening sputum evaluation should be done. The risk of having infection is extremely high in children who are the household contacts. Known exposed children < 6 years of age should have a chest x-ray done even if the PPD is negative, since these children can have a severe course if active TB is left untreated. If a household contact's first PPD is negative, another PPD should be placed in 8-12 weeks (which, if the patient has been truly exposed, should be positive at this time). If the second PPD is negative, preventative therapy can be stopped if the patient is no longer in danger of being exposed.

### **Prevention Among Health Care Workers**

Health care workers should have regular PPD checks unless they have a history of PPD positivity. Most centers recommend yearly PPDs. PPDs should be placed on anyone who is a household contact of a patient with active TB or anyone who has had close contact with an active case of TB. Also, patients who are in extended-care facilities or correctional facilities should have a PPD at the time of initial placement because of the high risk of infecting a large group of people.

Patients who qualify for preventative therapy should receive INH, 300 mg by mouth daily for a minimum of 6 months ([Table 61-4](#)). If the patient has radiographic evidence of previous tuberculosis, he or she should be treated with INH for 12 months. Children should be given a dose of INH of 10 mg/kg/d to a maximal dose of = 300 mg/d. People receiving INH for prevention should be monitored monthly for signs of INH toxicity. Patients with symptoms of hepatitis, such as gastrointestinal complaints, jaundice, anorexia, or some combination of these symptoms, should have liver function tests performed. If those tests are abnormal, INH should be stopped. Patients with an increased risk of INH hepatitis should have their liver function checked regularly. These patients include those > 35 years of age, alcohol users, and those with preexisting liver disease. INH therapy should not be given to patients with active liver disease or to pregnant women. It is important to remember that patients with radiographic evidence of tuberculosis must be first evaluated for active disease before beginning preventative treatment.

If a person has a high risk of exposure to INH- or rifampin-resistant organisms, the data for the efficacy of preventative therapy are limited. If the risk of infection with INH-resistant organisms is high and the patient would be unable to tolerate the disease, rifampin should be used. If the patient was exposed to INH- and rifampin-resistant organisms, a multidrug preventive therapy should be used. Each case must be assessed individually ([Table 61-5](#)).

BCG vaccination has been used in some countries to improve the ability of a person who is acutely infected with *Mycobacterium* TB to contain the infection. The reported effectiveness of BCG vaccination varies, and the indications for use are limited. In the United States, the only people who might benefit from a BCG vaccination could be people who are repeatedly exposed to TB. Because BCG will cause a PPD test to be positive, it can complicate the diagnosis of a TB infection. However, the history of a BCG vaccination should be ignored when a PPD is placed, and the patient should be treated based on the guidelines in [Table 61-4](#) or the patient's symptoms of active disease.

## 62 . Other Mycobacteria — Julie Brahmer, MD, Yenjean Hwang, MD & Merle A. Sande, MD

### Essentials of Diagnosis

- Demonstration of the acid-fast bacillus.
- Infections more common in immunocompromised hosts.
- Infections mainly pulmonary or soft tissue.

### General Considerations

The increasingly relative importance of the atypical mycobacteria, many of which are ubiquitous in the environment, was recognized with the decline in tuberculous disease. Generally, atypical mycobacteria are unusual causes of disease in patients who are immunocompetent but can in immunocompromised hosts such as AIDS and cancer patients. Most infections caused by atypical mycobacteria are skin and soft tissue abscesses, sometimes following pulmonary infection or implantation of prosthetic devices. There have been a few reports of epidemics of iatrogenic infection with atypical mycobacteria, associated with injection of contaminated materials.

**A. Epidemiology.** Atypical mycobacteria may account for 35% of isolations of potentially pathogenic mycobacteria in the United States; the rate of infection from atypical mycobacteria, however, ranges from 0.5% to 30% of all infections caused by mycobacteria. An estimated 3 million of the 6 million cases of leprosy worldwide remain untreated.

**B. Microbiology.** The atypical mycobacteria are classified into four groups according to their growth characteristics, as well as pigment production in culture. Runyon class I includes organisms such as *Mycobacterium kansasii*, which are characterized by pigment production upon exposure to light (photochromogens). Runyon class II, including *Mycobacterium scrofulaceum*, are scotochromogens, which produce pigment in the light or in the dark. Runyon class III includes nonpigment producers (nonchromogens) such as *Mycobacterium avium* complex (MAC). Runyon class IV organisms, such as *Mycobacterium abscessus*, are characterized by rapid growth in culture, on the order of 2-30 days, as compared with the other mycobacteria, which often take 6-8 weeks to cultivate.

**C. Pathogenesis.** Sources of the atypical mycobacteria include soil, water, and domestic and wild animals (see [Table 62-1](#) for habitats of common medically important mycobacteria). Most infections are acquired through aspiration or inoculation of atypical mycobacteria from the environment. Incubation periods are very long, averaging 5 years. Affected patients are of all age groups, but the peak age of onset is in young adults; children are rarely affected.

Pulmonary disease often results from inhalation of organisms, whereas direct

inoculation of the organism or a foreign body contaminated with the organism results in soft-tissue disease. Ingestion of organisms can result in gastrointestinal involvement. Person-to-person transmission does not usually occur, with the exception of *Mycobacterium leprae*, which is transmitted by nasal droplets, although there is some evidence that transmission may occur by soil. Disseminated disease does not usually occur except in immunocompromised hosts.

## CLINICAL SYNDROMES

### **MYCOBACTERIUM AVIUM COMPLEX (DISSEMINATED & PULMONARY DISEASE)**

#### **Introduction**

*M avium* is the most common atypical mycobacterium to cause disease in humans. In immunocompetent patients, *M avium* can cause pulmonary disease ([Box 62-1](#)). It is the most common pulmonary pathogen of all the atypical mycobacteria. There are several risk factors for pulmonary *M avium* infection besides AIDS. Patients with underlying pulmonary disease, those who have had a gastrectomy, and those with cystic fibrosis can develop pulmonary infection. Pulmonary disease can also develop in a subgroup of women without pulmonary disease but with mitral valve prolapse, pectus excavatum, and thoracic scoliosis.

In immunocompromised patients such as those with AIDS who have a CD4 lymphocyte count of < 100, *M avium* can cause osteomyelitis, peritonitis, oral lesions, and disseminated disease ([Box 62-2](#)). It may also cause colonization without disease in these patients. In children with AIDS, MAC is also common, occurring in 24% of children with a CD4 count of < 100. Patients with underlying malignancies and defects of cell-mediated immunity and those on chronic steroids or cytotoxic chemotherapy are also susceptible.

*M avium* can cause other disease syndromes, including skeletal infections, lymphadenitis, deep subcutaneous nodules, fascitis, panniculitis, and synovitis. In children, it can cause superficial lymphadenitis and cutaneous disease such as ulcers, abscesses, or plaques, and intracerebral infection has been reported.

#### **Clinical Findings**

**A. Signs and Symptoms.** Patients with pulmonary disease caused by *M avium* infection can present with a productive cough, fever, weight loss, and, less commonly, hemoptysis ([Table 62-2](#)). Symptoms of disseminated disease are constitutional, such as fever, weight loss, and malaise. MAC very rarely causes pneumonia in AIDS patients. Hepatosplenomegaly and adenopathy can be noted by physical exam. Gastrointestinal involvement in AIDS patients can present with three different syndromes, including chronic diarrhea and abdominal pain, chronic malabsorption, and extrabiliary obstructive jaundice secondary to periportal lymphadenopathy. MAC should be suspected in AIDS patients who exhibit all of the following signs or symptoms: CD4 counts of < 100, fever lasting for > 30 days, a hematocrit of < 30%, and an albumin concentration of < 3.0 mg/dL.

**B. Imaging.** MAC involving the lung can classically cause pulmonary infiltrates seen on chest x-ray in the upper lobes or disseminated. Chest x-ray findings in these patients can vary from small thin-walled cavities to lobar infiltrates and isolated nodules. In older women, x-ray abnormalities include fibronodular and interstitial abnormalities with upper-lobe predominance. Chest x-rays can mimic reactivation tuberculosis with cavitation.

## **MYCOBACTERIUM LEPRAE (LEPROSY)**

### **Introduction**

*M leprae* is the etiologic agent of Hansen's Disease or leprosy. Although not a common problem in the United States, it is in other parts of the world. With the advent of effective antimicrobial agents, the number of cases of leprosy worldwide has fallen from 12 million in 1982 to 6 million in 1991. It remains a significant problem, however, because the incidence of new cases has not yet declined, and much of the affected population lives in areas where effective medical treatment is difficult to obtain. Leprosy is endemic in Asia, Africa, Latin America, and the Pacific.

In the United States, Canada, and Europe, there are virtually no cases of leprosy except those that are imported from areas where leprosy is endemic. Risk factors for acquisition of leprosy in endemic areas include poverty and rural residence. However, even in endemic areas, the distribution of leprosy can vary greatly, sometimes with significant differences in incidence of leprosy in adjacent villages. In North America, armadillo contact has been reported as a risk factor for acquisition. Other risk factors that have been reported in certain populations are the human leukocyte antigens HLA-DR3 (with the tuberculoid or paucibacillary form of disease) and HLA-MTI (with the lepromatous or multibacillary form of disease). Interestingly, the proportions of the lepromatous and tuberculoid types of leprosy ([Box 62-3](#)) vary geographically; in Mexico, 90% are lepromatous, whereas, in India and Africa, 90% are tuberculoid.

### **Clinical Findings**

**A. Signs and Symptoms.** The manifestations of leprosy involve the skin, upper respiratory system, peripheral nerves, and, in men, testes ([Table 62-3](#)). The peripheral neuropathy that is seen in leprosy results in impaired sensation of fine touch, temperature, and pain, whereas proprioception and vibratory sensation are intact. Such loss of sensation leads to recurrent trauma and ulceration in the extremities. For example, loss of sensation in the feet can lead to chronic nonhealing ulcers, especially at the metatarsal heads. Large nerve trunks may also be affected. A common nerve trunk that is affected in leprosy is the ulnar nerve at the elbow, which results in clawing of the fourth and fifth digits of the hand, dorsal interosseus muscle atrophy, and loss of sensation in the hand along the ulnar nerve distribution.

The lepromatous or multibacillary form of leprosy is characterized by symmetric skin nodules, plaques, and thickened dermis. Usually, the ear lobes and extremities are affected. Diffuse lepromatosis is seen usually in patients from Mexico, who show areas of diffuse dermal infiltration and no focal lesions. Untreated, lepromatous leprosy results in a high level of continuous bacteremia. Peripheral neuropathy is symmetric and

generalized. There is a characteristic deformity associated with this type of leprosy, "saddle-nose deformity," which occurs because of infiltration of the upper respiratory system and nasal cartilage. Other upper respiratory system effects include chronic nasal congestion and epistaxis.

The tuberculoid, or paucibacillary, form of leprosy is characterized by one or few hypopigmented macules, which are anesthetic and variable in size. These macules have distinct and elevated borders. Peripheral neuropathy in this form of leprosy is usually asymmetric and affects large nerves. Neural leprosy is characterized by functional impairment of large nerve trunks without skin lesions. The upper respiratory system is not involved.

**B. Laboratory Findings.** *M leprae* is an acid-fast, Gram-stain-variable bacillus. Its size varies from 1 to 8  $\mu\text{m}$  long by 0.3 to 0.5  $\mu\text{m}$  wide. It cannot be distinguished morphologically from other mycobacteria. *M leprae*'s distinguishing characteristics include loss of acid fastness by pyridine extraction, presence of dopa-oxidase activity, and a doubling time of 12 days in the mouse footpad. It is an obligate intracellular parasite but can remain viable outside its natural hosts, i.e. humans and the nine-banded armadillo, for several days. Doubling time of the bacillus is very slow, but, by the time of diagnosis in a lepromatous patient, the number of bacilli present,  $10^{15}$ , is enormous, greater than any human bacterial infectious agent. *M leprae* has a predilection for cooler areas of the body because it grows best at temperatures under  $37^{\circ}\text{C}$ , hence its characteristic effects on extremities, the nose, and the pinna of the ears.

**C. Complications.** Leprosy patients may develop Lepra type 1 reaction (downgrading and reversal reactions), Lepra type 2 reaction (erythema nodosum leprosum), or a reaction called Lucio's reaction. Lepra type 1 reactions usually occur in borderline leprosy patients, before therapy (downgrading reaction) or after initiation of therapy (reversal reaction). The reaction consists of inflammation within previous skin lesions, new multiple-satellite maculopapular skin lesions, neuritis, and low-grade fever. Irreversible nerve damage can occur unless therapy with corticosteroids is started promptly. The recommended treatment is prednisone, 40-60 mg daily, tapered over 2-3 months. Lepra type 2 reactions affect nearly half of lepromatous patients, usually within 2 years of instituting antimicrobial therapy. Painful papules on the extensor surface of extremities, neuritis, fever, uveitis, lymphadenitis, orchitis, and glomerulonephritis can occur. Treatment of erythema nodosum leprosum requires a short course of corticosteroids. Lucio's reaction is seen in patients with diffuse lepromatosis and consists of shallow recurrent ulcerations on the lower extremities. Occasionally, the lesions can be generalized, and, in that case, Lucio's reaction can be fatal.

## **MYCOBACTERIUM KANSASII (CHRONIC PULMONARY INFECTION)**

### **Introduction**

*M kansasii* is the most common nontuberculous mycobacterium after MAC to be isolated in tertiary care centers. *M kansasii* is a pathogen worldwide, and in the United States the incidence is highest in the Midwest and Southwest. It commonly affects individuals in certain occupations, such as miners, welders, and sandblasters. Patients with underlying pulmonary pathology can be infected also. However, *M kansasii* rarely

causes disease in children. Children who are affected tend to be immunocompetent and without an underlying pulmonary disease.

## **Clinical Findings**

The most common clinical syndrome caused by *M kansasii* is a chronic pulmonary infection that resembles pulmonary tuberculosis.

**A. Signs and Symptoms.** Symptoms of infection are nonspecific and can include cough, fatigue, and shortness of breath. Uncommonly, *M kansasii* can cause local lymphadenitis, a skin infection that resembles sporotrichosis. With disseminated infections, skin lesions can be present, such as erythema nodosum, erythema multiforme, and induration.

In AIDS patients, *M kansasii* is the second most common infection caused by atypical mycobacterium. It tends to produce a disseminated disease similar to MAC. *M kansasii*-disseminated disease was present at the time of the index AIDS diagnosis in 0.2% of patients. *M kansasii* can also produce isolated oral ulcers, osteomyelitis, soft tissue infections, tenosynovitis, and arthritis. It may also produce necrotizing pulmonary nodules.

**B. Laboratory Findings.** Nonspecific.

**C. Imaging.** On chest x-ray, *M kansasii* is difficult to distinguish from *M tuberculosis*. In children, mediastinal and hilar lymph nodes are commonly enlarged.

**D. Differential Diagnosis.** Atypical mycobacterium should be suspected if a patient does not respond to conventional therapy for *M tuberculosis*.

## **MYCOBACTERIUM SCROFULACEUM (LYMPHADENITIS)**

### **Introduction**

*M scrofulaceum* is a ubiquitous scotochromogenic mycobacterium that commonly exists in soil and water and contaminates reagents and foodstuffs. It readily colonizes respiratory secretions of healthy children and adults. The most common clinically evident disease in humans is lymphadenitis, which is commonly seen in children < 12 years old.

### **Clinical Findings**

**A. Signs and Symptoms.** The clinical presentation is a single node or cluster of nodes in the submandibular area. The nodes slowly enlarge over weeks. The patient experiences very few local or systemic symptoms except for mild lymph node tenderness on palpation. Over weeks to months, if left untreated, the infection comes to the surface, ruptures, and forms a draining sinus, which then calcifies.

**B. Laboratory Findings.** Nonspecific.

## **MYCOBACTERIUM BOVIS (TUBERCULOSIS IN ANIMALS)**

### **Introduction**

*M bovis* is considered to be part of the *M tuberculosis* complex. It is a nonchromogen and generally takes 21-40 days to isolate in culture. Its natural reservoir is humans and cattle, and it generally causes tuberculosis in cattle, goats, cats, dogs, primates, and other wildlife. It is rarely a cause of tuberculosis in humans, although there are reports of it causing 3% of the tuberculosis cases in certain places such as San Diego, California. An attenuated strain of *M bovis* is used for bacille Calmette-Guerin (BCG) vaccine. Transmission of the organism occurs by inhalation of aerosol or by direct inoculation. Transmission by ingestion of contaminated milk from infected cows did occur prior to routine pasteurization. Clinical syndromes associated with *M bovis* include soft tissue infection. Soft tissue infection has been reported after accidental self-inoculation with BCG by a health care worker.

### **Clinical Findings**

*M bovis* will cause pulmonary infection indistinguishable from that caused by *M tuberculosis*. Bacteremia, mycotic aortic aneurysm, vertebral osteomyelitis, and granulomatous hepatitis have been reported as complications of bladder instillation of BCG for the treatment of bladder cancer.

**A. Laboratory Findings.** Nonspecific.

## **MYCOBACTERIUM MARINUM (CLASSIC FISH TANK GRANULOMA)**

### **Introduction**

*M marinum* is an acid-fast bacillus that is in Runyon class I, the photochromogens. It grows optimally at 32 °C and inhabits water and marine organisms. Infection of humans generally occurs after a trauma that takes place in water (eg, fish spines, nips by crustaceans); it can be acquired through open skin that comes into contact with swimming pools, aquariums, domestic fish tanks, or stagnant bodies of water.

### **Clinical Findings**

**A. Signs and Symptoms.** The typical lesions of *M marinum* infection, which can resemble cutaneous sporotrichosis, are small papules on the extremities that enlarge, turn blue-purple, and then suppurate and ulcerate. Dissemination is rare, although it can occur in immunocompromised hosts.

**B. Laboratory Findings.** A skin biopsy should be taken for culture. Pathology shows granulomatous inflammation, but it is rare to find acid-fast bacilli on stain.

**C. Differential Diagnosis.** *M marinum* can resemble sporotrichosis.

### **Diagnosis**

The diagnosis of atypical mycobacterial infections may be difficult to make with certainty. It is often unclear whether the presence of an atypical mycobacterium in a clinical specimen indicates infection or colonization. The diagnosis of an infection with mycobacteria should be made only in the presence of an illness associated with mycobacteria and when other causes of disease have been excluded. Another clue that helps distinguish colonization from infection is the quantity of growth in culture. Heavy growth of one organism in culture is more suggestive of infection than of colonization; light growth is suggestive of colonization, unless the organism was isolated from a normally sterile body fluid. It is often helpful to notify the microbiology laboratory when infection with an atypical mycobacterium is suspected, because the nontuberculous mycobacteria often have very specialized culture requirements.

Experience is needed for accurate interpretation of the appearance of mycobacteria in stained specimens. Typically, fluorochrome, Kinyoun, and Ziehl-Neelsen stains are used. Cultures are incubated at 37 °C in 10% carbon dioxide and 90% air, usually for = 6-8 weeks. (More detailed information regarding laboratory diagnosis can be found in a standard microbiology text.) Typically, detection of growth in culture can be made within 2 weeks, but identification and speciation may take = 2-4 weeks. Susceptibility testing has not been standardized, and all significant isolates need to be tested for antibiotic susceptibility. However, susceptibility to an antibiotic in vitro has not been directly correlated to clinical efficacy.

Diagnosis of MAC, *M bovis*, and *M marinum* infections is determined by acid-fast bacillus smear and culturing from the infected tissue. Diagnosis of *M scrofulaceum* infection is made by identification of granulomatous inflammation in skin biopsy and isolation of the organism from culture. Diagnosis of *M kansasii* infection is difficult, especially since there can be a concurrent infection with *M tuberculosis*.

Diagnosis of leprosy depends on clinical information as well as biopsy of affected dermis; viable organisms stain brightly and uniformly (see [Table 62-3](#)). Nonviable organisms stain in an irregular manner. A skin biopsy taken from a patient with suspected leprosy should be stained with hematoxylin and eosin, as well as with Fite stain for acid fastness.

The two polar forms of leprosy are the lepromatous, or multibacillary, and the tuberculoid, or paucibacillary (see [Box 62-3](#) for features of both). Most patients will have intermediate forms. In lepromatous patients, skin biopsies should be taken at sites of skin lesions, but normal looking skin will also have pathologic changes. Lesions will show many bacilli in clumps and foam cells loaded with bacilli in the dermis. Granulomatous changes may be seen in the liver, spleen, and lymph nodes. In tuberculoid patients, biopsies should be done only at sites of lesions because biopsies of normal appearing skin will be nondiagnostic. Skin biopsies from tuberculoid patients will show few or no organisms but will show granulomas of epithelial cells, lymphocytes, and foreign-body giant cells near dermal appendages, especially dermal nerves. The pathognomonic lesion for tuberculoid leprosy is acute granulomatous invasion and destruction of dermal nerves. Most patients, however, have intermediate, or borderline, forms of leprosy, and their biopsies will show a mixture of findings.

An intradermal skin test is available that uses heat-killed *M leprae*. However, use of the

skin test to make the diagnosis of leprosy is unreliable. Although the skin test will be positive in tuberculoid patients, treated lepromatous patients and unaffected individuals in endemic areas will show positive results as well. Lepromatous patients will be anergic specifically to *M leprae* but will have a normal response to intradermal recall antigens, such as purified protein derivative. Various *M leprae* lipid and carbohydrate constituents are believed to impair macrophage and T-lymphocyte function specifically against *M leprae*. There also seems to be an increase in the number of T-suppressor cells. Cytokines such as interleukin 2 (IL-2), interferon  $\gamma$  (IFN- $\gamma$ ), IL-4, IL-5, and IL-10 are also thought to play a role in expression of disease.

### **Treatment of Atypical Mycobacterial Infections**

MAC Infection. Treatment of pulmonary disease, disseminated disease, subcutaneous infections, and bone infections in immunocompetent patients consists of a regimen of three drugs ([Box 62-4](#)). Clarithromycin at a dose of 500 mg by mouth two times a day is given with ethambutol at a dose of 15-25 mg per kg by mouth every day. These two drugs are also then given with rifabutin, 300 mg by mouth every day for = 24 months. If there is an isolated lung lesion, surgical removal of the nodule is a treatment option. Other second-line drugs include azithromycin, clofazimine, ciprofloxacin, and amikacin. The regimen used should be tailored to in vitro susceptibility tests. Patients with pulmonary disease should have sputum samples tested every month during the course of treatment. In 80-90% of patients, the sputum should convert to negative in 1-2 months. The therapy should be extended for 12 months after the sputum conversion.

HIV-positive patients with disease can be treated with a three-drug regimen that includes clarithromycin or azithromycin, ethambutol, and/or rifabutin ([Box 62-5](#)). An alternative regimen includes clarithromycin or azithromycin, ethambutol, plus/ minus rifabutin and one of the following: ciprofloxacin, ofloxacin, or amikacin. A recent study of treatment regimens showed that therapy with rifabutin, ethambutol, and clarithromycin resulted in a longer mean survival than did therapy with rifampin, ethambutol, clofazimine, and ciprofloxacin. The efficacy of these regimens in children with HIV infection has not been well established.

Once immunosuppressed patients with AIDS are treated, they must be placed on lifelong suppressive therapy that includes clarithromycin or azithromycin plus ethambutol. Alternative drugs include clarithromycin or azithromycin alone or rifabutin.

AIDS patients who do not have documented active MAC disease and whose CD4 count is < 100 may be placed on primary prophylactic therapy, which consists of a single drug ([Box 62-6](#)). Those drugs used in primary prophylaxis are clarithromycin, azithromycin, or rifabutin. Clarithromycin reduces the MAC infection rate by 68% and was associated with a 38% mortality rate as compared with 47% with placebo.

*M leprae* Infection. Leprosy generally requires a long duration of treatment, and compliance is a major problem. Lepromatous leprosy requires a longer treatment time course than tuberculoid leprosy because of the greater number of organisms involved. Currently, the recommended treatment is dapsone and rifampin for 6 months for tuberculoid leprosy ([Box 62-7](#)). Dapsone alone is not recommended because of reports of emerging resistance. For lepromatous leprosy, dapsone with rifampin or clofazimine

for 24 months is recommended. Nonetheless, there have been reports of relapses even after such long courses of treatment. Other agents such as ethionamide, prothionamide, the aminoglycosides, minocycline, clarithromycin, and the fluoroquinolones may also prove to be beneficial.

*M kansasii* Infection. Response to antimycobacterial therapy tends to be poor, but there have been reports of clinical responses. Treatment must be tailored to each individual patient depending on the in vitro sensitivities of *M kansasii* and whether immunosuppression is present. Treatment should consist of a three- to five-drug regimen depending on sensitivities. A common regimen for *M kansasii* includes rifampin (10 mg/kg/d for a maximum of 400 mg/d), isoniazid (5 mg/kg/d for a maximum of 300 mg/d), and ethambutol (15-25 mg/kg/d). Treatment should be continued for ~ 18 months and has been shown to have about a 90% response rate.

*M kansasii* has been shown to be sensitive in vitro to clarithromycin, erythromycin, amikacin, and the fluoroquinolones. These medications, along with sulfamethoxazole or bactrim, are second-line drugs. If lymphadenitis is present, the lymph node should be totally excised. There is no rationale for incision and drainage. In AIDS patients with disseminated disease, treatment should be extended for 15 months after cultures are negative. Treatment regimens in children have not been well established.

*M scrofulaceum* Infection. Antituberculosis drugs are not helpful. The treatment of choice is surgical excision of involved nodes. Clarithromycin may be useful in patients not responsive to excision.

*M bovis* Infection. Treatment of *M bovis* is the same as for *M tuberculosis*, although *M bovis* is uniformly resistant to pyrazinamide.

*M marinum* Infection. Treatment of *M marinum* infection consists of rifampin and ethambutol.

## **Prevention & Control of Atypical Mycobacterium Infection**

No isolation measures are needed since the organisms are found in the environment. Prophylaxis is needed only in AIDS patients with MAC (see [Box 62-6](#)).

**Table 62-2.** Clinical findings in *Mycobacterium avium* complex infection.<sup>1</sup>

Acid-fast bacillus, nonphotochromogen

Slow grower (10-21 days) at 36°C

CXR findings vary from small thin-walled cavities to lobar infiltrates and isolated nodules.

Diagnosis clinically:

- Presence of pulmonary cavities not attributable to another disease and 2 or more positive sputum or bronchial wash specimens with moderate to heavy growth of MAC
- Infiltrate present but no cavities present, with failure of sputum cultures to convert to negative with either pulmonary toilet or 2 weeks of specific antimicrobial therapy
- Lung biopsy with histological confirmation and positive culture
- One positive blood culture
- Isolation of MAC from any other sterile body site
- Positive bone marrow, lymph node, or liver biopsy

<sup>1</sup>For clinical findings in AIDS patients, see Box 62-7.

### **BOX 62-3. *Mycobacterium leprae* Syndromes**

#### **Lepromatous Forms**

- Symmetrical skin plaques, nodules, or thickened dermis, usually on cooler parts of the body
- Infiltration of upper respiratory system and nasal cartilage, resulting in "saddle nose" deformity
- Symmetric and generalized peripheral neuropathy
- Diffuse lepromatosis seen in Mexican patients, diffuse dermal infiltration without focal lesions
- Normal-looking skin will show organisms in clumps, foam cells in deep dermis, and granulomas in liver, spleen, and lymph nodes

#### **Tuberculoid Forms**

- Few hypopigmented anesthetic macules with distinct elevated and erythematous borders
- Large and asymmetric peripheral nerve involvement
- Neural leprosy causes large functionally impaired nerve trunks without skin lesions
- Lesions and rims should be biopsied (normal-looking skin will not have abnormalities); granulomas with invasion and destruction of dermal nerves

## 63 . Actinomycetes — Phyllis C. Tien, SM, MD & David A. Relman, MD

### INTRODUCTION

Actinomycetes are variably acid-fast, gram-positive bacilli that are sometimes filamentous and branched. Originally thought to be fungi due to their hyphae-like appearance, they are now recognized as bacteria based on their cell wall components, reproduction by fission without sporulation or budding, inhibition by antibacterial agents, and molecular phylogenetic analysis. The actinomycete chromosomes contain a high content of guanosine and cytosine. The actinomycetes include the genera *Mycobacterium* and *Corynebacterium*, which are discussed in [Chapter 61](#) and [Chapter 62](#), respectively. The actinomycetes also include the genera *Nocardia*, *Actinomyces*, *Rhodococcus*, *Tsukumurella*, *Gordona*, *Actinomadura*, and *Streptomyces*, as well as the Whipple's disease bacillus *Tropheryma whippelii*. Of these, members of the genus *Nocardia* are the most significant from a clinical standpoint, followed by organisms from the genus *Actinomyces*. The other actinomycetes discussed in this chapter are less common causes of disease in humans.

### NOCARDIA

#### Essentials of Diagnosis

- Gram-positive, variably acid-fast, branching filaments with aerial hyphae.
- Colonies have characteristic chalky-white or cotton ball appearance.
- Suspect when chronic pulmonary disease is accompanied by CNS or skin lesions.
- No specific antibody or antigen detection tests.

#### General Considerations

**A. Epidemiology.** *Nocardia* spp. are strictly aerobic, ubiquitous soil-dwelling organisms that are largely responsible for the decomposition of organic plant material. Infection usually occurs via inhalation of these organisms in airborne dust particles, leading to pulmonary disease. However, infection can also be acquired via direct percutaneous inoculation by thorns, animal scratches, bites, surgical wounds, and intravenous catheters. Dissemination commonly occurs to the central nervous system (CNS), skin, and subcutaneous tissues.

Nocardiosis is chiefly an opportunistic infection and occurs especially in patients with lymphoma and leukemia and to a lesser extent in patients with solid tumors. It is becoming more frequently recognized in patients with AIDS (~ 10% of all nocardial infections since 1980), those receiving organ transplants (especially renal and heart), and those receiving therapy with cytotoxic agents. Underlying pulmonary conditions, such as chronic obstructive pulmonary disease and bronchiectasis, also predispose individuals to pulmonary nocardiosis. Children with chronic granulomatous disease are

at elevated risk of developing this infection. One-third of patients with nocardiosis, however, have no apparent predisposing factor. The disease affects men approximately threefold as often as it affects women and most often affects men and women between the ages of 30 and 50 years.

Approximately 90% of nocardial infections in the United States are due to *Nocardia asteroides* (and the related species *Nocardia farcinica* and *Nocardia nova*, which together form the *N asteroides* complex). Other pathogenic species implicated in disease include *Nocardia brasiliensis*, *Nocardia otitidiscaviarum*, and *Nocardia transvalensis*. While infection with *N asteroides* is geographically widespread, most cases of *N brasiliensis* infection in the United States have originated in the southern regions of the United States, especially Texas, southern California, Oklahoma, and Florida. Cases have also been reported from North Carolina.

**B. Microbiology.** See earlier introductory comments.

**C. Pathogenesis.** Disease occurs after virulent strains of *Nocardia* successfully evade the bactericidal defenses of the host's immune response. *Nocardia* virulence is to a large extent determined by the dynamically changing and complex structure of the bacterial cell envelope. Structural changes result in alterations of cell surface characteristics, of cell-cell interactions, and of specific growth patterns, and all have important effects on *Nocardia* virulence and host-parasite interactions.

Neutrophils predominate in the early lesions, inhibiting nocardial cell growth, but not killing the organism. *N asteroides* has the ability to resist intracellular killing by inhibiting phagosome-lysosome fusion, decreasing lysosomal enzyme activity in macrophages, and neutralizing phagosomal acidification. It also resists the oxidative killing mechanism of phagocytes by producing a unique surface-associated and secreted superoxide dismutase.

As a result of this evasive bactericidal response, cell-mediated responses are required for eventual control of this disease. The host mounts a lymphocyte response and releases antibodies and/or lymphocyte signals enabling activated macrophages to kill *Nocardia* spp. When there is an inadequate cell-mediated immune response, a more indolent infection may ensue, because neutrophils alone are not sufficient to resolve infection.

### **Clinical Findings (See [Box 63-1.](#))**

**A. Pulmonary Disease.** Pulmonary disease is the most common manifestation of nocardiosis. *N asteroides* is estimated to cause 80% of pulmonary cases. It may present as a necrotizing pneumonia with or without cavitation, a slowly enlarging pulmonary nodule, or pneumonia with associated empyema. The course of disease ranges from acute to chronic with a tendency to wax and wane.

Pulmonary nocardiosis comprises a constellation of protean and nonspecific findings. Symptoms and signs include fever, night sweats, anorexia, weight loss, productive cough with hemoptysis, and pleural pain. Initial pulmonary parenchymal disease may spread to adjacent lung tissue, progress to form one or more pulmonary abscesses, and

spread to pleural surfaces or to distant sites, such as the skin and the brain. Nocardiosis must be suspected when soft-tissue and/or CNS disease develops in conjunction with chronic or subacute pulmonary disease.

Radiographic findings are also variable but most frequently include localized infiltrates, irregular nodules, pleural effusions, and hilar adenopathy. Less common findings include masses, miliary lesions, diffuse alveolar and interstitial infiltrates, and calcified granulomatous lesions suggestive of fungal infection or tuberculosis.

Other respiratory tract manifestations include tracheitis, bronchitis, and pleuropulmonary fistula. Mediastinitis with superior vena cava syndrome and sinusitis have also been reported.

**B. Disseminated Disease.** Approximately 50% of all *Nocardia* infections disseminate, usually from a primary pulmonary infection. Disseminated nocardiosis is defined as disease involving two or more organs of the body. It often occurs late in the course of disease and may be life threatening, especially in severely immunocompromised patients. The CNS is the most frequently affected site, but cutaneous and subcutaneous tissues, eyes (especially the retina), kidneys, joints, bone, and heart tissue can also be involved.

**C. CNS Disease.** CNS infections are seen in about one-third of all cases of nocardiosis, usually as part of disseminated disease. Patients with pulmonary or disseminated nocardiosis should have a magnetic resonance imaging (MRI) examination of the head to rule out occult CNS *Nocardia* infection. A single *Nocardia* colony isolated from the cerebrospinal fluid or another normally sterile site with a suggestive clinical picture should not be ignored, because these organisms are rarely laboratory contaminants and are not common members of the normal flora. Of patients with systemic nocardiosis, 45% have CNS infections, with the lung being the most common source of infection. Brain abscess is the most common clinical manifestation. Rarely, meningitis can also occur. Presentations may vary from an acute, rapidly evolving infection to a more common, insidious onset with infection persisting for months or even years without fever or leukocytosis. Hemiparesis, body tremors, Parkinsonian features, seizures, coma, and ataxia can occur. Bizarre (even psychotic) personality and behavioral presentations dominate certain chronic cases.

Lesions can be found in any anatomic site of the CNS and are often loculated with satellite extensions. CNS nocardiosis is associated with high morbidity and mortality if prompt antimicrobial therapy is not initiated. In compromised hosts, infection is more rapidly progressive and associated with increased mortality.

**D. Cutaneous Disease.** Cutaneous nocardiosis, in contrast to invasive pulmonary and disseminated nocardiosis, usually occurs in immunocompetent individuals. Primary disease is often precipitated by local trauma or surgical wound. Secondary cutaneous disease is the result of hematogenous dissemination. *N brasiliensis* is the predominant agent in primary cutaneous disease.

Localized cutaneous nocardiosis presents as pustules, abscesses, or cellulitis, all of which are usually self-limited. These lesions mimic those of cutaneous *Streptococcus* or

*Staphylococcus* infection. *Nocardia* infections tend to be more indolent, however. Frequently, infection spreads to regional lymph nodes, which then suppurate. The resulting lymphocutaneous syndrome is referred to as the sporotrichoid form of cutaneous nocardiosis because it is difficult to distinguish from infection with the fungus *Sporothrix schenckii*. Thus, an appropriate laboratory diagnostic workup is required for a definitive diagnosis.

Mycetoma is a separate, distinct manifestation of cutaneous and subcutaneous nocardial infection. Other organisms can cause mycetomas, but *Nocardia* species appear to be the most common cause in the United States. Mycetoma is a chronic, localized, slowly progressive subcutaneous infection that can eventually invade the fascia, muscle, and bone if left untreated. It usually starts as a painless nodule after traumatic inoculation. It may become purulent and necrotic, and suppurate with formation of draining sinus tracts containing granules. Granules are conglomerations of the causal organism whose size, color, and degree of hardness vary by microbial species. Mycetoma is the only clinical form of nocardiosis regularly associated with the presence of such granules. The granules tend to be white, unlike the granules of *Actinomyces* spp., which are yellow and hence named "sulfur granules."

Mycetomas can be caused by a number of actinomycetes, in which case they are properly termed actinomycetomas as a group, or they can be caused by fungi, in which case they are referred to as eumycetomas. Microorganisms known to cause actinomycetomas include *N brasiliensis*, *Actinomadura madurae*, *Actinomadura pelletieri*, *Streptomyces somaliensis*, and, less commonly, *N asteroides*, *N otitidiscaviarum*, *Nocardiosis dassonvillei*, and *N transvalensis*. In North America, South America, Mexico, and Australia, *N brasiliensis* is the chief cause of actinomycetomas, whereas in Africa, it is *S somaliensis*. Mycetomas tend to be well-delineated infections. Actinomycetomas most often affect persons who live in warm, rural environments. The most common site of infection is the foot, but infections in the leg, arm, hand, face, and neck are also seen.

**E. Ocular Disease.** Ocular infections such as keratitis and endophthalmitis with *Nocardia* spp. have been reported in both immunocompetent and immunocompromised patients. Though rare, these occur after traumatic corneal injury. *Nocardia* keratitis may mimic noninfectious inflammatory eye conditions and precipitate steroid therapy, which may worsen this (and other) ocular infection(s). Corneal scrapings should be performed on all patients with keratitis for the purpose of diagnosis.

## Diagnosis

A Gram stain that shows thin, delicate, variably gram-positive, irregularly stained or beaded branching filaments is suggestive of nocardiosis. The diagnosis must be confirmed by culture. Currently, there is no reliable serodiagnostic test.

This normally elusive organism can usually be detected in pus or abscess drainage from a fistula, which should be submitted in a sterile tube or syringe. Fibers from sterile cotton swabs can interfere with the interpretation of smears, so the use of swabs should be discouraged. Surgical tissues and biopsy material from lung, skin, or brain should be kept moist during transport. When examining sputum specimens, early-morning

expectorated samples should be collected on 3 separate days. Single smears and cultures are positive in only one-third of cases, so multiple specimens are encouraged.

*Nocardia* spp. grow readily on most of the media used for bacterial, fungal, and mycobacterial growth. Their growth can be enhanced if they are incubated at between 32 and 35 °C in the presence of 5-10% carbon dioxide. They are slow growing, so the laboratory should be alerted when *Nocardia* infection is suspected. Colonies from pure cultures form within 48-72 h, but, with complex specimens such as respiratory samples, other more rapidly growing bacteria can easily obscure small *Nocardia* colonies. To enhance recovery and inhibit bacterial and fungal overgrowth, a variety of selective media have been used including paraffin agar and buffered charcoal-yeast extract medium (originally designed to isolate *Legionella* species).

After recovery of a *Nocardia* isolate, biochemical tests to determine the ability of the isolate to decompose casein, xanthine, hypoxanthine, and tyrosine are performed to distinguish the different *Nocardia* species. Additional biochemical tests are often necessary for further speciation. Gas chromatography and high-performance liquid chromatography (HPLC) analyses of the mycolic acid composition of nocardiae provide a more rapid technique to distinguish the different species. However, the results must be interpreted cautiously, because the type of culture medium, incubation temperature, and other factors can alter mycolic acid composition. A more rapid and accurate approach to identify different species may be polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) analysis.

## Differential Diagnosis

Clinically, pulmonary nocardiosis must be distinguished from other bacterial infections such as mycoplasma infections, actinomycosis, tuberculosis, and fungal infections and carcinomas.

## Treatment

Sulfonamides have been the mainstay of therapy for *Nocardia* infections since the first report of a cure in 1944. Prior to the 1940s, infections with *Nocardia* spp. were almost always fatal. Today the combination of trimethoprim and sulfamethoxazole (TMP-SMX) is generally the drug of choice despite inadequate in vitro data regarding synergy with this drug combination ([Box 63-2](#)). Between 90 and 95% of pulmonary infections with susceptible strains of *N. asteroides* respond favorably to treatment. Oral or intravenous TMP-SMX is recommended for adults with normal renal function. Sulfonamide levels should be followed initially to ensure that a serum level of between 100 and 150 mg/dL is achieved. Levels should be drawn 2 h after oral ingestion of the drug.

Intolerance of sulfonamides, especially in AIDS patients and in transplant patients, is reported frequently. Rash is a common adverse effect in these patients. TMP-SMX may enhance the nephrotoxicity of cyclosporin A in transplant recipients. Treatment failure has been reported in individuals with CNS infection and/or in immunocompromised individuals. Issues of patient compliance, microbial susceptibility, sequestered pus, and superinfection may have contributed to the poor outcome in these patients.

Other antimicrobial agents have shown in vitro activity against *Nocardia* spp. There are three oral agents other than sulfonamides which are useful in treating nocardiosis. Minocycline is the only tetracycline with excellent in vitro activity against the majority of pathogenic strains. Amoxicillin-clavulanate is effective, but certain species such as *N nova*, *N otitidiscaviarum*, and *N transvalensis* are resistant to this antibiotic. The fluoroquinolones such as ciprofloxacin and ofloxacin are less consistent in their activity against *Nocardia* spp., but penetrate most tissues well. Susceptibility studies should guide the choice of therapy.

Useful parenteral agents include imipenem, amikacin, and the third-generation cephalosporins. These drugs can be used alone or in combination with sulfonamides. Although good clinical responses have been achieved with imipenem, drug-induced seizures may deter use in individuals with brain abscesses. Amikacin has variable penetration of the CNS, but has been successfully used to treat CNS infection when the minimum inhibitory concentration (MIC) of the isolate was < 0.12 ug/mL. Third-generation cephalosporins have excellent CNS penetration and low toxicity.

The optimal duration of therapy and the indications for combination therapy remain uncertain, but long-term therapy is the rule, because relapse is common. In the nonimmunosuppressed individual, therapy for pulmonary and systemic nocardiosis should be continued for a minimum of 6-12 months. Complete resolution of primary cutaneous nocardiosis without bone involvement can be achieved with 2-4 months of therapy.

Immunosuppressed patients, regardless of their presentation, should receive a minimum of 12 months of therapy. Parenteral therapy may be necessary for only 3-6 weeks, depending on patient response. The use of immunosuppressive agents should be minimized, especially early in treatment of nocardiosis. Because high failure rates occur in patients with CNS disease and patients who are immunosuppressed, combination parenteral therapy with TMP-SMX and amikacin, imipenem, or a third-generation cephalosporin might be considered. Once a clinical response is achieved, the patient can be switched to single-agent therapy. Individuals with HIV coinfection should probably receive continuous suppressive therapy.

## **Prevention & Control**

Because *Nocardia* spp. are ubiquitous and nocardiosis is sporadic and dependent on host factors, there are no effective prevention and control measures.

## **ACTINOMYCES**

### **Essentials of Diagnosis**

- "Sulfur granules" in specimens and sinus tract drainage: hard, irregularly shaped, yellow particles measuring from 1 to 5 mm in size
- Gram-positive branching filaments arranged in ray-like projections under the microscope

- Colonies with characteristic "molar tooth" appearance
- Production of extensive fibrosis with "woody" induration
- No specific antibody or antigen detection tests

## General Considerations

**A. Epidemiology.** The *Actinomyces* species are facultative anaerobes that commonly inhabit the oral cavity, the gastrointestinal tract, and the female genital tract, where they exist as commensals. Diversity within this genus is broad, which has led to taxonomic revision and reclassification of some species as members of the *Arcanobacterium* genus, eg, *Actinomyces pyogenes*. Disease occurs when mechanical insult disrupts the mucosal barrier or organisms gain access to privileged sites. For example, actinomycosis commonly occurs after dental procedures, trauma, surgery, or aspiration. *Actinomyces israelii* causes the majority of human disease owing to this genus, but other species, including *Actinomyces naeslundii*, *Actinomyces viscosus*, *Actinomyces enksonii*, *Actinomyces odontolyticus*, and *Actinomyces meyeri* have also been implicated. Actinomycosis is threefold more common in men than women.

**B. Microbiology:** See earlier introductory comments.

**C. Pathogenesis.** After inoculation into submucosal tissues, infection spreads slowly across anatomic boundaries, forming chronic, destructive abscesses and sinus tracts surrounded by thick fibrotic tissue, creating what is often described as "woody" induration. Lesions enlarge, become soft and fluctuant, and then suppurate, discharging purulent material containing granules. The neutrophil is the dominant responding leukocyte cell type; however, granulomata form over time. As the disease progresses, fistulas may extend from the abscess to either the skin or, less commonly, bone.

*Actinomyces* infections are usually polymicrobial. Multiple other organisms, including *Actinobacillus*, *Eikenella*, *Fusobacterium*, *Bacteroides*, and *Capnocytophaga* spp., members of the *Enterobacteriaceae*, staphylococci, and streptococci, are usually present in various combinations. These organisms may exert a synergistic effect on the disease process by secreting collagenase and hyaluronidase and thus facilitating extension of the lesion. *Actinomyces* virulence factors are not well understood. *Actinomyces* fimbriae may play an important role in bacterial self- or coaggregation with other oral bacterial species.

## Clinical Findings (See [Box 63-3](#).)

There are three major clinical presentations and types of disease: cervicofacial (~ 50% of all cases), abdominal (~ 20%), and thoracic (~ 15%).

**A. Cervicofacial Disease.** Cervicofacial actinomycosis usually follows dental or gingival manipulations or intraoral trauma. The most common site of involvement is the perimandibular region, where soft tissue swelling, abscess, or mass lesions can occur. Pain and fever are variably present. Actinomycosis can also cause periapical dental infections and sinusitis, especially of the maxillary sinus, as well as soft tissue infections

of the head, neck, salivary glands, thyroid, external ear, and temporal bone.

**B. Abdominal Disease.** Abdominal disease usually follows gastrointestinal surgery, particularly emergency gall bladder and colonic surgery, appendicitis, or foreign-body penetration. Ileocecal involvement, which often follows appendicitis, is seen most frequently. Infection is indolent with symptoms reported from 1 month to 2 years before a definitive diagnosis. Associated findings include weight loss, fever, palpable tender mass, visible sinus tracts with drainage, or fistulas. Fistulas invading the abdominal wall or perineum form in approximately one-third of abdominal actinomycotic abscesses. Unless draining sinus tracts are present, surgery is required for diagnosis.

**C. Thoracic Disease.** Thoracic disease usually follows aspiration of infected oral material. However, direct extension from cervicofacial or abdominal disease can occur. The usual presentation is either a mass or pneumonia. Occasionally there is pleural involvement. The disease has an insidious onset and a subacute course. Typical symptoms include cough, hemoptysis, chest wall discomfort, fever, and weight loss. Radiographic findings are variable, including patchy infiltrates, mass lesions, or cavitory lesions. Empyema, osteomyelitis, and draining fistulous tracts can occur when there is extension directly into the pleural space, ribs, and chest wall. In the presence of pleural or chest wall involvement, diagnosis should not be difficult. However, because *Actinomyces* spp. are members of the normal oral flora, organisms cultured from sputum or bronchoscopic washings are not diagnostic. Diagnosis requires percutaneous needle aspiration, bronchoscopic biopsy, or open-lung biopsy.

**D. Other Manifestations.** Other less frequent presentations include pelvic actinomycosis, which has been recognized with greater frequency since its association with the use of intrauterine contraceptive devices. Clinical disease may take the form of endometritis, salpingo-oophoritis, or tubo-ovarian abscess. Liver, bone, pericardial, endocardial, CNS, and perianal involvement has also been reported.

## Diagnosis

"Sulfur granules" are hard, irregularly shaped yellow particles that range in size from 0.1 to 5 mm. Microscopically, they appear as masses of bacterial filaments that may be arranged in ray-like projections. Their presence is typical, but not unique to this disease. Other organisms such as *Nocardia* spp., *Streptomyces* spp., and staphylococci in botryomycosis may form similar granules. A definitive diagnosis is made by growing the organism from an appropriate specimen in anaerobic culture media.

Timely procurement of specimens before initiation of antimicrobial therapy and submission to the laboratory using anaerobic transport kits optimize recovery of the organism by culture. Tissue, pus, or sulfur granules are the specimens of choice, and swabs should be avoided because the cotton filaments may be confused on microscopy with the organism. Multiple specimens should be obtained because organisms may be scarce in pathology specimens.

Growth usually appears within 5-7 days but can take as long as 2-4 weeks, so the lab should be alerted if actinomycosis is suspected. Growth plate media containing 5% sheep blood or rabbit blood supplemented with hemin and vitamin K should be used.

However, other types of media including anaerobic blood culture medium, enriched thioglycolate medium, and chopped meat-glucose medium will support the growth of these organisms. Plates should be incubated at 35 to 37 °C in an anaerobic chamber. Often colonies are viewed first as "spiderlike" in appearance and mature to resemble a "molar tooth." Biochemical tests are performed to distinguish the various species. There are no specific antibody or antigen detection tests.

## Differential Diagnosis

Cervicofacial actinomycosis is often clinically misdiagnosed as a tumor, tuberculosis, or fungal infection. Actinomycosis often imitates a carcinoma, sarcoma, diverticular abscess, inflammatory bowel disease, or tuberculosis. Thoracic actinomycosis must be differentiated from other bacterial disease (tuberculosis and nocardiosis), systemic mycoses, and neoplastic disease.

## Treatment

Penicillin is the drug of choice for actinomycosis ([Box 63-4](#)). Prolonged therapy is necessary to achieve a cure and minimize relapse. Intravenous penicillin G for 2-6 weeks followed by oral penicillin for 6-12 months is a reasonable regimen. Treatment should extend beyond the resolution of measurable disease. Long-term therapy is necessary because of the amount of reactive fibrosis formed by infection. Relapse is common especially after a short course of empiric antibiotic therapy. For patients with penicillin allergies, tetracycline is the preferred agent. Minocycline erythromycin and clindamycin are also reasonable alternatives. In vitro susceptibility data suggest that oxacillin, dicloxacillin, cephalexin, metronidazole, and the aminoglycosides should be avoided.

## Prevention & Control

Currently, there are no recommended prevention and control measures. However, because of the association between intrauterine device (IUD) use and pelvic actinomycosis, women should consider alternative forms of contraception.

## OTHER ACTINOMYCETES

Species of the *Rhodococcus* genus have occasionally been implicated in human disease. *Rhodococcus* spp. differ from *Nocardia* spp. in that they do not produce aerial hyphae. *Gordona* and *Tsukumurella*, formerly classified in the *Rhodococcus* genus, are also rare causes of human disease. *Rhodococcus equi*, the species that is most commonly implicated in human disease, is found in soil and in the intestinal contents of grazing herbivore animals. Because most infections have been associated with immune system dysfunction, there has been an increase in reported cases of *R equi* infection since the onset of the HIV epidemic in the 1980s.

Pulmonary disease is the most common clinical manifestation of *R equi* infection, and occurs after inhalation of the organisms. Cutaneous infections, bacteremia, and catheter-associated sepsis have also been reported. Prolonged combination therapy with erythromycin or imipenem plus rifampin is currently the treatment of choice.

Intestinal *R equi* disease may mimic Whipple's disease.

The disease that bears George Whipple's name affects primarily white, middle-aged males and causes arthralgias, abdominal pain, diarrhea, weight loss, fever, and lymphadenopathy. The causative agent, *T whippelii*, is an actinomycete that is difficult to cultivate in vitro. The gastrointestinal tract and its lymphatic drainage, the heart, and the CNS are the sites most commonly involved by this chronic, systemic disease. The diagnosis can be made by detection of numerous periodic acid-Schiff reagent (PAS)-positive macrophages within the intestinal lamina propria or by detection of the characteristic bacilli or their DNA within affected tissues or fluids, using electron microscopy or the polymerase chain reaction, respectively. Most patients respond to antibiotics; the recommended regimen consists of a combination of parenteral penicillin and streptomycin for 2 weeks, followed by = 1 year of TMP-SMX. If untreated, the disease is fatal. Relapse within the CNS occurs in approximately one-third of patients, despite treatment.

The genus *Streptomyces* consists of a plethora of species of which most are considered saprophytes; they are found throughout the environment. *Streptomyces* spp. are primarily soil inhabitants. Three species, *S somaliensis*, *Streptomyces paraguayensis*, and *Streptomyces anulatus*, have been implicated in human disease, primarily in the formation of actinomycetomas. *S somaliensis* and *S paraguayensis* are rarely, if ever, found in the United States. They primarily inhabit Latin America, although *S somaliensis* is also known to cause disease in the arid regions of Africa and Arabia. *S anulatus*, on the other hand, has been associated with lung disease and sepsis, brain abscess, and panniculitis, as well as cervical lymphadenitis in an immunocompromised patient in the United States. Isolation of the streptomycetes should follow procedures used for the isolation of nocardiae. Colonies are usually glabrous or waxy and heaped. Definitive identification usually is extremely difficult. Streptomycin in combination with either dapsone or TMP-SMX has been suggested as treatment for infection with *Streptomyces* spp.

## 64 . *Treponema pallidum* — Fred A. Lopez, MD & David A. Relman, MD

### Essentials of Diagnosis

- Spiral, motile, coil-shaped, elongated (0.10  $\mu\text{m}$   $\times$  5-20  $\mu\text{m}$ ) spirochete.
- No reliable method for sustained in vitro cultivation.
- Direct detection with darkfield microscopy or immunofluorescent antibody in early syphilis.
- Nontreponemal antibody tests (rapid plasma reagin, Venereal Disease Research Laboratory [VDRL]) for screening, treatment follow-up.
- *Treponema*-specific antibody tests (fluorescent treponemal antibody test, microhemagglutination-*T pallidum* test) for confirmation.
- Cerebrospinal fluid (CSF) lymphocytosis, elevated CSF protein, or reactive CSF VDRL test suggests neurosyphilis.
- PCR, DNA probes, and immunoblotting techniques promising in congenital syphilis, early syphilis, or neurosyphilis.
- All patients with *T pallidum* infection should be tested for HIV coinfection and vice versa.

### General Considerations

The term syphilis was first used in 1530 by the Italian physician Girolamo Fracastoro in his epic poem *Syphilis Sive Morbus Gallicus*. Much has been learned since then about this sexually transmitted disease caused by *T pallidum*. Public health screening programs and the introduction of antibiotics led to a marked decline in the number of new cases of syphilis in the United States after World War II. However, the advent of AIDS was associated with an increase in new cases of syphilis, necessitating the reeducation of health care personnel in the evaluation and management of this disease.

**A. Epidemiology.** Genital herpes and syphilis are the most common causes of genital ulcerations in patients presenting to sexually transmitted disease clinics in the United States. Syphilis is usually transmitted by sexual contact with the infectious lesions of primary and secondary syphilis. Syphilis develops in ~ 30-60% of sexual contacts of individuals with infectious syphilis. Syphilis is less commonly transmitted in utero or by means of blood transfusion, nongenital body contact, and accidental direct inoculation.

The incidence of primary and secondary syphilis (called early syphilis) reached a nadir in 1956 and then increased slowly. Two "epidemics" of early syphilis in the past 20 years have highlighted the role of human behavior in syphilis epidemiology: one peaked

in 1982 and primarily involved bisexual and homosexual men; the second peaked in 1990 when 50,223 new cases of primary and secondary syphilis were reported. This epidemic was associated with crack cocaine use and its effects on sexual behavior and disproportionately involved African Americans. The incidence of this outbreak was highest in the southern United States and in the nation's large metropolitan areas. The incidence of congenital syphilis also rose from 4.3 cases/100,000 live births in 1983 to 107 cases/100,000 births in 1991, a change attributed to the increase in primary and secondary syphilis among women, more active surveillance, and the adoption of a more sensitive case definition for congenital syphilis in 1988-1989.

The incidence of all stages of syphilis including congenital syphilis has decreased since 1991. The number of new cases of primary and secondary syphilis in the United States in 1997 was 8,500, an incidence of 3.2 cases/100,000 persons, the lowest rate since 1941. In 1997, the incidence of congenital syphilis was 27 cases/100,000 live births, the lowest rate since the change in the surveillance case definition.

**B. Microbiology.** The order *Spirochaetales* and family *Spirochaetaceae* include human pathogens within the three genera, *Treponema*, *Leptospira*, and *Borrelia*. *T pallidum* subspecies *pallidum* is the causative agent of syphilis and is transmitted primarily through sexual contact. Nonvenereally transmitted treponemal infections include those caused by *T carateum* (pinta), *T pallidum* subspecies *pertenue* (yaws), and *T pallidum* subspecies *endemicum* (bejel or endemic syphilis). Clinical and epidemiological characteristics are used to distinguish among these treponemal infections because of the similarities in serologic host responses, microbial morphology, and antigenic composition. No currently available nucleic acid-based test reliably differentiates between the subspecies of *T pallidum*.

*T pallidum* is a microaerophilic spirochete that is tightly wound into a spiral shape, measuring 5-20  $\mu\text{m}$  in length and 0.1-0.2  $\mu\text{m}$  in width. With the ability to bend along its long axis, active motility is achieved with "corkscrewlike" motions. These organisms, too slender to be seen with light microscopy, can be readily visualized by darkfield microscopy, by direct immunofluorescent staining, or by silver staining.

This agent has resisted characterization because it cannot be sustained by in vitro culture methods. Instead, it requires rabbit or guinea pig inoculation for laboratory propagation. The organism is surrounded by an outer membrane consisting primarily of phospholipids and a low concentration of membrane proteins, a characteristic that when coupled with the organism's slow multiplication time may explain its ability to persist in the infected host. Examination of the full 1.14-Mbp genome sequence of *T pallidum* reveals a large family of duplicated genes that are predicted to encode outer membrane porins and adhesins. These genes may reflect a mechanism for antigenic variation as well as targets for vaccine-induced immunity.

Axial filaments, or endoflagella, are attached to each end of the organism in the periplasmic space and mediate host cell adherence and motility. Recent investigations suggest that a sensory transducing chemotaxis protein may modulate this flagella-associated motility. The organism also contains a peptidoglycan layer and is susceptible to  $\beta$ -lactam agents such as penicillin. Replication of this organism occurs by transverse fission.

**C. Pathogenesis.** *T pallidum* gains access to subepithelial tissues through microperforations in the skin or intact mucous membranes. A visible localized reaction occurs at the site of inoculation after 10-90 days, a reflection of the slow dividing time of this organism. This reaction takes the form of a papule before ulcerating to form the classic lesion of primary syphilis, the chancre ([Figure 64-1](#)).

Histopathologic examination reveals perivascular inflammation consisting of lymphocytes and plasma cells. Spirochetes also disseminate to regional lymph nodes and enter the bloodstream during this stage. The chancre usually heals spontaneously within 1-8 weeks, likely because of the phagocytosis of treponemes by macrophages. The secondary stage of infection begins ~ 6-10 weeks after the disappearance of the chancre. Spirochetemia is at its greatest level during this stage, despite a vigorous humoral immune response, and patients often present with constitutional complaints of malaise, fever, weight loss, and generalized lymphadenopathy.

Most patients develop skin and mucous membrane lesions. The lesions of both primary and secondary syphilis are highly infectious. The resolution of the signs and symptoms of untreated secondary syphilis heralds the beginning of the latent stage of infection, a clinically asymptomatic stage belied only by a positive treponemal serology. This phase is divided into an early latent stage, that is, the first year after infection, and the late latent stage. Approximately one-third of untreated patients with latent infection will go on to develop manifestations of late (or tertiary) disease after an indeterminate period of time.

Destructive tissue lesions of the tertiary stage of infection involve the skin and bone (leading to a gumma), the aorta, and the central nervous system (CNS). Histopathologic examination of these lesions reveals the characteristic obliterative endarteritis seen in other stages of syphilis. The lesions of late syphilis contain few visible spirochetes, suggesting a role for a delayed-type hypersensitivity reaction to *T pallidum*.

Much of the information regarding the natural course of untreated syphilis was obtained from two reports including the Oslo Study of untreated Norwegian patients diagnosed with early syphilis (1890-1951), and the Tuskegee Study, initiated by the United States Public Health Service (U.S. PHS) in 1932. This prospective study of ~ 400 black men with untreated latent syphilis in Macon County, Alabama, was terminated in 1972.

## PRIMARY SYPHILIS

### Clinical Findings

**A. Signs and Symptoms.** The lesions of primary syphilis appear at the site of inoculation after an incubation period that is inversely proportional to the number of infecting organisms, usually 3 weeks ([Box 64-1](#)). The chancre is an ulcerative lesion that varies in size from several millimeters to 2 cm. Although classically described as a solitary lesion, multiple lesions may be present ([Figure 64-2](#)). They are generally located on the genitalia and anorectal areas, but any area on the body can be affected including the oropharynx and the extremities. This superficial ulcer is usually painless with well-defined, indurated borders surrounding a firm, clean base. Local and regional

lymphadenopathy is bilateral, nonsuppurative, painless, and often described as "rubbery."

**B. Laboratory Findings.** Definitive diagnosis can be made by visualization of spirochetes in exudates from these lesions with darkfield or immunofluorescent antibody microscopy. Nontreponemal serologic testing is reactive in 70-80% of patients with primary syphilis but is less sensitive at the time that the chancre first appears. Treponemal antibody tests, specifically the fluorescent treponemal antibody test, are more sensitive during this stage of infection.

**C. Differential Diagnosis.** Primary syphilitic genital lesions can be mistaken for lesions associated with trauma, herpes simplex virus, malignancy, chancroid, lichen planus, granuloma inguinale, or lymphogranuloma inguinale. Darkfield examination is helpful in diagnosis. The painful vesicular lesions of herpes are distinguished by multinucleated giant cells when unroofed and examined with a microscope. The ulcerated and nonindurated lesions of chancroid are associated with painful lymphadenopathy. Lymphogranuloma venereum and granuloma inguinale infections are seen primarily in tropical countries.

## SECONDARY SYPHILIS

### Clinical Findings

**A. Signs and Symptoms.** The secondary stage of syphilis occasionally overlaps with the primary phase but usually begins ~ 6 weeks after resolution of the chancre; however, it can develop as late as 6 months after infection (see [Box 64-1](#)). Most patients have some degree of skin or mucocutaneous involvement. A faint and evanescent macular rash of the trunk and abdomen known as *roseola syphilitica* is sometimes seen initially. A generalized, symmetric, nonpruritic rash consists of some combination of erythematous or copper-colored macular, papular, papulosquamous, or pustular lesions. These lesions can be found on the palms, soles, genitalia, and oral mucous membranes ([Figure 64-3](#)). The rash of syphilis often provides a diagnostic challenge, deserving of its moniker "the great imitator."

Condylomata lata refer to eroded papules that can fuse together to create flat, highly infectious lesions in moist, intertriginous areas such as the anogenital region ([Figure 64-4](#)). They occur in 10-25% of secondary infections. Mucous patches refer to the slightly raised, grayish, painless ulcerations seen on mucous membranes in ~ 15-30% of patients with secondary syphilis. A patchy, "moth-eaten" appearance of hair on the scalp, eyebrows, and beard is well described.

The CNS and gastrointestinal, renal, and musculoskeletal systems may also be affected during the secondary stage of syphilis. Patients with syphilitic meningitis typically present with headache, nausea and emesis, stiff neck, and cranial neuropathies involving the third, sixth, seventh, and eighth cranial nerves. CSF analysis reveals a mononuclear pleocytosis, an elevated protein, and, in half of patients, hypoglycorrhachia. Optic neuritis, iritis, and uveitis can be seen during this stage as well. Although only 1-2% of patients with secondary syphilis have documented acute aseptic meningitis, CSF findings may be abnormal in ~ 25-50% of patients.

Syphilitic gastritis causes emesis and epigastric pain. Endoscopic examination usually reveals ulcerations or pronounced gastric folds that contain spirochetes. Of patients with primary or secondary syphilis, ~ 10% will have elevated liver function tests (characteristically alkaline phosphatase) and hepatomegaly, the results of hepatic necrosis and granulomatous inflammation. Renal disease is caused by immune complex-mediated mechanisms and presents as nephrotic syndrome or glomerulonephritis. Synovitis, osteitis, or periostitis can be seen in = one-fifth of patients.

**B. Laboratory Findings.** *T pallidum* can be detected directly with darkfield and immunofluorescent microscopy in condylomata lata and mucous patches. Nontreponemal and treponemal serologic tests are usually reactive during this stage of disease (see Diagnosis below).

**C. Differential Diagnosis.** The differential diagnosis of the dermatologic manifestations of secondary syphilis is quite extensive and should include pityriasis rosea, tinea versicolor, erythema multiforme, drug eruption, viral exanthems, psoriasis, ringworm, and scabies. The pale, pinkish condylomata lata lesions tend not to be as raised as the venereal warts of condyloma acuminata. Mucous patches can be confused with herpes simplex lesions, aphthous ulcerations, candidiasis, and Stevens-Johnson syndrome. Both mucous patches and condylomata lata contain spirochetes, which can be visualized by darkfield examination.

## LATENT SYPHILIS

### Clinical Findings

The manifestations of primary and secondary syphilis resolve without therapy, and the ensuing clinically silent phase of infection known as the latent stage is characterized by positive serologies and normal CSF (see [Box 64-1](#)). Patients can relapse with manifestations of secondary syphilis during this stage, usually during the early latent period. Asymptomatic infection lasting greater than one year, late latent syphilis, persists for the remainder of life in approximately two-thirds of untreated patients. The other one-third of patients develops symptomatic disease, ie, late syphilis.

## LATE SYPHILIS

### Clinical Findings

Tertiary disease, usually seen 5-20 years after initial infection, traditionally includes cardiovascular syphilis, late benign (or gummatous) syphilis, and neurosyphilis (see [Box 64-1](#)). Fewer organisms are found in lesions during this stage.

**A. Cardiovascular Syphilis.** The incidence of cardiovascular involvement is probably underestimated, although clinically significant disease eventually develops in ~ 10% of all untreated patients. Lesions include coronary ostial stenosis and coronary artery insufficiency, aortic valvular regurgitation with left ventricular hypertrophy and congestive heart failure, and saccular aortic aneurysms of the ascending and transverse

portions of the thoracic aorta. These aneurysms usually do not dissect and rupture but can present as pulsating supraclavicular chest wall masses with associated hoarseness, dysphagia, dyspnea, and cough due to impingement on adjacent vital structures. Syphilis should always be considered in patients whose chest radiograph reveals ascending aortic calcifications or those with isolated aortic valvular disease and positive treponemal serologies, particularly if other manifestations of late disease are present.

**B. Late Benign Syphilis.** The classic lesion of late benign syphilis seen in ~ 15% of untreated patients is the gumma, a granulomatous inflammatory process that usually affects the skin, subcutaneous tissues, and bone but may involve the liver, respiratory tract, stomach, heart, and almost any other organ of the body. Usually nodular before ulcerating, gummas are noninfectious, indurated, violaceous, and painless. Gummas may heal or become chronic, resulting in destructive local disease. The differential diagnosis includes causes of other granulomatous processes such as mycobacterial and fungal infections, sarcoidosis, and malignancies.

**C. Neurosyphilis.** Clinically apparent CNS involvement is estimated to occur in ~ 5-10% of all syphilis patients and can be seen at any stage of infection; however, early silent dissemination of *T pallidum* to the CNS is almost the rule. Asymptomatic neurosyphilis is usually accompanied by CSF cellular or protein abnormalities, the presence of *T pallidum* in the CSF, or a positive CSF VDRL test. These CSF abnormalities resolve spontaneously in many patients; the likelihood of developing symptomatic CNS infection is proportional to the degree of these abnormalities.

Symptomatic neurosyphilis classically takes the forms of aseptic meningitis (see Secondary Syphilis), meningovascular syphilis, and parenchymatous neurosyphilis (general paresis and tabes dorsalis), in ascending order of frequency. Meningovascular syphilis usually occurs 4-10 years after infection and presents with stroke-like symptoms in younger patients, a consequence of endarteritis obliterans of the cerebral arteries. CSF abnormalities characteristically include a lymphocytic pleocytosis, an elevated protein, and a reactive VDRL.

Parenchymatous neurosyphilis, a consequence of neuronal destruction by *T pallidum*, is divided into two discrete syndromes, tabes dorsalis (more common) and general paresis. It is not uncommon, however, to see patients exhibiting neurologic features of both syndromes. Tabes dorsalis results from progressive demyelination of the posterior columns and dorsal roots. It is manifested by sharp pains of the lower extremities, dysuria, and ataxia; physical findings may include areflexia and loss of pain, temperature, and position sense. Patients with general paresis present with a slowly progressive dementia. Neuropsychiatric manifestations include tremors, dysarthria, ataxia, delusions, and personality changes. The irregular Argyll-Robertson pupil of parenchymatous syphilis results from pupillary constriction to accommodation but not to light. The clinical diagnosis is supported by CSF abnormalities in patients with positive treponemal serologies. Unlike the other forms of late syphilis, the lesions of general paresis contain a significant number of spirochetes.

The effect of concomitant HIV infection on the clinical course of syphilis, including neurosyphilis, is discussed in a later section (see Syphilis and HIV, below).

## CONGENITAL SYPHILIS

### Clinical Findings

**A. Signs and Symptoms.** Most infants acquire congenital syphilis from the transplacental dissemination of maternal *T pallidum* after the 16th week of gestation and less commonly from contact with an infectious lesion during the time of delivery ([Box 64-2](#)). The likelihood of fetal infection is inversely related to the duration of time that the mother has been infected; the risk of fetal transmission declines from 70-100% during early syphilis to 10-30% during latent disease. Congenital infections can be prevented by the appropriate identification and treatment of infected pregnant women. In 1988, the Centers for Disease Control increased the sensitivity of the congenital syphilis case definition by including all infants, symptomatic and asymptomatic, born to mothers with untreated or inadequately treated syphilis.

Congenital syphilis is divided into an early stage and a late stage. The early stage, seen primarily in infants 2-25 weeks of age, may be asymptomatic or may be associated with long bone skeletal abnormalities including osteochondritis and periostitis, hepatosplenomegaly and abnormal liver function studies, low birth weight, serous nasal discharge (*snuffles*), maculopapular rash, anemia, nephrotic syndrome, and CNS abnormalities. If untreated, these lesions may result in late congenital syphilis, which classically appears after 2 years and is manifest by frontal bossing, saddle nose, interstitial keratitis, notched and peg-shaped upper Hutchinson's incisors ([Figure 64-5](#)), poorly developed mulberry molars, anterior bowing of the lower extremities, perioral and perinasal fissures, bilateral effusions of the knee (Clutton's joints), and deafness.

**B. Laboratory Findings.** See Diagnosis below.

**C. Differential Diagnosis.** The differential diagnosis of congenital syphilis includes other congenitally acquired infections such as toxoplasmosis, rubella, cytomegalovirus, herpes simplex, and hepatitis B.

**D. Complications.** Infants with untreated early syphilis may develop manifestations of late congenital syphilis, as previously described.

### Diagnosis

**A. Direct Microscopic Examination.** Darkfield microscopy reveals *T pallidum* in the transudative fluid of a chancre in which the density of organisms approaches 10,000-100,000/mL ([Figure 64-6](#)). These spirochetes exhibit "corkscrew" motility and central flexion. Highly suspicious lesions should be examined on three successive days before excluding syphilis. Alternative diagnostic methods such as fluorescent antibody staining should be considered for the evaluation of oral lesions because saprophytic spirochetes in the oral cavity morphologically mimic *T pallidum*. Silver or specific immunofluorescent antibody stains may be useful in detecting pathogenic spirochetes in tissue biopsy specimens.

**B. Serologic Tests.** The majority of syphilis cases are diagnosed with serologic testing. These tests are categorized according to the type of antibody produced by the host:

nonspecific and specific. Nonspecific, or nontreponemal, antibody tests use reaginic lipoidal antigens to demonstrate the presence of cross-reacting antibodies (immunoglobulin G [IgG] and IgM) elicited by *T pallidum* infection. Specific, or treponemal, antibody tests use *T pallidum* antigens for the detection of antibodies.

The nontreponemal antibody tests include the rapid plasma reagin and the VDRL flocculation assays. These screening tests may be reactive in the setting of other infectious and noninfectious conditions such as intravenous drug use, tuberculosis, vaccinations, pregnancy, infectious mononucleosis, HIV infection, rickettsial diseases, other spirochetal diseases, connective tissue diseases, and bacterial endocarditis. False-negative nontreponemal tests can be seen early in the course of disease when antibody levels are low and later in the disease in the face of overwhelming antibody levels, for example, during secondary syphilis, necessitating dilution of the serum sample to overcome this "prozone" effect. Approximately 75%, 100%, and 75% of patients with untreated primary, secondary, and late syphilis, respectively, will have reactive nontreponemal tests. Positive test results are usually quantitated in order to monitor therapy. The nontreponemal tests are not interchangeable (rapid plasma reagin titers usually higher at any given time), and the optimal approach for patient management should include the use of the same laboratory and test. Conversion to nonreactivity (seroreversion) or a sustained decline in titer of at least fourfold is expected in patients with early syphilis 2 years after effective therapy.

The more sensitive and specific treponemal antibody tests are used primarily for confirmation of results from nontreponemal antibody testing. The *T pallidum* hemagglutination and the microhemagglutination-*T pallidum* tests are dependent on the agglutination of antitreponemal antibodies from the patient's serum with red blood cells that have surface-associated *T pallidum*. In the fluorescent treponemal antibody test, a killed strain of *T pallidum* serves as the antigen for the patient's absorbed serum. Labeled antihuman immunoglobulin is then visualized with fluorescent microscopy. The fluorescent treponemal antibody test is more sensitive in detecting early syphilis than the other specific tests.

Seropositivity with the specific treponemal tests usually persists for the lifetime of the individual, a quality that does not allow monitoring response to therapy. However, seroreversion can be seen in promptly treated primary syphilis and in advanced HIV infection. In addition, treponeme-specific antibody tests are reactive in diseases caused by other pathogenic treponemes including yaws, pinta, and bejel, as well as Lyme disease, relapsing fever, and leptospirosis; false positives have also been reported in individuals with malaria and leprosy.

Molecular techniques, including polymerase chain reaction, are not routinely available, but may have use in resolving selected diagnostic conundrums involving early primary syphilis, congenital syphilis and neurosyphilis.

**C. Neurosyphilis.** The diagnosis of neurosyphilis is based on both clinical and laboratory findings. Although some experts evaluate the CSF of all patients with late latent syphilis, the U.S. PHS recommends a lumbar puncture when any of the following are present: clinical manifestations of neurologic involvement, evidence of nonneurologic late active syphilis, treatment failure, or late latent disease (including

syphilis of unknown duration) in the HIV coinfecting host. VDRL reactivity in the CSF is specific for the diagnosis of neurosyphilis, although caution should be exercised when interpreting a positive result from a traumatic lumbar puncture. In addition, the modest sensitivity of this test (~ 50%) does not rule out neurosyphilis when negative. Patients with systemic serologic evidence of syphilis and a CSF lymphocytic pleocytosis or an elevated CSF protein level should be treated for presumptive neurosyphilis.

**D. Congenital Syphilis.** U.S. PHS recommendations for the evaluation of an infant with suspected congenital syphilis include radiographs of the long bones, routine examination of the CSF including VDRL reactivity, nontreponemal serologies of the infant's blood, and immunofluorescent antibody staining of the placenta or amniotic fluid/cord. If this initial evaluation is negative, specific antitreponemal IgM antibody testing is indicated. The definitive diagnosis of congenital syphilis requires identification of *T pallidum* in neonatal tissue.

## Treatment

The drug of choice for all stages of syphilis is penicillin. Specific treatment recommendations are dictated by the stage of disease. Because of the organism's slow replication, prolonged treponemidal antimicrobial therapeutic levels are necessary. Although alternatives to penicillin are available, nonpenicillin-based therapy is not recommended for patients who are pregnant or have congenital syphilis, neurosyphilis, or HIV coinfection.

Patients with spirochetal diseases may develop an acute systemic reaction consisting of fever, chills, headache, and myalgias within the first day after effective therapy. This Jarisch-Herxheimer reaction is usually seen during treatment of the earlier stages of syphilis, especially the secondary stage, and resolves spontaneously after 12-24 h. This reaction is probably caused by the lysis of spirochetes with subsequent release of antigen and toxic by-products. Symptomatic relief with anti-inflammatory agents may be helpful.

The recommendations given in [Boxes 64-3](#), [64-4](#), and [64-5](#) for therapy and follow-up are based primarily on U.S. PHS recommendations.

**A. Incubating Syphilis.** Treatment of presumed incubating syphilis with the same regimen prescribed for early syphilis is recommended for all sexual contacts of patients with primary, secondary, or early latent syphilis, within the prior 90 days. Although the use of multiple-dose azithromycin and ceftriaxone appear promising in the treatment of early syphilis, single-dose therapy with either agent for incubating syphilis requires further evaluation.

**B. Primary and Secondary Syphilis.** The recommended therapy for adults with acquired primary and secondary syphilis is indicated in [Box 64-3](#). Erythromycin therapy is less effective than penicillin, doxycycline, or tetracycline. Single-dose ceftriaxone or azithromycin therapy should not be used as alternative therapy. Follow-up in non-HIV infected patients should include nontreponemal titers at 3, 6, and 12 months after treatment.

Clinical manifestations of infection that recur or do not resolve or fourfold increases in nontreponemal titers suggest treatment failure or reinfection and should dictate further evaluation for neurosyphilis and HIV infection. Effective therapy usually results in a fourfold decrease in titer by 3-6 months after treatment, and a sustained fourfold or greater decline is considered an appropriate therapeutic response. Seroreversion fails to occur by 24 months after appropriate treatment in ~ 25% of patients with primary and secondary infection. Patients who are considered treatment failures and have no evidence of neurosyphilis should be treated with the benzathine penicillin G regimen recommended for late latent syphilis.

**C. Early Latent Syphilis.** Adults and children with early latent infection are treated in the same manner as those with primary and secondary syphilis.

**D. Late Latent Syphilis or Syphilis of Unknown Duration.** Nontreponemal serologic follow-up is recommended at 6, 12, and 24 months. Assessment for neurosyphilis and possible retreatment should be considered for patients in whom titers increase fourfold, in those in whom a fourfold decline is not seen in 1-2 years, or in whom clinical manifestations develop.

**Late Syphilis.** Patients with late benign syphilis or cardiovascular syphilis and no evidence of neurosyphilis are treated in the same manner as those with late latent disease. In addition to antitreponemal agents, therapy for cardiovascular syphilis consists of appropriate medical and surgical management of heart failure and aneurysm. Reversal of the complications of aortitis is unlikely, although progression of disease may be halted with antibiotics. The lesions of late benign syphilis are responsive to penicillin therapy.

**Neurosyphilis.** All patients with ocular and auditory involvement secondary to syphilis should be treated for presumed neurosyphilis. Follow-up examination of the CSF should be performed every 6 months. Effective therapy should result in a decrease of the CSF cell count by 6 months. CSF protein and VDRL titers do not respond as quickly as the cell count, but repeat therapy may be warranted if these two parameters are still abnormal 2 years after treatment. Treatment of the late stages of neurosyphilis is most effective at hindering further CNS damage but is unlikely to result in resolution of symptoms.

**Congenital Syphilis.** The appropriate therapy and follow-up of early congenital syphilis should prevent the development of late congenital syphilis (see [Box 64-5](#)). Benzathine penicillin G, 50,000 U/kg administered once intramuscularly, is recommended for neonates without clinical or laboratory evidence of syphilis when the mother's syphilis serologies indicate treatment failure; neonates whose mothers have received prenatal erythromycin therapy for syphilis or have received therapy for syphilis in the month before parturition should also be treated with this regimen.

Treponemicidal CSF concentrations of penicillin may not be attained with the procaine penicillin regimen recommended for early congenital syphilis. Nontreponemal antibody test results should be negative by 6 months after therapy. Rising or persistent titers should prompt appropriate reevaluation and management including CSF examination and retreatment. Infants with abnormal CSF examinations should have follow-up lumbar

punctures performed every 6 months with an expected serial decline in the cell count to normal levels by 2 years after therapy and a negative CSF-VDRL by 6 months. Retreatment is indicated if these parameters are not met.

### **Syphilis & Pregnancy**

Therapy for all pregnant women known to be infected for <1 year should include benzathine penicillin G, 2.4 million U given intramuscularly 1 week apart for a total of two doses. Other stages of disease are treated in the same manner outlined for nonpregnant adults, except there is no alternative to penicillin-based therapy. Nontreponemal antibody titers should be performed monthly with principles of retreatment guided by the disease stage. Treatment of all sexual partners is imperative.

### **Syphilis & HIV**

HIV antibody testing is recommended for all patients with *T pallidum* infection because of the increased incidence of HIV coinfection in these patients. Transmission of HIV may be facilitated by genital ulcer disease. A weakened cellular immune system may explain why HIV-infected individuals develop atypical laboratory and clinical features of syphilis. Persistent chancres and initial presentations with secondary syphilis are reported more frequently in HIV-infected individuals. False-positive and false-negative serologies are more common in this patient population. Diminished serologic responses to therapy have also been observed in patients with early syphilis and HIV coinfection. The earlier appearance of neurosyphilis and other later stages of disease in HIV-infected patients has been ascribed to a decrease in the efficacy of standard therapy for early syphilis, although at least one recent randomized, double-blind study does not confirm this observation.

Confounding the evaluation and management of neurosyphilis in these patients are the elevated CSF protein and cell counts that can be seen in HIV infection alone. Despite these observations, standard serologic tests for syphilis are still recommended for diagnosis. However, some experts recommend more aggressive treatment of syphilis and more thorough evaluation of CNS infection in the HIV-infected host regardless of the stage of *T pallidum* infection. Penicillin-based therapies are recommended; close follow-up of response to therapy is essential.

### **Prevention & Control**

No vaccine is currently available for the prevention of syphilis ([Box 64-6](#)). Primary prevention measures include behavior modification of patients engaged in high-risk practices such as sexual promiscuity and health programs designed to educate the public about sexually transmitted diseases, including the benefits of condom use. Secondary prevention measures include effective, affordable, prompt, and more accessible diagnostic and therapeutic interventions with appropriate follow-up for infected patients. Screening of all HIV-infected individuals and pregnant women is part of any effective public health prevention program. Reliable and thorough case reporting with partner notification and epidemiologic treatment is also essential.

## **BOX 64-6. Control of Syphilis**

### **Prophylactic Measures**

- Prompt notification of public health department for contact followup and treatment
- Recommend safe sexual practices including condom use
- Screening of patients with HIV-infection, and those who are pregnant or have another STD
- Consider screening individuals who are sexually active and live in endemic areas
- Education and behavior modification of high-risk individuals
- Effective, expedient, accessible, and affordable diagnostic and therapeutic interventions for infected individuals
- Appropriate clinical and laboratory followup of treated individuals

### **Isolation Precautions**

- Contact isolation for moist mucocutaneous lesions of congenital syphilis, primary, and secondary syphilis

## 65 . *Borrelia* & *Leptospira* Species — Sandra Chaparro, MD & Jose G. Montoya, MD

### BORRELIA SPECIES

#### RELAPSING FEVER

##### Essentials of Diagnosis

- The most common presentation is fever with rash, headache, shaking chills, myalgias, arthralgias, and—during the acute phase—hepatosplenomegaly.
- Louse-borne relapsing fever (LBRF) is epidemic, caused by *B. recurrentis*, and characterized by one or two relapses.
- Tick-borne relapsing fever (TBRF) is endemic, caused by several *Borrelia* species, and characterized by multiple clinical relapses.
- Organisms can be visualized in blood smears of febrile patients, unlike other spirochetal pathogens, using dark-field microscopy or Giemsa or Wright stains.
- Helical (3-10 spirals) spirochetes, 8-30  $\mu\text{m} \times 0.3 \mu\text{m}$ , motile (flagella).
- Weil-Felix reaction: Proteus OX-K agglutinin titers are elevated (this is more common in LBRF).

##### General Considerations

The syndrome of relapsing fever consists of two clinical entities: epidemic relapsing fever caused by *Borrelia recurrentis* (LBRF) and transmitted by the human body louse and endemic relapsing fever caused by *Borrelia* spp. (TBRF) and transmitted by arthropods ([Table 65-1](#)).

##### A. Epidemiology.

**1. Louse-borne epidemic relapsing fever (LBRF).** This form of relapsing fever is transmitted person to person. Human body lice (*Pediculus humanus corporis*) ingest human blood infected with *B recurrentis*. The spirochetes multiply in the hemolymph of the lice. Humans become infected with *B recurrentis* when the fluids from a crushed louse contaminate mucous membranes or abrasions or other breaks in the skin. Humans are the only host for *B recurrentis*—its occurrence reflects socioeconomic and ecologic factors. Endemic foci are still observed in parts of Africa, South America, and the Far East.

**2. Tick-borne endemic relapsing fever (TBRF).** TBRF is caused by = 15 different types of *Borrelia* spp. and is transmitted to humans by ticks (*Ornithodoros* spp.). The

spirochete is capable of invading all tissues of the tick. Infections in humans occur when saliva or excrement is released while the tick is feeding. The ticks are nocturnal feeders and are rarely noticed. The tick's bite does not cause pain, and feeding is completed after 5-20 min. Many rodents and small animals are reservoirs for *Borrelia* spp. The spirochete's geographic distribution and occurrence is determined by the biology of the tick. Ticks carrying *Ornithodoros* spp. are mostly found at altitudes of 1500-6000 feet and in humid, warm climates. TBRF has been reported in Africa, Asia, South America, and the western United States during the summer.

**B. Microbiology.** *Borrelia* spp. belong to the family *Treponemataceae*. They are motile helical bacteria, 8-30  $\mu\text{m}$  long, 0.2-0.5  $\mu\text{m}$  wide, and with 3-10 loose spirals. Desiccation and UV light kill *Borrelia* spp. The generation time of these organisms is 18-26 h. They are not cultured in routine clinical laboratories but can be grown in chick embryos.

**C. Pathogenesis.** After inoculation in humans from the tick or louse vector, an acute febrile illness ensues, accompanied by a spirochetemia. The bacteria are present in the bloodstream only during the febrile illness. During the afebrile period the bacteria are sequestered in internal organs such as the central nervous system (CNS), bone marrow, liver, and spleen. There is a cycle of antigenic variation with specific antibody responses that explains the relapses of the disease. Each remission is the result of mobilization, opsonization by antibodies produced against the variant strain, agglutination, and phagocytosis of the organism by antibodies produced against the variant strain. *Borreliae* can cross the placenta and produce abortion or severe infection in neonates.

## Clinical Findings

**A. Signs and symptoms.** LBRF and TBRF have similar signs and symptoms. The mean incubation period is 7 days (range, 2-18 days). Symptoms include sudden onset of fever, headache, photophobia, sweats, shaking chills, cough, nausea, vomiting, myalgias, and arthralgias ([Box 65-1](#)). Common findings include conjunctival suffusion, petechia, upper-quadrant abdominal tenderness, and hepatosplenomegaly. Other complications include gastrointestinal or CNS hemorrhage or both and myocarditis. A truncal rash at the end of the primary febrile episode with tachycardia is common. The fever may be accompanied by hypotension and shock. Fever can reappear with less intensity after 10 days. LBRF has usually a single or few relapses; TBRF has multiple relapses. Each successive relapse of TBRF is milder and of shorter duration. Each intervening afebrile period is longer than the previous one.

**B. Laboratory findings.** LBRF and TBRF are established by the detection of the spirochetes in blood from febrile patients. *Borrelia* spp. can be detected in 70% of cases with dark-field microscopy, Giemsa-, Wright-, or acridine orange-stained preparations of blood smears or thick and thin smears. Serologies have limited value and are not standardized because of antigenic variation. Cross-reaction may occur with other spirochetes (5-10%). Welix-Felix agglutination of Proteus OX-K in convalescent-phase serum supports the diagnosis. Leukocytosis, mild normocytic anemia, and thrombocytopenia are common. There may also be an elevated sedimentation rate, increased prothrombin and partial thromboplastin times, and an increase in aspartate aminotransferase and bilirubin.

## Differential Diagnoses

LBRF and TBRF may be confused with malaria, typhoid fever, hepatitis, leptospirosis, salmonellosis, infectious mononucleosis, viral respiratory infections, rat bite fever, Colorado tick fever, Rocky Mountain spotted fever, and dengue fever. Epidemiologic features and detection of spirochetemia can help to exclude these diagnoses.

## Treatment

Relapsing fever responds to doxycycline, tetracycline, erythromycin, penicillin, and chloramphenicol ([Box 65-2](#)). One single dose of 500 mg of tetracycline (or erythromycin in children, pregnant patients, or patients with penicillin allergies) for LBRF and a 10-day course for TBRF are usually satisfactory. Antibiotic treatment can induce a Jarisch-Herxheimer reaction within 2 h; this reaction coincides with clearing of the spirochetes. This reaction is not prevented with corticosteroids.

## Prognosis

With appropriate therapy, mortality rates from relapsing fever are < 5%. In untreated patients the fatality rate for LBRF may reach 40%, and in TBRF is = 5%.

## Prevention

LBRF can be prevented with good personal hygiene, delousing procedures, and secondary prevention with case detection and treatment ([Box 65-3](#)). TBRF requires avoidance or elimination of the tick, using acaricides.

## LYME DISEASE

### Essentials of Diagnosis

- Most common in the northeastern, upper midwestern, and western parts of the United States.
- *Borrelia burgdorferi* is the longest (20-30  $\mu\text{m}$ ) and narrowest (0.2-0.3  $\mu\text{m}$ ) spirochete member of the *Borrelia* genus and has the fewest flagella (7-11).
- Erythema migrans (EM) is a red expanding lesion with central clearing that is commonly seen during the early stage of Lyme disease.
- The most common systems affected are the skin (EM), the joints (arthritis), the CNS (facial palsy), and the heart (conduction defects).
- Serology is not standardized; it is insensitive in early infection and does not distinguish active from inactive infection.
- Grows in Barbour-Stoenner-Kelly medium from skin biopsy and other specimens.

- Polymerase chain reaction (PCR) can be useful in synovial-fluid analysis. It has limited value with blood, cerebrospinal fluid (CSF), and urine.

## General Considerations

Lyme disease is a tick-borne illness caused by the spirochete *B burgdorferi*. Lyme disease can be divided into early disease (stage 1, EM), disseminated infection (stage 2), and late disease (stage 3, persistent infection). The first stage involves the skin, followed by stages 2 and 3, which often affect the skin, joints, CNS, and heart. However, any of the stages may fail to appear or may overlap with one another ([Table 65-2](#)).

**A. Epidemiology.** Lyme disease is the most common vector-borne infection in the United States. In 1997, there were 12,801 cases reported in the United States. It is transmitted by ticks from the genus *Ixodes*. The *Ixodes* tick goes through a 2-year life cycle that is composed of three stages: larva, nymph, and adult. Tick larvae acquire the spirochete via a blood meal from an infected host. Both the nymph and female adult infect humans. A tick must be attached for at least 24 h to transmit the spirochete. Tick engorgement and attachment for = 72 h are predictors of subsequent human infection. *Ixodes* ticks in the northeastern and midwestern United States belong to the *Ixodes dammini* (*scapularis*) species, in the western United States to *Ixodes pacificus*, in Europe to *Ixodes ricinus*, and in Asia to *Ixodes persulcatus*. Rodents and small mammals are the natural hosts of the larval and nymphal stages. The incidence of Lyme disease reflects a changing dynamic between the principal reservoir, the white-footed mouse, its food supply, and the suitability of its local habitat. Deer, horses, dogs, and other larger mammals and birds may be occasional hosts to the adult ticks. Most cases have their onset during summer and occur in association with hiking, camping, and residence in wooded, rural, or coastal areas.

**B. Microbiology.** Of spirochetes in the *Borrelia* genus, *B burgdorferi* is the longest (20-30  $\mu\text{m}$ ) and narrowest (0.2-0.3  $\mu\text{m}$ ), and has the fewest flagella (7-11). This organism can be grown from skin biopsy and other specimens on an artificial medium called Barbour-Stoenner-Kelly at 33°C. The *B burgdorferi* surface membrane is studded with lipoproteins called outer-surface proteins (OSPs) A, B, C, D, E, and F; other prominent flagellar antigens include flagellar protein, heat shock protein, and protoplasmic cylinder antigen. *B burgdorferi* is capable of altering its surface lipoproteins by recombining gene cassettes in a manner that resembles the mechanism of antigenic variation among the relapsing fever borreliae. The antigenic variability seen among different isolates has important implications for serologic tests and vaccine development. In the United States, most strains belong to the genomic group *B burgdorferi sensu stricto*, and in Europe most strains belong to the groups known as *B garinii* and *B afzelii*.

**C. Pathogenesis.** After inoculation in the skin, *B burgdorferi* replicates within the dermis producing EM and spreads hematogenously to other organs. The organism has tropism for the skin, joints, heart and CNS. A rise in immunoglobulin M (IgM) is detected within 2-3 weeks after the onset of infection; an increase in IgG and IgA is established after 2-3 months of infection. Host genetic factors may determine the likelihood of tissue damage; for example, patients with human leukocyte antigens DR4 and DR2 may be more susceptible to chronic arthritis.

## Clinical Findings

**A. Signs and symptoms.** *B burgdorferi* infection can involve the skin, musculoskeletal system, CNS, and cardiac tissues ([Box 65-4](#)).

**1. Skin.** EM appears at the site of the tick bite 3-30 days after the bite and begins as a red macule or papule with areas of redness that expand with partial central clearing. The lesion often feels warm to hot; it may burn, prickle, or itch, and it is more common in the thigh, groin, and axilla. The lesion usually fades within 3-4 weeks (range, 1 day-14 months). The migratory nature of skin lesions most likely represents spirochetemia with secondary seeding of the skin rather than multiple tick bites. EM may be accompanied by fatigue, fever, chills, achiness, headache, and lymphadenopathy. It can also present with CNS and liver involvement. Multiple annular secondary lesions tend to be smaller and less migratory and to lack indurated centers. Acrodermatitis chronica atrophicans lesions follow years after EM. There is usually bluish-red discoloration, and then the lesion becomes sclerotic or atrophic. This condition has been associated with elevated antibodies to *B burgdorferi* and usually responds to antibiotic therapy; it is seen primarily in elderly women in Europe.

**2. Musculoskeletal system.** Joint symptoms are the second most common clinical manifestation after EM. These symptoms may begin 5-6 weeks (range, 1 week to 2 years) after the bite, and they include, at one end of the spectrum, subjective joint pain, and at the other, arthritis or chronic erosive synovitis. The arthritis is usually of sudden onset, monoarticular or oligoarticular, and migratory. The knee is the most frequently involved joint, followed by the shoulder, elbow, temporomandibular joint, ankle, wrist, and hip. Initially, recurrent attacks of arthritis are common, but their frequency decreases by 10-20% each year. During recurrences, usually more joints are involved than in the initial episode. These attacks last ~ 1 week, with intervals of 1 week to 2 years between attacks. Joint fluid leukocyte counts range from 500 to 110,000 cells/mm<sup>3</sup>. Of all patients with Lyme disease, ~ 10% develop a severe chronic erosive arthritis often associated with IgG antibody response to OSPs A and B of the organism and with human leukocyte antigen DR4.

**3. CNS.** Neurologic abnormalities begin within 4 weeks (range, 2-11 weeks) after the tick bite. The most common symptoms are headache, stiff neck, photophobia, facial palsy, and peripheral nerve paresthesias. CSF findings are similar to those seen in viral meningitis with lymphocytic pleocytosis of ~ 100 cells/mm<sup>3</sup> and elevated protein levels. Cranial nerve VII is the most frequently involved; unilateral or bilateral facial palsies occur in 11% of patients, and these findings can be seen in 50% of patients with meningitis. Other cranial nerves, particularly III, IV, V, and VIII, are less often involved. Months to years after the initial infection, patients may have chronic encephalopathy (manifested by memory impairment, mood changes, sleep disturbances, and difficulty with concentration), polyneuropathy, or, less commonly, leukoencephalitis. These patients may present with neuropsychiatric symptoms, focal CNS disease, or severe fatigue. However, it is often difficult to establish *B burgdorferi* as the etiologic agent in patients who present with fatigue or psychiatric manifestations.

**4. Cardiac tissue.** Cardiac involvement begins within 5 weeks (range, 3-21 weeks) after the bite, in ~ 5-10% of patients. Such abnormalities usually consist of atrioventricular block (first degree, Wenckebach, or complete heart block) and can last for 3 days-6 weeks. Some patients can present with myopericarditis, pericardial effusion, and chronic cardiomyopathy.

**5. Other clinical findings.** Other unusual manifestations include ophthalmologic involvement (conjunctivitis, keratitis, uveitis, choroiditis, retinal detachments, and optic neuritis), hepatitis, myositis, dermatomyositis, eosinophilic lymphadenitis, and adult respiratory distress syndrome.

**6. Congenital infection.** Maternal-fetal transmission of *B burgdorferi* has been reported with adverse fetal and neonatal outcome in a few cases (congenital heart disease, encephalitis, cortical blindness, intrauterine fetal death, and premature birth). Of note, a prospective study found no association between congenital malformation and infection by *B burgdorferi*. Despite the fact that there is no definitive proof that *B burgdorferi* causes fetal damage or an adverse outcome in the offspring, prompt diagnosis in the mother and treatment should be emphasized.

**B. Laboratory findings.** The diagnosis of Lyme disease is made on clinical findings, epidemiologic features, and an elevated antibody response to *B burgdorferi*. The available laboratory tests (with the exception of a positive culture from an EM lesion) can be unreliable. Serologic testing only should be undertaken when clinical and epidemiologic features suggest Lyme disease as the diagnosis. Most patients with *B burgdorferi* are found to have detectable antibodies when tested with enzyme-linked immunosorbent assay (60-70% within 2-4 weeks of infection and 90% by the disseminated and persistent stages). However, serologic tests lack standardization, their accuracy is often unsubstantiated, and false-positive results are common. IgM antibody appears 2-4 weeks after the EM lesion, peaks at 6-8 weeks, and declines after 4-6 months. IgG antibody appears 6-8 weeks after the EM lesion, peaks at 4-6 months, and remains at low levels despite antibiotic therapy. A fourfold rise in antibody titer would be suggestive of recent infection. Western blot analysis is used to confirm results obtained by enzyme-linked immunosorbent assay. The finding that a patient has significant amounts of anti-*B burgdorferi*-specific antibodies can be interpreted only in the context of the clinical setting. Demonstrating that a patient has an immune response against this organism does not mean that the patient is actively infected or that any symptoms are necessarily related to *B burgdorferi* infection. Detection of spirochetal DNA by PCR is useful in synovial fluid (75-85% of sensitivity). However, the sensitivity of PCR in CSF, blood, or urine samples has not been well established.

## Differential Diagnosis

Lyme disease mimics many different diseases ([Table 65-3](#)). The EM lesion may be confused with streptococcal cellulitis, erythema multiforme (the latter lesions tend to be smaller, urticarial, or vesicular and may occur on mucosal surfaces), and erythema marginatum (these lesions are smaller and migrate rapidly in minutes to hours). Lyme arthritis can be distinguished from other rheumatoid diseases, such as acute rheumatic fever, based on the EM lesion and the brief episode of synovitis. The chronic form of Lyme arthritis may resemble pauciarticular juvenile rheumatoid arthritis, psoriatic

arthritis, Reiter's syndrome, and reactive arthritis caused by members of the *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia* genera. This form of arthritis may also be associated with rubella, hepatitis B, or echoviruses. The aseptic meningitis in Lyme disease may resemble enteroviral, leptospiral, or early tuberculous meningitis. It is important to consider sarcoidosis, Behcet's disease, and multiple sclerosis when the disease becomes chronic.

## Treatment

Early disease responds readily to several oral agents (such as doxycycline, amoxicillin, or cefuroxime), which are usually prescribed for 2-3 weeks ([Box 65-5](#)). There are few published, controlled trials that compare different regimens for late Lyme disease. Intravenous therapy, usually ceftriaxone or penicillin, is used for 2-3 weeks for late Lyme disease.

**A. Erythema migrans.** In EM, oral antibiotic therapy with doxycycline shortens the duration of the rash and prevents the development of late sequelae. Amoxicillin is also effective and preferred for children under 9 years of age and in pregnant or lactating women.

**B. Musculoskeletal disease.** Treatment for one month with oral doxycycline or amoxicillin is usually effective. For refractory cases, intravenous therapy with ceftriaxone or penicillin G, and arthroscopic synovectomy may lead to clinical improvement. Analgesics such as acetaminophen or nonsteroidal anti-inflammatory agents should be used in patients with symptomatic arthritis.

**C. Neurologic disease.** Patients with facial nerve palsy alone can be treated with oral doxycycline or amoxicillin. Intravenous penicillin G, ceftriaxone, or cefotaxime is effective for meningitis, cranial or peripheral neuropathies, encephalitis, or other late neurologic complications.

**D. Cardiac disease.** Patients with cardiac atrioventricular block can be treated with doxycycline or amoxicillin if the PR interval is  $< 0.3$  s. For those patients with more severe cardiac involvement, intravenous ceftriaxone or penicillin should be considered. High-degree atrioventricular block may require temporary pacing.

## Prognosis

Most patients treated promptly with an appropriate antibiotic have an uncomplicated course. True failures are rare, and in most cases re-treatment or prolonged treatment is the result of misdiagnosis and misinterpretation of serologic results rather than inadequate therapy.

## Prophylaxis

Routine use of antimicrobial prophylaxis after a tick bite is not recommended. However, some experts recommend amoxicillin for pregnant women who remove an engorged deer tick after exposure in an endemic area. Persons who develop a rash or illness within a month after a tick bite should seek prompt medical attention. Strategies to

prevent Lyme disease include avoiding tick habitats, wearing protective clothing, using repellents to avoid tick attachment, promptly removing attached ticks, and using community measures to reduce tick abundance ([Box 65-6](#)). The Lyme vaccine is made from recombinant OSP-A of *B burgdorferi*. Antibodies produced in response to the vaccine destroy spirochetes in the gut of the engorged tick before they can be transmitted. It is indicated for use in adults, in three doses intramuscularly at 0, 1, and 12 months. Ideally the third dose should be given in March because the tick season in the Northeast and upper Midwest usually begins in April. The efficacy of the vaccine has been reported to be 76% after the third dose; however, the long-term safety, timing of booster doses, and cost effectiveness are unknown. Use of this vaccine should be limited to persons with frequent or prolonged exposure to tick habitats in endemic areas.

## **LEPTOSPIRA SPECIES**

### **Essentials of Diagnosis**

- The most severe forms of leptospirosis commonly present with liver and renal involvement.
- Transmission occurs by indirect contact with an infected animal.
- Predisposing factors include occupational exposure (veterinarians and farmers) and recreational exposure (campers and swimmers).
- These organisms can be detected by dark-field examination, silver or fluorescent antibody stains, or PCR. Tween 80-albumin is the best medium for culture.
- Motile spirochete, 0.1 x 6-20 um, with hooked end.
- Isolation from any clinical specimen or seroconversion or fourfold increase in antibody titers is diagnostic.

### **General Considerations**

Leptospirosis is caused by multiple species of *Leptospira* and is characterized by two different forms of disease. There is a mild form (anicteric) and a severe form (icteric, also known as Weil's syndrome) of leptospirosis.

**A. Epidemiology.** Leptospirosis is a zoonosis of worldwide distribution and is especially common in tropical regions. Rodents, dogs, cats, other wild mammals, fish, and birds are important reservoirs. The bacteria can live in the renal tubules of dogs for long periods of time. Transmission to humans occurs by indirect contact with urine, blood, or tissue of an infected animal (eg, by veterinarians or farmers); human-to-human transmission is rare. It can be contracted during recreational activities involving water. Leptospirosis has been reported during the summer and autumn months in the southern and western United States and especially in Hawaii.

**B. Microbiology.** Leptospire are spirochetes belonging to the genus *Leptospira*, which is composed of two species: *L interrogans* and *L biflexa*. The pathogenic leptospire

belong to the first species and are divided into 200 serotypes that have major antigens in common and are combined into 23 serogroups. Leptospire are motile spirochetes, 0.1 um wide, 6-20 um long, and with hooked ends.

**C. Pathogenesis.** The bacteria enter the abraded skin or mucous membranes and spread by blood to multiple organs including liver (liver disease occurs in severe cases due to hepatocellular dysfunction including decreased production of clotting factors and albumin, and reduced esterification of cholesterol), kidneys (renal failure due to tubular damage by immune complexes, hypoxemia, or direct toxic effect of the leptospire), CNS (in the first week, the leptospira can be found in the CSF, but no meningitis is seen until the serum antibody appears), eye (can produce chronic or recurrent uveitis), muscle (changes include cytoplasmic vacuoles and polymorphonuclear leukocyte infiltration), and blood vessels (vasculitis, capillary injury, and hemolysis are characteristic features).

## Clinical Findings

**A. Signs and symptoms.** Leptospirosis has an incubation period of 1-2 weeks. Among infected patients who develop leptospirosis, 90% have the anicteric form, and 10% have the icteric form. There are two phases—septic and immune. The septic phase lasts 4-7 days and consists of a flulike syndrome; during this phase leptospiras can be found in the bloodstream. The immune phase lasts 4-30 days and consists of aseptic meningitis, uveitis, iritis, rash, and hepatic and renal involvement. During this phase, leptospiras can be found in urine and aqueous humor ([Box 65-7](#)).

**1. Anicteric leptospirosis.** The septic phase is characterized by fever, headache, myalgias, abdominal pain, nausea, and vomiting. The immune phase consists of less prominent fever, intense headache, aseptic meningitis, conjunctival suffusion, uveitis, hepatosplenomegaly, pulmonary involvement, and skin rashes.

**2. Icteric leptospirosis.** The septic phase resembles that of the anicteric leptospirosis. The most prominent manifestation during the immune phase is hepatorenal dysfunction with hemorrhagic diathesis.

**B. Laboratory findings.** Laboratory findings in anicteric leptospirosis include normal leukocyte counts with neutrophilia and elevated ESR and CSF protein. Pulmonary and myocardial involvement; high bilirubin levels; increases in alkaline phosphatase, aspartate aminotransferase, alanine aminotransferase, creatine phosphokinase, creatinine, and blood urea nitrogen; and thrombocytopenia are commonly found in icteric leptospirosis. The diagnosis is made by isolation of the organism from any clinical specimen or seroconversion or fourfold increase in antibody titer. The bacteria can be isolated from blood or CSF during the first 10 days. Tween 80-albumin medium is preferred, and multiple cultures should be performed. The organisms can also be detected by dark-field examination, PCR, silver stains of body fluids or fluorescent antibody stains of tissue. *Leptospira*-specific antibodies can be detected by macroscopic agglutination with killed antigen, microscopic agglutination with live antigen (more specific) and enzyme-linked immunosorbent assay. Agglutinins appear after 6-12 days, and peak titers are reached in 3-4 weeks. Cross-reaction is common with other spirochetal diseases.

## Differential Diagnoses

Differential diagnoses include dengue, dengue fever, hemorrhagic fever, LBRF, TBRF, and other diseases caused by arthropod-borne and rodent-borne pathogens.

## Complications

Aseptic meningitis is the most common complication in the anicteric cases. Renal failure, liver damage, pulmonary hemorrhage, vasculitis, and myocarditis are less common but are the usual causes of death.

## Treatment

Penicillin G or doxycycline are effective even when treatment is delayed ([Box 65-8](#)). Penicillin G or ampicillin should be used in severely ill patients. In less severely ill patients, an oral dose of ampicillin, doxycycline, or amoxicillin can be used.

## Prognosis

In the absence of jaundice, the disease is rarely fatal. The mortality rate in icteric patients under 30 years of age is 5%; in the elderly the rate is 30-40%.

## Prevention

Doxycycline can prevent infection ([Box 65-9](#)). However, prevention is problematic because exposure is difficult to predict. Effective rat control and avoidance of infected urine and known contaminated water sources are important preventive measures.

## 66 . *Mycoplasma & Ureaplasma* — Jose G. Montoya, MD

### INTRODUCTION

*Mycoplasma* and *Ureaplasma* species (mycoplasmas) are ubiquitous in nature and are commonly found in plants, animals, and humans. These bacteria contain the smallest amount of double-stranded DNA that is capable of producing a free-living microorganism; they measure between 0.15 and 0.3  $\mu\text{m}$  in diameter and = 2  $\mu\text{m}$  in length. They are believed to have evolved from a putative common ancestor of the gram-positive bacteria by a process of genome reduction and adoption of a dependent, parasitic life style. *Mycoplasma* and *Ureaplasma* spp. lack a cell wall. Therefore, they cannot be visualized with the Gram stain and are not susceptible to antibiotics that act on cell wall synthesis (eg, penicillins and cephalosporins). They are capable of growing in cell-free media, but require many exogenous nutrients for growth, including sterols. In addition to *Ureaplasma urealyticum*, 13 species of *Mycoplasma* have been isolated from humans; however, most of them are not regarded as pathogens.

Mycoplasmas are the etiologic agents and cofactors of several clinical syndromes in humans. *Mycoplasma pneumoniae* is a common cause of community-acquired pneumonia. *U urealyticum* and *Mycoplasma genitalium* most often cause genitourinary tract infections; *U urealyticum* has also been associated with perinatal morbidity and mortality, as well as with disease outside the genitourinary tract, especially in children. *Mycoplasma hominis* is an infrequent cause of bone, joint, and upper urinary tract disease.

### ***M PNEUMONIAE* INFECTION & DISEASE**

#### Introduction

*M pneumoniae* is an important cause of upper and lower respiratory infections in both adults and children. Extrapulmonary involvement, including dermatological, neurological, cardiac, musculoskeletal, and vasculitic involvement, has also been associated with *M pneumoniae* infection in humans.

#### Essentials of Diagnosis

- Community acquired pneumonia.
- Extrapulmonary involvement is not infrequent.
- Inflammatory cells on sputum Gram stain but no predominant bacterial type.
- Coombs-positive hemolytic anemia.
- Cold agglutinin titer of = 1:32.
- Fourfold change in specific immunoglobulin G (IgG) or IgM titers.

## General Considerations

**A. Epidemiology.** Infected humans are the only source of *M pneumoniae* organisms for transmission to new susceptible hosts. *M pneumoniae* is spread from one individual to another by respiratory droplets produced by coughing. Individuals at any age can be infected and develop disease, but those between the ages of 5 and 20 years are most often affected. *M pneumoniae* is a leading cause of pneumonia in school-aged children and young adults—especially those in military and college populations. Infections occur throughout the world and without regard for time of year. Immunity after infection is not long lasting.

**B. Microbiology.** *M pneumoniae* cannot be visualized with any routine stain because of its small size and lack of cell wall. It is difficult to cultivate in the laboratory due to its fastidious growth requirements; however, it does grow slowly in enriched liquid culture media and on special mycoplasma agar, such as SP 4, under aerobic conditions. *M pneumoniae* may require = 21 days before growth can be easily detected in a culture; *M hominis* and *U urealyticum* require 2-5 days.

**C. Pathogenesis.** The initial step in disease causation by *Mycoplasma* spp. is attachment to the cilia and microvilli of epithelial cells lining the respiratory tract. Respiratory epithelial cells express complex oligosaccharides containing sialic acid in their apical regions that bind a *Mycoplasma* surface protein known as P1, located on a polar attachment structure. *Mycoplasma* attachment to these cells precipitates a cascade of events characterized by ciliostasis, desquamation of the involved cells, and an inflammatory reaction. Mechanisms of cytotoxicity may include direct damage to respiratory epithelial cells by substances elaborated by mycoplasmas such as hydrogen peroxide and free-oxygen radicals or damage resulting from the host inflammatory response. The plasma membrane surfaces of *Mycoplasma* spp. are covered with variable lipoproteins that display antigenic and immunomodulatory properties.

## Clinical Findings (Box 66-1.)

### A. Respiratory Involvement.

**1. Signs and Symptoms.** *M pneumoniae* is associated with pharyngitis, nonpurulent otitis media, tracheobronchitis, and community-acquired pneumonia in humans. The latter two syndromes are by far the most common among those caused by *M pneumoniae*. Despite earlier descriptions of an association with bullous myringitis, this finding does not appear to be a common feature of *M pneumoniae* infection. The pneumonia is usually self-limited and does not require hospitalization. However, in patients with sickle cell disease and other hemoglobinopathies, respiratory involvement by *M pneumoniae* can be severe and life-threatening.

Patients develop respiratory symptoms 2-3 weeks after exposure to the respiratory secretions of another infected individual. *M pneumoniae* respiratory tract disease usually presents with gradual onset of fever, malaise, headache, and cough. The cough is usually minimally productive or nonproductive and is "hacking" in most patients; it can become debilitating or incapacitating and may produce sternal discomfort. Most of these

symptoms resolve spontaneously in the vast majority of patients. However, in a minority, these upper respiratory symptoms progress to tracheobronchitis or pneumonia. On occasion, *M pneumoniae* pneumonia begins abruptly. Pleuritic chest pain is rare and must be distinguished from the chest soreness due to muscle strain in cases of severe cough. Body temperature usually fluctuates between 101 and 102 °F; however, occasional temperature spikes > 102 °F can be seen. On physical examination, most patients do not appear acutely ill. The pharynx may appear erythematous, but cervical lymphadenopathy is rare or absent. *M pneumoniae* is a rare cause of isolated pharyngitis in children and adults. Lung auscultation may be entirely normal or may disclose only a few crackles.

**2. Laboratory findings.** Examination of sputum with the Gram stain usually reveals inflammatory cells in the absence of large numbers of bacteria or a predominant type. The peripheral leukocyte count is either within normal range or moderately elevated.

**3. Imaging.** Chest radiographic abnormalities are usually out of proportion to the physical examination findings. *M pneumoniae* has a predilection for the lower lobes and usually causes patchy alveolar or reticular infiltrates; however, lobar infiltrates have been described. Pleural effusions, if present, are small. Unusual radiological findings described in association with *M pneumoniae* pneumonia include diffuse interstitial infiltrates, mediastinal mass, hilar adenopathy, and pneumatoceles.

**B. Dermatologic Involvement.** *M pneumoniae* infection has been associated with erythema multiforme major, or the Stevens-Johnson syndrome. Erythema multiforme major is an acute and often recurrent inflammatory disease of skin and mucous membranes. Erythema multiforme has been reported in as many as 7% of patients with *M pneumoniae* pneumonia, but has been associated, albeit less often, with other infectious agents including herpes simplex virus. Skin lesions of erythema multiforme include urticarial papules, macules with a "target" appearance, vesicles, and bullae. They occur on the backs of hands, palms, soles, and extensor surfaces of limbs, and they may become generalized. Stevens-Johnson syndrome is a vesiculobullous disease of the skin, mouth, eyes, and genitals. Most bullae affect the trunk, mouth, and genitals. The conjunctiva are usually injected. Drugs such as phenytoin, phenobarbital, sulfonamides, and penicillins can also be implicated as causative agents of erythema multiforme and Stevens-Johnson syndrome.

**C. Cardiac and Vascular Involvement.** Raynaud's phenomenon has been described particularly in women with *M pneumoniae* infections. It may be related to the development in these patients of cold-sensitive IgM antibodies directed against the I antigen on circulating erythrocytes (cold agglutinins). These autoantibodies are responsible for a subclinical hemolytic anemia in ~ 50% of patients and a clinically significant anemia in a smaller percentage of patients. Cardiac arrhythmias including conduction defects, hemopericardium, myopericarditis, and congestive heart failure have also been associated with *M pneumoniae* infection. Other reported vascular complications include internal carotid artery occlusion, cerebral infarction, and infection of aneurysms and vascular grafts.

**D. Neurologic Involvement.** A number of neurologic syndromes have been ascribed to *M pneumoniae*, although a causal relationship is not well established. These syndromes

include aseptic meningitis, meningoencephalitis, transverse myelitis, brain stem dysfunction, Guillain-Barre syndrome, and peripheral neuropathy. Cerebrospinal fluid (CSF) examination usually reveals  $< 500$  leukocytes/mm<sup>3</sup>, a slightly elevated protein concentration, and normal to slightly decreased glucose concentration. In most cases a microbiological diagnosis has been established by serology. *M pneumoniae* rarely has been cultivated from CSF and has never been cultivated from brain tissue. A case of fatal encephalitis has been described in which *M pneumoniae* DNA was detected in CSF by polymerase chain reaction. It is important to emphasize that efforts should be made to rule out other causes of CNS disease before *M pneumoniae* is established as the etiologic agent.

**E. Other Clinical Manifestations.** Polyarthralgia, arthritis, and immune complex-associated renal disease have been associated with *M pneumoniae* infection.

## Diagnosis

Methods for diagnosing *M pneumoniae* infection include cultivation, antigen and nucleic acid detection, and serology. Cultivation of *M pneumoniae* from tracheal aspirates, nasopharyngeal swabbings, sputum, or any body fluid should be attempted if the methods are available but they have a low yield and are cumbersome to perform due to the complex growth requirements of the organism. Specimens for culture should be transported in special media.

Detection of *M pneumoniae* antigens directly in sputum specimens is feasible by using a direct fluorescent antibody method or antigen-capture enzyme immunoassay, but the role of these antigens in the diagnosis of *M pneumoniae* disease has not been well established. Methods for detecting *M pneumoniae* DNA are also commercially available for use with throat swabs but are not available in most laboratories.

Serological testing is the most widely available and widely used approach for diagnosing *M pneumoniae* infections. Serological tests are rarely helpful during the acute illness. Paired measurements are most helpful; a fourfold titer difference between the acute and the convalescent serum antibody titer is considered diagnostic. Single measurements are of value for epidemiological purposes. IgG- and IgM-specific antibodies can be detected with indirect immunofluorescent antibody or enzyme immunoassay methods. Because of ease of use and reliability, enzyme immunoassay has become the preferred method. A complement fixation assay is less sensitive and is reserved for epidemiological purposes.

Demonstration of cold agglutinins can help to support the diagnosis of *M pneumoniae* pneumonia, although the finding is nonspecific. Cold agglutinins have been observed in adenovirus infections, infectious mononucleosis, cytomegalovirus infection, lymphoma, and other diseases. Nonetheless, a titer of  $= 1:32$  is highly suggestive of infection with *M pneumoniae*. Cold agglutinins can also be detected at the bedside by drawing 1 mL of the patient's blood into a blue top tube (containing citrate as the anticoagulant) and cooling the tube at 4 °C for 3-4 min. The reversible appearance of macroagglutination indicates the presence of cold agglutinins at a titer of approximately  $= 1:64$ .

## Differential Diagnosis

*Legionella* spp., *Chlamydia pneumoniae*, *Chlamydia psittaci*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* can cause a pneumonia with clinical features that are indistinguishable from those associated with *M pneumoniae*.

## Treatment

The efficacy of antimicrobial agents in patients with *M pneumoniae* pneumonia is difficult to evaluate because this is often a self-limited disease. Antibiotics most likely shorten the duration of symptoms and may have an important role when infected patients are immunocompromised or are severely affected by the disease.

The most effective antimicrobial agents are macrolides, fluoroquinolones, and tetracyclines ([Box 66-2](#)). Macrolides are the first-line agents for treatment of *M pneumoniae*-associated disease. Azithromycin and clarithromycin are better tolerated and easier to administer than erythromycin, but are more expensive. Fluoroquinolones should not be used in patients younger than 18 years, and tetracyclines should not be used in children younger than 9. The newer fluoroquinolones (levofloxacin, moxifloxacin, and gatifloxacin) with enhanced activity against *S pneumoniae* have reliable activity in vitro against *M pneumoniae*. Most patients with pneumonia do not require hospitalization and are treated on an empirical basis. The recommended duration of therapy is not clear. Clinical relapse occurs in ~ 10% of patients and may warrant a longer course of antibiotic therapy, eg, 3 weeks.

Radiological improvement may lag behind clinical improvement for weeks.

## Prevention

There are currently no recommended specific control measures for *M pneumoniae* outbreaks in closed communities. However, some studies have suggested the usefulness of prophylactic antibiotics administered to close contacts of case patients. One study demonstrated that the administration of azithromycin, 500 mg on day 1 and 250 mg on days 2-5, to individuals at risk was beneficial in reducing the disease attack rate during an institutional outbreak of *M pneumoniae* pneumonia. There is no available vaccine.

## INFECTIONS CAUSED BY *U UREALYTICUM* & OTHER MYCOPLASMAS

*U urealyticum*, *M hominis*, and *M genitalium* are commensals of the genitourinary tract of both women and men and in newborns. *U urealyticum* is an infrequent cause of urethritis in males, urinary calculi, chorioamnionitis, spontaneous abortion, and premature birth. *M genitalium* is also associated with male urethritis. *M hominis* is a rare cause of pyelonephritis, pelvic inflammatory disease, and postabortal and postpartum fevers.

*U urealyticum* and *M hominis* can cause disease outside the genitourinary tract in immunosuppressed patients or in otherwise immunocompetent patients after

manipulation or trauma of the genitourinary tract. *M hominis* can cause sternal wound infections and osteomyelitis, arthritis (especially in hypogammaglobulinemic patients), brain abscess, pneumonia, and peritonitis. It has been associated with neonatal pneumonia and sepsis. In immunosuppressed patients, *U urealyticum* can cause arthritis, osteomyelitis, sinusitis, and pneumonia. It can also cause neonatal pneumonia and sepsis.

A thorough search for other causes should be completed before *U urealyticum* or *M hominis* can be considered the etiologic agent of any of the above syndromes.

*Mycoplasma penetrans*, *Mycoplasma pirum*, and *Mycoplasma fermentans* have been associated with HIV infection and with the progression to AIDS; however, there is little evidence for a causal role of these organisms in this disease process. The associations more likely reflect the enhanced susceptibility of the HIV-infected host to secondary mycoplasma infection.

*M hominis* can be treated with tetracyclines or with clindamycin. *U urealyticum* infections can be treated with tetracyclines, erythromycin, or azithromycin. Both *U urealyticum* and *M hominis* can be resistant to the tetracyclines. *M hominis* is resistant to the macrolides.

**BOX 66-2. Treatment of *Mycoplasma pneumoniae* Infections<sup>1</sup>**

- First Choice**
- Azithromycin, orally, 500 mg on day 1 followed by 250 mg daily on days 2-5 **OR**
  - Azithromycin, IV, 500 mg daily **OR**
  - Clarithromycin,<sup>2</sup> orally, 500 mg daily **OR**
  - Erythromycin, orally, 250-500 mg four times daily **OR**
  - Erythromycin, IV, 500 mg four times daily
- Second Choice**
- Levofloxacin, orally or IV, 500 mg daily **OR**
  - Doxycycline, orally or IV, 100 mg twice daily
- Pediatric**
- Use macrolide only
- Considerations**
- Erythromycin 40 mg/kg/day
  - Tetracyclines are contraindicated in children < 9 years of age
  - Fluoroquinolones are not recommended in persons < 18 years of age

<sup>1</sup>Cell wall antibiotics have no role in the treatment of mycoplasma infections.

<sup>2</sup>IV clarithromycin is not available.

## 67 . Chlamydia — Jose G. Montoya, MD

### General Considerations

*Chlamydia trachomatis*, *Chlamydia psittaci*, and *Chlamydia pneumoniae* are among the most prevalent microbial pathogens in humans worldwide. *C trachomatis* is responsible for a variety of sexually transmitted disease (STD) syndromes in both sexes. In addition, certain serotypes of *C trachomatis* are responsible for trachoma, the most common infectious cause of blindness in humans. *C psittaci* is a zoonotic pathogen associated with atypical pneumonia. *C pneumoniae* infects approximately one-half of the world's human population and is a cause of upper and lower respiratory tract disease. It has also been associated with atherosclerotic cardiovascular disease.

**A. Epidemiology.** In the United States, genital infections by *C trachomatis* serovars D through K occur frequently among sexually active adolescents and young adults. These serovars are also important perinatal pathogens. In 1998, > 600,000 cases were reported in the United States (237 per 100,000 population), making it the most common notifiable infectious disease in this country. Asymptomatic infection is rather common in both women and men. Prevalence rates vary according to the geographic locale and the specific populations. The prevalence of urethral infection among young men is < 10% for those seen in general medical settings, between 10% and 15% for asymptomatic soldiers undergoing routine medical care, and > 10% for heterosexual men seen in STD clinics. The prevalence of *C trachomatis* genital infection among women is 5% for asymptomatic college students, > 10% for women monitored in family-planning clinics, and > 20% for women seen in STD clinics. Chlamydial genital infections are found at a higher rate among women who use oral contraceptives or have cervical ectopy. It is estimated that 5-25% of pregnant women in the United States carry *C trachomatis* in their cervix. Of the neonates who get infected during birth, ~ 25% develop inclusion conjunctivitis, and 10% develop pneumonia.

Lymphogranuloma venereum (caused by serovars L1, L2, and L3) is a rare disease in the United States. The vast majority of cases are transmitted sexually, but transmission by nonsexual routes has been documented.

*C trachomatis* serovars A, B, Ba, and C cause trachoma, one the most common causes of preventable blindness in the world. These serovars are usually transmitted from person to person (most often involving a child) via hands and fomites. Endemic areas include Asia, the Middle East, sub-Saharan Africa, and northern Africa.

*C psittaci* is usually transmitted to humans by contact with birds or from occupational exposure in avian-processing plants or poultry farms. Essentially all common birds and several wild species are capable of carrying the organism and shedding it while remaining healthy. Only brief exposure to an area where an infected bird has been present is necessary for transmission of *C psittaci*. Rarely, the bite of a bird transmits the disease.

*C pneumoniae* was established as a human respiratory pathogen in 1983, and it is now

associated with 6-12% of cases of community-acquired pneumonia. Approximately 50% of persons worldwide have been infected by early adulthood. Outbreaks of *C pneumoniae* respiratory disease have been described especially in military recruits but also in the general population; the highest rates of *C pneumoniae* pneumonia are found among the elderly. There is no seasonal predominance. Exchange of respiratory secretions by aerosol route or by hand appears to be the primary mode of transmission of *C pneumoniae*. In more recent years, this organism has been associated with atherosclerosis and coronary artery disease.

**B. Microbiology.** Members of the genus *Chlamydia* are small, obligate intracellular prokaryotic organisms. They contain DNA, RNA, ribosomes, and a discrete cell envelope. The envelope lacks peptidoglycan between the inner and outer membranes, which explains why cell wall-active antibiotics have no role in the treatment of chlamydial infections. During their unique life cycle, *Chlamydia* species are observed in two distinct forms: the extracellular elementary body and the intracellular reticulate body. The elementary body is responsible for person-to-person transmission. It attaches to, and is engulfed by mammalian target cells. Within the phagosome, the elementary bodies reorganize and develop into reticulate bodies, which are adapted for intracellular survival and multiplication. After multiple rounds of replication by binary fission, the reticulate bodies condense and form elementary bodies. The elementary bodies eventually rupture the host cell to continue the cycle by infecting other contiguous cells. The complete genome sequences of *C trachomatis* and *C pneumoniae* reveal a large number of genes that are most similar to versions found in eukaryotes, emphasizing the coevolution of pathogen and host. Despite their distant relationship with the gram-negative bacilli, both *Chlamydia* species contain genes that appear to encode a "type III" secretion system typically associated with invasiveness and other virulence attributes.

Members of the genus *Chlamydia* share a common heat-stable lipopolysaccharide antigen and specific cell envelope protein antigens which facilitate their classification into a number of serotypes. Protein antigenic and gene sequence variability of the major outer-membrane protein have led to the identification of at least 20 sero- and sequence types of *C trachomatis*. The vast majority of the serotypes can be assigned to one of three major groups: (1) serovar group A, B, Ba, and C, which is associated with trachoma; (2) serovar group D, E, F, G, H, I, J, and K, which is associated with sexually transmitted and perinatally acquired infections; and (3) serovar group L1, L2, and L3, which is associated with lymphogranuloma venereum and hemorrhagic proctocolitis.

**C. Pathogenesis.** *Chlamydia* species rupture mammalian cells after unregulated replication of elementary bodies; pathology results from this cell lysis, as well as damage caused by recruited inflammatory cells and cytokine mediators. Repeated or persistent exposure is believed to elicit more intense host inflammatory responses, some of which may be directed at chlamydial heat shock proteins. A crucial and common pathologic endpoint of chlamydial infection is scarring of mucous membranes, especially of the conjunctiva (trachoma) and female upper genital tract (resulting in infertility).

The elementary body of *C trachomatis* attaches to host epithelial cells by using heparan sulfate as a bridging ligand and later infects mononuclear leukocytes in lymph nodes via

the local lymphatic draining system. Immunity against *C trachomatis* appears to protect only partially against reinfection.

*C psittaci* is acquired through inhalation of respiratory secretions or aerosolized droppings of infected birds; it spreads via the bloodstream and eventually reaches reticuloendothelial cells of the spleen and liver. Pneumonitis is characterized by edema, necrosis, erythrocytes, and a chronic inflammatory cellular infiltrate.

Little is known regarding the pathogenesis of *C pneumoniae*. It appears that *C pneumoniae* has a less rigid cell wall than that in other chlamydial species.

## Diagnosis

Chlamydial infections require laboratory studies for a definitive diagnosis. Available laboratory techniques include cytology, culture, serology, and demonstration of chlamydial antigens or nucleic acid sequences.

## Treatment

Antimicrobial agents such as the tetracyclines, certain macrolides, and some fluoroquinolones are highly active against *Chlamydia* infections. Clinically relevant resistance to these antibiotics has not been observed. All sex partners of patients with sexually transmitted chlamydial infections should be referred for evaluation and treatment.

## **C TRACHOMATIS INFECTIONS**

### Essentials of Diagnosis

- Typical intracytoplasmic inclusions in Giemsa-stained cell scrapings from the conjunctiva.
- Ligase chain reaction (LCR) or polymerase chain reaction (PCR) in first-void urine.
- Positive culture in McCoy or HeLa cells of body fluids or secretions.
- Positive microimmunofluorescence serology for suspected cases of lymphogranuloma venereum and infants with pneumonia.
- Complement fixation titer of 1:64 or greater in patients with presumed lymphogranuloma venereum.

### Clinical Syndromes

*C trachomatis* is associated with urethritis, proctitis, conjunctivitis, and arthritis in women and men; epididymitis in men; and mucopurulent cervicitis (MPC), acute salpingitis, Bartholin's glanditis, and the Fitz-Hugh and Curtis syndrome in women ([Box 67-1](#)). *C trachomatis* and *Neisseria gonorrhoeae* (see [Chapter 52](#)) coinfections are common in women with MPC and men with urethritis. In men, *C trachomatis* is the most common

etiologic agent of the nongonococcal (NGU) and postgonococcal urethritis (PGU) syndromes. In college-age women, in the absence of infection with *Escherichia coli* or *Staphylococcus saprophyticus*, *C trachomatis* is the most common etiologic agent of urethritis.

**A. Urethritis.** Urethritis is characterized in women by the presence of dysuria and frequency without urgency or hematuria and in men by discharge, frequency, and dysuria. Urethritis should be documented by the presence of mucopurulent or purulent discharge, by a Gram stain of urethral secretions demonstrating = 5 leukocytes per oil immersion field, or by demonstrating a positive leukocyte esterase test or = 10 leukocytes per high-power field on first-void urine. NGU is diagnosed in men with urethritis in whom gram-negative intracellular diplococci (*N gonorrhoeae*) cannot be detected in a gram-stained urethral discharge or swab specimen. PGU is diagnosed in men with persistent urethritis 2-3 weeks after treatment of gonococcal urethritis with beta-lactam antibiotics, which are ineffective against *C trachomatis*. Although the discharge from chlamydial urethritis is more watery, less purulent, and less abundant than the discharge from gonococcal urethritis, attempts to distinguish between the two on clinical grounds alone can be problematic. Physical examination in cases of chlamydial urethritis can be entirely normal or reveal meatal erythema and tenderness, urethral discharge, or both. It should be emphasized that asymptomatic *C trachomatis* infections can lead to long-term sequelae in the genitourinary tract.

**B. Mucopurulent Cervicitis.** MPC is defined by the presence of mucopurulent or purulent endocervical discharge in the endocervical canal or in an endocervical swab specimen. It has been suggested that the diagnosis can also be made on the basis of easily induced cervical bleeding. The most common complaints are vaginal discharge, vaginal bleeding, abdominal pain, and dysuria, although most infected women are asymptomatic. Physical examination reveals cervical edema, ectopy, and a propensity of the endocervical mucosa to bleed when rubbed with a swab.

**C. Proctitis.** Proctitis can be caused by *C trachomatis* serovars D through K and serovars L1, L2, and L3. It occurs primarily in men who have sex with men and practice receptive anorectal intercourse. It can occur also in heterosexual women. Patients usually present with rectal pain, tenesmus, and rectal exudate; hematochezia may be present. Gram stain of the rectal discharge reveals neutrophils. Anoscopic examination reveals mucopurulent discharge with a patchy mucosal friability of the distal third segment of the rectum. The L1, L2, and L3 strains rarely cause disease in the United States and produce a more severe syndrome of ulcerative proctitis or even proctocolitis; this presentation can be confused with herpes simplex virus (HSV) proctitis or Crohn's disease. Proctocolitis can lead to perianal fistulas and rectal strictures.

**D. Lymphogranuloma Venereum.** *C trachomatis* serovars L1, L2, and L3 are also responsible for the syndrome of lymphogranuloma venereum (LGV). The most frequent manifestation of LGV among heterosexual men is tender unilateral inguinal or femoral lymphadenopathy or both. The lymphadenopathy becomes associated with perinodal inflammation and formation of a bubo. Men who have sex with men and women may present with the proctocolitis syndrome (see above). Most patients present at the time of lymphadenopathy and no longer have the primary painless self-limited nodular or ulcerative lesion at the inoculation site.

**E. Epididymitis.** Epididymitis should be suspected in patients with unilateral testicular pain, with or without fever, and unilateral epididymal tenderness or swelling on physical examination. In men younger than 35 years, *C trachomatis* is by far the most common etiologic agent, followed by *N gonorrhoeae*. In men older than 35, *E coli* and *Pseudomonas aeruginosa* are the most common etiologic agents; these infections usually occur in the setting of urologic manipulation. In each case of suspected epididymitis, torsion of the ipsilateral testicle should be ruled out. Clinically available tests to rule out testicular torsion include Doppler ultrasound and nuclear medicine studies. In patients in whom the clinical suspicion for testicular torsion is high (eg, a young person who presents with acute unilateral testicular pain without urethritis), surgical exploration may be indicated. In patients with chronic unilateral testicular pain who do not respond to appropriate antibacterial therapy, other etiologies such as carcinoma or tuberculosis should be considered.

**F. Pelvic Inflammatory Disease.** Pelvic inflammatory disease (PID) comprises a spectrum of inflammatory disorders of the female upper genital tract, including any combination of endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. *C trachomatis* and *N gonorrhoeae* are the two most common etiologic agents. Other organisms such as anaerobes, *Streptococcus agalactiae*, *Gardnerella vaginalis*, enteric gram-negative bacilli, *Ureaplasma urealyticum*, and *Mycoplasma hominis* have also been implicated as etiologic agents of PID. PID can present with subtle or mild symptoms and may also be asymptomatic. Initially, symptoms may not necessarily indicate involvement of the genital tract. PID should be suspected in sexually active women who present with lower abdominal pain or tenderness, adnexal tenderness, and/or cervical motion tenderness and in whom no other cause for these symptoms can be identified. Other causes of abdominal pain in this setting include ectopic pregnancy and acute appendicitis. In addition, PID can present with fever (>101 °F), abnormal vaginal or cervical discharge, vaginal bleeding, dyspareunia, or some combination of these symptoms. Erythrocyte sedimentation rate or C-reactive protein may be elevated.

**G. Reiter's Syndrome.** Reiter's syndrome consists of conjunctivitis or uveitis, urethritis, arthritis, and mucocutaneous lesions that usually occur in human leukocyte antigen (HLA)-B27-positive individuals ~ 1-6 weeks after acquisition of a sexually transmitted or dysenteric agent. The first three features constitute the classic triad. Reiter's syndrome can present with all of the features mentioned above or in any combination of those symptoms. NGU may in fact be the first sign of this syndrome. In women, cervicitis can be part of the syndrome. The knees are the most commonly affected joints. Reiter's has been described after infection with enteric pathogens such as *Salmonella*, *Shigella*, or *Campylobacter* species, as well as *C trachomatis* genital-tract infection.

**H. Perinatal Infections.** Perinatal infections with *C trachomatis* result from exposure of the neonate to the organism present in the mother's cervix. Initial infection results in colonization of the mucous membranes of the eye, oropharynx, urogenital tract, and rectum. Infection of the newborn with *C trachomatis* is first manifested by the presence of conjunctivitis, which usually develops between 5 and 14 days after birth. Other infectious agents capable of causing conjunctivitis in neonates include *N gonorrhoeae*, *Haemophilus influenzae*, *S pneumoniae*, and HSV. Typically, *N gonorrhoeae* has an incubation period of only 1-3 days. However, laboratory tests are required for a

microbiologic diagnosis. Pneumonia can develop in neonates as a subacute, afebrile respiratory syndrome with onset at between 1 and 3 months of age. Infants usually develop cough, tachypnea, and bilateral diffuse interstitial infiltrates. Neonatal infections of the oropharynx, genital tract, and rectum are usually asymptomatic.

**I. Eye Infections.** *C trachomatis* causes eye disease in children and adults, and this disease takes two distinct clinical and epidemiological forms: trachoma and adult inclusion conjunctivitis. Trachoma is a chronic inflammatory condition of the ocular and palpebral conjunctiva and cornea caused by *C trachomatis* serovars A, B, Ba, and C. It occurs in the setting of poor hygiene and crowded conditions. A follicular conjunctivitis is usually followed by superficial neovascularization of the cornea (pannus formation). Subsequent scarring of the conjunctiva and cornea eventually leads to blindness. Adult inclusion conjunctivitis results from sexual transmission of *C trachomatis* serovars D through K. It usually presents as an acute unilateral follicular conjunctivitis and periauricular lymphadenopathy; this presentation is clinically similar to that of adenovirus or HSV conjunctivitis. If left untreated, it can evolve into a syndrome of chronic conjunctivitis but rarely results in conjunctival or corneal scarring.

## Diagnosis

**A. Urethritis.** In men with suspected nongonococcal or postgonococcal urethritis, the diagnosis of urethritis should be confirmed based on the results of urinalysis with = 10 leukocytes per high-power field or on Gram stain examination of the urethral discharge revealing > 4 neutrophils per oil immersion field. The absence of *N gonorrhoeae* should be documented with a properly performed Gram stain examination of the urethral material. Nucleic acid amplification methods for use with either urine or urethral/cervical swab specimens are the most sensitive and specific tests for the definitive diagnosis of *C trachomatis* genital-tract infection. The two most commonly used amplification methods are LCR and PCR. Since these methods can be used with first-void urine, an uncomfortable swab procedure is not necessary, thereby facilitating widespread diagnostic testing and screening of populations at risk.

**B. Epididymitis, Proctitis, and Mucopurulent Cervicitis.** In young men with epididymitis, urethritis needs to be ruled out (see preceding section). In a similar fashion, *N gonorrhoeae* should be excluded in patients who have both testicular pain and urethral discharge. Amplification of *C trachomatis* DNA from urine based on PCR or LCR is the diagnostic approach of choice. This sensitive and specific approach has also replaced cervical-swab specimen culture for assessing the possibility of *C trachomatis* cervicitis. For the diagnostic workup of proctitis, a rectal culture or direct immunofluorescence test for *C trachomatis* is indicated.

**C. PID.** The diagnosis of PID is difficult. Symptoms, signs, and laboratory tests are not specific. Women with symptomatic PID can present with any combination of the following: pelvic pain including adnexal and/or cervical-motion tenderness, palpable adnexal mass, and/or elevated erythrocyte sedimentation rate, C-reactive protein, or peripheral leukocyte count.

**D. Reiter's Syndrome.** In those with clinical features of Reiter's syndrome, evidence of *C trachomatis* should be sought. A stool examination should also be performed for the

gastrointestinal-tract pathogens associated with Reiter's syndrome, and the possibility of the HLA-B27 haplotype should be assessed.

**E. Lymphogranuloma Venereum.** The diagnosis of LGV is confirmed by isolation of an LGV serovar from the lymph node or rectum and occasionally from the urethra or cervix. An LGV complement fixation titer of = 1:64 or a microimmunofluorescence titer of = 1:512 is considered diagnostic.

**F. Perinatal Infections.** Purulent conjunctival discharge in a neonate should be evaluated with Gram stain and bacterial cultures to rule out *N gonorrhoeae*, *Haemophilus* spp., *S pneumoniae*, and *Staphylococcus aureus*. *C trachomatis* antigen can be detected directly, and the organism can be cultivated from conjunctival discharge. A Giemsa-stained scraping of the conjunctiva is less sensitive for detecting *Chlamydia* cells but is the most rapid method for diagnosis. Chlamydial culture of sputum, pharynx, eye, and rectum should be obtained in infants with pneumonia. Serological tests may help if a fourfold change is observed in immunoglobulin (Ig) G or IgM titers, but a single IgG measurement may be misleading because of passive transfer of maternal antibody. The two samples should be obtained = 4 weeks apart and analyzed in parallel.

**G. Eye Infections.** Trachoma can be diagnosed on clinical grounds and in the proper epidemiological setting. Confirmation of the diagnosis can be achieved by Giemsa-stained cell scrapings from the conjunctiva and detection of typical intracytoplasmic inclusions.

## Treatment

**A. Urethritis.** Adults with NGU or PGU should be treated as soon as possible after diagnosis. A single-dose regimen based on azithromycin for example has the important advantage of improved adherence ([Box 67-2](#)). Doxycycline, erythromycin, or ofloxacin can also be used. Ofloxacin is also often effective against *N gonorrhoeae*. Other drugs used against *N gonorrhoeae* such as the cephalosporins and ciprofloxacin are not effective against *C trachomatis*. Patients with recurrent or persistent urethritis should be evaluated for the possibility of nonadherence, reinfection, or an alternative diagnosis. In this setting, patients should be re-treated if they do not comply fully or have been re-exposed to an untreated sex partner. A combination regimen consisting of metronidazole plus erythromycin has been suggested for patients with a history of recurrent urethritis, who have adhered to the initial regimen and have not been re-exposed. In the absence of reliable negative data for *N gonorrhoeae*, empiric antibiotic coverage for this organism should be provided as well.

**B. Mucopurulent Cervicitis, Proctitis, Epididymitis, and PID.** Patients with mucopurulent cervicitis, proctitis, and epididymitis should be tested for *C trachomatis* and *N gonorrhoeae*, as above, and treated with drugs effective against both ([Box 67-2](#)). PID is managed similarly, except that antimicrobial coverage against anaerobes is often included. In addition, treatment is often begun via an intravenous route. Erythromycin is the drug of choice for pregnant women with *C trachomatis* infection; amoxicillin has also been successful in this setting. Single-dose azithromycin is another alternative during pregnancy. Tetracyclines and fluoroquinolones are contraindicated in pregnant women.

**C. Lymphogranuloma Venereum.** LGV is treated with doxycycline ([Box 67-3](#)).

Alternative drugs include macrolides such as erythromycin. The activity of azithromycin against *C trachomatis* suggests that it may be effective in treating LGV given in multiple doses over 2-3 weeks, but clinical data regarding its use for this disease are lacking.

Patients with suspected or proven *C trachomatis* infection should be instructed to refer their sex partners (sexual contacts during the 60 days preceding onset of symptoms or diagnosis of chlamydial infection) for diagnostic testing, treatment, or both. However, the last sexual contact should be treated even if the time of the last sexual contact was > 60 days before onset of symptoms or diagnosis. Patients and their sex partners should abstain from sexual activity until treatment courses are completed.

Unless symptoms persist or reinfection is suspected, patients treated with doxycycline or azithromycin do not need to be retested for chlamydial infection because these drugs are highly effective. A test of cure may be considered 3 weeks after completion of a course of erythromycin.

**D. Perinatal Infection.** Erythromycin is the drug of choice for infants with *C trachomatis* ocular infection, as well as with *C trachomatis* pneumonia ([Box 67-4](#)). Mothers of infants with chlamydial infection and the sex partners of these women should be assessed and treated for *C trachomatis* infection. Newborns of mothers who have untreated chlamydial infections should be monitored closely for symptoms of conjunctivitis or pneumonia. Prophylactic antibiotics are not indicated in this setting.

**E. Infections in Young Children.** Chlamydial infections in preadolescent children should raise the possibility of sexual abuse. Because of the potential for a criminal investigation, the diagnosis of *C trachomatis* in this situation requires isolation in cell culture.

In children who weigh < 45 kg, erythromycin is the drug of choice. In children who weigh = 45 kg but who are < 8 years of age, azithromycin is the drug of choice. In children, = 8 years of age, doxycycline can be used as an alternative to azithromycin. (See [Box 67-2](#).)

**F. Eye Infections.** Patients with trachoma conjunctivitis respond well to a tetracycline, azithromycin, or erythromycin ([Box 67-4](#)). Public health programs for management of endemic trachoma consist of mass application of tetracycline or erythromycin ophthalmic ointment to all children in affected communities for 21-60 days or on an intermittent basis. Surgical correction of eyelids is also undertaken.

Adult inclusion conjunctivitis is usually treated with an oral tetracycline or erythromycin. All sexual contacts should be evaluated, treated for *C trachomatis* infection, or both.

## Prevention

Programs aimed at the detection of asymptomatic chlamydial infection and treatment of both symptomatic and asymptomatic cases have proven to be effective in decreasing the prevalence of *Chlamydia* infections in the United States. In addition, behavioral

interventions designed for primary prevention of STDs are of paramount importance. A sexual history should be obtained from all patients who are sexually active as a first step in identifying patients at risk and in delivering prevention messages. A professional, compassionate, and nonjudgmental attitude is essential. The most effective strategy for prevention of STDs is avoidance of infected sex partners; however, this is difficult given the prevalence of asymptomatic infection. Information should be provided regarding abstinence especially to those who are being treated for an STD or whose partners are undergoing treatment. The direct relationship between the number of sex partners and the likelihood of STDs must be discussed. A vaccine against chlamydial disease has not yet been developed. Institution of basic hygienic practices such as hand washing is beneficial in reducing the prevalence of trachoma. In addition, mass treatment with azithromycin appears to result in markedly decreased levels of disease.

## ***C PSITTACI* INFECTIONS**

### **Essentials of Diagnosis**

- History of contact with birds.
- Positive *C psittaci*-specific microimmunofluorescence serologies.
- Positive complement fixation titers (not species specific).

### **Clinical Findings**

**A. Signs and Symptoms.** Pneumonia, pericarditis, myocarditis, and endocarditis have been attributed to *C psittaci* infection (psittacosis or ornithosis) ([Box 67-5](#)). The incubation period for the pneumonia is usually 1-2 weeks. Its onset is gradual with body temperature increasing over a period of 5-7 days; however, there are cases in which the onset is sudden with rigors and temperatures as high as 104 °F. Headache is a salient and important symptom; it can be severe and incapacitating. Cough is usually nonproductive and hacking; however, on occasion a mucoid sputum or hemoptysis may develop. Epistaxis, photophobia, myalgias, and back and neck muscle stiffness are also common accompanying symptoms. Pleurisy, friction rub, and pleural effusion are rare, as are mental status changes, which can eventually progress to coma. Other unusual manifestations include gastrointestinal symptoms, such as abdominal pain, nausea, vomiting, or diarrhea.

On physical exam, the pulse rate may be slow relative to the degree of fever (pulse-temperature dissociation). However, this relative bradycardia may be influenced by the physical conditioning and resting heart rate of the individual. Lung auscultation may be entirely normal even in patients who are severely ill or have extensive radiological changes. Splenomegaly has been described in = 70% of patients with *C psittaci* pneumonia. Abdominal distension, constipation, or pulmonary infarction can occur as late complications.

**B. Laboratory Findings.** The peripheral leukocyte count and erythrocyte sedimentation rate are usually normal or can be only slightly elevated.

**C. Imaging.** Chest radiographic changes are protean and nonspecific. Radiological abnormalities include infiltrates, which can be patchy, diffuse, lobar, atelectatic, wedge shaped, nodular, or miliary.

## Diagnosis

The diagnosis of psittacosis can be confirmed by isolation of *C psittaci* or by serological tests. However, owing to its fastidious growth requirements and the associated hazards of its growth to laboratory personnel, most clinical laboratories do not attempt cultivation of this organism. Serological testing is best performed using acute and convalescent serum samples.

## Treatment

Patients with *C psittaci* infection should be treated with a tetracycline ([Box 67-6](#)). Patients usually respond with amelioration of their symptoms within 24-48 h after institution of therapy. In patients allergic to or intolerant of tetracyclines, erythromycin can be used as an alternative.

The recommended treatment of psittacosis in children = 8 years of age is 500 mg of tetracycline every 6 h, orally, for 7-10 days. Erythromycin also can be used (50 mg/kg/d up to 2 g/d for 7-10 days). Tetracycline may be more effective than erythromycin.

## Prevention

Imported birds should be quarantined and treated with a tetracycline for 30 days. An additional course of tetracycline for 15 days should be given by the importers or owners. Some birds will still shed the organism if treatment courses of < 45 days are used.

## **C PNEUMONIAE INFECTIONS**

### Essentials of Diagnosis

- Hoarseness may accompany atypical pneumonia.
- Positive *C pneumoniae*-specific microimmunofluorescence serologies.
- Positive complement fixation titers (not species specific).
- Isolation and PCR techniques available in research laboratories only.

### Clinical Findings

Upper- and lower-respiratory-tract infections including sinusitis, pharyngitis, bronchitis, and pneumonia have been associated with *C pneumoniae* infection ([Box 67-7](#)). Bronchitis and pneumonia are the most common syndromes seen in clinical practice. The incubation period for *C pneumoniae* pneumonia has been estimated at ~ 21 days. Patients usually present with a history of fever and prominent upper respiratory symptoms followed by sore throat and nonproductive cough. Physical exam can be

entirely normal or can reveal mild to moderate respiratory distress, usually with minimal auscultatory changes. The leukocyte count is usually normal or slightly elevated. Chest radiography may reveal minimal segmental infiltrates. Despite this more common picture, *C pneumoniae* pneumonia can be life threatening in patients older than 65 years. More recent serologic and anatomic data suggest that chronic *C pneumoniae* infections may play a role in atherosclerosis and in the progression of coronary artery disease. The clinical relevance of this information is not clear at this time.

## Diagnosis

Serological methods are commonly used for the diagnosis of *C pneumoniae* infections. They are rarely helpful in the acute setting, and they are mostly used for surveillance purposes. Complement fixation methods do not differentiate among infections caused by *C trachomatis*, *C psittaci*, and *C pneumoniae*. Microimmunofluorescence methods detect *C pneumoniae*-specific antibodies and are the approaches most commonly used in clinical practice. Acute and convalescent sera samples obtained = 3-4 weeks apart should be analyzed in parallel. Isolation of this organism and PCR-based methods are not routinely performed outside research laboratories.

## Treatment

*C pneumoniae* infection should be treated with a tetracycline, a macrolide, or a fluoroquinolone ([Box 67-8](#)).

The recommended treatment regimens for *C pneumoniae* infections in children include erythromycin (50 mg/kg/d for 10-14 days) or clarithromycin (15 mg/kg/d for 10 days). Some patients may require retreatment.

## 68 . *Coxiella, Ehrlichia, & Rickettsia* — Jeffery Loutit, MB, ChB

### INTRODUCTION

*Coxiella, Ehrlichia,* and *Rickettsia* spp. are small, obligate intracellular bacteria that usually cause disease when they accidentally encounter a human host. Once inside a host cell, *Coxiella* and *Ehrlichia* spp. remain within a vacuole where they progress through distinct developmental stages; in contrast, the *Rickettsia* spp. escape the endocytic vacuole and replicate within the host cell cytoplasm. *Ehrlichia* and *Rickettsia* spp. are transmitted by arthropod vectors.

### **COXIELLA BURNETII INFECTION (Q FEVER)**

#### Essentials of Diagnosis

##### Acute Infection

- Key symptoms and signs: fever, severe headache, myalgias, arthralgias, retrobulbar pain, cough; possible pneumonitis and hepatitis on examination.
- Predisposing factors: occupation as a dairy farmer, abattoir worker, or veterinarian; exposure to parturient or newborn animals, particularly cattle, sheep, and goats.
- Commonest environment for infection: a rural setting, but urban cases of Q fever also reported.
- Commonest infections: acute febrile illness, pneumonitis, and hepatitis.
- Key laboratory feature: positive antibodies to the phase-II antigens.

##### Chronic Infection

- Key symptoms and signs: fever and heart murmur.
- Predisposing factors: same as those for acute disease, plus prosthetic or abnormal heart valves.
- Commonest features: fever and endocarditis; echocardiogram rarely positive.
- Key laboratory features: levels of antibodies to phase-I antigens in excess of phase-II antigens.

#### General Considerations

*Coxiella burnetii* is the causative agent of Query or Q fever. This disease name originated with the description of a 1935 outbreak of a febrile illness of unknown etiology

in nine abattoir workers in Brisbane, Australia. The disease agent, based on its morphology and obligate intracellular lifestyle, was originally classified as a member of the family *Rickettsiaceae*. However, molecular analysis and in particular ribosomal-DNA sequencing have revealed the relationships between *C burnetii* and the *Legionella* spp. within the gamma subdivision of the *Proteobacteria*, and its more distant relationships to the rickettsia and the alpha subdivision of *Proteobacteria*.

**A. Epidemiology.** Cattle, sheep, and goats are the primary reservoirs for *C burnetii*, although the organism is found in a wide variety of domesticated animals. Inhalation of aerosolized organisms and ingestion of unpasteurized milk or cheese are common mechanisms of transmission to humans. Infection of domestic livestock usually occurs via the aerosol route and fails to cause clinically apparent or significant disease. Persistence of *C burnetii* in a latent phase in a host may be followed years later by reactivation and disease, especially during the late stages of pregnancy, because the organism exhibits tropism for the placenta. Many cases of human Q fever occur as a result of close association with animals at the time of parturition or soon thereafter, particularly sheep, cattle, cats, rabbits, and dogs. Ticks can also serve as transmission vehicles for *C burnetii*, but this mechanism is primarily involved in transmission of the organism to animals rather than humans.

Humans at risk for disease include dairy farmers and slaughterhouse and laboratory workers. Q fever is endemic throughout the world, except in New Zealand, but it is particularly common in the Middle East and Mediterranean regions. Although seemingly uncommon in the United States, Q fever is believed to be grossly underdiagnosed owing to its protean manifestations and to low clinical suspicion of Q fever as a probable disease; 70% of cases are reported from California and the western mountain states. Urban transmission has been described and is thought to result from close association with parturient animals.

**B. Microbiology.** *C burnetii* is a short, pleomorphic gram-negative rod and an obligate intracellular pathogen.

**C. Pathogenesis.** *C burnetii* enters cells, allows the endocytic vacuole to fuse with lysosomes, multiplies within the acidic environment of the resulting phagolysosome, and ultimately destroys the host cell ([Figure 68-1](#)). Although the exact mechanisms by which *C burnetii* survives within the phagolysosome are unclear, it does require an acid environment at that point in its life cycle; in fact, pharmacologic strategies to block acidification of intracellular vacuoles, for example using chloroquine, are therapeutic (see Treatment section below). *C burnetii* also has the ability to form sporelike structures, enabling it to survive diverse environmental conditions. The organism exists in either of two antigenic phases (I or II), owing to variation in the expression of different membrane lipopolysaccharides and proteins. Fresh isolates exhibiting phase-I antigens are highly infectious. Conversion to phase II occurs after serial passage in the laboratory, although reversion to phase-I antigen occurs with passage through laboratory animals. The immune response to these phase-associated antigens is useful in the diagnosis of *C burnetii* infections. Antibodies to phase-II antigen are found in the blood of patients with acute disease, whereas antibodies to phase-I antigen are more often detected in patients with chronic disease, such as endocarditis. The virulence-associated mechanisms of this organism are poorly understood.

Tissues affected by Q fever reveal vascular injury and granulomatous inflammation along with hemorrhage and necrosis. Q fever is one of many causes of granulomatous hepatitis.

## Clinical Findings

**A. Acute infection.** Seroepidemiologic studies indicate that ~ 50% of "cases" of Q fever in humans are asymptomatic. Symptomatic cases usually present with an acute febrile illness. Disease manifestations include a flulike illness, isolated fever, pneumonitis, hepatitis, exanthema with fever, pericarditis, myocarditis, and meningoencephalitis ([Box 68-1](#)). Most important in the diagnosis of acute Q fever is a history of contact with a newborn or parturient animal, which is found in two-thirds of all cases. There is marked geographic variation with respect to the clinical features of disease presentation; eg, hepatitis is seen more commonly in France than in Nova Scotia, and pneumonitis is more common in Nova Scotia than in France. The route of transmission does not seem to be a major factor in determining disease presentation.

The incubation period of Q fever ranges from 4 to 39 days, with an average of 14 days. Patients frequently present with an acute onset of fever  $>38.5^{\circ}\text{C}$ , rigors, and a severe headache. Other symptoms may include retrobulbar pain, malaise, myalgias, arthralgias, neck stiffness, nausea, vomiting, cough, pleuritic chest pain, diarrhea, and jaundice. Hepatosplenomegaly may be found on examination, and a maculopapular rash is present in 20% of cases. Hepatic involvement may range from mild subclinical elevations of hepatic transaminase levels to marked enzyme and bilirubin elevations accompanied by typical clinical features of hepatitis. A patchy interstitial infiltrate, as seen with other causes of "atypical" pneumonia such as *Mycoplasma pneumoniae*, is often found on chest radiograph. The leukocyte count is usually normal, but thrombocytopenia may be seen on 25% of cases. The illness is usually self-limited and lasts 2-4 weeks.

**B. Chronic Infection.** Approximately 2% to 11% of patients with Q fever progress to a chronic infection, of which endocarditis accounts for 60-70% of cases. Q fever endocarditis develops almost exclusively in patients with previous valvular heart disease, in transplant recipients, and in patients with underlying immunosuppression. Aortic and prosthetic valves are most commonly involved. Vegetation is rarely seen on echocardiogram, and routine blood cultures are negative. A clue to the diagnosis of Q fever endocarditis is the finding of a systemic inflammatory syndrome or unexplained accelerated valve failure in a patient with a history of valvular heart disease. Manifestations of this disease may include hepatosplenomegaly, a purpuric rash, renal insufficiency, and embolic phenomena. Laboratory findings include leukocytosis (25% of patients), leukopenia (15%), increased hepatic transaminase levels (40-60%), thrombocytopenia (25-50%), anemia (40%), increased creatinine levels (65%), antinuclear antibodies (35%), and rheumatoid factor (60%). Another common presentation of chronic Q fever is fever of unknown origin. Bone and joint involvement due to Q fever are uncommon, but they have been reported in both children and adults. Chronic hepatitis is another uncommon manifestation of Q fever.

## Diagnosis

The diagnosis of Q fever is based on an appropriate clinical history, along with a clear or possible history of animal exposure. The bacteria can be cultured from the blood, urine, and sputum by inoculation into chicken embryos or cultured human fibroblasts, but this procedure requires a specialized laboratory. In addition, the risk of transmission to laboratory workers is high; therefore, it should only be attempted in laboratories with considerable experience in handling this organism. The routine approach for the diagnosis of Q fever is a serological one, with detection of antibody to phase-I and -II antigens. Complement fixation, indirect fluorescent antibody (IFA), and enzyme-linked immunosorbent assays are available. Acute Q fever is diagnosed by a fourfold or greater increase in levels of antibodies directed against the *C burnetii* phase-II antigens. Titers become positive by 8-14 days after onset of the illness and peak at 4-8 weeks using IFA testing or at 12-13 weeks using complement fixation testing. Chronic disease, eg, endocarditis, is diagnosed by detecting levels of antibodies to *C burnetii* phase-I antigens in excess of levels of antibodies directed against the phase-II antigens. A complement fixation antibody titer against the phase-I antigens of >1:200 is considered also diagnostic.

## Treatment

Acute Q fever is usually self-limited. However, antimicrobial agents are recommended to prevent the development of chronic infection and possibly to decrease the duration of symptoms ([Box 68-2](#)). Doxycycline is effective, provided that it is started early in the disease. Quinolones, because of their cerebrospinal fluid penetration, should be considered for the treatment of meningoencephalitis. Treatment of chronic Q fever has never been studied in a controlled setting. Recommended regimens include rifampicin or ciprofloxacin plus doxycycline ([Box 68-3](#)). The duration of therapy necessary for a cure is also unknown, but =12 months is required, and some experts recommend a minimum of 3 years. In many cases, lifelong treatment may be necessary. Current studies are assessing the use of hydroxychloroquine in conjunction with doxycycline and/or ciprofloxacin, since blockade of intracellular acidification with the former improves the bactericidal activity of the latter for *C burnetii* in vitro.

## Prevention & Control

There is no currently available vaccine for the prevention of Q fever. Procedures should be in place to protect laboratory workers from being exposed to the organism and patients with the disease should be placed in standard-precaution isolation.

## **EHRlichia Infection (Ehrlichiosis)**

### Essentials of Diagnosis

- Key symptoms and signs: abrupt onset of high fever, headache, myalgias, chills 8-9 days after tick bite; rash (36% of human monocytic ehrlichiosis [HME] patients; only 2% of human granulocytic ehrlichiosis [HGE] patients); central nervous system involvement (20-25% of patients).
- Predisposing factors: tick and rural exposure (April through September).

- Presentation: most present as flu-like illness.
- Key laboratory features: thrombocytopenia, leukopenia, and elevated liver transaminases.
- Diagnosis: confirmed by a fourfold or greater rise in titers with an IFA.

## General Considerations

Human ehrlichiosis was first recognized in the United States in 1986 as a life threatening tick-borne illness similar to Rocky Mountain spotted fever (RMSF), but with a much lower incidence of rash.

**A. Epidemiology.** Ehrlichiosis is not a reportable disease, so its true incidence is unknown. The majority of cases of HME have been reported from the south, central, and southeastern United States. Cases have also been reported from Western Europe, Scandinavia, and Africa. In contrast, most cases of HGE have been reported from the upper midwestern and northeastern United States. This difference in disease geography reflects the distinct habitats of the respective tick vectors. *Amblyoma americanum* transmits HME and is found throughout the southeastern and south central United States. The white-tailed deer serves as a reservoir for the etiologic agent, *E chaffeensis*. The *Ixodes* species are the tick vectors of HGE (as well as Lyme disease and babesiosis), and they are found in the Northeast, upper Midwest, and Pacific Coast regions of the United States. The white-tailed deer is the primary host for adult *Ixodes* ticks, but small rodents—especially the white-footed mouse—play an important role in the deer-tick-rodent cycle and transmission of the agent of HGE to humans. Of infected humans, 80-100% report tick exposure within the 10 days preceding the onset of illness.

The median age of patients reported with HME is 44 years; 75% are male. The median age of HGE cases is 60 years, with a similar sex ratio. Cases of HME occur from April through December, but HGE cases are seen throughout the year, owing to the seasonal feeding patterns of the different tick vectors in different regions of the United States.

**B. Microbiology.** There are two forms of human ehrlichiosis in North America, HME and HGE; their clinical features are indistinguishable. The causative agent of HME, *Ehrlichia chaffeensis*, was the first member of this genus to be detected in humans in the United States; HGE was first recognized in 1994, and it is caused by an organism closely related to *Ehrlichia equi* and *Ehrlichia phagocytophila*. *Ehrlichia sennetsu* is the only other known pathogen for humans in this genus, but it has been reported only in Western Japan. Canine ehrlichiosis is caused by *Ehrlichia canis* and *Ehrlichia ewingii*, which infect macrophages and granulocytes, respectively. *E phagocytophila* is a pathogen of ruminants in Europe and exhibits tropism for neutrophils. *E equi* causes both equine and canine disease.

**C. Pathogenesis.** *Ehrlichia* species are small, obligate intracellular organisms whose life cycle includes the formation of intraleukocytic inclusions, termed morulae. Replication and development of organisms within morulae lead to rupture and release of elementary bodies into the circulatory system and subsequent infection of other

leukocytes. Recent data indicate that the granulocytic *Ehrlichia* species may enhance their survival within neutrophils by down-regulating expression of one component of the host NADPH oxidase enzyme complex, a critical feature of the oxidative burst machinery.

## Clinical Findings

**A. Signs and Symptoms.** The symptoms and signs of human ehrlichiosis are nondescript, thereby making the diagnosis difficult. The median incubation period is 8-9 days after tick bite, with a range of 0-34 days. The clinical presentation characteristically includes an abrupt onset of high fever (>39°C), headache, myalgias, and shaking chills ([Box 68-4](#)). Other symptoms include malaise, confusion, rigors, sweats, nausea, vomiting, and abdominal pain. Rash is reported in 36% of patients with HME but only 2% of those with HGE.

**B. Laboratory Findings.** The laboratory findings of human ehrlichiosis are relatively consistent and include thrombocytopenia in 72-92% of patients, elevated liver transaminase levels in the serum in 85-90% of patients, and leukopenia in 50-75% of patients. These laboratory findings are most pronounced at the end of the first week of illness. Morulae are rarely seen on acute-phase peripheral blood smears of patients with HME but are seen more commonly in the peripheral blood smears of patients with HGE. Detection of morulae in peripheral blood smears remains an insensitive and time-consuming task, and, when found, morulae have been reported most often by clinical hematology laboratory technicians ([Figure 68-2](#)).

**C. Differential Diagnosis.** Diseases in the differential diagnosis include ehrlichiosis (see Diagnosis section), typhus, Q fever, tularemia, early Lyme disease, viral hepatitis, leptospirosis, influenza, and Colorado tick fever. Coinfection with other tick-borne agents must always be considered.

**D. Complications.** Central nervous system involvement is reported in 20-25% of patients, with symptoms ranging from confusion through coma. Other severe complications may occur, such as disseminated intravascular coagulation, respiratory failure, renal insufficiency, and opportunistic infections secondary to neutropenia. Most elderly patients with HME who have been reported have also been hospitalized. Case fatality rates are 2-5% for HME and 7-10% for HGE. However, it is also now clear from seroprevalence studies that many patients have mild or asymptomatic infection.

## Diagnosis

It is necessary and important to consider the diagnosis of ehrlichiosis based only on epidemiological and clinical features, to facilitate administration of empiric therapy, because there is no widely available rapid diagnostic test other than detection of visible morulae. Ehrlichiosis should be considered in any febrile patient in an endemic region with exposure to ticks within the preceding 3 weeks. The diagnosis becomes more likely if thrombocytopenia, elevated hepatic transaminases, or leukopenia is present. There are no absolute clinical criteria that distinguish ehrlichiosis from RMSF, although patients with ehrlichiosis are less likely to have a rash and more likely to have leukopenia and elevated hepatic transaminases. In addition to finding intraleukocytic

morulae, serology offers a reliable but retrospective method for diagnosing *Ehrlichia* infection. Acute and convalescent titers are required. IFA detection assays are available for both HME and HGE. Although *E chaffeensis* and the agent of HGE can be cultured, this method of detection and PCR-based assays are not widely available.

## **Treatment**

Doxycycline is the agent of choice for both HGE and HME ([Box 68-5](#)). The clinical response is rapid, usually within 24-48 h. Chloramphenicol has been used in younger children to prevent teeth discoloration secondary to tetracyclines; however, in vitro and in vivo failures have been described. Enhanced mortality and morbidity from ehrlichiosis are associated with delayed administration of appropriate therapy, advanced age, and a higher percentage of infected leukocytes. Although most patients respond to therapy within several days, most experts advocate a 14-day course of therapy, in part to treat more adequately for possible concomitant *Borrelia burgdorferi* infection.

## **Prevention & Control**

Preventive measures against tick exposure should be used to prevent transmission of ehrlichiosis. If tick exposure occurs, thorough whole-body examination for and prompt removal of attached ticks are important for prevention of transmission.

# **RICKETTSIAL INFECTIONS**

## **INTRODUCTION**

The *Rickettsia* species are small, pleomorphic coccobacilli and obligate intracellular pathogens that depend on the host as a source of energy. Humans are only accidental hosts for these organisms and are usually infected by means of an arthropod vector. *Rickettsia* multiply at the bite site, invade the bloodstream, and establish infection by infecting endothelial cells throughout the microvasculature. Subsequent vascular lesions caused by damage to endothelial cells accounts for the pathologic changes that occur throughout the body. This damage is most marked in RMSF.

## **ROCKY MOUNTAIN SPOTTED FEVER**

### **Essentials of Diagnosis**

- Key symptoms and signs: abrupt onset of high fevers, headaches, myalgias, malaise, and a flu-like illness 3-12 days after tick bite; rash (80-90% of patients, initially maculopapular, then petechial, classically involving the palms and soles).
- Predisposing factors: tick exposure (April through September), pet owners, animal handlers, and outdoor activities.
- Commonest geographic location of infection: rural.
- Confirmatory serology via IFA.

- PCR with blood or skin biopsy: sensitive and specific but not widely available.

## General Considerations

RMSF is caused by *Rickettsia rickettsii* and is an acute tick-borne illness occurring during seasonal tick activity. The disease is characterized by acute onset of fever, headache, and a rash of the extremities spreading to the trunk.

**A. Epidemiology.** Transmission of *R. rickettsii* to humans by the *Dermacentor* tick occurs only if there is prolonged contact of at least several hours between the tick and the human host. RMSF is found only in the Western Hemisphere, with ~600 reported cases per year in the United States. Of those cases, ~50% occur in the mid-Atlantic states, but all states except Hawaii and Vermont have reported cases. Most (90%) of cases occur from April through September. Children in the 5- to 9-year age group have the highest incidence of infection. Another peak of disease incidence is observed among males >60 years of age.

## Clinical Findings

**A. Signs and Symptoms.** Only 3% of cases present with the classic triad of fever, rash, and history of a tick bite. The incubation period is 3-12 days (average 7 days), which is then followed by abrupt onset of high fevers, headaches, malaise, and myalgias, followed by 1 to 2 days of a nonspecific flulike illness ([Box 68-6](#)). Early in the course of illness, chills, rigors, neck stiffness, anorexia, nausea, vomiting, and abdominal pain occur frequently. Conjunctival suffusion, photophobia, cough, and neurologic symptoms may also be present. In severe cases, mental confusion and obtundation may develop. Only 14% of patients with RMSF will have a rash on day 1, but, by day 3, 49% will have the characteristic rash. In 20% of cases, the rash occurs only after day 6, while 9-16% of patients will never develop a rash even though their illness is equally severe.

The initial rash of RMSF is erythematous and macular, involving the ankles and wrists. It then spreads to involve the palms, soles, trunk, and face. The rash becomes papular as local edema and perivascular inflammatory cell infiltrates accrue ([Figure 68-3](#)). The lesions are petechial in 41-59% of patients after day 6 of the illness if antibiotics are not administered early. The centripetal progression and the involvement of the palms and soles are the important diagnostic features. However, it is important to realize that, at day 3, at which time most people will present for care, the features considered most critical for rendering a diagnosis of RMSF are absent.

Gastrointestinal manifestations such as nausea, vomiting, diarrhea, and abdominal pain occur in 39-63% of patients. Liver involvement is frequently manifested by mild to moderate elevations of hepatic enzymes. Pulmonary findings in RMSF are the most worrisome. The pathology of lung biopsy specimens from infected patients is characterized by widespread endothelial damage. Neurological involvement is the most significant cause of morbidity and mortality in RMSF. Clinically evident encephalitis is seen in =28% of cases. Symptoms vary from confusion, lethargy, stupor, delirium, and ataxia to coma and convulsions. Of all patients, 30% will have lymphohistiocytic meningitis. The course of untreated RMSF is marked by slowly advancing severity of

illness, with high temperatures plus hemorrhagic and neurologic signs.

**B. Laboratory Findings.** The leukocyte count is usually slightly decreased or normal, but an elevated band count of >10% is seen in 69% of patients. Thrombocytopenia occurs in 52% of patients, and 32% will have platelet counts of <100,000/ml<sup>3</sup>. Other abnormalities include hyponatremia and elevated serum aminotransferase and bilirubin levels.

**C. Imaging.** Pneumonitis and capillary endothelial injury can result in life-threatening noncardiac pulmonary edema which may be seen on chest x-ray.

**D. Differential Diagnosis.** The differential diagnosis of RMSF includes influenza, enteroviral infection, typhoid fever, leptospirosis, infectious mononucleosis, viral hepatitis, and bacterial sepsis—especially meningococcemia, HME, and HGE.

**E. Complications.** Fulminant RMSF (>5 days from onset to death) is seen more commonly in black male patients with glucose-6-phosphate dehydrogenase deficiency and in the elderly. For those patients with RMSF who are hospitalized for >2 weeks, ~50% will have long-term neurologic complications.

## Diagnosis

Confirmatory serology is retrospective in nature; therefore, the physician must have a high index of suspicion based on clinical findings to start therapy. There are no diagnostic laboratory tests other than specific serologic and PCR-based tests. The leukocyte count is usually slightly decreased or normal, but an elevated band count of >10% is seen in 69% of patients. Thrombocytopenia occurs in 52% of patients, and 32% will have platelet counts of <100,000/ml<sup>3</sup>. Other abnormalities include hyponatremia and elevated serum aminotransferase and bilirubin levels. A PCR assay for RMSF using whole blood is now available through state health departments or the Centers for Disease Control and Prevention. None of the currently available serologic tests are useful for diagnosis in the acute phase of illness. The most sensitive and specific serologic assay is an IFA test. A diagnostic titer of >64 is usually detectable between 7 and 10 days after the onset of symptoms. The less sensitive latex agglutination test is more widely available and will demonstrate a rise in titer to >128, 7-9 days after the onset of symptoms. Immunohistologic examination by immunofluorescence or immunoenzyme staining for *R rickettsii* in skin biopsy specimens can demonstrate the presence of the organism as early as days 3-8 of the illness and has a reported sensitivity and specificity of 70% and 100%, respectively.

## Treatment

Doxycycline is the drug of choice for the treatment of RMSF, except in cases of pregnancy and drug allergy or in children <9 years of age ([Box 68-7](#)). Although chloramphenicol has been recommended in these groups, many experts feel that it is safe to give a short course of doxycycline for the treatment of a potentially life-threatening infection in children <9 years old. The likelihood of permanent tooth staining from a short course of doxycycline is very low. Although there are in vitro data

indicating that fluoroquinolones may be efficacious, these agents have not been widely used in the treatment of RMSF and cannot be recommended at this time. Treatment is continued for =2 days after defervescence to reduce the risk of relapse. If therapy is started early, most patients defervesce within 48 to 72 h. Severely ill patients treated late in the course of disease may take considerably longer to recover.

## **Prevention**

Avoidance of tick bites is the best method of prevention. Protective clothing, tick repellents, and careful total body inspection can reduce the risk of inoculation. Prompt removal of ticks with forceps by firm traction is the preferred method. It is essential not to crush the tick so as to prevent release of rickettsiae.

## **RICKETTSIALPOX**

### **Essentials of Diagnosis**

- Eschar at site of mite bite.
- Regional lymphadenopathy.
- Generalized erythematous papulovesicular eruption on the trunk, extremities, and mucous membranes 9-14 days after exposure.
- Systemic symptoms including chills, fever, myalgias, anorexia, and photophobia.
- Predisposing factors include urban dwelling in close proximity to house mice.
- Serology for *R rickettsii* will cross-react with antibodies to *Rickettsia akari*.

### **General Considerations**

Rickettsialpox has been reported infrequently in the United States. This disease is a mild, self-limited illness caused by *R akari* and is transmitted to humans by a house mite. Both the house mouse and house mite are reservoirs for the organism.

### **Clinical Findings**

A painless papule develops 7-14 days after the mite bite. The papule then becomes vesicular, dries, crusts over, and evolves into a black eschar. The onset of clinical illness, characterized by abrupt onset of high fever, sweats, headache, myalgias, and malaise, occurs 4-7 days after the appearance of the initial papule. The systemic symptoms are usually mild, but, if untreated, the patient will have daily temperature elevations up to 39-39.5°C for 7-10 days. A maculopapular rash appears at the onset of fever and quickly becomes vesicular. The vesicles are small and nonpruritic, and they may be numerous or few. Within a week, the vesicles crust over and disappear with no sequelae. The diagnosis is best established by the epidemiologic history, the presence of a primary eschar, and a serum IFA test. Therapy with doxycycline or chloramphenicol is effective (see Treatment section for Rocky Mountain spotted fever). Preventive steps

involve eliminating house mice and their mites.

## **OTHER SPOTTED FEVERS**

Other spotted fevers include Mediterranean spotted fever, South African tick bite fever, Siberian tick typhus, Queensland tick typhus, and Oriental spotted fever. All of these rickettsioses are associated with an eschar and regional adenopathy. A generalized maculopapular rash involving the palms and soles usually appears about 5 days into the illness. Fever lasts ~5 to 10 days if untreated. Diagnosis is based on epidemiology, clinical features including the presence of an eschar, and serology. Treatment with doxycycline is effective.

## **ENDEMIC (MURINE) TYPHUS**

The organism principally responsible for endemic or murine typhus is *Rickettsia typhi*. More recently, *Rickettsia felis* has been characterized as a cause of endemic typhus in southern California and Texas. Transmission of these organisms to humans occurs via the flea. Clinical features include fever, headache, myalgias, and a maculopapular rash. Infected rats and opossums are the reservoirs for *R typhi* and *R felis*. The disease is endemic in the Southeast and Gulf states of the United States, especially Texas, and in southern California. During feeding on humans, when normal hosts are not available, the fleas deposit feces containing rickettsias. Humans become infected when the organisms are rubbed into the bite wound.

The incubation period for endemic typhus is 6-14 days. Initial symptoms include headache, malaise, backache, and chills. Severe shaking chills, fever, and a more severe headache soon follow. Symptoms last for 10-14 days if untreated. The rash appears at about the fifth day and comprises pink macules starting on the extremities, which then spread to the trunk but do not involve the palms and soles. The rash may become maculopapular but is not hemorrhagic, and in fact it is not seen at all in 20-46% of cases. Pulmonary manifestations are common, particularly a nonproductive cough. Although many patients will have a severe headache, analysis of cerebrospinal fluid is usually normal. Complement-fixing antibodies are important in making the diagnosis. Treatment with tetracycline, doxycycline, or chloramphenicol usually resolves symptoms within 24-48 h. Prevention of endemic typhus involves reduction of the rodent reservoir and control of the flea vector.

## **EPIDEMIC (LOUSE-BORNE) TYPHUS**

The etiologic agent of epidemic typhus is *Rickettsia prowazekii*. Epidemic typhus is a severe acute disease characterized by high fever, intense headache, a macular skin rash, and diffuse vascular lesions. Although this organism was responsible for the deaths of millions of people during World Wars I and II, the disease is now most commonly reported from northeastern and central Africa. A large proportion of the population is usually louse infested before epidemic typhus occurs. An infected louse deposits infected feces at the feeding site. Scratching then distributes the organism into the broken skin. Typhus is spread from human to human only via the body louse. In the eastern United States, cases of *R prowazekii* infection have been reported in patients with no history of lice infestation. These patients all described contact with flying

squirrels or their nests.

Epidemic typhus is far more severe than endemic typhus. After 7 days of incubation, patients develop sudden onset of severe headache, prostration, and high fever. A rash, appearing on the fifth day, consists of pink macules and is most common in the axillae. It occurs in 50-90% of patients. The rash coalesces, becomes petechial, and spreads to the trunk but usually does not involve the palms or soles. Conjunctival involvement is common. The disease is similar to RMSF, but the character and evolution of the rash, as well as the epidemiologic setting, distinguish the two diseases. An IFA test is the most sensitive and practical approach for diagnosing epidemic typhus. Chloramphenicol and tetracycline are effective therapies; patients usually become afebrile within 48 h. Relapse is rare if treatment is started early. A single 100-mg dose of doxycycline has also resulted in successful resolution of symptoms. Prevention requires mass delousing of the population at risk with permethrin or lindane.

## SCRUB TYPHUS

*Orientia tsutsugamushi* causes scrub typhus; it is transmitted by the bite of an infected mite. The disease is found in Southeast Asia, India, and northeastern Australia. Symptoms and signs of disease consist of an eschar at the bite site, regional and then generalized adenopathy, high fever, and a macular rash on the trunk, which appears after 5 days. The rash becomes maculopapular as it spreads to the extremities. Serology is the most practical diagnostic approach. Chloramphenicol and doxycycline are the therapeutic agents of choice, with rapid resolution of symptoms after the onset of therapy. A recent report of doxycycline-resistant scrub typhus in northern Thailand was the first to describe drug resistance in a rickettsial organism.

## 69 . *Bartonella* — Phyllis C. Tien, SM, MD & Jeffery S. Loutit, MB ChB

### Essentials of Diagnosis

- Key signs and symptoms include dermal lesion (bacillary angiomatosis and chronic phase of *Bartonella bacilliformis* infection); papule at inoculation site followed by proximal lymphadenopathy (cat scratch disease); fever, bacteremia, acute hemolytic anemia (acute phase of *B bacilliformis* infection); persistent or relapsing fever (fever and bacteremia/endocarditis).
- Predisposing factors include louse exposure, low income, and homelessness (*Bartonella quintana*-associated bacillary angiomatosis, fever, and bacteremia/endocarditis); cat exposure (cat scratch disease and *Bartonella henselae*-associated bacillary angiomatosis, fever and bacteremia/endocarditis); sandfly exposure in endemic areas of South American Andes (*B bacilliformis* infection).
- History of HIV or immunocompromise (bacillary angiomatosis).
- Key laboratory findings include small, curved, pleomorphic weakly gram-negative bacilli, best visualized with Warthin-Starry silver stain of tissue.

### General Considerations

There are currently 11 known species of *Bartonella*, four of which are considered to be pathogenic in humans, namely *B bacilliformis*, *B quintana*, *B henselae*, and *Bartonella elizabethae*. *B henselae* and *B elizabethae* have only recently been isolated and identified, but *B quintana* and *B bacilliformis* have long been known as the causes of trench fever (*B quintana*) and Oroya fever and verruga peruana (*B bacilliformis*). The bartonellae establish intimate relationships with animal hosts, often within the vascular compartment but without causing disease.

The relationship between *B bacilliformis* and the other three *Bartonella* species that are pathogenic in humans was established in the early 1990s. This followed the recognition of a new clinical syndrome, bacillary angiomatosis in HIV-infected individuals, in 1983. *B henselae* was first identified with molecular methods as a cause of this syndrome in 1990, and both *B henselae* and *B quintana* were cultured from tissue samples of patients with bacillary angiomatosis in 1992. *B henselae* was also associated with cat scratch disease in 1992.

*B bacilliformis* is closely related to *B henselae*, *B quintana*, and *B elizabethae*, as indicated by 16S ribosomal RNA gene sequence analysis. Therefore, these last three organisms, formerly designated as *Rochalimaea* species, have been reclassified as members of the genus *Bartonella*.

The spectrum of human disease associated with the bartonellae includes regional and disseminated granulomatous disease in immunocompetent hosts (cat scratch disease), persistent bacteremia or endocarditis, and vascular proliferative disease (verruca

peruana or bacillary angiomatosis) in immunocompromised hosts ([Box 69-1](#)). *B henselae* and *B quintana* are the recognized causes of bacillary angiomatosis, while only *B henselae* has been implicated as a cause of cat scratch disease. Finally, these two species along with *B elizabethae* have all been identified in patients with endocarditis and bacteremia.

**A. Epidemiology.** *B quintana* is globally endemic. However, epidemics do occur. These epidemics are associated with conditions of poor sanitation and personal hygiene as seen in battlefield troops in World War I. Recent reports have shown a reemergence of trench fever among chronic alcoholics and the homeless in urban areas of the United States and western Europe. Urban trench fever is sporadic, both geographically and temporally, for unclear reasons. The human body louse, *Pediculus humanus*, is the only known vector of *B quintana*.

*B henselae* is also globally endemic. Cat contact appears to be the single most important factor in the development of cat scratch disease and *B henselae*-associated bacillary angiomatosis, which reflects the fact that cats are the most important reservoir for *B henselae*.

There are ~ 22,000 cases of cat scratch disease reported per year in the United States, making this the most common *Bartonella*-associated disease. Over 80% of cases occur in individuals < 21 years of age. The number of cases peaks in the fall and winter months. This seasonality may reflect differences in human behavior that place persons at risk of exposure to *Bartonella* species, or it may reflect breeding patterns of cats and fleas. Approximately 18% of household members with cats are seropositive for *B henselae* antibodies. Risk factors for the development of cat scratch disease include ownership of a kitten (especially one with fleas) and being scratched or bitten by a kitten.

Cats in the southeastern United States, coastal California, the Pacific Northwest, and the south central plains have the highest prevalence of *B henselae* antibodies (36-81%). These areas of high prevalence are regions of greater warmth and humidity and closely correlate with the distribution in the United States of the cat flea, *Ctenocephalides felis*. The lack of *B henselae* antibody in cats is highly predictive of the absence of bacteremia. Approximately 40% of cats are bacteremic with *B henselae*; kittens are more likely to be bacteremic than adult cats, as are cats that spend most of their time outdoors. *B henselae* has also been isolated from fleas of bacteremic cats. The cat flea has been shown to be a competent vector in the transmission of *B henselae* among cats. In the absence of the cat flea, direct cat-to-cat transmission among kittens has not been demonstrated. The role of the flea in transmission of *B henselae* to humans has not been elucidated.

Recently, an association between another *Bartonella* species, *Bartonella clarridgeiae*, and cat scratch disease was reported after isolation of this organism from the blood of a flea-infested kitten that induced cat scratch disease in a human. However, the role of *B clarridgeiae* as a cause of human infection is unclear.

Although > 90% of patients with cat scratch disease report recent cat contact, only two-thirds of patients with bacillary angiomatosis report recent cat exposure, suggesting

that there are other risk factors for developing bacillary angiomatosis. Both *B henselae* and *B quintana* are known causes of bacillary angiomatosis, and yet the risk factors and reservoirs for infection with these organisms are quite different. For *B quintana*-associated disease, risk factors include low income, homelessness, and exposure to lice. Risk factors for *B henselae*-associated bacillary angiomatosis are similar to those for cat scratch disease, including cat ownership and being scratched or bitten by a cat. *B henselae* has also been found in fleas from cats owned by patients with bacillary angiomatosis.

Despite the advent of serologic testing for *Bartonella* species, the incidence of bacillary angiomatosis remains unknown. Of all reported cases of bacillary angiomatosis, ~ 90% are men that are coinfecting with HIV. Cases have been reported from all areas of the United States, with greater numbers in New York City, San Francisco, and some parts of Florida and Texas. Bacillary angiomatosis is uncommon in immunocompetent individuals; conversely, it can occur in patients who are immunosuppressed from causes other than HIV. *Bartonella* bacteremia with fever occurs in both immunosuppressed and immunocompetent individuals. Because special, nonroutine techniques are required for its isolation, bacteremia with *Bartonella* spp. is likely to be underreported.

*B bacilliformis* is geographically confined to intermediate altitudes (between 1000 and 3000 m) of the South American Andes. This coincides with the limited distribution of its sandfly vector, *Lutzomyia vernicarum*.

**B. Microbiology.** *Bartonella* species are small, slightly curved gram-negative rods measuring 2µm by 0.6 µm. They are classified within the alpha subdivision of the division *Proteobacteria*, as are the *Rickettsia*, *Ehrlichia*, and *Brucella*. They are oxidase-negative, aerobic, and fastidious in their laboratory growth requirements. *B henselae* and, to a lesser extent, *B quintana*, display twitching motility when mounted in saline, due to the presence of pili. *B bacilliformis* has polar flagella.

*Bartonella* species can be cultivated when plated on freshly prepared, enriched (blood-containing) solid media and placed in a humidified atmosphere containing 5% CO<sub>2</sub>. Optimum temperature for growth is 35-37 °C, except for *B bacilliformis*, which grows best at 25-30 °C. Colonies are detected in 5-21 days. The colonies of *Bartonella* species from primary isolation are either white, raised, rough, and autoadherent or small, tan, moist appearing, and imbedded in the agar. Both types of colonies are usually seen in the same culture, but *B henselae* is usually more heterogeneous with a larger proportion of the rough morphology than *B quintana*, which has predominantly smooth colonies. *B henselae* and *B quintana* are difficult to distinguish because they are closely related at both the phenotypic and genotypic levels.

**C. Pathogenesis.** Pili are believed to be key factors in host cell attachment as well as important virulence factors for *B henselae* and *B quintana*. The pathologic features of cat scratch disease and bacillary angiomatosis are quite different. The hallmark of cat scratch disease is granuloma formation, with progression from lymphoid hyperplasia through granuloma formation to suppuration. Involved lymph nodes demonstrate a mixture of nonspecific inflammatory reactions including granulomata and stellate necrosis with lymphocytic infiltrates and multinucleated giant cells.

Bacillary angiomatosis is a result of lobular proliferation of blood vessels. Small capillaries are arranged around ectatic ones with edema, mucin, or fibrotic stroma surrounding the lobules. The endothelial cells that make up the vascular lobules occur either singly, in small groups, or in areas of solid proliferation. Endothelial cell necrosis may also be seen along with neutrophils and sometimes macrophages. In most cases, clusters of neutrophils and neutrophilic debris are seen adjacent to the capillaries scattered throughout the lesion. It is believed that *B henselae* and *B quintana* directly stimulate the vascular proliferation seen in the lesions of bacillary angiomatosis. Angioproliferative lesions, however, have not been reported in patients with other forms of *B henselae* and *B quintana* infection such as trench fever and cat scratch disease.

The flagella of *B bacilliformis* allow invasion of human erythrocytes, and the resulting cell lysis leads to the severe hemolytic anemia seen in the early stages of South American bartonellosis (Oroya fever). The nodular skin lesions that develop in the late stages of this disease reveal a characteristic vascular proliferation of endothelial cells that resembles bacillary angiomatosis.

## CLINICAL SYNDROMES

### BACILLARY ANGIOMATOSIS

**A. Signs and Symptoms.** The most common manifestation of bacillary angiomatosis is a dermal lesion ([Table 69-1](#)). Three types of lesions are seen: cutaneous papules, subcutaneous nodules, and hyperpigmented plaques, in decreasing order of frequency. Papules are usually red-purple in color and range in size from a few millimeters to several centimeters, often surrounded by a collarette of scale ([Figure 69-1](#)). They vary in number, are often friable and bleed easily, are occasionally tender, and may resolve spontaneously even in immunosuppressed patients. These lesions are easily removed by curettage. Slight hyperpigmentation and induration may persist.

Subcutaneous nodules or lobules are the second most common presentation and may vary markedly in size and number. Underlying cortical bone erosion may be associated with these nodules. There is often minimal epidermal change or hyperpigmentation, but, infrequently, the overlying skin changes may resemble cellulitis. While cutaneous disease is associated with both *Bartonella* species, subcutaneous and bony disease is associated almost exclusively with *B quintana*. Regional lymph node enlargement may be present; these nodules may be tender but rarely ulcerate or bleed.

Less common are indurated hyperpigmented plaques, which are often oval in shape and several centimeters in diameter. These hyperkeratotic plaques are typically found on the extremities.

Liver and spleen involvement by *Bartonella* spp. with or without cutaneous disease is frequently associated with *B henselae* in the immunocompromised host. The spectrum of liver and spleen pathology varies from a nonspecific necrotizing inflammatory reaction to bacillary peliosis. Bacillary peliosis is characterized by cystic blood-filled spaces throughout the tissue parenchyma. Since the advent of AIDS, peliosis, a previously rare entity associated with chronic debilitating illnesses (such as tuberculosis and

malignancy) and anabolic steroid use, has increased. Bacillary peliosis is fatal in rare cases.

Bacillary angiomatosis may also involve the mucous membranes of the mouth, nose, larynx, bronchi, conjunctiva, and anus; the lung and pleura; bone; and the central nervous system. Bacillary angiomatosis should strongly be considered in any HIV-infected patient with skin and lytic bone lesions.

**B. Laboratory Findings.** Patients with bacillary peliosis may have elevated serum alkaline phosphatase levels, as well as thrombocytopenia or pancytopenia.

**C. Imaging.** Computed tomographic scans of patients with bacillary peliosis often show multiple hypodense areas that are enhanced following the use of contrast agents, scattered throughout an enlarged liver, and ascites.

**D. Differential Diagnosis.** The differential diagnosis of a bacillary angiomatosis skin lesion includes Kaposi's sarcoma, pyogenic granuloma, simple hemangioma, angiokeratoma, and verruga peruana (in the appropriate geographic region). Lesions of bacillary angiomatosis and Kaposi's sarcoma cannot be distinguished by gross appearance.

## CAT SCRATCH DISEASE

### Clinical Findings

**A. Signs and Symptoms.** Cat scratch disease typically begins with an erythematous ("inoculation") papule 3-5 days after cat contact or scratch ([Table 69-1](#)). The papule may appear on the skin, conjunctiva, or other mucous membrane. Lymphadenopathy follows 1-7 weeks later in a proximal distribution with the lymph nodes of the axilla, cervical, and submandibular areas most commonly involved. The lymph node is often tender, markedly swollen, and may ultimately suppurate. In 75% of all cases, the illness is mild, with myalgias, malaise, anorexia, and, rarely, nausea and abdominal pain. Fever is present in about one-third of patients; temperatures above 39 °C occur in < 10%. Cat scratch disease is typically a benign and self-limited illness that lasts 6-12 weeks. Most cases of cat scratch disease occur in individuals with normal immune systems, but several cases have been described in immunocompromised patients.

**B. Differential Diagnosis.** The differential diagnosis of cat scratch disease includes many infections known to cause lymphadenopathy: atypical mycobacterial infection, tuberculosis, streptococcal and staphylococcal adenitis, toxoplasmosis, infectious mononucleosis, tularemia, histoplasmosis, and brucellosis.

**C. Complications.** In as many as 14% of patients, dissemination or other complications occur. Parinaud's oculoglandular syndrome is the result of conjunctival inoculation and is characterized by granulomatous conjunctivitis and preauricular adenopathy. It occurs in ~ 2% of all patients with cat scratch disease and usually resolves without sequelae. Hepatosplenic granulomata, lytic bone lesions, pneumonitis, and central nervous system involvement with encephalopathy and neuroretinitis can also occur. Symptoms of encephalopathy usually occur 1-6 weeks after the initial symptoms of cat scratch

disease. Patients may become acutely confused and disoriented, rapidly progressing to coma, but they usually recover completely within 4 weeks. Neuroretinitis may be associated with a decrease in visual acuity, but marked improvement has been noted both with and without antibiotic treatment.

## ***B BACILLIFORMIS*-ASSOCIATED DISEASE**

About 3 weeks after the bite of an infected sandfly, acute *B bacilliformis* infection becomes manifest as a febrile bacteremic illness (Oroya fever). It is accompanied by an acute hemolytic anemia that is caused by bacterial attachment and invasion of erythrocytes ([Table 69-1](#)). Patients exhibit malaise, fever, chills, diaphoresis, headache, and mental status changes. Lymphadenopathy, hepatosplenomegaly, and thrombocytopenia are also seen. At the end of the acute bacteremic phase, there is a transient immunosuppression that renders the patient susceptible to a wide range of opportunistic bacterial, viral, and parasitic secondary infections. Mortality during this acute phase is higher among persons without previous exposure to this agent. Overall, mortality is estimated to be ~ 8%.

After the acute phase of infection, 15% of patients develop a chronic form of disease manifested by painless superficial or subcutaneous nodules (verruca peruana). These nodules are histologically similar to those of bacillary angiomatosis.

## **FEVER & BACTEREMIA/TRENCH FEVER/ENDOCARDITIS**

### **Introduction**

The four *Bartonella* species that are pathogenic for humans are capable of causing sustained or relapsing bacteremia accompanied by only fever ([Table 69-1](#)). All except *B bacilliformis* also cause endocarditis. After *B quintana* enters the body through broken skin from the excreta of the infected human body louse (*Pediculus humanus*), there is an incubation period of between 5 and 20 days before the onset of trench fever. Patients complain of fever, myalgias, malaise, headache, bone pain—particularly of the legs, and a transient macular rash. Usually the illness continues for 4-6 weeks. Sustained or recurrent bacteremia is common, with or without symptoms.

The form of trench fever described in the United States and Europe in the 1990s (urban trench fever) has no distinguishing features other than fever, malaise, and weight loss. Endocarditis has been reported in conjunction with *B quintana* bacteremia.

In HIV-infected patients, *B henselae* bacteremia usually presents insidiously with malaise, fatigue, weight loss, and fevers. Endocarditis may occur in immunocompetent hosts with patients presenting with fever and malaise.

### **Diagnosis**

Difficulty in the identification and isolation of *Bartonella* species from blood and tissue has made a diagnosis of infection with these organisms a challenge. Direct examination of tissue (not blood) with special stains is required, and special conditions for cultivation from tissue and blood are necessary.

The detection of these small, curved gram-negative bacilli in pathology specimens is best made by using the Warthin-Starry silver stain, electron microscopy, immunofluorescence, or the polymerase chain reaction. Conventional stains such as acid-fast, Giemsa, periodic acid-Schiff, and the Brown-Brenn modification of Gram's stain fail to demonstrate the bacilli. The Warthin-Starry stain results are not pathognomonic since it also stains other bacteria, including spirochetes and species of *Nocardia*, *Legionella*, and *Campylobacter*. Polymerase chain reaction-based assays offer high sensitivity and specificity but are not widely available.

Isolation of *B henselae* and *B quintana* after homogenization of tissue such as liver, spleen, lymph node, and skin can be performed by direct plating or by cocultivation with an endothelial cell line. The cocultivation method, while useful in recovering organisms, may not be practical for most microbiology laboratories. Growth of strains on freshly prepared heart infusion agar containing 5% or 10% defibrinated rabbit or horse blood has been more successful than growth on other cell-free media such as chocolate or 5% sheep blood agar.

The lysis-centrifugation blood culture system is currently the best method to isolate *Bartonella* species from the blood. If bacteremia with a *Bartonella* species is suspected, the laboratory must be informed in order that lysis centrifugation-processed blood can be placed on the appropriate media and incubated for at least 7-14 days. Because of the fastidious nature of these organisms, the interval from collection to processing should be minimized. Other alternatives to the lysis centrifugation method include screening suspected blood culture bottle contents with an acridine orange staining procedure and subculturing positive bottles.

Differentiation of the *Bartonella* species can be accomplished with biochemical and molecular methods. Cellular fatty acid analysis by gas liquid chromatography can be helpful, but many laboratories do not have the necessary capabilities to perform this test. The Microscan rapid anaerobic panel has been used with some success to distinguish between *B henselae* and *B quintana*. Other methods have included polymerase chain reaction-restriction fragment length polymorphism analysis of the citrate synthase gene and 16S rDNA sequence analysis.

Serologic testing is easier and more rapid than cultivation of the organism and has become the mainstay for confirming the diagnosis of cat scratch disease. Both immunofluorescence assays and enzyme immunoassays are available to detect cerebrospinal fluid and serum immunoglobulin G (IgG) and IgM directed against *Bartonella* spp. A titer of > 1:64 or a fourfold rise in titer is considered positive. Because of the cross-reactivity of antibodies against *B quintana* and *B henselae*, definitive species identification is difficult with these methods.

## Treatment

Treatment of *Bartonella*-associated disease varies according to the clinical syndrome ([Box 69-2](#)). All recommendations are based on anecdotal evidence of treatment response since controlled trials have not been performed.

Bacillary angiomatosis should always be treated. Spontaneous resolution of superficial skin papules has been reported, but relapse and bacterial dissemination are common. Nevertheless, therapeutic endpoints remain undefined.

Anecdotal evidence strongly favors the use of oral erythromycin for treatment of bacillary angiomatosis at a dose of 500 mg four times per day for 8-12 weeks. Intravenous erythromycin should be administered to patients with severe disease or patients who are unable to take oral medications. Longer courses may be necessary in patients with bacteremia/endocarditis or bacillary peliosis and those with disease recurrence. The newer macrolides, azithromycin and clarithromycin, may also be effective, but experience with these drugs is more limited. Oral doxycycline (100 mg twice daily) has been consistently successful in the treatment of bacillary angiomatosis. Jarisch-Herxheimer-like reactions after the first several doses of doxycycline or erythromycin can occur, however. Use of an antipyretic before treatment may attenuate this response.

Limited data support the use of ciprofloxacin in the treatment of bacillary angiomatosis. Inhibitors of cell wall synthesis, such as the penicillins and cephalosporins, uniformly fail to cure the disease, despite the fact that in vitro testing indicates that both *B quintana* and *B henselae* are sensitive to these antibiotics. Susceptibility testing is not standardized for *B henselae* or *B quintana* and is difficult to perform. In vitro data should not be used to guide therapy at this time.

Cat scratch disease usually resolves spontaneously over a 2- to 8-week period. Aspiration of a suppurative node may provide symptomatic relief. Antibiotic therapy is not consistently successful, nor is it routinely indicated, unless the disease occurs in an immunocompromised host. Despite the success of macrolides and tetracyclines in the treatment of bacillary angiomatosis, they have not been used as widely in the treatment of cat scratch disease. A prospective, randomized, double-blind trial has suggested that azithromycin treatment for 5 days reduces lymph node size more rapidly than placebo. Rifampin, ciprofloxacin, trimethoprim-sulfamethoxazole, and gentamicin have been proposed as effective agents, based only on a retrospective review of the literature. Mild or moderate disease should receive only symptomatic therapy, since antimicrobial agents do not change the clinical outcome of cat scratch disease in the majority of cases.

Urban trench fever has been suppressed and sometimes cured with erythromycin or azithromycin given for at least 4 weeks; however, as with *B henselae* bacteremia, response to antimicrobial agents is variable, and some patients experience a relapse of symptoms after cessation of antibiotics. Some cases of endocarditis require valve replacement and most require prolonged antibiotic therapy.

The response of Oroya fever and verruga peruana to therapy is variable. Chloramphenicol has been recommended in endemic regions due to the possibility of intercurrent *Salmonella* infection and the high case fatality rate.

## **Prevention & Control**

Cat owners can, and immunocompromised individuals should, reduce their risk of cat

scratch disease or bacillary angiomatosis ([Box 69-3](#)). Cat owners who are immunocompromised should (1) wash hands after animal contact and keep all wounds and abrasions as clean as possible; (2) avoid cats < 1 year of age or avoid rough play with them since they are more prone to "carry" the organism; and (3) keep cats as free from fleas as possible. Declawing of cats is not recommended. Antibiotic treatment of infected cats is not useful.

*B quintana* infection may be prevented or controlled by delousing procedures. These include regular changing or washing of clothes and bedding. Insecticides such as permethrin should also be used to control louse infestation. Oroya fever and verruga peruana can be prevented by avoiding the bite of the sandfly vector. These insects tend to be nocturnal feeders.

## Section VI. Fungal Infections

### 70 . *Histoplasma capsulatum* — Zelalem Temesgen, MD

#### Essentials of Diagnosis

- Thin-walled oval yeast measuring 2-4  $\mu$ m in diameter.
- Dimorphic: mycelial in nature, yeast in tissue.
- Endemic within Ohio and Mississippi River Valleys.
- Associated with activities that disturb dust or soil enriched with bird, chicken, and bat excrement.
- Complement fixation antibody titer 1:32 or greater.
- Simultaneous appearance of anti-H and anti-M antibodies.
- Infection most often is asymptomatic or may cause chronic pulmonary infection; less commonly, disseminated infection involving the adrenals, ulcerative gastroenteritis lesions, or central nervous system.
- Recovery of organism from culture of tissue, blood, sputum, or other source.

#### General Considerations

**A. Epidemiology.** *Histoplasma capsulatum*, the etiologic agent of histoplasmosis, is an endemic, dimorphic fungus that causes a wide spectrum of disease in both immunocompetent and immunocompromised individuals. It is found in temperate zones around the world. In the United States, it is endemic within the Ohio and Mississippi River Valleys. Its natural habitat is soil, especially soil with high organic content such as soil enriched with bird, chicken, and bat excrement. Many types of both occupational and recreational activities (eg, cave exploring, excavation) have resulted in outbreaks of histoplasmosis.

**B. Microbiology.** *H capsulatum* is dimorphic; it grows as a mycelial form outside the human host but converts into its pathogenic yeast form at the body temperature of mammals. The yeast forms seen in tissue are small, thin-walled, oval structures measuring 2-4  $\mu$ m in diameter.

**C. Pathogenesis.** The vast majority of infections caused by *H capsulatum* are acquired by inhalation and deposition of mycelial fragments into the alveoli. The organism converts into its pathogenic yeast form and is phagocytosed by alveolar macrophages. The yeast forms multiply within the macrophages, eventually causing the destruction of these macrophages. The released yeasts spread to the regional lymph nodes and other

organs via the lymphatics and blood. Specific T cell-mediated immunity develops in 2-4 weeks and inhibits the growth of the organisms. Resolution occurs with production of a granulomatous inflammatory response and leads to the formation of granulomas, which may be caseating but usually become calcified. The yeasts persist for prolonged periods within caseating granulomas.

## CLINICAL SYNDROMES

### INTRODUCTION

A variety of clinical syndromes have been described in association with histoplasmosis ([Box 70-1](#)).

### PULMONARY INFECTIONS

#### 1. ACUTE PRIMARY HISTOPLASMOSIS

##### Clinical Findings

**A. Signs and Symptoms.** Among persons with normal cell-mediated immunity, only ~ 1% will develop a mild symptomatic but usually self-limited infection after a low-inoculum exposure to *H capsulatum*. Fever, malaise, nonproductive cough, chest pain, and fatigue are the most common symptoms.

**B. Imaging.** In symptomatic persons, chest roentgenograms show focal infiltrates, hilar or mediastinal lymphadenopathy, or a combination.

**C. Differential Diagnosis.** The differential diagnosis of pulmonary histoplasmosis includes tuberculosis, pneumonia caused by other fungi, and bacterial pneumonia.

**D. Complications.** Most patients recover fully without treatment but some may experience fatigue and weakness for months. Persons with defects in cell-mediated immunity or persons who have been exposed to a high inoculum of the organisms may develop severe symptomatic infection characterized by severe dyspnea and hypoxemia. Diffuse infiltrates or multiple poorly defined pulmonary nodules are noted on chest roentgenograms. Some may present with disseminated disease.

About 10% of patients develop acute pericarditis. Another 10% experience arthritis with erythema nodosum. These responses are thought to represent immunologic reactions and as such respond to anti-inflammatory therapy and do not usually require antifungal treatment.

#### 2. CHRONIC PULMONARY HISTOPLASMOSIS

##### Clinical Findings

**A. Signs and Symptoms.** Chronic pulmonary histoplasmosis consists of progressive focal consolidation and cavitation and is most often seen in those with preexisting lung

disease such as chronic obstructive pulmonary disease. The main symptoms are productive cough, malaise, fatigue, and weight loss. The lesions are localized in the apical or subapical regions of the lung. The early form of the disease usually presents as interstitial infiltrates but later undergoes necrosis, cavitation, and fibrosis that extend to involve adjacent areas of the lung.

**B. Laboratory Diagnosis.** Though anemia and leukocytosis may occasionally be present, routine laboratory studies are usually not helpful to suggest or establish diagnosis.

**C. Differential Diagnosis.** Differential diagnosis of chronic histoplasmosis includes tuberculosis and pneumonia caused by other endemic fungi.

**D. Complications.** Cavities may extend into adjacent lung tissue. This may undergo fibrosis and contribute to progressive restrictive and obstructive lung disease, which may in turn result in respiratory failure and death.

### 3. MEDIASTINAL GRANULOMATOSIS

**A. Signs and Symptoms.** After exposure to *H capsulatum*, the healing process in the lungs is characterized by a granulomatous inflammatory response resulting in the formation of caseated lymph nodes surrounded by fibrosis. Occasionally, these nodes coalesce to form a large lesion in the mediastinum and may attach to adjacent structures such as the bronchi, trachea, and esophagus. Fibrosis of the attached nodes can result in compression of these structures, causing various symptoms such as cough, dysphagia, odynophagia, formation of esophagopulmonary fistula, and development of post-obstructive pneumonia or bronchiectasis.

**B. Laboratory Findings.** Thoracoscopy or thoracotomy is required for definitive diagnosis. Necrotizing granulomata are usually found in histological specimens, but the microorganisms themselves may be difficult to stain or recover from cultures.

**C. Complications.** Approximately 40% of mediastinal granulomas are asymptomatic, but as many as a third of cases may progress to fibrosing mediastinitis within a 2-year period.

### 4. FIBROSING MEDIASTINITIS

In rare instances, the healing process may be complicated by a hyperintense fibrotic reaction culminating in a relentless progressive invasion of mediastinal structures including the esophagus and respiratory and vascular structures. Fibrosing mediastinitis due to histoplasmosis is the most common cause other than malignancy of the superior vena cava syndrome. The intense fibrotic reaction is thought to be caused by continuous antigenic stimulation by the yeast forms that persist within the granuloma.

### DISSEMINATED HISTOPLASMOSIS

**A. Signs and Symptoms.** Although occasionally seen in normal adults, disseminated histoplasmosis is mainly a disease of infants and adults with defective cell-mediated

immunity. It presents as a systemic febrile illness with malaise and weight loss as the main and consistent symptoms. Extrapulmonary involvement is common and may be manifested by hepatosplenomegaly, meningitis or focal central nervous system parenchymal lesions, oral and mucocutaneous lesions, adrenal insufficiency, and endocarditis.

**B. Laboratory Findings.** Anemia, leukopenia, thrombocytopenia, and elevation of serum alanine aminotransferase and alkaline phosphatase values are often noted on laboratory evaluation.

**C. Imaging.** The most common findings on chest roentgenograms are diffuse infiltrates, but as many as a third of affected individuals may have normal chest x-ray findings.

## HISTOPLASMOSIS IN AIDS

### Clinical Findings

**A. Signs and Symptoms.** Histoplasmosis has been recognized as an opportunistic infection in patients with AIDS since the early days of the HIV epidemic and has been an AIDS-defining illness since 1987. It occurs in ~ 5% of patients residing in areas known to be endemic for *H capsulatum*. Sporadic cases have also been reported in nonendemic areas, but many of these patients have resided for variable periods of time in or near endemic areas, and their disease likely represents reactivation of infection acquired elsewhere. In the vast majority of cases, infection with *H capsulatum* in AIDS patients presents as disseminated disease with fever, weight loss, and malaise.

**B. Laboratory Findings.** Associated laboratory abnormalities may include a decrease in peripheral blood counts (leukopenia, anemia, thrombocytopenia), hyponatremia, and elevated liver enzymes. Lymphadenopathy and hepatosplenomegaly may be present.

**C. Imaging.** Diffuse reticulonodular infiltrates are typically noted on chest roentgenograms. However, as many as one third of patients have normal findings on the initial chest roentgenograms.

**D. Complications.** Central nervous system involvement in the form of meningitis, focal brain lesion, or diffuse encephalitis may complicate the course in 10-20% of cases. In 10-20% of cases, histoplasmosis in AIDS patients presents as septic shock, with fever, disseminated intravascular coagulopathy, and multiorgan failure.

### Diagnosis

Histoplasmosis can be diagnosed on the basis of serologic testing, antigen detection, histopathological examination, or culture.

**A. Serology.** Serologic tests provide important supplemental information in cases where proof of infection cannot be obtained through culture or histopathological examination. Currently, the complement fixation and immunodiffusion tests are the serologic tests that are most commonly employed.

**Complement Fixation Test.** Complement fixation antibodies may be detected at ~ 3 weeks after acquiring infection and wane over several months. In chronic or disseminated infection, they might remain elevated for years. Titers of 1:32 or greater may be indicative of active infection. Titers of 1:8 or 1:16 should raise suspicion for infection. Cross-reaction may occur with blastomycosis and coccidiomycosis, but in these instances, titers are usually lower.

**Immunodiffusion.** Immunodiffusion assays detect antibodies to two glycoprotein antigens, designated M and H antigens. Antibodies to M and H antigens appear later in infection than complement fixation antibodies. Anti-M antibodies may persist for years after acute infection. Anti-H antibodies are detected later than antibodies to M antigen and also disappear earlier. Thus they are more specific indicators of active infection. The simultaneous appearance of anti-M and anti-H antibodies occurs in < 20% of patients and is indicative of active infection.

**B. Antigen Detection.** A radioimmunoassay that detects a heat-stable *H. capsulatum* polysaccharide antigen has recently been developed. This assay may be applied to serum, urine, or cerebrospinal fluid and is particularly useful in cases of disseminated infection, where it has a sensitivity of > 90%. The sensitivity of this assay to detect *H. capsulatum* polysaccharide antigen in localized or chronic infection is considerably lower. Recent studies suggest that this test may also have a role in monitoring response to treatment. At present, this test is performed at only one laboratory in the United States.

**C. Histopathological Examination.** Histopathological evaluation of tissues can establish the diagnosis of histoplasmosis earlier than can culture. The site most commonly utilized for this purpose is the bone marrow, but other tissues such as lungs, skin, lymph nodes, liver, or respiratory tract secretions or washings can be evaluated. Organisms are identified through the use of special stains such as the Grocott silver methenamine and Wright-Giemsa methods.

**D. Culture.** A positive culture from samples of body fluids or tissue specimens is diagnostic. Newly available blood-culturing techniques, such as the lysis-centrifugation blood-culturing method, have greatly enhanced the yield of blood cultures in disseminated histoplasmosis. In AIDS patients with disseminated histoplasmosis, blood cultures are positive in = 90% of cases. The yield is much lower in chronic and localized infection. It may take 2-4 weeks or more of incubation for colonies of *H. capsulatum* to appear on culture media. After initial growth, rapid (within a few hours) identification of the organism may be performed with the aid of nucleic acid probe testing. Another method, the exoantigen test, which utilizes antigen-antibody reaction to identify the mold forms of dimorphic fungi, may be used for this purpose but usually requires a longer period (~ 2 weeks).

## Treatment

Amphotericin B is the drug of choice for immunocompromised patients and for patients with life-threatening disease or central nervous system disease ([Box 70-2](#)). For nonmeningeal, non-life-threatening histoplasmosis, the triazole antifungal agent itraconazole has become the preferred agent. It has supplanted the previous azole

mainstay of therapy, ketoconazole, because of its lower incidence of side effects and increased efficacy.

Histoplasmosis in AIDS should be treated with an intensive primary or induction therapy followed by lifelong suppressive or maintenance therapy since complete eradication of the organism is impossible. Amphotericin B is the antifungal agent of choice for induction treatment. Itraconazole is preferred for the maintenance phase of therapy. Nonmeningeal and nonseptic cases may be treated with itraconazole in both the initial and chronic phases of treatment. In situations where neither amphotericin B nor itraconazole may be used (because of intolerance, reactions, or allergy), fluconazole is an alternative option.

## Prognosis

Prognosis is variable and hard to generalize. Disseminated histoplasmosis, if untreated, especially in immunocompromised patients, will lead invariably to death.

## Prevention & Control

Individuals, such as HIV infected persons, who are at increased risk for acquiring serious infection, should be educated to avoid leisure and work activities that may lead to disturbance of potentially histoplasma-contaminated dust or soil ([Box 70-3](#)). At present, the routine use of azoles (eg, itraconazole) for primary prophylaxis of histoplasmosis in HIV-infected persons is not recommended but remains an option in highly endemic areas. HIV-infected persons diagnosed with histoplasmosis should remain on lifelong suppressive therapy with itraconazole to prevent relapse.

## 71 . *Blastomyces dermatitidis* — Zelalem Temesgen, MD

### Essentials of Diagnosis

- Round thick-walled yeast with broad-based budding.
- Dimorphic: mycelial in nature, yeast in tissue.
- Associated with activities in proximity to waterways.
- Associated with exposure to dust, eg excavation.
- Endemic in states surrounding the Mississippi and Ohio Rivers.
- Pyogranulomas on histopathological examination.
- Acute or chronic infection of lung, skin, bone, or genitourinary tract.
- Recovery of microorganism from culture of tissue.

### General Considerations

**A. Epidemiology.** *Blastomyces dermatitidis* is an endemic fungus that causes acute and chronic infections in humans and other animals. It is found primarily in the south central, southeastern, and midwestern United States, especially in the states surrounding the Mississippi and Ohio Rivers. Outside the United States, cases have been reported from Canadian provinces bordering the Great Lakes, Africa, India, the Middle East, and Central and South America.

Both clusters and sporadic cases of blastomycosis have been reported. Outdoor activities in proximity to waterways as well as exposure to dust from construction and excavation have been noted as possible risk factors for acquiring infection.

**B. Microbiology.** *B dermatitidis* is a dimorphic fungus, which means that it occurs as a mold in nature and in a yeast form in tissue (and at a temperature of 37 °C). The yeast cells are round and thick walled with daughter cells forming from a broad-based bud.

**C. Pathogenesis.** The lungs are the initial portal of entry for blastomycosis in humans, although primary cutaneous blastomycosis as a result of accidental skin inoculation in the laboratory or after dog bites has been reported.

Infection begins with inhalation of conidia of the mycelial phase of the organism. In the lungs, the fungus converts to its yeast phase. Inflammatory response occurs in the form of polymorphonuclear leukocyte infiltration followed by macrophage infiltration and granuloma formation. The infection can spread via the bloodstream and lymphatic system to distant sites. Cellular immunity is the major protecting factor in preventing progression of disease in blastomycosis.

# CLINICAL SYNDROMES

## INTRODUCTION

*B dermatitidis* may cause disease in virtually every organ of the body. The most common clinical syndromes associated with blastomycosis are described in the following sections ([Box 71-1](#)).

## PULMONARY INFECTION

### INTRODUCTION

Pulmonary blastomycosis characteristically presents as an acute or chronic pneumonitis.

### 1. ACUTE PULMONARY INFECTION

#### Clinical Findings

**A. Signs and Symptoms.** After exposure to *B dermatitidis*, a significant proportion of individuals have asymptomatic disease. The true frequency of asymptomatic or subclinical disease is unknown. In one large outbreak, 46% of infected individuals were asymptomatic.

Symptomatic acute pulmonary infection presents similarly to an acute bacterial pneumonia with fever, chills, and productive cough, with or without hemoptysis or pleuritic chest pain.

**B. Imaging.** The appearance of the chest radiograph is variable and nonspecific. The most common radiological appearance of pulmonary blastomycosis is airspace consolidation. Other radiographic features include nodular masses, interstitial disease, and cavitation. Pleural effusions are occasionally noted, but they are usually small. Hilar and mediastinal adenopathy or calcification of parenchymal lesions is uncommon.

**C. Differential Diagnosis.** Differential diagnosis of pulmonary blastomycosis includes other types of pneumonia (eg, bacterial and fungal) and tuberculosis, as well as lymphoma and malignant neoplasms.

**D. Complications.** The course of pulmonary infection is variable. The disease may clear with or without treatment or progress to chronic pulmonary disease. Occasionally, overwhelming pulmonary infection with *B dermatitidis* results in the adult respiratory distress syndrome (ARDS) and respiratory failure, indistinguishable from ARDS caused by bacterial sepsis and characterized by severe impairment of gas exchange and hemodynamic instability.

This syndrome is also associated with significant mortality. In one report, only 13 of 29 patients survived. Although also seen in immunocompetent individuals, it is much more

often encountered in immunocompromised individuals, including those with AIDS. Large amounts of *B dermatitidis* are easily recovered from respiratory cultures, and examination of lung tissue will show histopathological changes characteristic of ARDS, as well as the presence of a large number of the causative organisms. Aggressive therapy with large doses of amphotericin B (0.7-1.0 mg/kg) should be initiated promptly, and many patients require mechanical ventilatory assistance. Survivors may regain good pulmonary function.

## 2. CHRONIC PULMONARY INFECTION

### Clinical Findings

**A. Signs and Symptoms.** The symptoms usually noted in chronic pneumonia caused by blastomycosis include weight loss, fever, night sweats, productive cough, and pleuritic chest pain. These symptoms are usually present for 2-6 months before diagnosis. Chronic pulmonary blastomycosis may be accompanied by extrapulmonary disease.

**B. Imaging.** The radiological presentation of chronic disease is variable and nonspecific and includes alveolar infiltrates, masses, nodules, and cavities. There is no specific pattern or distribution that corresponds with disease stage.

**C. Differential Diagnosis.** Same as for acute pulmonary infection.

**D. Complications.** Complications of chronic pulmonary blastomycosis include acute deterioration and respiratory failure, as well as hematogenous dissemination to extrapulmonary sites.

## EXTRAPULMONARY INFECTION

### INTRODUCTION

Extrapulmonary disease is usually seen in conjunction with pulmonary infection and is the result of hematogenous dissemination of *B dermatitidis*. The exception is primary cutaneous blastomycosis, which occurs as a result of accidental inoculation in the laboratory, during autopsy, or after dog bites.

### 1. CUTANEOUS BLASTOMYCOSIS

Cutaneous blastomycosis is the most common manifestation of extrapulmonary blastomycosis (40%- 80% of reported cases). Areas of the body not covered by clothing are sites of predilection, but lesions can occasionally be found on mucocutaneous surfaces. The skin lesions start as papules or pustules but later advance to form either verrucous (ie, fungating, heaped up) or ulcerative lesions. The verrucous lesions, both by their gross and microscopic (hyperplasia, acanthosis) appearance, may be mistaken for cancer. Other differential diagnosis includes skin lesions caused by other fungi (eg, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Sporothrix schenckii*), as well as lesions caused by nocardiosis and atypical mycobacteria (eg, *Mycobacterium marinum*). Both types of skin lesions may be present in the same patient.

## **2. SKELETAL BLASTOMYCOSIS**

Bone involvement represents the second most frequent manifestation of extrapulmonary disease, having been reported in = 25% of extrapulmonary cases. The most commonly affected bones are the vertebrae, pelvis, sacrum, ribs, and long bones, but any bone can be involved. The usual presenting symptoms consist of soft tissue abscesses or chronic draining sinuses adjacent to areas of osteomyelitis. Vertebral disease, with involvement of the vertebral body and development of large paraspinal abscesses, may be indistinguishable from tuberculosis. The typical radiographic appearance is a well-circumscribed osteolytic lesion.

Vertebral disease may be indistinguishable from tuberculosis. In addition, differential diagnosis includes bacterial osteomyelitis, osteomyelitis caused by other fungi, and a Brodie abscess.

## **3. GENITOURINARY BLASTOMYCOSIS**

Blastomycosis of the genitourinary tract follows skin and bone infection in the frequency of its extrapulmonary involvement. Men are more prone to be infected than women. Prostatic involvement is the most common presentation, followed by epididymo-orchitis. Symptoms include urinary obstruction with an enlarged and tender prostate and pyuria.

Yield of cultures may be improved by collection of urine after prostatic massage. In women, both endometrial infection as a result of sexual contact with a man with blastomycosis on the penis and tuboovarian abscess after hematogenous dissemination have been reported.

## **4. BLASTOMYCOSIS OF THE CENTRAL NERVOUS SYSTEM**

Central nervous system blastomycosis is an uncommon complication of disseminated disease. It presents either as an abscess or meningitis. Abscesses present as mass lesions, either intracranially or in an epidural location. Meningitis is difficult to diagnose. Cerebrospinal fluid evaluation is usually not diagnostic. Culture of ventricular fluid may on occasion yield the organism. Cultures of large volumes of spinal fluid increase the likelihood of a positive culture.

## **BLASTOMYCOSIS & AIDS**

Blastomycosis is an uncommon infection among patients with AIDS and is not recognized as an AIDS-defining opportunistic infection according to present Centers for Disease Control guidelines. When it occurs, it is a late manifestation of HIV infection, usually affecting individuals with prior diagnosis of an AIDS-defining illness and CD4 lymphocyte counts of  $< 200$  cells/mm<sup>3</sup>. It can present either with disease limited to the lungs and pleura or with disseminated infection involving multiple visceral organs. There is also more frequent involvement of the central nervous system. Cutaneous lesions appear to be less common.

A higher frequency of diffuse interstitial or miliary pattern is noted on chest radiograms.

Relapse is common, necessitating chronic maintenance treatment to prevent recurrent disease.

## **BLASTOMYCOSIS IN OTHER IMMUNOCOMPROMISED HOSTS**

### **Introduction**

Blastomycosis has been reported to cause infection in other immunocompromised patients including patients on long-term glucocorticoid treatment, solid-organ transplant recipients, patients with hematological malignancies, patients with disorders of neutropenia, patients demonstrating humoral immune dysfunction, and patients with combined immunologic dysfunction. Infection in these individuals differs from that of normal hosts in several ways. The pulmonary involvement is more extensive; a greater frequency of progression to respiratory failure and ARDS is observed.

Diffuse interstitial alveolar changes and pleural effusions are much more common than in normal hosts. Multiple visceral organ disease, with or without central nervous system involvement, is also more common.

### **Diagnosis**

Blastomycosis is diagnosed by identification and isolation of the organism in tissue, exudate, or histopathologic sections.

**A. Direct Examination.** Sputum, pus, and body fluids such as urine, pleural fluid, or cerebrospinal fluid can be evaluated by direct microscopic examination. Wet preparation, potassium hydroxide preparation, or calcofluor white stain can be used for this purpose. *B dermatitidis* is recognized and identified on the basis of its size and characteristic morphologic features (broad-based buds, refractile cell wall).

**B. Histopathologic Examination.** Histopathologic sections should be screened for presence of the fungus by using the Gomori methenamine silver stain or the periodic acid-Schiff stain. Fluorescent stains may be helpful when the fungal elements are sparse. Pyogranulomas, if noted, suggest the possibility of blastomycosis.

**C. Culture.** *B dermatitidis* usually requires 5 days to 4 weeks for growth to be detected but may be detected in as little as 2-3 days. Conversion of the mycelial form to the yeast form is required for confirmation of the diagnosis. *B dermatitidis* may also be identified by nucleic acid probe testing or by the presence of a specific A band in the exoantigen test.

**D. Serology.** Several serologic methods, including serum complement fixation tests, immunodiffusion tests, radio immunoassays, and enzyme-linked immunosorbent assays, have been developed. None has been useful because of low sensitivity and specificity rates.

### **Treatment**

Acute pulmonary infection caused by *B dermatitidis* sometimes resolves spontaneously

without specific therapy. However, it is not possible to determine which patients will progress to serious infection or develop extrapulmonary disease. For this reason, many authorities recommend treating all cases of active blastomycosis. If withholding treatment is considered, extrapulmonary disease should be excluded. If treatment is withheld, patients must be carefully monitored for a prolonged period for evidence of relapse, progression, or extrapulmonary infection.

Amphotericin B is the drug of choice for immunocompromised patients, including those with AIDS, patients with life-threatening infections, and patients with central nervous system disease ([Box 71-2](#)). Because relapse of blastomycosis after amphotericin therapy is dose related and rarely occurs in patients who had received > 1.5 g of the drug, a total cumulative dose of amphotericin between 1.5 and 2.5 g is recommended.

Itraconazole, a triazole antifungal agent, is the drug of choice for those patients who do not require amphotericin B (see above). It should be used at a dose of 200 mg/d orally. The dose can be increased to 400 mg/d for persistent or progressive disease. A minimum of 6 months of therapy is recommended by most authorities.

Ketoconazole, another oral antifungal agent with a similar mechanism of action to itraconazole, may be used at a dose of 400 mg/d by mouth. Doses of = 800 mg/d may be required for persistent and unresponsive disease. Treatment should be continued for = 6 months.

Both itraconazole and ketoconazole require gastric acid for absorption. There are significant drug-drug interactions with drugs such as terfenadine, rifampin, phenytoin, and carbamazepine. In addition, neither itraconazole nor ketoconazole is excreted in the urine as an active drug. Therefore treatment of genitourinary blastomycosis with these agents may be inadequate.

Fluconazole, another triazole antifungal agent, has been shown to be moderately effective in the treatment of non-life-threatening blastomycosis at a dose of 200-400 mg/d.

Patients with AIDS and immunocompromised patients with ongoing immunosuppression require chronic oral maintenance treatment (eg, itraconazole, 200 mg/d) to prevent recurrence.

Surgery may be indicated for evacuation of large abscesses, diagnostic biopsy, or removal of central nervous system mass lesions, or debridement of devitalized and necrotic bone in patients with osteomyelitis refractory to pharmacotherapy.

## **Prognosis**

The mortality rate for blastomycosis in HIV-infected patients is much higher than the mortality rate from blastomycosis in the general population. In one report, of 24 patients with HIV and blastomycosis, 15 (63%) had disseminated disease, and 13 (54%) died as a result of their infection. Previous reports have suggested a mortality rate of ~ 10% in those with disseminated blastomycosis but without concomitant HIV infection.

## Prevention & Control

Individuals residing in endemic areas who are at increased risk (eg, immunocompromised or HIV-infected individuals) should avoid activities associated with acquiring infection, such as exposure to dust, construction, or excavation. AIDS patients with blastomycosis who have completed initial therapy should receive lifelong suppressive treatment with itraconazole ([Box 71-3](#)).

## 72 . *Coccidioides* — Caroline Milne, MD, & Merle Sande, MD

### Essentials of Diagnosis

- Predisposing factors include travel to the dry desert climates found in the southwestern United States and exposure to dust.
- The commonest source of infection is dust inhalation in the southwestern United States.
- The commonest infection is pneumonia.
- Key laboratory findings include growth of the fungus and complement fixing (CF) antigen detection by immunodiffusion.

### General Considerations

Coccidioidomycosis was first described as a disease a little more than a century ago in Buenos Aires, Argentina. It was in San Francisco that the organism causing the clinical disease was given its name, *Coccidioides immitis*. Many diseases were later found to be caused by this organism, including San Joaquin Valley Fever.

**A. Epidemiology.** Coccidioidomycosis is not a new disease. Recently, however, there has been an increase in the number of cases reported in the United States. *C immitis* is endemic to the southwestern United States, found primarily in southern California, southern Nevada, southern New Mexico, and Arizona. Other endemic areas have similar dry desert climates such as Mexico and South and Central America. This disease is no longer limited to residents of these areas. As travel increases, coccidioidomycosis must always be considered when the clinical picture fits. This fact emphasizes the importance of obtaining a good travel history.

Exposure to dust affects the incidence of coccidioidomycosis. Incidence is highest in the summer and fall when the soil is dry and dusty. Earthquakes and dust storms also increase incidence. In the United States an estimated 100,000 infections occur annually.

Infection doesn't necessarily mean clinical manifestation of disease. Infection has been studied among soldiers stationed in the San Joaquin Valley during WWII. The soldiers were skin tested and questioned about illnesses. Of all reported infections, 60% were found to be asymptomatic, another 35% were self-limited, and 5% resulted in disseminated disease.

**B. Microbiology and Pathogenesis.** *C immitis* is a fungus that lives in the soil. As the fungus matures it forms alternate cells along a hypha, called arthroconidia. This stage of the fungus can become airborne and be inhaled by a human host, which causes infection. A very small number of arthroconidia are needed to cause infection. Once the host is infected, multiple divisions of the inhaled arthroconidia occur in the lung, forming spherules and then thousands of endospores. Each endospore can repeat the

development of a spherule. Thus, a cyclic process occurs, and multiplication is rapid. The immunologic response to *C immitis* is primarily cellular. Functioning T lymphocytes are essential to control infection.

## Clinical Findings

**A. Signs and Symptoms.** In symptomatic disease, first manifestations occur 1-3 weeks after initial exposure. The symptoms are clinically nonspecific and include cough with scant sputum production, fever, headache, and pleuritic chest pain in the majority of cases ([Table 72-1](#)).

A skin rash is common with primary infection. Both erythema nodosum and erythema multiforme are referred to as "specific erythemas" of coccidioidomycosis. These erythemas are associated with an intense immunologic response and with a good prognosis. People who exhibit these erythemas will likely not progress to disseminated disease.

The most common clinical manifestation of disease is pneumonia ([Box 72-1](#)). Most are self-resolved and likely go undiagnosed. Pulmonary complications occur infrequently and include asymptomatic nodules or thin-walled cavities, slow resolving pneumonia, or chronic lung infection.

Nodules occur in 5-7% of patients and are usually solitary and asymptomatic. The morbidity associated with these lesions occurs during surgical resection of the nodules to exclude cancer. More recently percutaneous fine-needle biopsy has been used for diagnosis.

Cavities occur in younger patients, are most frequently asymptomatic, and are usually self-resolved, disappearing within 2 years of appearance. Complications, however, can occur and are usually associated with air fluid levels or infiltrates surrounding the cavity. Infection rarely spreads to other areas of the lung. If rupture of the cavity occurs, surgical repair is required.

Disseminated disease is unusual. Fewer than 5% of infected persons experience disseminated disease. Extrapulmonary disease includes granulomatous skin lesions or subcutaneous abscess, septic arthritis, osteomyelitis, and meningitis. Risk factors for extrapulmonary disease have been found to be male sex, pregnant women, immunosuppression, nonwhites (especially Filipinos and blacks), and possibly age (the very old or young).

Meningitis occurs in one-third to one-half of all patients with coccidioidal dissemination. The clinical symptoms are not specific to *C immitis* infection and include headache, vomiting, nuchal rigidity, confusion, and diplopia. Lumbar puncture is essential to diagnosis. The cerebrospinal fluid reveals a pleocytosis with a predominance of mononuclear cells. Most have an eosinophilia as well. Usually the glucose is low, and the protein elevated. The cerebrospinal fluid should be sent both for culture and serologic tests (complement-fixing antigen).

Coccidioidal meningitis should be suspected in patients with the clinical syndrome and a

recent coccidioidal infection. Meningitis usually occurs within 6 months of initial infection; however, meningitis can occur late if immunosuppressed. Early diagnosis is important, and, if left untreated, coccidioidal meningitis is fatal. Even with diagnosis, treatment is difficult.

**B. Laboratory Findings.** Coccidioidal infections should be considered in patients with a pulmonary syndrome and who live in or have a history of travel to endemic areas. As stated earlier, most of these infections are self-limited, and physicians living outside endemic areas will likely see only complicated cases.

The vast majority of cases are asymptomatic and will be identified by a positive skin test only. Positive skin tests are neither definitive nor helpful in establishing the diagnosis of coccidioidomycosis, because of the high number of asymptomatic infections. Definitive diagnosis is established via culture of the organism or antibody or antigen detection. Antigen detection kits are not currently commercially available.

*C immitis* readily grows in the laboratory and is detectable as early as 2-5 days after inoculation. The fungal growth is further evaluated via a species-specific DNA probe. Results are available the day growth is detected. It is important to notify the laboratory of your suspicions, because laboratory identification may be dangerous to the lab technician. Arthrospores readily become airborne and may be inhaled.

There are two coccidioidal antigens that are targeted for antibody detection, the tube precipitin reading (TP) antigen and the CF antigen. Antibody detection kits are not available, and instead laboratories use immunodiffusion tests. Both tests are reported qualitatively; if immunodiffusion CF is positive, a follow-up quantitative test is necessary. The concentration of CF antibodies is proportional to the extent of the disease. Ordering physicians must be aware of false-negative results in detecting anticoccidioidal antibodies; these results are most prevalent in early primary infection or in immunosuppressed patients.

## Differential Diagnosis

Coccidioidal infections are suspected in patients with pulmonary symptoms and the appropriate travel or residence in an endemic area. Bacterial or other fungal pneumonias should be included in the differential.

## Complications

Most coccidioidal infections are self-resolved. Pulmonary complications can occur and include asymptomatic nodules, slowly resolving pneumonia, or chronic lung infection. The most serious complication includes disseminated disease and can affect any organ system.

## Treatment

In most cases the decision to treat is the real question. Recall that even for patients who develop symptoms of initial infection, the disease is usually self-limited. In patients in whom treatment is indicated, coccidioidomycosis is very difficult to cure. Treatment for

initial infection is indicated only for patients with deficiencies in T-cell immunity. A physician may decide to treat a severe pulmonary infection, but there is no expert consensus. Treatment is indicated for chronic pulmonary infection and extrapulmonary dissemination. Accepted-standard-of-care therapies include amphotericin B and oral azole antifungal agents ([Boxes 72-2](#) and [72-3](#)). Fluconazole and itraconazole have been shown to have similar success rates. Length of treatment is controversial, because relapse is common. Treatment may be lifelong. Most physicians will treat pulmonary and disseminated disease for 12-18 months. It has been found that negative serial coccidioidin skin tests and very high CF antibody titers are independently associated with increased risk of relapse. Rising CF titers after completion of therapy are an indication of relapse and warrant retreatment. Patients with meningitis are likely never cured and require indefinite treatment. Only fluconazole and amphotericin B have been shown to be effective therapies. If amphotericin B is used, both parenteral and intrathecal therapy is indicated.

## Prevention

There is no vaccine available against *C immitis* infection. General prevention includes avoiding exposure to the fungus in its natural setting and decreasing the amount of airborne dust. Environmental measures including paving dirt roads and planting grass may be implemented (see Kirkland and Fierer, 1996).

**Site/Indications**

Fever lasting longer than 1 month  
Extensive or progressive pulmonary disease  
Immunosuppressed patients  
HIV-infected patients  
Pregnant patients

Disseminated disease

**Treatment**

Amphotericin B is used as initial drug of choice because of rapid improvement in symptoms, followed by oral azoles.  
Amphotericin B: 0.6-1.0 mg/kg/day for 7 days, then 0.8 mg/kg/every other day. Total dose 2.5 g.  
Oral azoles: Itraconazole 200 mg twice a day **OR** fluconazole 400 mg/day for 3-12 months.  
Amphotericin B, 0.5-0.7 mg/kg/day. Total dose, usually 15-45 mg/kg.  
Total dose not clearly defined.

## 73 . *Candida* species — Christopher R. Fox, MD & Merle A. Sande, MD

### Essentials of Diagnosis

- Characteristic appearance of yeast and hyphae on KOH preparations.
- Formation of germ tubes in serum is presumptive diagnosis for *Candida albicans*.
- Cultures must be interpreted with caution because positive culture may represent colonization rather than infection.
- Serology not useful.

### General Considerations

**A. Epidemiology.** *Candida* organisms are commensal with humans and, in the absence of alterations in host defense mechanisms, usually do not cause disease. *Candida* exists as normal flora within the oral cavity, throughout the gastrointestinal (GI) tract, in expectorated sputum, in the vagina, and in the bladder of patients with indwelling catheters. There are >150 species within the genus *Candida*, although the majority are not known to cause disease in humans. *C albicans*, *C krusei*, *C glabrata*, *C tropicalis*, *C pseudotropicalis*, *C guilliermondii*, *C parapsilosis*, *C lusitaniae*, and *C rugosa* are known human pathogens.

*Candida* species cause a wide spectrum of clinical diseases that range from mild, superficial infection of the skin and mucous membranes to life-threatening, invasive, multisystem disease. Infection with *Candida* requires an alteration in the normal milieu that allows the fungus to proliferate and evade host responses.

Under correct conditions, *Candida* is able to infect any of the body's mucosal surfaces, as well as the skin. Three-quarters of women report vaginal candidiasis within their lifetime, and the incidence appears to have increased over the last 20 years. Risk factors include recent antibiotic use, pregnancy, oral contraceptive use, diabetes, and human immunodeficiency virus (HIV) infection.

Oral thrush is another frequent manifestation of mucosal candidiasis with similar risk factors to vaginal candidiasis. These risks include systemic disease such as HIV infection or diabetes, inhaled or oral corticosteroid use, and neutropenia induced by chemotherapy.

In addition to the local forms of disease described above, *Candida* species may cause invasive disease with systemic manifestations and multiple infected organs. Although once limited to the oncology ward and bone marrow transplant unit, candidemia is now more frequent in all areas of the hospital, with *Candida* the fourth most common organism reported from hospital blood cultures. Specific risk factors for invasive disease include previous isolation of *Candida* from another site, the use of antimicrobial agents, prolonged neutropenia, indwelling central catheters, and the use of parenteral nutrition.

Although the majority of *Candida* infections are caused by *C albicans*, several non-*albicans* species are emerging as important pathogens and deserve mention. *C krusei* appears to be less virulent than *C albicans* and rarely causes disease in the normal host. However, in those with depressed immune function, *C krusei* is able to cause significant infection. Candidemia, ocular infection, endocarditis, and renal disease all occur with some frequency. *C krusei* infection has important therapeutic implications as the organism is generally resistant to fluconazole. *C glabrata*, another *Candida* species with increasing recovery rates, usually has intermediate resistance to fluconazole.

**B. Microbiology.** *Candida* is a fungus that exists primarily in the yeast state, although it may be found in tissue in both yeast and mold forms. The yeast cells are 4-6 um in diameter and reproduce primarily by budding but also by sexual reproduction. In culture, *Candida* forms smooth white colonies, and a presumptive diagnosis of *C albicans* can be made by observing the formation of germ tubes within 90 min of placing the organism in serum. *Candida* will grow on agar plates and in routine blood culture bottles, although the lysis-centrifugation and the BACTEC systems have increased recovery of the organism.

**C. Pathogenesis.** As previously mentioned, *Candida* is part of the normal flora in many areas of the body and, without alteration in host defense, does not cause disease. Factors particularly important to preventing infection are normal bacterial flora, intact skin and mucous membranes within the GI tract, and normal cell-mediated immunity. Alterations of any of the above mechanisms predispose to infection. This is seen clinically as the use of antibiotics (which alter the normal bacterial flora), maceration of the skin, GI surgery, HIV infection, and chemotherapy-induced neutropenia, all of which increase rates of *Candida* infection.

*Candida* produces proteins expressed within the cell wall that promote binding and adherence to epithelial cells, endothelium, platelet and fibrin clots, and plastics. These proteins likely help the organism attach to and invade damaged mucosa and may play a role in *Candida* infection in hosts with indwelling bladder and central venous catheters. *Candida* species also produce proteases and phospholipases, which may aid the organism in evading host defenses and invading mucosal surfaces.

## CLINICAL SYNDROMES

### CANDIDA DERMATITIS

#### Clinical Findings

**A. Signs and Symptoms.** Skin infections with *Candida* are common and may manifest in a variety of forms. Intertrigo occurs in warm, moist areas of skin, such as under the breast, in the groin, and in the axilla. Initially pustular or vesicular, lesions eventually become confluent to form an erythematous, macerated area of skin with a scalloped border and satellite lesions ([Box 73-1](#)). Erosio interdigitalis blastomycetica is similar to intertrigo but involves the areas between the fingers and toes. Paronychia is infection of the nail bed, seen more commonly in diabetics and people who frequently immerse their

hands in water. *Candida* spp. may cause onychomycosis, particularly in HIV-infected patients. *Candida* spp. cause a rash in neonates in the region of diaper contact. Other common skin manifestations include folliculitis, balanitis, perianal candidiasis, and a generalized cutaneous eruption with widespread lesions resembling intertrigo that spread to involve the abdomen, chest, back, and extremities.

Chronic mucocutaneous candidiasis (CMC) is an abnormality of cell-mediated immunity that presents with recurrent infections of the skin and mucus membranes that may progress to disfiguring lesions (*Candida* granulomas) despite antifungal therapy. Symptoms usually begin in the first several years of life. CMC is associated with autoimmune endocrine failure, particularly hypoparathyroidism and adrenal insufficiency (polyglandular autoimmune syndrome type I), and endocrine disease often presents years to decades after the onset of CMC.

Cutaneous lesions may be superficial evidence of disseminated candidiasis and candidemia. Lesions are typically red or pink nodules 5-10 mm in diameter and may be single or widespread. Lesions resembling ecthyma gangrenosum or purpura fulminans have also been described.

**B. Laboratory Findings.** *Candida* organisms, seen as budding yeast and hyphae, may be present on wet mount or KOH preparations of skin scrapings. Biopsy specimens may reveal characteristic fungal elements on histology.

**C. Differential Diagnosis.** *Candida* infection of the skin and nails may be confused with other infections, both fungal and nonfungal, as well as noninfectious conditions such as contact or allergic dermatitis.

**D. Complications.** *Candida* infection of the skin and nails may cause discomfort and disturb cosmetic appearance of the skin but does not usually cause long-term sequelae. CMC may progress to cause large disfiguring lesions.

## Diagnosis

Diagnosis of *Candida* infection involving the skin or nails is generally made by recognition of the clinical pattern followed by demonstration of fungal elements on a KOH preparation of skin scrapings. *Candida* infection may also be diagnosed by microscopic examination of biopsy specimens. Culture of the skin should be interpreted with caution, as the presence of *Candida* spp. may represent colonization rather than infection.

## Treatment

Treatment of *Candida* skin infections is generally straightforward. Intertrigo is managed by decreasing moisture in infected areas and by application of topical antifungal therapy. Nystatin cream, topical azoles (miconazole, clotrimazole), and amphotericin B cream are all effective when applied 2-3 times daily. Paronychia may be treated by keeping the area dry and with topical antifungal therapy. Onychomycosis requires several months of treatment with oral azoles, such as itraconazole, or terbinafine. Relapses may occur. Griseofulvin is not active against *Candida*.

CMC is treated with oral ketoconazole or fluconazole. Transfer factor, an immunomodulating factor composed of a cell-free leukocyte extract, was used in the past but has fallen out of favor because of lack of efficacy. Months to years of treatment are generally required.

## ORAL CANDIDIASIS

### Clinical Findings

**A. Signs and Symptoms.** *Candida* infections of the oral cavity are relatively common and may present in several forms. Any of the forms may be asymptomatic or may cause soreness and burning. The most common, acute pseudomembranous candidiasis, or oral thrush, presents with multiple white patches on the tongue, palate, and other areas of oral mucosa. These lesions may be easily removed by scraping with a tongue blade to reveal an erythematous, irritated mucosa ([Box 73-1](#)).

In addition to oral thrush, oral *Candida* infection occurs in several distinct forms. Acute atrophic candidiasis causes erythematous mucosa found typically on the palate and tongue, chronic atrophic candidiasis results in erythema and edema of the mucosa of denture wearers who do not practice adequate hygiene, and angular cheilitis causes erythema and fissuring of the corners of the mouth. Finally, *Candida* leukoplakia is described as adherent white nodules on an erythematous base and often does not respond to topical therapy. This condition also carries an increased risk of malignant transformation.

**B. Laboratory Findings.** Budding yeast and hyphae may be seen on a KOH preparation or on preparations made with para-aminosalicylic acid (PAS) stain, Giemsa stain, or Gram stain. Culture of oral scrapings may grow *Candida* species, although this is not a specific test.

**C. Differential Diagnosis.** Oral candidiasis must be differentiated from bacterial and viral infection as well as malignancy.

**D. Complications.** While uncomfortable for those affected, it is unclear if oral candidiasis predisposes to *Candida* infection at other sites. There are reports that *Candida* esophagitis may follow oral thrush, although esophagitis was not excluded at the initial presentation in these reports. In those with oral infection and infection at a second site, it is likely that immune system deficits allow for multiple infections rather than spreading from the oral cavity.

### Diagnosis

The diagnosis of oral *Candida* infection may be suspected when the characteristic appearance of the mucosa is present and, in the case of oral thrush, when scraping of the mucosa removes the white plaque and leaves an inflamed mucosa. Demonstration of dimorphic fungi on KOH-, Giemsa-, Gram-, or PAS-stained oral scrapings strongly supports the diagnosis. Culture of *Candida* species from oral scrapings is not generally required, and as *Candida* may be part of the normal flora of the oral cavity, positive

cultures may not represent true infection.

## Treatment

Generally, oral *Candida* infection should initially be treated with topical agents ([Box 73-3](#)). Nystatin suspension or clotrimazole troches are generally effective therapy. If infection occurs in a denture wearer, the dentures must be removed. Once the infection is cured, proper dental hygiene is important to prevent recurrence. Topical antifungal creams will treat angular cheilitis.

If topical therapy fails, or in those with severe infection, systemic therapy may be used. In patients with advanced HIV infection, itraconazole doses may require adjustment because of achlorhydria and impaired absorption. Treatment failure should prompt a search for other causes, such as bacterial infection or malignancy.

In those infected with HIV or with other immune deficits, frequent recurrences are common, and maintenance therapy may be necessary. Daily treatment with topical antifungal agents or fluconazole, 50-100 mg daily, every other day, or once weekly may prevent recurrence. Maintenance therapy with fluconazole should be avoided if possible because of concerns for the emergence of resistant fungal strains.

## ESOPHAGEAL CANDIDIASIS

### Clinical Findings

**A. Signs and Symptoms.** *Candida* infection of the esophagus can present with a range of clinical findings ([Box 73-1](#)). Between 20 and 50% of patients may be asymptomatic. Others will note dysphagia, odynophagia, epigastric pain, nausea and vomiting, or hematemesis. Fever may be present. Frequently, patients will have concurrent symptoms of oral thrush. Physical exam of patients with esophagitis yields few clues to its diagnosis. Oral thrush is seen in the majority.

**B. Imaging.** Barium studies and endoscopy are both useful for diagnosis of *Candida* esophagitis. The findings found with these methods are described in the diagnosis section.

**C. Differential Diagnosis.** *Candida* esophagitis may be confused with other causes of esophagitis, including bacterial, viral, and reflux esophagitis. Host factors (such as the status of the immune system), clinical findings, and endoscopic appearance of the esophagus are helpful in making this distinction, although frequently more than one cause of esophagitis are present concurrently.

**D. Complications.** Complications of esophagitis relate to deep invasion and inflammation of the mucosa. Although uncommon, perforation and strictures do occur. In some cases, long and complex strictures are not amenable to endoscopic dilatation and require surgical intervention. Dissemination of the fungus from the lower esophagus and stomach may occur, especially in neutropenic patients.

### Diagnosis

Radiographic techniques using barium contrast (barium swallow) and endoscopy are useful for diagnosis of *Candida* esophagitis. The barium swallow has a characteristic appearance, with a shaggy-appearing mucosa and sometimes nodules and cobblestoning. This technique does not allow firm diagnosis, which requires histology or culture.

Endoscopy is the preferred method of diagnosis, as it allows direct visualization of the mucosa and biopsy of affected areas. The mucosa typically has adherent white plaques that may be removed with the endoscope to reveal an erythematous mucosa. Brushings of the mucosa may be prepared as for oral disease. Histologic specimens reveal fungal elements, which are more apparent on PAS-stained and silver-stained material than with hematoxylin-eosin staining.

## **Treatment**

A subset of patients may be treated empirically. In those with HIV infection, oral thrush, and mild to moderate symptoms of esophagitis, treatment with topical agents or an azole may be warranted. If no oral thrush is present, or if treatment fails, endoscopy should be performed to exclude other causes of disease.

As with oral thrush, topical agents may be successful in treating esophagitis ([Box 73-4](#)). If patients fail topical treatment, have severe disease, or are considered to be at high risk for disseminated disease, systemic therapy should be used. Therapy for 10 days is generally adequate.

## **CANDIDA VULVOVAGINITIS**

### **Clinical Findings**

**A. Signs and Symptoms.** Risk factors for *Candida* infection of the vagina include pregnancy, oral contraceptive use, diabetes mellitus, HIV infection, and antimicrobial therapy, although the majority of infections occur in the absence of these risks. Typical complaints are vulvar pruritus and vaginal discharge ([Box 73-1](#)), although a wide range of symptoms exists. Pruritus, the most common complaint, is often intense, and the discharge, classically described as cottage cheese-like, may range from a thin, white, scant discharge to homogeneously thick. Odor, if present, is mild. Other symptoms may include vulvar burning, external dysuria, vaginal irritation and soreness, and dyspareunia. Symptoms may peak the week prior to menses and wane with the onset of menstrual flow.

Examination may reveal discrete papular or pustular lesions of the vulva, with erythema and swelling of the vulva and labia. The discharge is present within the vaginal vault, and the vaginal mucosa is inflamed and may have adherent white plaques similar to oral thrush. The cervix appears normal.

**B. Laboratory Findings.** The vaginal pH is normal (<4.5). Examination of a saline or wet mount preparation of the vaginal discharge may show fungal elements and should not reveal abundant white cells. A KOH preparation is more sensitive in detecting the

fungus, as other cellular debris is lysed. Both budding yeast and hyphae are typically present. Culture of the vagina will usually isolate *Candida*, although this must be interpreted cautiously, as *Candida* can be part of the vaginal flora without causing disease.

**C. Differential Diagnosis.** The signs and symptoms of *Candida* vulvovaginitis are relatively nonspecific, and therefore the presentation may be confused with bacterial vaginosis, trichomoniasis, and other sexually transmitted diseases. Two or more of these conditions may coexist.

**D. Complications.** Some women may develop severe, recurrent infections despite removal of identified risk factors and antifungal therapy. Infection of the vagina is not associated with risk of deep tissue or bloodstream invasion.

## Diagnosis

The diagnosis of vulvovaginitis is typically made by history, physical examination, and light microscopy. In women with appropriate symptoms and fungal elements on wet mount or KOH preparation, therapy is indicated without further testing. As up to 50% of symptomatic women with culture-proven infection have negative microscopy, vaginal culture is indicated in those patients with symptoms and no microscopic findings. A vaginal pH >4.5 or a large number of white cells on wet mount should prompt a search for a different or possibly coexistent process.

## Treatment

Numerous agents are available for treatment of *Candida* vulvovaginitis in both topical and oral preparations ([Box 73-5](#)). Among topical agents, cure rates range from 75 to 90%, with the azole preparations (clotrimazole, miconazole, terconazole) having slightly better efficacy than nystatin. The formulation (cream versus suppository versus vaginal tablet) does not alter the success rate; therefore the choice of formulation is a matter of patient preference. Currently there is a trend toward higher doses of topical agents with shorter durations of therapy, with success reported with even high-dose, one-time therapy. Anecdotal failure rates are fairly high with one-dose therapy; thus this is best reserved for women with infrequent infections and mild or moderate symptoms.

Oral azole agents are quite effective for vaginal infection and are more convenient than topical therapy but are more expensive. Fluconazole and itraconazole single-dose therapy are at least as effective as topical therapy.

Cure of *Candida* vulvovaginitis during pregnancy can be difficult, with relapses frequently occurring. If therapy is extended to 1-2 weeks, topical antifungal therapy is effective. Oral azoles should be avoided during pregnancy.

In women with frequent recurrent infections, therapy is often disappointing, with symptoms recurring within weeks of withdrawal of antifungal agents. In these women, predisposing factors such as diabetes or HIV infection should be considered. HIV testing is appropriate in women with risk factors for HIV infection. If fasting blood glucose values are normal, further testing for diabetes is not required. Oral

contraceptives should be discontinued if possible, although continuation of low-dose estrogen preparations, as long as long-term antifungal therapy is used, may be considered. Vaginal douching and treatment of the sexual partner are not recommended. Frequently, no risk factors are identified, and prophylactic therapy is required. The best-studied regimen with proven efficacy for prophylaxis is ketoconazole, 100 mg daily. Toxicity, such as hepatitis, is infrequent but may occur. Other regimens with anecdotal support include fluconazole, 100-200 mg once weekly, and clotrimazole vaginal tablets, 500 mg once weekly.

## **CANDIDURIA, *CANDIDA* CYSTITIS & URINARY TRACT CANDIDIASIS**

### **Introduction**

The presence of *Candida* spp. in the urine is common and does not necessarily represent infection. Candiduria is commonly associated with antibiotic use, indwelling urinary catheters, and diabetes mellitus and frequently resolves if predisposing factors can be corrected. Patients are generally asymptomatic, although some will have symptoms similar to bacterial cystitis, with dysuria, frequency, and urgency ([Box 73-2](#)). Urinalysis shows fungal elements and may reveal pyuria. At cystoscopy, the mucosa of the bladder typically has an inflamed appearance with adherent white plaques that may be removed with the scope.

*Candida* spp. may also cause urethritis, typically in male sexual partners of women with vaginal *Candida* infection, as well as higher urinary tract infection. The upper urinary tract and renal parenchyma may be infected from ascending infection or, more commonly, from hematogenous spread as part of a syndrome of disseminated candidiasis. With ascending infection, perinephric abscesses, papillary necrosis, fungus balls, and calyceal involvement have all been described. Risk factors are generally present and include diabetes mellitus, urinary tract obstruction, and renal stones. With hematogenous spread, the renal parenchyma becomes studded with multiple microabscesses.

### **Diagnosis**

Candiduria is usually discovered when a urine culture reveals the presence of *Candida* spp. The presence of pyuria generally indicates true infection if other etiologies, such as bacterial infection, have been excluded. Infection may also be diagnosed by demonstrating the presence of a typical appearing fungus in biopsy specimens obtained during cystoscopy.

Of particular importance for treatment is whether candiduria represents colonization or true infection, and whether the upper urinary tract is involved, a distinction that can be troublesome. Those with risk factors for ascending infection (diabetes, stones) and those at risk for disseminated disease are more likely to have upper urinary tract infection. Computerized tomographic scans or ultrasound may reveal microabscesses or fungus balls.

### **Treatment**

When treating *Candida* infection of the urinary tract, careful consideration must be given to whether candiduria represents colonization or true infection, and whether the upper urinary tract is involved. Asymptomatic candiduria usually does not require antifungal treatment, but indwelling catheters should be removed as soon as possible. (Treatment is summarized in [Box 73-6](#).) In the presence of pyuria, diabetes mellitus, or renal transplantation, treatment is indicated. Oral fluconazole is recommended as the initial agent. Bladder irrigation with amphotericin B is also effective. Patients with candiduria should be treated prior to instrumentation of the urinary tract.

In patients with evidence of systemic toxicity, *Candida* infection at other sites, risk factors for ascending infection (structural or metabolic abnormality of the urinary tract such as stones or diabetes), or risk factors for disseminated candidiasis (burns, neutropenia, or GI surgery), consideration must be given to the possibility of upper urinary tract infection or disseminated candidiasis. Upper urinary tract involvement usually will respond to oral fluconazole, although intravenous amphotericin B is required for infections resistant to fluconazole or unresponsive to initial fluconazole treatment. Fungus balls and large perinephric abscesses may require surgical intervention. Treatment of disseminated candidiasis is discussed next.

## **CANDIDEMIA & DISSEMINATED CANDIDIASIS**

### **Introduction**

Candidemia may present in a variety of fashions, ranging from asymptomatic to fulminant sepsis. The candidemic patient generally has risk factors for infection, such as malignancy, chemotherapy-induced neutropenia, organ transplantation, GI surgery, burns, indwelling catheters, or exposure to broad-spectrum antibiotics.

Disseminated candidiasis must be assumed to be present in those with positive blood cultures, although negative cultures do not preclude the possibility of disseminated disease. Dissemination usually manifests with many microabscesses involving multiple organs, especially the liver, spleen, and eye, but almost any organ may be involved ([Box 73-2](#)).

### **Diagnosis**

Candidemia is diagnosed by recovering *Candida* species in blood culture. Candidemia may be isolated or may occur in the setting of disseminated candidiasis. The possibility of disseminated candidiasis should be considered in any patient with deep *Candida* infection, multiple sites of infection, or positive blood cultures. Disseminated candidiasis is diagnosed by tissue culture of biopsy material or demonstration of *Candida* in histologic specimens. At present, serology is available but has false-negative and false-positive rates too high to be of use clinically.

### **Treatment**

The treatment of candidemia is the subject of much debate and controversy. Because isolation of *Candida* from the blood carries a high morbidity and because there is currently no method to predict which patients will not require treatment, there is

agreement that all patients with candidemia should be treated. The standard treatment in the past has been amphotericin B, with or without 5-FC. Currently, fluconazole appears to be a reasonable alternative, although there are limited data comparing mortality of fluconazole-treated patients versus those treated with amphotericin. One randomized study of candidemic patients demonstrated fluconazole to be equally efficacious but associated with less toxicity when compared with amphotericin.

Fluconazole may be used as initial treatment of candidemia in a stable patient ([Box 73-7](#)). If patients had been treated with fluconazole for 2 days or greater at the time of candidemia, deteriorate on fluconazole therapy, or are unstable (hypotension, need for mechanical ventilation, multiple comorbid factors, etc.) at the time their candidemia is diagnosed, then treatment with amphotericin is warranted. Smaller doses may be used if amphotericin is chosen as the initial regimen for stable patients. Because of the potential bone marrow toxicity of 5-FC, particularly when combined with amphotericin, the dose of 5-FC is generally reduced when part of the treatment regimen. Treatment is generally continued until clinical improvement is seen and for 2 weeks after the last positive blood culture.

For all patients with candidemia, the possibility of disseminated infection must be considered. If infection with *C krusei* is suspected or documented, fluconazole should not be used as initial therapy because this species has a high level of resistance to fluconazole. *C glabrata* has an intermediate level of resistance, and fluconazole therapy may be used with caution. Clinical deterioration should prompt an early change of therapy to amphotericin. Treatment for disseminated disease should continue until there is definite resolution of parenchymal involvement and for 2 weeks after the last positive blood culture.

Intravenous catheters should be removed from candidemic patients if possible. In addition, all patients with candidemia should be followed clinically for at least 3 months, as deep infection caused by hematogenous spread may not manifest initially. Patients should be instructed to report any symptoms, which may represent late complications, such as fever, fatigue, jaundice, visual disturbances, abdominal pain, or bone pain.

## **CANDIDA ENDOCARDITIS**

### **Introduction**

Endocarditis caused by *Candida* species has been reported with increasing frequency, particularly after valvular surgery. Other predisposing factors include underlying valvular disease, concomitant bacterial endocarditis, intravenous drug use, intravenous catheters, and chemotherapy. Aortic and mitral valves are commonly infected. The symptoms are similar to that of bacterial endocarditis with fever, malaise, weight loss, and signs and symptoms of embolic phenomena. Splinter hemorrhages, Osler's nodes, Janeway lesions, hepatosplenomegaly, hematuria, proteinuria, and pyuria may all occur. *Candida* has the ability to cause large vegetations and large emboli, which may be catastrophic, and valvular lesions may progress to cause perforation, congestive heart failure, and myocarditis ([Box 73-2](#)).

### **Diagnosis**

Blood cultures are generally positive in *Candida* endocarditis, although negative cultures may occur in up to 25% of patients. Echocardiography reveals vegetations, which may become quite large. Transesophageal echocardiography is more sensitive for detection of vegetations than transthoracic echocardiography. The role of serologic tests (*Candida* antibodies) is uncertain, as both false positive and false negative results occur with some frequency.

## Treatment

Treatment of *Candida* endocarditis generally requires combined surgical and medical therapy. Once the diagnosis is established, therapy with amphotericin B should be initiated and the valve replaced as soon as possible ([Box 73-8](#)). Antifungal therapy is generally required for a total of 6-10 weeks, and patients should be monitored for a minimum of 2 years after completion of therapy because of the high risk of relapse. For those in whom surgical treatment is not possible, such as those too ill to survive an operation, there exist case reports of treatment success with medical therapy alone (amphotericin B followed by fluconazole).

## GI CANDIDIASIS (NONESOPHAGEAL)

### Introduction

*Candida* species may infect any mucosal surface of the GI tract. After esophageal candidiasis, infection of the stomach is most common. Typically, the organism is seen infecting benign ulcers, although a diffuse mucosal form of infection resembling thrush has been described. In the small and large bowel, ulceration and pseudomembrane formation are common. Mucosal GI involvement may cause deep ulcerations with resulting hemorrhage or perforation ([Box 73-1](#)).

*Candida* may also infect the peritoneum, liver, spleen, gallbladder, or pancreas. Peritoneal infection is associated with peritoneal dialysis, GI surgery, and GI perforation. Dissemination beyond the abdomen is uncommon. Involvement of the liver, spleen, and pancreas occurs most commonly in immunocompromised hosts, particularly with chemotherapy-induced neutropenia. Often, other manifestations of disseminated candidiasis are present. Fungus balls may form in the gallbladder and biliary tree and cause obstruction. Abscesses may involve the liver and spleen.

### Diagnosis

Involvement of nonesophageal mucosal involvement of the GI tract is generally diagnosed by characteristic appearance during endoscopy and by demonstration of *Candida* by histology or culture of biopsy specimens. Involvement of the peritoneum, liver, spleen, gallbladder, and pancreas may be difficult to diagnose. Fluid returned after peritoneal dialysis may grow *Candida* in culture. Computer tomography or magnetic resonance imaging may reveal splenic or hepatic abscesses. Laparoscopy may be required for definitive diagnosis.

### Treatment

Fluconazole is recommended for initial therapy of mucosal involvement in the stomach, small intestine, or colon ([Box 73-9](#)). Amphotericin B may also be used. *Candida* peritonitis may also be treated with fluconazole alone or amphotericin B followed by fluconazole. Peritoneal dialysis catheters should be removed if possible. For patients with a perforated viscus, prophylactic therapy is not indicated and should be reserved for those patients with intraoperative findings consistent with *Candida* infection and positive peritoneal cultures.

Involvement of the liver, spleen, gallbladder, or pancreas should be treated with fluconazole or amphotericin followed by fluconazole. Dosages and duration of therapy are the same as for candidemia and disseminated disease. Large abscesses and fungus balls may require drainage or surgical removal.

## **OTHER *CANDIDA* SYNDROMES**

### **Introduction**

*Candida* species are capable of causing many other infectious syndromes, which will be mentioned briefly. Infection of the respiratory tract may result in bronchopneumonia or diffuse nodular infiltrates. Within the central nervous system (CNS), *Candida* spp. may cause meningitis and parenchymal abscesses, usually as part of a disseminated infection. *Candida* spp. have been described as the etiologic agents for osteomyelitis, septic arthritis, myositis, and chondrochondritis. Ocular infection may involve any structure within the eye and is common following hematogenous dissemination.

### **Diagnosis**

The diagnosis of *Candida* infection of the lung, CNS, musculoskeletal system, or eye generally requires demonstration of the organism by tissue culture or on histologic examination. However, visualization of the typical well-demarcated white retinal or vitreal lesion by fundoscopic examination in the setting of positive blood cultures is adequate for the diagnosis of *Candida* endophthalmitis. It should be noted that sputum culture is generally not sufficient for diagnosis of respiratory involvement, particularly in an intubated patient, as the organism may only be colonizing the respiratory tract.

### **Treatment**

Amphotericin B has been the standard treatment for *Candida* infection in the CNS, eye, lung, and musculoskeletal system. Prosthetic material or other foreign bodies should be removed, if possible. The role of 5-FC is not clear, but it may be added to amphotericin. There is growing support for the use of the azole class, particularly fluconazole, as treatment for deep *Candida* infection. While case reports of success with fluconazole exist, there are very limited data regarding fluconazole in these settings and virtually no data comparing fluconazole with amphotericin.

### **Prevention & Control of *Candida* Infections**

*Candida* species are ubiquitous; thus prevention of disease is best accomplished by

elimination of risk factors as opposed to elimination of the organism ([Box 73-10](#)). Antibiotic therapy should be focused to treat specific organisms whenever possible. Indwelling vascular and bladder catheters should be removed as early as possible. In the hospital environment, health care professionals should practice good hand washing to minimize introduction of *Candida* infection to patients at risk.

The role of prophylactic therapy is unclear but generally not supported. Prophylactic therapy has been shown to reduce mortality in bone marrow transplant patients but not in any other setting. Prophylactic therapy for candidemia may be warranted in patients' with negative blood cultures who have multiple risk factors for infection and have isolation of *Candida* from multiple sites but is generally discouraged because of concern for creating resistant organisms. Empiric therapy may also be employed in certain settings, such as neutropenic patients who remain persistently febrile for 7-14 days despite broad spectrum antibiotics and exclusion of other possible causes of infection or in patients with two or more risk factors for invasive *Candida* infection and isolation of *Candida* from sputum or urine. Fluconazole is the preferred agent in these settings.

## **BOX 73-6. Treatment of Urinary Tract Candidiasis**

### **Asymptomatic Candiduria**

- Remove prosthetic material (e.g., urinary catheters)
- No antibiotic therapy required unless patient is diabetic, neutropenic, transplant recipient, has anatomic abnormality of GU tract, or is undergoing GU procedure
- Fluconazole 200 mg PO on first day, then 100 mg PO every day x 4 days
- Amphotericin bladder irrigation<sup>1</sup>

### **Upper Urinary Tract Infection**

- Fluconazole 400-800 mg PO/IV every day<sup>2</sup>
- Amphotericin B 0.8-1.0 mg/kg/day IV<sup>2</sup>
- Remove bladder catheters if possible
- Fungus balls or large perinephric abscesses may require surgery
- Rule out disseminated Candidiasis

<sup>1</sup>Amphotericin 50 mg in 1 liter sterile water infused at 40 mL/hour through continuous infusion/drainage system.

<sup>2</sup>Treatment continued until clinical improvement, definite resolution of parenchymal involvement, and for 14 days after any positive blood cultures.

---

## 74 . *Cryptococcus neoformans* — James J. Chamberlain, MD & Donald L. Granger, MD

### Essentials of Diagnosis

- Routine laboratory tests often normal.
- One-third of patients are afebrile.
- Definitive diagnosis made by fungal culture maintained at 37°C for 6 weeks.
- Cryptococcal antigen 95% sensitive in CNS infection in centrifuged CSF.
- India ink examination positive in only 50% of meningoencephalitis cases.
- CSF lymphocytes often low in CNS infection, especially in AIDS patients.
- Cryptococcal antigen most sensitive detection method in serum.
- Chest radiograph variable—multiple areas of infiltration in lower lobes most common in pulmonary disease.
- Molecular detection by PCR might soon become laboratory standard.

### General Considerations

**A. Epidemiology and Ecology.** *Cryptococcus neoformans* exists as two distinct varieties known as variety *neoformans* and variety *gattii* ([Table 74-1](#)). *Cryptococcus neoformans* variety *neoformans* exists throughout the world and is found frequently in pigeon droppings that have accumulated over time. The concentrations of these organisms are often quite high in old pigeon droppings found in barns, on window ledges, and around the upper floors of old buildings. Pigeons carrying the organism do not seem to be clinically affected, and wet or fresh droppings rarely contain *C neoformans*. *C neoformans* variety *neoformans* has been isolated from the droppings of other birds as well, including parakeets and canaries.

The variant *gattii* has been isolated most frequently from tropical and subtropical climates, most commonly in Australia, Southeast Asia, Brazil, Venezuela, Zaire, and southern California. This finding appears to be related to the distribution of the river red gum tree (*Eucalyptus camaldulensis*), which harbors the organism. Infectivity correlates with flowering of eucalyptus trees. The organism does not cause outbreaks or clusters of infection, and a lack of history of exposure to bird droppings or flowering Eucalyptus trees should not exclude the diagnosis of *Cryptococcus* infection—or "cryptococcosis."

AIDS and the use of immunosuppressive drug therapy have produced a dramatic rise in the number of infections due to *C neoformans* over the past 25 years (see [Chapter 40](#)). In fact, more cases of cryptococcosis were described in the United States in 1976 (338

cases) than had been described worldwide by 1955 (~ 300 cases). Prior to the AIDS epidemic, nearly half of the cases of *Cryptococcus* infection were described in patients with altered cellular immunity, including leukemias, lymphomas, sarcoidosis, and chronic corticosteroid use, and in immunosuppressed patients who had undergone organ transplantation. It is interesting that nearly every case of cryptococcosis in patients with AIDS has been caused by the variety *neoformans*. This phenomenon has led to a dramatic increase in the incidence of cryptococcosis caused by variety *neoformans*, especially in central Africa, where the majority of infections were caused by variety *gattii* before the AIDS epidemic. The reason for this skewed epidemiologic finding remains speculative at this time.

Cryptococcosis remains the most common life-threatening fungal infection seen in patients with AIDS and usually is seen in patients with CD4 counts of < 100 cells/mm<sup>3</sup>. Estimates of the prevalence of cryptococcosis in patients with AIDS range from 6% to 10%. *C. neoformans* is also the third most common organism affecting the central nervous system (CNS) in AIDS cases. Considerable variation seems to exist in the frequency of cryptococcosis among AIDS patients in different regions of the world, with as few as 3% of patients being infected in parts of Europe but possibly = 30% of sub-Saharan Africans being affected. Males are affected approximately threefold as often as females, regardless of the presence of AIDS.

**B. Microbiology.** *Cryptococcus neoformans* is an encapsulated, yeastlike fungus that reproduces by budding. During budding, one or two daughter cells are often seen being released but are still connected to the mother cell by a thin pole of extracellular polysaccharide material.

Encapsulated yeast cells generally appear round or oval shaped in tissue samples and are usually 4 to 8 μm in size. *Cryptococcus* cells may be as large as 15 μm as they begin to bud. The size of the polysaccharide capsule encircling the organism varies greatly and depends mainly on surrounding growth conditions. The size of the capsule in vitro does not correlate with virulence of a particular strain.

*C. neoformans* grows at 37 °C on Sabouraud's or malt extract agar, a characteristic that distinguishes this species from other nonpathogenic *Cryptococcus* species. The organisms are usually visible within 72 h as white or tan-colored, mucoid, smooth colonies.

The variety *neoformans* comprises capsular serotypes A and D, and variety *gattii* capsular serotypes B and C. The two varieties of *C. neoformans* may be distinguished on canavanine-glycol-bromthymol blue agar. Variety *gattii* grows to produce a color change to cobalt blue; variety *neoformans* does not grow, and the indicator remains yellow. In addition, *Cryptococcus* spp. hydrolyze urea and assimilate maltose, sucrose, glucose, and galactose, but not lactose. Carbohydrates are not fermented by species in this genus. *C. neoformans* produces melanin from catecholamines by phenoloxidase. This enzyme has recently been cloned and characterized. It is a type of laccase. Melanin production has been shown to be a virulence factor.

**C. Pathogenesis.** *C. neoformans* is thought to be acquired by humans through inhalation of infected particles from bird droppings (var. *neoformans*) or from flowering

*Eucalyptus camaldulensis* trees (var. *gattii*). Some infections caused by *C neoformans* may be the result of reactivation of latent infection, although this point is controversial. There is no evidence that acquisition occurs directly from other humans or animals. Soil that is contaminated with the organism, when disturbed by wind, allows the organism to become airborne. Inhaled *C neoformans* particles, often < 2  $\mu\text{m}$  in size, are usually deposited in the lungs and quickly phagocytized by alveolar macrophages. This cellular response in normal hosts usually results in inapparent infection. Whether the organism is usually eradicated at this stage is not known, but anecdotal reports suggest that a dormant state may occur in some individuals. It is during the primary exposure that a defect in cellular immunity or a particularly large inoculum may lead to the proliferation and dissemination of the organism, most commonly to the CNS.

The main factors responsible for virulence include (a) the surrounding polysaccharide capsule, (b) the enzyme phenoloxidase, (c) ability to grow at 37°C, and (d) alpha mating type. The polysaccharide capsule has been shown to impair host phagocytosis and may impede migration of leukocytes. Phagocytic cells may be unable to engulf heavily encapsulated organisms due to the size of the pathogen. Capsular elements also activate the complement system, which probably has a significant effect on host defense, depending on the amount of capsular material surrounding the organism. In addition, the alternative complement pathway could be activated by cell wall components that might deplete host humoral factors locally. Oxidative killing mechanisms of macrophages and neutrophils are important elements of host defense and may be impeded by *Cryptococcus* spp. *C neoformans* produces the enzyme phenoloxidase, which converts hydroxybenzoic substrates to melanin. This activity may protect against oxidative host defenses. The organism has never been shown to produce toxins.

Before the advent of highly active antiretroviral therapy (HAART), cryptococcosis carried a high mortality. During diagnosis and initial treatment with antifungal therapy, = 25% of patients with AIDS died. At 1 year after diagnosis of *C neoformans*, 30-60% of patients with AIDS died from the disease. Cancer patients diagnosed with cryptococcal meningitis have a median overall survival of only 2 months. These findings serve to emphasize the importance of immunocompetence in susceptibility to cryptococcosis and its correlation with severity of either AIDS or lymphoreticular malignancy.

## Clinical Findings

### A. Signs and Symptoms.

**CNS Infection.** The most common clinical manifestation of *C neoformans* infection is chronic infection of the brain and meninges, termed meningoencephalitis. The use of this term has become customary because cryptococcal organisms truly invade the cerebral, cerebellar, and brain stem parenchyma as well as the meninges.

The most common symptom of meningoencephalitis is headache. Signs of meningeal inflammation including stiff neck and photophobia are present in ~ 50% of patients but are usually mild. Malaise, dizziness, and nausea may be present as well. As the disease progresses over several weeks, patients may develop altered mental status, visual loss, cranial nerve palsies, ataxia, seizures, coma, and brain stem herniation. Signs and

symptoms of increased intracranial pressure may predominate, including severe headache, neck stiffness, projectile vomiting, altered consciousness, and papilledema. Many patients with cryptococcosis never have fever.

**Pulmonary Infection.** Pulmonary disease is another potentially fatal manifestation of infection with *C neoformans*. However, the majority of patients probably experience subclinical disease, with half experiencing no symptoms. Still, the scope of disease may range from acute, self-limited pneumonia in otherwise healthy individuals or chronic, stable colonization in patients with underlying lung disease to a severe, progressive pneumonia in AIDS patients, with mortality approaching 50%. The most common symptoms seen in pulmonary infection include dry cough, low-grade fever, sputum production, and pleuritic chest pain. Pleural effusions are rarely seen on chest radiograph. Dissemination to the CNS should probably be regarded as the most serious complication of pulmonary cryptococcosis and may occur during any stage of pulmonary infection, even as the pulmonary disease seems to be resolving.

**Other Infections.** *C neoformans* may affect other organ systems as well. Skin lesions may be observed in = 10% of patients and signify disseminated disease with a high risk of CNS involvement. Up to 5-10% of patients have skeletal involvement with cryptococcosis. The vertebrae and long bones are most often affected. Cryptococcosis may affect the eyes, adrenal cortex, genitourinary system, gastrointestinal system, and most any other organ system in rare instances.

**D. Infections in AIDS or Immunocompromised Patients.** In patients who are infected with the human immunodeficiency virus (HIV), cryptococcosis is considered an AIDS-defining illness. The clinical course of CNS infection in AIDS patients seems to be more acute, with fever and headache being prominent early in the course. Findings are similar to those seen in non-AIDS patients as the disease progresses but may develop more rapidly. The vast majority of AIDS patients have meningoencephalitis at the time of diagnosis with cryptococcosis. Pulmonary disease seems to produce symptoms more commonly in patients with AIDS, with a greater proportion experiencing fever, cough, dyspnea, and weight loss. *Cryptococcal* organisms may be cultured from areas outside the CNS in < 20% of AIDS patients. Skin lesions are seen more commonly in AIDS patients and often resemble the papules seen in molluscum contagiosum infection. Liver and spleen involvement is probably more common in AIDS patients but is nonetheless rare.

**B. Laboratory Findings.** Routine laboratory tests including leukocyte counts, hematocrit, and blood chemistries are often normal in cryptococcosis, even in severe infections. Molecular identification of *C neoformans* in serum and other fluids and tissues by polymerase chain reaction may soon become standard practice in many laboratories.

**CNS Infection.** The diagnosis of *C neoformans* infection of the CNS is made definitively by fungal culture of the pellet of centrifuged CSF. Culture media should be maintained aerobically at 37°C for 6 weeks before a culture is deemed negative. Cryptococcal antigen is positive by latex agglutination nearly 95% of the time in the supernate of centrifuged CSF. Serial dilutions of CSF run by latex agglutination allow titers to be reported, which may be useful in assessing prognosis or monitoring response to therapy

in patients who are not immunocompromised. Antigen titers do not seem to correlate with severity of infection or response to treatment in patients with AIDS. The presence of cryptococcal antigen in serum is suggestive but not diagnostic of CNS disease in non-AIDS patients. However, = 95% of AIDS patients with documented CNS infection will have positive cryptococcal antigen in serum. Positive identification of cryptococcal organisms in CSF by India ink preparation occurs in = 50% of cases of meningoencephalitis. Lymphocytes in the CSF are present in low numbers, especially in AIDS patients. One study of cryptococcal meningitis in patients with AIDS showed an average of four lymphocytes/mm<sup>3</sup> in the CSF. CSF glucose is generally low but may be normal. Protein in the CSF is usually elevated, as is the opening pressure. Computed tomography and magnetic resonance imaging may detect the presence of nodules (cryptococcomas), hydrocephalus, or gyral enhancement. Nearly 50% of patients may have an abnormal computed tomography scan. Cryptococcomas may be seen in = 25% of patients with meningoencephalitis.

**Pulmonary Infection.** Diagnosing the presence of *C neoformans* in the lung is less satisfying and more difficult to interpret. Colonization with cryptococcal organisms has often been noted on repeated cultures of sputum from patients with chronic pulmonary disease. Culture of sputum or bronchoalveolar lavage should be considered the gold standard for diagnosis of pulmonary cryptococcosis. Patients with symptoms of pulmonary disease and cryptococcal antigen titers = 8 on bronchoalveolar lavage specimens should be considered to have pulmonary cryptococcosis. The chest radiograph may not necessarily be helpful in the diagnosis of suspected pulmonary disease. Most commonly, chest radiographs are normal or show a nonspecific pattern of interstitial infiltrates and lymphadenopathy. Occasionally, patients have multiple large, dense nodules that are subsequently found to be caused by cryptococcosis. Pleural effusions are rarely noted on chest radiographs.

The diagnosis of disseminated infection in the bloodstream—or "cryptococemia"—is best made based on the presence of cryptococcal antigen, as detected by latex agglutination or by cultivating the organisms using "isolator" blood cultures. The capsular polysaccharide becomes soluble in the serum of infected patients and may be detected with rabbit anti-*C neoformans* antiserum with ~ 95% sensitivity. Antigen titers = 8 are thought to signal active disease. This method of detecting *C neoformans* infection is more sensitive than culture or India ink stain, which are roughly 75% and 50% sensitive, respectively. False-positive antigen detection may occur in patients with rheumatoid factor in their blood or by cross-reaction with the polysaccharide antigen of *Trichosporon beigelii*.

**Other Infections.** Skin and mucosal lesions, which may be secondary to disseminated cryptococcosis, should be biopsied for both histologic diagnosis and culture. Skeletal lesions should be biopsied as well if the diagnosis is in doubt.

## Treatment

The treatment of patients with cryptococcosis is determined by whether they are HIV positive or negative and whether they have localized pulmonary or disseminated (usually meningitis) involvement.

**A. HIV-negative patients.** For mild to moderate pulmonary infection without evidence of dissemination, oral fluconazole for 6-12 months is adequate ([Box 74-1](#)). In meningitis, cryptococemia, or severe pulmonary infection, preferred treatment includes a combination of amphotericin B plus 5-flucytosine for 2 weeks followed by oral fluconazole daily for a minimum of 10 weeks ([Box 74-1](#)). 5-Flucytosine is given every 6 h. Serum levels should be monitored and the dose adjusted to give 20-40 ug/ml peak concentrations. Complete blood counts are required to detect toxicity and should be done twice per week.

Amphotericin B is limited by significant adverse effects and complications including infusion-related toxicity, nephrotoxicity, and hypokalemia. 5-Flucytosine causes myelosuppression, most notably thrombocytopenia and neutropenia, as well as gastrointestinal complaints.

**B. HIV-positive patients.** For mild to moderate pulmonary infection, lifelong daily fluconazole is recommended ([Box 74-2](#)). Alternatively, a combination of fluconazole plus 5-flucytosine may be given for 10 weeks.

Treatment of CNS with severe pulmonary or disseminated involvement of other body sites consists of two phases. First, induction/consolidation therapy is given to control the infection and reduce viable cryptococci in CSF and tissues to an undetectable level. This is followed by maintenance therapy, which prevents relapse. It is currently unclear whether maintenance therapy may be discontinued in patients with prolonged successful HAART. Induction/consolidation therapy is with amphotericin B plus 5-flucytosine for 2 weeks followed by fluconazole for 10 weeks. Maintenance therapy consists of daily fluconazole for life ([Box 74-2](#)).

Drug interactions are an important consideration when azole antifungal drugs are used. In one case, a coadministered drug (eg, omeprazole) may decrease gastrointestinal absorption (eg, of itraconazole) or increase metabolism (eg, of fluconazole by rifampin), rendering antifungal therapy less active. Conversely, azoles may lead to unexpected toxicity of the coadministered drug (eg, warfarin) by altering hepatic metabolism via a cytochrome P-450 system. Drug interactions in HIV-infected patients taking complex therapeutic regimens require careful review when therapy with an antifungal drug, especially an azole, is initiated.

Another important consideration in the treatment of cryptococcal meningitis is that of increased intracranial pressure. A large proportion of deaths, especially early in the course of disease, are attributable to elevated intracranial pressure. Patients who present with or develop coma or other signs of increased intracranial pressure should undergo daily lumbar puncture with removal of 30 cc of CSF until symptoms resolve. Treatment with acetazolamide and ventriculoperitoneal shunting has been tried as well. The effect of these interventions on mortality is not known.

## Prognosis

Cure of CNS cryptococcosis in AIDS patients is rare. Consequently, management is aimed at long-term suppression therapy. The effect of HAART on ability to cure cryptococcosis is unknown. Close follow-up throughout the course of initial therapy and

maintenance therapy is imperative in AIDS-associated CNS cryptococcosis to monitor for relapse. Immunosuppressed patients with neoplastic disease may also be difficult to cure and require long-term suppressive therapy. In others the mortality rate of treated CNS infection may be 25-30%, although this varies in different series. Often prognosis is largely influenced by the underlying immunosuppressive condition, for example, in lymphoreticular malignancies.

Factors signaling a poor prognosis include abnormal mental status, advanced age (> 60 years), cryptococemia, high titers of cryptococcal antigen in CSF or blood, and CSF measurements of high opening pressure, low white blood cell count (< 20 cells/mm<sup>3</sup>), low glucose, and a positive India ink preparation. Serious morbid complications include chronic brain syndrome with dementia and acute and chronic hydrocephalus.

### **Prevention & Control**

Prophylaxis for cryptococcosis is not currently recommended. However, in AIDS patients with CD4 counts of < 200 cells/mm<sup>3</sup>, the incidence of cryptococcosis has been reduced from 7% to 1% in patients taking fluconazole (200 mg PO daily). Having AIDS patients or other immunocompromised patients avoid areas that are heavily populated with pigeons may be appropriate. The use of active immunization with capsular polysaccharide has not been successful.

## **75 . *Aspergillus*, *Pseudallescheria*, & Agents of Mucormycosis — Michael R. Keating, MD**

### **ASPERGILLUS INFECTION**

#### **Essentials of Diagnosis**

- Filamentous fungus with septate hyphae 3-6 um in diameter.
- Branching of hyphal elements typically at 45° angle.
- Specific IgG antibodies generally of no use diagnostically since most patients are immunosuppressed and will not generate antibody response.
- Pulmonary lesions, localized or cavitory in susceptible host.

#### **General Considerations**

**A. Epidemiology.** *Aspergillus* spp. are found worldwide and grow in a variety of conditions. They commonly grow in soil and moist locations and are among the most common molds encountered on spoiled food and decaying vegetation, in compost piles, and in stored hay and grain. *Aspergillus* spp. often grow in houseplant soil, and such soil may be a source of *Aspergillus conidia* or spores in the home, office, or hospital setting. The airborne conidia are extremely heat resistant and can withstand extreme environmental conditions.

Most human disease with *Aspergillus* spp. is acquired via inhalation of conidia. Conidia are 2.5-3 um in size and can easily reach the alveoli with inhalation. Other routes of transmission are by direct inoculation of skin, inhalation into the nose and sinuses, or injection into the bloodstream among drug abusers. Person-to-person transmission does not occur.

Nosocomial acquisition is an important problem among severely immunosuppressed, hospitalized patients. Hospital air and air ducts are known sources of *A conidia*. Unfiltered air is more likely to contain spores. Construction, building remodeling, and other forms of environmental disruption have been associated with nosocomial outbreaks of aspergillosis. Potted plants are frequently excluded from patient care areas where high-risk patients may be present.

The most critical determinant for inhalation of *A conidia* progressing to invasive disease is the status of the host defenses. The pulmonary macrophage is the first line of defense against inhaled conidia. Macrophage function may be rendered ineffective by high-dose corticosteroid therapy or other immunomodulating chemotherapy. The tissue neutrophil is also pivotal. Altered phagocytosis or cellular killing by the neutrophil may lead to invasive disease. Neutropenia caused by leukemia, chemotherapy, bone marrow transplantation, or aplastic anemia is a well-known risk factor for invasive aspergillosis. Patients with late stages of HIV infection also are prone to invasive disease. Increased

risk is also associated in children with chronic granulomatous disease and in patients with poorly controlled diabetes mellitus.

**B. Microbiology.** *Aspergillus* spp. are rapidly growing filamentous fungi or molds that are ubiquitous in the environment and found worldwide. The septate hyphae are characteristically 3-6  $\mu\text{m}$  in diameter and usually branch at 45° angles. Growth usually occurs in the laboratory within 2-3 days. Of the > 500 species of *Aspergillus*, only a few cause human infection. *A. fumigatus* is the most common human pathogen. Others, such as *A. niger*, *A. flavus*, and *A. terreus*, can also cause human infection but are encountered less frequently. Isolated cases have been caused by a number of other *Aspergillus* spp. The species of *Aspergillus* are differentiated by the structure of the asexual conidiophore or spore-forming structure on growth in the laboratory.

**C. Pathogenesis.** *Aspergillus* spp. may invade tissue in patients with altered host defenses or may colonize ectopic segments or cavities in the lung. Following inhalation of conidia, in the absence of appropriate host response, hyphal elements invade bronchial tissue with a particular propensity for angioinvasion. Angioinvasion may lead to disseminated invasive aspergillosis involving multiple organs in profoundly immunosuppressed patients. Furthermore, angioinvasion causes hemorrhagic infarction and necrosis of involved tissue. This may result in hemoptysis when there is pulmonary involvement or stroke when the brain is infected. The enlarging site of *Aspergillus* infection with central necrosis has a tendency to cavitate, yielding characteristic findings on imaging studies.

Colonization of preexisting cavitory lesions may lead to the formation of a fungus ball or aspergilloma composed of exuberant filamentous growth of *Aspergillus* spp. The cavity of an aspergilloma is lined by vascular granulation tissue, while the cavity itself contains hyphal elements, inflammatory cells, amorphous debris, and mucus. Superficial invasion of the cavity wall may occur, but dissemination is rare unless the patient also has other risk factors for invasive disease. Erosion into adjacent pulmonary vessels may occur and result in hemoptysis, which on occasion may be massive and result in death.

## CLINICAL SYNDROMES

### INTRODUCTION

Most individuals who are exposed to *Aspergillus* spores are asymptomatic. In fact, inhalation of spores is probably a common event; however, in an at-risk patient, the spectrum of disease caused by *Aspergillus* spp. can range from hypersensitivity phenomenon to colonization to overwhelming and rapidly progressing disseminated life-threatening disease (see [Box 75-1](#)).

### 1. INVASIVE PULMONARY ASPERGILLOSIS

#### Introduction

Invasive pulmonary aspergillosis in the immunocompromised host is among the most serious manifestations of disease caused by *Aspergillus* spp. Key risk factors for invasive aspergillosis include neutropenia, especially profound neutropenia (< 100

neutrophils/mL) and prolonged neutropenia (> 12 days); prolonged high-dose corticosteroid therapy, graft-versus-host disease after bone marrow transplantation, acute rejection after solid-organ transplantation, cytomegalovirus disease after transplantation, advanced AIDS, and poorly controlled diabetes mellitus. On very rare occasions, invasive pulmonary aspergillosis may occur in previously healthy adults or in patients with alcoholic liver disease. Chronic necrotizing aspergillosis is an indolent form of invasive pulmonary aspergillosis that occurs in patients who are less profoundly immunosuppressed than those with the risk factors cited above.

## Clinical Findings

**A. Signs and Symptoms.** Severely immunosuppressed patients with invasive aspergillosis may be completely asymptomatic when the disease is first suspected. The initial clue may only be a positive sputum culture or an abnormal chest x-ray. Nonproductive cough, dyspnea, and chest pain are common among patients with symptoms. Pleuritic chest pain is occasionally seen. Fever is usually present but may be suppressed by corticosteroid therapy. Hemoptysis may develop as a consequence of angioinvasion and, in the appropriate host, should raise the suspicion of invasive pulmonary aspergillosis.

**B. Laboratory Findings.** Hypoxemia is often present in patients with extensive pulmonary involvement. Other laboratory abnormalities are nonspecific. Because of the immunodeficient state, serum antibodies to *Aspergillus* spp. are usually negative. The detection of circulating *Aspergillus* antigen is a promising investigational test but is not yet available commercially. Cultures of the sputum or respiratory secretions are often positive. Unfortunately, recovery of *Aspergillus* isolates from the sputum of otherwise healthy people is occasionally seen so it may be difficult and a challenge to distinguish airway colonization from positive cultures caused by invasive disease. Furthermore, 20-30% of patients with invasive pulmonary aspergillosis will have negative sputum cultures unless serial sampling is done. Positive blood cultures for *Aspergillus* spp. are exceedingly rare.

**C. Imaging.** The chest x-ray findings in patients with invasive pulmonary aspergillosis vary considerably. Focal pneumonitis, diffuse patchy disease, mononodular and multinodular densities, and pleural-based infiltrates may be seen. Rounded nodular infiltrates are the most common finding. Serial chest x-rays may show rapid progression of pulmonary involvement, and cavitation in this setting is common. Computed-tomography (CT) imaging of the chest may show a characteristic halo sign around nodular infiltrates that are highly suggestive of angioinvasive *Aspergillus* infection.

**D. Differential Diagnosis.** The differential diagnosis of a new infiltrative lung process in an immunosuppressed patient is very broad. Other fungi including *Pseudallescheria boydii* and the order Mucorales can cause an identical syndrome. *Nocardia* lung infection can be similar in presentation. Mycobacterial infection is less likely but must be considered. Bacterial infection including that caused by *Staphylococcus aureus* and *Pseudomonas aeruginosa* is possible. *Rhodococcus equi* is a rare but emerging pathogen that presents this way, especially if cavitation is present.

**E. Complications.** The propensity for angioinvasion leads to hematogenous dissemination in undiagnosed or untreated cases. Virtually any organ may be involved (see disseminated aspergillosis).

## Diagnosis

The diagnosis of invasive pulmonary aspergillosis in the immunosuppressed patient is a significant challenge. A definitive diagnosis is established when tissue specimens demonstrate invasive fungal elements (see [Figure 75-1](#)); however, a positive sputum specimen in a high-risk patient and imaging evidence consistent with *Aspergillus* infection should be regarded as presumptive invasive pulmonary aspergillosis and justification for empiric antifungal therapy. In patients with negative cultures or in whom sputum cultures cannot be obtained, bronchoscopy and bronchoalveolar lavage may help establish a microbiologic diagnosis. Bronchoscopic transbronchial biopsy may yield a false negative result due to the patchy nature of pulmonary aspergillosis and to a sampling error of the biopsy. In patients with pleural-based nodular disease, percutaneous lung biopsy may be considered. Pneumothorax and bleeding are potential complications of this approach. Thorascopic or open lung biopsy is the most effective method to establish the diagnosis.

## Treatment

Invasive pulmonary aspergillosis may be a rapidly progressive infection and prompt institution of antifungal therapy is critical once the diagnosis is suspected or confirmed (see [Box 75-2](#)). Amphotericin B remains the drug of choice. Treatment failures are common. Alternatives to amphotericin B include lipid amphotericin B preparations. These preparations are considerably less nephrotoxic than standard amphotericin B and appear to be equally efficacious. Unfortunately, these new lipid preparations are currently exceedingly expensive. Itraconazole is an oral azole with activity against *Aspergillus* spp. Its use should be reserved for patients who are not severely immunosuppressed, who have an indolent or chronic infection, or who are intolerant of amphotericin B therapy. The optimal duration of antifungal therapy is not known, but the cumulative total dose is = 2 g of amphotericin B. In patients with a single focus of pulmonary infection, resection should be considered.

## Prognosis

The prognosis for invasive pulmonary aspergillosis is generally poor. Cure or improvement on therapy is seen in ~ 50% of cases. Response is more likely if neutropenia recovers and immunosuppression is reduced or reversed.

## Prevention & Control

Because invasive aspergillosis in the immunosuppressed or neutropenic patient is difficult to diagnosis and treat, much attention has been focused on prevention as a way of reducing the frequency of infection ([Box 75-3](#)). Two general approaches have been used: reduction of environmental exposure and prophylactic antifungal therapy. *Aspergillus* spp. are an ubiquitous component of dust, building material, and organic debris.

Reducing exposure to at-risk hospitalized patients can be achieved in several ways. Potted plants should be removed from the environment adjacent to at-risk patients. Certain foods, such as cereal and spices, have been found to be contaminated with *Aspergillus* spores and should not be offered to hospitalized patients that are at risk for aspergillosis. Construction in and adjacent to hospitals has been associated with outbreaks of nosocomial aspergillosis. Patients should not be treated in areas of the hospital where construction or remodeling is occurring. If a patient must be transported through areas of construction within the hospital, an efficient mask should be worn by the patient. Efforts should be made to seal areas undergoing construction or remodeling to prevent contamination of the air in patient areas.

HEPA filtration of air has been shown to significantly reduce or eliminate *Aspergillus* spores. Patient rooms with laminar airflow and HEPA filtration appear to be effective in reducing the risk of exposure in the hospital. Unfortunately, the construction and maintenance of HEPA-filtered facilities are very expensive and not available to all patients. Other strategies that have been used include high air exchange rates, surveillance air sampling, positive pressure in the patient's room and immediate environment, and regular filter changing of point-of-use air filtration systems.

The use of intravenous amphotericin B for prophylaxis against *Aspergillus* spp. has been investigated. When given prophylactically at a dose of 1 mg/kg/d, the toxicity is prohibitively high. When used prophylactically at lower doses of 0.1-0.25 mg/kg/d, the toxicity is less, but in most studies, this dosage was insufficient to prevent aspergillosis. The lipid formulations of amphotericin B are attractive for prophylaxis alternatives; however, the high cost of these preparations limit their widespread use.

Among the oral azoles, only itraconazole has sufficient activity against *Aspergillus* to be considered as a viable prophylactic agent. There are limited data confirming its efficacy in preventing aspergillosis in high-risk patients. Moreover, the absorption of itraconazole from the gastrointestinal tract may be inadequate in these patients.

Use of intranasal installation of amphotericin B or aerosolization of amphotericin B was an effective prophylaxis in several small pilot studies. More data are necessary regarding optimal dose, frequency, and duration before this approach can be widely recommended for prophylaxis.

## **2. ASPERGILLOMA**

### **Introduction**

An aspergilloma of the lung may develop in individuals who have preexisting cavitory lung disease caused by conditions such as tuberculosis, sarcoidosis, silicosis, or bronchiectasis. Also known as a fungus ball or mycetoma, aspergillomas can be regarded as heavy *Aspergillus* colonization of the preexisting cavity.

### **Clinical Findings**

**A. Signs and Symptoms.** The most common symptom is hemoptysis, and, on rare

occasions, severe or fatal hemoptysis can develop. Other symptoms are usually related to the underlying lung disease.

**B. Laboratory Findings.** Patients with an aspergilloma of the lung typically have elevated IgG levels specific for *Aspergillus* spp. Sputum smear may show the presence of filamentous fungi, and culture is intermittently positive for *Aspergillus* spp.

**C. Imaging.** The chest x-ray will show typical findings of a fungus ball with an air crescent sign. Both CT and magnetic resonance imaging (MRI) of the chest reveal the fungus ball (see [Figure 75-2](#)).

**D. Differential Diagnosis.** In a patient with a history of prior lung disease, hemoptysis should lead to the suspicion of a fungus ball. Other fungi including *Pseudallescheria boydii* can cause a similar syndrome. Other causes of hemoptysis including tuberculosis, pulmonary embolism, lung cancer, and bronchiectasis need to be considered.

**E. Complications.** Death due to overwhelming hemoptysis is a rare complication of aspergilloma.

## Diagnosis

The diagnosis is established by demonstrating the typical findings on imaging studies and the presence of *Aspergillus* organisms from sputum culture. The other common causes of hemoptysis need to be excluded with the appropriate investigations.

## Treatment

Treatment for aspergilloma must be individualized (see [Box 75-2](#)). For patients with mild hemoptysis, observation alone is warranted. Patients with more significant hemoptysis may benefit from lobectomy, but preexisting lung disease may place the patient at increased risk for surgical complications. There is no role for systemic antifungal therapy. No consistent benefit has been derived from intracavitary installation of amphotericin B.

## Prognosis

Most patients with mild stable hemoptysis do very well. In some patients, the fungus ball may gradually enlarge, and close observation of these patients is warranted.

## 3. DISSEMINATED ASPERGILLOSIS

### Introduction

Disseminated aspergillosis is a life-threatening, usually fatal form of aspergillosis that occurs in immunosuppressed patients. By definition, two or more noncontiguous sites are involved. Most patients with disseminated disease have invasive pulmonary aspergillosis as the primary site of infection. Common sites of dissemination include central nervous system, skin, liver, kidney, skin, and gastrointestinal tract.

## Clinical Findings

**A. Signs and Symptoms.** Patients with disseminated aspergillosis are usually critically ill. There are no typical signs or symptoms of disseminated disease, and findings will depend on the sites of dissemination. Pulmonary symptoms may predominate if invasive pulmonary aspergillosis is present. Altered mental status, particularly when associated with focal neurological findings, is suggestive of central nervous system involvement. Renal and hepatic involvement may be completely asymptomatic. Invasion of the renal artery or vein may cause thrombosis or infarction. Cutaneous involvement may appear as small erythematous papules and microabscesses or as large black necrotic lesions.

**B. Laboratory Findings.** Despite hematogenous route of dissemination, blood cultures are rarely positive. Urine cultures may be positive for *Aspergillus* cells when the kidney is involved. Elevated hepatic enzymes or serum creatinine may reflect involvement of the liver or kidney.

**C. Imaging.** CT imaging or MRI of the brain may show a single lesion or multiple mass lesions. CT imaging of the abdomen may reveal nodules in affected organs. Cavitation is common.

**D. Complications.** The complications of disseminated disease are related to the sites of specific organ involvement. For example, brain abscesses may be associated with mental status changes or seizure, splenic abscesses may be suspected if there is left upper quadrant pain, or complete heart block may be present if there is cardiac involvement. Multiorgan dysfunction often develops.

## Diagnosis

The diagnosis can be suspected in severely immunosuppressed hosts with multiorgan dysfunction. Often the diagnosis is presumptive, but the diagnosis may be confirmed by biopsy of suspected sites of dissemination. Unfortunately, in = 30% of cases of disseminated aspergillosis, the diagnosis is established at autopsy.

## Treatment, Prevention, & Control

The treatment, prevention, and control of disseminated aspergillosis are identical to that of invasive pulmonary aspergillosis.

## 4. ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

### Introduction

Allergic bronchopulmonary aspergillosis is an eosinophilic pneumonia or hypersensitivity reaction, which generally occurs in adults with a prior history of allergic asthma. It is also seen in patients with cystic fibrosis.

## Clinical Findings

**A. Signs and Symptoms.** The presenting symptoms are usually worsening asthma that is difficult to control and cough productive of thick brownish plugs of sputum. Low-grade fever may be present, and some patients may exhibit nonspecific constitutional symptoms such as malaise and fatigue.

**B. Laboratory Findings.** Peripheral eosinophilia is a hallmark of allergic bronchopulmonary aspergillosis and is usually > 1000 cells/mL. Other findings include elevated serum IgE levels, serum precipitans to *Aspergillus fumigatus*, and immediate wheal and flare response to *Aspergillus* skin testing. Culture of the sputum reveals large numbers of *A fumigatus* colonies. Antibodies in both the IgG and the IgE class that are specific for *A fumigatus* are elevated.

**C. Imaging.** Pulmonary infiltrates are commonly seen on chest x-ray and usually involve the upper lobes. Transient recurrent infiltrates may also be seen. CT imaging of the chest is helpful in identifying the presence of central bronchiectasis that may develop in untreated patients.

**D. Differential Diagnosis.** Other common causes of eosinophilic pneumonia include parasitic infestation and drug-induced lung disease. Allergic bronchopulmonary aspergillosis must also be distinguished from a number of idiopathic eosinophilic pneumonias including Löffler's syndrome, chronic eosinophilic pneumonia, Churg-Strauss syndrome, and hypereosinophilic syndrome.

**E. Complications.** Undiagnosed disease may develop into a chronic state typically with involvement in the upper lobes of the lungs. Bronchiectasis, usually involving the central airways, and fibrosis may develop. Hemoptysis with chronic disease is common.

## Diagnosis

The main criteria for establishing the diagnosis of allergic bronchopulmonary aspergillosis are a history of bronchial asthma, presence of peripheral eosinophilia, immediate reaction to *Aspergillus fumigatus* antigen, pulmonary infiltrates on chest x-ray, serum precipitans to *A fumigatus*, elevated serum IgE level, and central bronchiectasis on CT imaging of the chest (see [Table 75-1](#)). Supportive diagnostic criteria include a history of brownish sputum production, sputum culture positive for *A fumigatus*, and elevated antibodies specific for *A fumigatus* of the IgG and IgE class. Microscopic examination of sputum may reveal brown, lancet-shaped crystals originating from the Charcot-Leyden crystal proteins found in the cytoplasm of eosinophils.

## Treatment

Treatment of allergic bronchopulmonary aspergillosis requires corticosteroids therapy ([Box 75-2](#)). After initial control of symptoms, the corticosteroid therapy should be slowly tapered. Itraconazole has been used in some patients who have difficulty controlling allergic bronchopulmonary aspergillosis, but its role is still under investigation. Inhaled corticosteroid therapy does not appear to be effective.

## Prognosis

Recurrent disease is common, and prolonged maintenance of low-dose corticosteroid therapy is required in many patients.

## 5. FARMER'S LUNG

### Introduction

Farmer's lung, also known as extrinsic allergic alveolitis or hypersensitivity pneumonitis, is an allergic inflammatory reaction induced by inhalation of *Aspergillus* spores, often in exposure to mold and hay. It usually occurs after inhalation during an overwhelming exposure to spores. A multitude of other antigenic stimuli can induce a similar syndrome. Other examples of hypersensitivity pneumonitis induced by *Aspergillus* include compost lung, tobacco worker's disease (from mold on tobacco leaves), and malt worker's lung (from moldy barley).

### Clinical Findings

**A. Signs and Symptoms.** Symptoms include cough and shortness of breath, which generally develop 6-8 h after exposure. On occasion, fever and chills may be present. The presentation tends to be acute, but subacute and chronic forms of the disease may be present when there is chronic low-level exposure.

**B. Laboratory Findings.** Neutrophilia may be seen, but eosinophilia is typically not present. *Aspergillus* serum precipitans will be elevated in most cases, but their presence is not diagnostic. Skin testing with *Aspergillus* antigen may be positive but is not diagnostic and is most helpful for epidemiological purposes.

**C. Imaging.** Chest x-ray findings may be normal even in patients with significant symptoms. Conversely, the chest x-ray may show diffuse bilateral pulmonary infiltrates or discrete nodular infiltrates. With more chronic symptoms, pulmonary function testing may show a restrictive pattern.

**D. Differential Diagnosis.** Acute and subacute Farmer's lung will occasionally resemble an infectious pneumonitis. Farmer's lung must be distinguished from other conditions that cause respiratory symptoms and pulmonary infiltrates, including collagen vascular diseases, eosinophilic pneumonitis, and drug-induced lung disease. In its more chronic form, it may resemble idiopathic pulmonary fibrosis and other interstitial lung disorders.

**E. Complications.** Recovery from acute Farmer's lung is the most common outcome. Individuals with chronic exposure and ongoing allergic reaction may develop pulmonary fibrosis with a restrictive pattern seen on pulmonary function testing.

### Diagnosis

The diagnosis should be suspected from the history of exposure and the symptom complex. Laboratory testing can help distinguish *Aspergillus*-induced Farmer's lung from

other causes of Farmer's lung.

### **Treatment**

The optimal treatment for Farmer's lung is removal or avoidance of exposure. In most individuals, the syndrome is self-limited; however, patients with prolonged subacute or chronic symptoms may require prednisone therapy (see [Box 75-2](#)).

### **Prognosis**

In most individuals, symptoms are self-limited, especially when the source of exposure can be avoided or removed. In patients with more chronic symptoms, with exposure avoidance and short-course prednisone therapy, the prognosis is excellent.

### **Prevention & Control**

The cornerstone of prevention of Farmer's lung involves identification and avoidance of exposure to *Aspergillus* spores. Since the majority of individuals will not develop a hypersensitivity reaction after exposure, prevention and control measures only need to be instituted after the initial diagnosis.

## **6. ASPERGILLUS SINUSITIS**

### **Introduction**

*Aspergillus* spp. are capable of causing a variety of infections involving the paranasal sinuses ([Table 75-2](#)). Although uncommon, *Aspergillus* sinusitis is related to the immune status and immunologic response of the host.

**A. Signs and Symptoms.** In the severely immunosuppressed or neutropenic patient, *Aspergillus* sinusitis or rhinosinusitis may occur. Symptoms include headache, toothache, nasal congestion, purulent nasal discharge, and sinus or eye pain. Fever is commonly encountered. The nasal mucosa may exhibit hyperemia or necrosis that may extend into the mouth. Ptosis and loss of extraocular eye movement are prominent signs, indicating extensive invasion into the orbit. Sudden onset of blindness may occur.

In patients with normal immune status and a history of chronic sinusitis, a fungus ball or aspergilloma can form in the sinus. Persistent pain and discharge are common symptoms. An allergic fungal sinusitis may develop in patients with a history of allergic rhinitis and recurrent sinusitis. Facial pain and nasal discharge are predominant symptoms of this syndrome.

**B. Laboratory Findings.** Cultures of nasal secretions are usually positive for *Aspergillus* spp. in patients with invasive and noninvasive forms of sinus infection.

**C. Imaging.** High-resolution CT imaging of the sinuses is essential for assessing the extent of invasive disease. Destruction of bone is common in advanced cases with erosions into the orbit, the brain, or the roof of the mouth. No bony destruction occurs in noninvasive disease.

**D. Differential Diagnosis.** The differential diagnosis of fungal sinusitis varies according to the extent of invasion. Noninvasive sinusitis must be distinguished from neoplasia, inflammatory conditions, and bacterial causes. Other noninvasive fungal pathogens include *Fusarium* spp., *Curvularia* spp., *Bipolaris* spp., and *Pseudallescheria boydii*. Other fungal pathogens capable of causing invasive disease include the order Mucorales, *Fusarium* spp., and *P boydii*.

**E. Complications.** Untreated invasive fungal sinusitis can rapidly develop into the rhinocerebral form with direct invasion into the central nervous system. Angioinvasion may lead to widespread dissemination and death.

## Diagnosis

Aspiration of sinus contents should be cultured and stained for fungal elements. Endoscopic examination of the nose should be considered. High-resolution CT imaging can detect invasion and extent of involvement.

## Treatment

Treatment of invasive sinusitis in the immunosuppressed patient requires a combination of surgical debridement and antifungal therapy. Proper presurgical assessment of the extent of disease is vital to ensure that operative debridement and drainage are adequate. Antifungal therapy with amphotericin B is illustrated in [Box 75-2](#). For noninvasive disease, including chronic sinusitis and sinus aspergilloma, surgical excision and drainage alone are adequate, and systemic antifungal therapy is usually not needed.

## Prognosis

The prognosis of noninvasive fungal sinusitis is excellent after adequate debridement and drainage. For locally invasive disease, the prognosis is fair with debridement and antifungal therapy. The prognosis with extensive invasive disease is poor.

## Prevention & Control

Prevention and control of invasive sinusitis is identical to that for invasive pulmonary aspergillosis.

## 7. OTHER FORMS OF ASPERGILLUS INFECTION

A variety of less commonly encountered infections may occur in both immunocompetent and immunosuppressed patients. Endophthalmitis may occur following surgery or trauma to the globe or as a rare manifestation of invasive disseminated aspergillosis. Osteomyelitis may occur in children with chronic granulomatous disease and in adults who are immunosuppressed. Disk space infection with adjacent vertebral osteomyelitis has been described in both normal hosts and in injection drug abusers. Endocarditis may occur in patients with a prosthetic valve or native valve endocarditis may occur in injection drug abusers. Otomycosis can occur in the setting of chronic external otitis.

In immunosuppressed patients, an invasive form of the disease with extensive bony destruction can occur. *Aspergillus* tracheobronchitis is seen most commonly in lung transplant recipients but can also occur in other immunosuppressed patients (Figure 75-3). Invasive aspergillosis may begin in the skin and disseminate to other sites. For example, focal infection may develop at intravenous catheter sites in neutropenic patients and cause progressive local infection before there is evidence of systemic dissemination.

## **PSEUDALLESCHERIA BOYDII INFECTION**

### **Essentials of Diagnosis**

- Filamentous fungus that is morphologically similar to *Aspergillus* spp.
- Most serious infections occur in immunosuppressed patients.
- Recovery from culture must be distinguished from colonization or contamination.

### **General Considerations**

*P boydii* is a mold that is capable of causing infection in immunosuppressed patients and less frequently in immunocompetent patients. Overall, infection with *P boydii* is rare.

**A. Epidemiology.** Although a relatively common environmental mold, *P boydii* is a rare cause of human disease. It can be easily recovered from soil, water, and manure. Both community and nosocomial acquisition have been documented. In most instances, its recovery from culture specimens will reflect colonization or contamination; however, it is capable of causing serious infection in selected patients. When recovered from clinical specimens, it cannot be dismissed as a nonpathogen without careful consideration of its pathogenic potential in the clinical setting from which it was recovered.

**B. Microbiology.** *P boydii* is a common environmental mold sometimes referred to as *Petrolidium boydii*. It is the sexual spore-producing form of *Scedosporium apiospermum*. In tissue, *P boydii* produces thin septate hyphae that are similar in appearance to *Aspergillus* hyphae. Hence it is not possible to distinguish *P boydii* infection from *Aspergillus* infection based on histopathology, and culture confirmation is necessary to establish the diagnoses and guide therapy.

**C. Pathogenesis.** The portal of entry of *P boydii* is inhalation for lung and sinus infection or by direct inoculation of the skin at the site of trauma. Little is known about specific host defense mechanisms that permit opportunistic infection. Abscess formation and tissue necrosis are the typical findings of infection.

### **Clinical Findings**

Infection caused by *P boydii* is similar to that caused by *Aspergillus* spp. but considerably rarer. Among normal hosts, *P boydii* may cause fungus balls in the sinuses or in the lungs in patients with preexisting cavitary lung disease or chronic sinusitis.

Penetrating trauma may result in soft tissue infection. It is the most common cause of maduromycosis in the United States. Infection involving the globe after penetrating trauma has been reported relatively frequently. A unique syndrome of *P boydii* in normal hosts is an overwhelming pneumonia after near drowning and aspiration of fresh or brackish water. Dissemination to the brain and other tissues has been reported in this setting.

Among immunosuppressed patients, infection occurs in those with prolonged and profound immunodeficiency. Susceptible hosts include those with severe neutropenia, those with prolonged high-dose corticosteroid therapy, children with chronic granulomatous disease, and patients with HIV infection. Clinically and histologically, *P boydii* opportunistic infection in the immunosuppressed patient resembles invasive aspergillosis. This includes the propensity for hematogenous dissemination. Pulmonary infection is the most commonly encountered site of infection, but soft tissue infection, central nervous system infection, and other sites may be seen.

## Diagnosis

Diagnosis of infection with *P boydii* is based on the recovery from biopsy specimens taken from the site of infection. Its recovery from sputum in a susceptible host with an appropriate syndrome is presumptive evidence of infection. Blood cultures are rarely positive.

## Treatment

The microbiologic differentiation of *P boydii* infection from that of aspergillosis is important because *P boydii* is resistant to amphotericin B. The preferred therapy in adults is intravenous miconazole (see [Box 75-4](#)). Miconazole is rarely used to treat other fungal infections because of its substantial toxicity, which includes nausea, vomiting, anemia, and a variety of central nervous system effects. Cardiac arrest while receiving miconazole therapy has been reported. Nevertheless, for life-threatening infections, miconazole remains the drug of choice. Preliminary data suggest that other azoles, such as itraconazole and ketoconazole, are effective. Their use should be reserved for indolent cases or in patients who are intolerant of miconazole. The duration of therapy is not well established and should be based on response to treatment and improvement of underlying predisposing factors.

## MUCORMYCOSIS

### Essentials of Diagnosis

- Filamentous fungus with hyphae of uneven, often very large diameter (5-50  $\mu$ m).
- No or rare septation of the hyphal elements, which branch at irregular angles.
- No availability of antibody or antigen testing to assist diagnosis.
- Often abundant in biopsy or clinical specimens on fungal stain but no growth from fungal cultures.

## General Considerations

Mucormycosis refers to a spectrum of infections caused by fungi of the phylogenetic order Mucorales. These infections are generally quite rare and usually occur in patients with either severe immunodeficiency, uncontrolled diabetes, or trauma.

**A. Epidemiology.** The agents of mucormycosis are ubiquitous in nature and commonly recovered from decaying organic matter. *Rhizopus* spp. are especially common on moldy bread. Nevertheless, in contrast to *Aspergillus* species, the agents of mucormycosis are rarely recovered in the hospital setting.

**B. Microbiology.** Although there are numerous fungi capable of causing mucormycosis, the four most common genera in order of frequency are *Rhizopus*, *Rhizomucor*, *Absidia*, and *Cunninghamella*. These fungi are relatively rapid growing and will grow on most media in the mycology laboratory in 2-5 days. They grow only as mold, and the hyphae tend to be uneven in diameter and often quite large, ranging in size from 5 to 50  $\mu\text{m}$  (Figure 75-4). Branching occurs at irregular angles, in contrast to the 45° angles of branching by *Aspergillus* spp. Septation of the hyphae is usually absent. Environmental specimens often grow rapidly and abundantly, but it is common for no growth to occur from specimens obtained from infected tissue in patients with mucormycosis. The reason for this is unknown.

**C. Pathogenesis.** Although inhalation of spores produced by these fungi is probably a daily occurrence, infection rarely occurs, even among susceptible hosts. Therefore the presumed portal of entry is respiratory with deposition of spores on the nasal mucosa for rhinocerebral mucormycosis and in the alveoli for pulmonary mucormycosis. Gastrointestinal mucormycosis is thought to occur following ingestion of spores, and cutaneous mucormycosis is a consequence of direct inoculation of traumatized skin. Alteration of macrophage and neutrophil function secondary to diabetic ketoacidosis and corticosteroids allows the initial sporulation and filamentous growth. Once tissue invasion is achieved in a susceptible host, the disease can progress at an alarming rate or be quite indolent. Angioinvasion by hyphal elements is common and results in ischemic and hemorrhagic necrosis.

## CLINICAL SYNDROMES

### 1. RHINOCEREBRAL MUCORMYCOSIS

#### Introduction

Rhinocerebral mucormycosis occurs most commonly in patients with uncontrolled diabetes, especially after an episode of diabetic ketoacidosis. It may also occur in leukemic patients who have had prolonged neutropenia and therapy with broad-spectrum antibiotics and occasionally in organ transplant recipients.

#### Clinical Findings

**A. Signs and Symptoms.** The earliest symptoms in rhinocerebral mucormycosis are

facial pain, headache, and nasal stuffiness. As the disease progresses, orbital pain and facial anesthesia may be noted. Double vision or loss of vision may develop after invasion of the orbit by the rapidly spreading infection. Mental status changes herald the penetration into the brain with ensuing cavernous sinus thrombosis, carotid artery thrombosis, and cerebral abscess formation. Serial cranial nerve abnormalities, especially of nerves 5 and 7, can occur.

Physical findings include proptosis of the globe and loss of extraocular movement as orbital involvement progresses. Inspection of the nares may reveal black necrotic tissue indicative of angioinvasion and necrosis. A black eschar on the hard palate is a hallmark of mucormycosis.

**B. Laboratory Findings.** There are no typical laboratory abnormalities associated with the condition except as noted above. The onset of symptoms may occur during the recovery phase of diabetic ketoacidosis. Most leukemic patients that develop this syndrome do so while still profoundly neutropenic. Cultures of nasal secretions or biopsy specimens are commonly negative even when hyphal elements are present.

**C. Imaging.** X-rays of the sinuses are generally insensitive but will demonstrate opacification of one or more sinuses. CT imaging or MRI is an essential part of the evaluation. Bony destruction can be found where disease has extended into the orbit, the mouth, or the central nervous system.

**D. Differential Diagnosis.** Few other conditions are able to produce the syndrome of rhinocerebral mucormycosis in the appropriate patient population. Invasive *Aspergillus* or *Fusarium* sinusitis may cause a similar syndrome, particularly in the neutropenic leukemic patient.

## 2. PULMONARY MUCORMYCOSIS

Pulmonary mucormycosis occurs most commonly in patients with prolonged neutropenia due to chemotherapy for the treatment of leukemia or malignancy. Most of the patients have had antecedent prolonged courses of broad-spectrum antibiotics. It occurs less commonly in diabetic patients and tends to be less fulminant in this setting.

**A. Signs and Symptoms.** The onset of symptoms may be subacute to acute to fulminant. Most patients are critically ill and toxic appearing. Respiratory localization is evident based on the common occurrence of cough and shortness of breath. Pleuritic pain and hemoptysis are common. Fever is usually present and may have an abrupt spiking onset. Physical findings may be absent or reflect focal pulmonary infection.

**B. Laboratory Findings.** Hypoxemia may be present depending on the extent of pulmonary involvement. Sputum cultures may grow an agent of mucormycosis or may be negative.

**C. Imaging.** Chest x-ray may reveal unifocal or multifocal infiltrates or nodules. As the disease progresses, cavitation is very common.

**D. Differential Diagnosis.** Mucormycosis may simulate other opportunistic fungal

infections involving the lung such as invasive pulmonary aspergillosis. At the onset of symptoms, pulmonary mucormycosis can resemble pulmonary embolization caused by the presence of dyspnea, hemoptysis, and pleuritic chest pain.

**E. Complications.** Hematogenous dissemination of infection, particularly in the fulminant form of disease is common. Frequent sites of dissemination include the central nervous system, gastrointestinal tract, spleen, kidneys, heart, and liver. Fulminant disease is almost uniformly fatal, and patients rarely survive > 2 weeks.

### 3. OTHER FORMS OF MUCORMYCOSIS

#### Introduction

Mucormycosis endocarditis is a rare infection that occurs in patients with prosthetic valves. Most of the symptoms are caused by embolization from the large valvular vegetations that form. Valve replacement surgery can be curative. Gastrointestinal mucormycosis develops in patients with profound malnutrition. Involvement of multiple sites in the gastrointestinal tract is seen. Abdominal pain and fever are the usual symptoms. Cutaneous mucormycosis can occur by direct inoculation of the skin in patients with burns, diabetes mellitus, or trauma ([Figure 75-5](#)). The skin may also be a sight of hematogenous dissemination. Hemodialysis patients receiving desferoxamine therapy for aluminum overload are at increased risk for any form of mucormycosis caused by *Rhizopus* spp.

#### Diagnosis

The diagnosis of mucormycosis usually requires demonstration of the organism in biopsy specimens ([Figure 75-6](#)). In the rhinocerebral form of mucormycosis, nasal specimens are usually satisfactory for establishing the diagnosis. The tendency to angioinvasion and tissue necrosis often produces a black eschar that should suggest a diagnosis from physical findings. Open lung biopsy may be necessary to establish the premortem diagnosis of pulmonary mucormycosis in the absence of sites of hematogenous dissemination that may be sampled. In general, the full-blown clinical syndrome in the appropriate host should suggest the diagnosis. It requires a high index of suspicion in the early stages of infection. Culture of infected material may be negative, but staining of biopsy specimens can show abundant angioinvasive hyphal elements, suggesting the diagnosis.

#### Treatment

Once the diagnosis of mucormycosis has been established, the initial approach to therapy should be to correct aggressively any predisposing factors (see [Box 75-5](#)). In patients with diabetic ketoacidosis or hyperglycemia, metabolic abnormalities need to be corrected and controlled. Patients receiving immunosuppressive therapy, especially corticosteroids, should have this reduced as much as possible. Antifungal therapy should be instituted with amphotericin B. The duration of therapy should be based on clinical response. The available azoles do not appear to be effective against the agents of mucormycosis. The newer liposomal preparations of amphotericin B are attractive alternatives to standard amphotericin B because of their reduced nephrotoxicity,

although they are no more effective than the standard preparation. Amphotericin B toxicity is high in patients with mucormycosis because of the high dose required and underlying patient conditions.

In the rhinocerebral form of mucormycosis, aggressive debridement of the involved sinuses, enucleation, and extensive orbital debridement may be necessary. Some patients will require serial debridements that can be quite disfiguring but may improve their chances for survival. Cutaneous mucormycosis should also be aggressively debrided.

## **Prognosis**

Patients with pulmonary mucormycosis, gastrointestinal mucormycosis, or disseminated disease rarely survive. Rhinocerebral infection also has a poor prognosis but with early diagnosis and aggressive surgical and antifungal therapy, survivors have been reported.

## **Prevention & Control**

Fortunately, mucormycosis is rare. There are no proven preventative or prophylactic strategies. Because it is a relatively ubiquitous spore-transmitted fungal infection, many of the strategies used to prevent transmission of *Aspergillus* spp. may be effective in reducing the transmission of the agents of mucormycosis. It is unknown whether antifungal prophylaxis has any impact on the incidence of mucormycosis.

## 76 . *Sporothrix schenckii* — Zelalem Temesgen, MD

### Essentials of Diagnosis

- Cigar-shaped yeast.
- Dimorphic: mycelial in nature, yeast in tissue.
- Associated with activities that involve contact with soil, sphagnum moss, decaying wood, or vegetation.
- Gardeners, forestry workers, miners, animal health care providers most at risk.
- Raised skin lesions with proximal spread along lymphatic channels.
- Recovery of microorganism from culture.

### General Considerations

**A. Epidemiology.** *Sporothrix schenckii*, the causative agent of sporotrichosis, is a ubiquitous fungus commonly found in the soil, on sphagnum moss, on decaying wood, and on a variety of other vegetation. It is found worldwide but prefers a temperate or tropical climate with high humidity. Most cases of sporotrichosis are sporadic, but large human epidemics have been reported. Sporotrichosis has been reported in a variety of animal species including dogs, cats, horses, cows, camels, dolphins, goats, mules, birds, pigs, rats, and armadillo. Most human cases are secondary to vocational exposure. Gardeners, forestry workers, miners, laboratory workers, veterinarians, animal health technicians, and veterinary students are considered most at risk. Cases of zoonotic transmission as well as person-to-person transmission have been reported.

**B. Microbiology.** *S schenckii* is a dimorphic fungus. It forms mycelia (hyphal form) in vitro in temperatures <37 °C. It converts to its characteristic cigar-shaped yeast form in vivo and in cultures incubated at 37 °C. Colonies appear rapidly within 3-5 days of incubation. Moist and white at first, they develop a brown to black pigmentation with prolonged incubation.

**C. Pathogenesis.** Most cases of sporotrichosis result from direct inoculation of the fungus into the skin. Less frequently, access occurs through inhalation of spores leading to development of primary pulmonary infection.

## CLINICAL SYNDROMES

### INTRODUCTION

*S schenckii* causes three distinct clinical syndromes: cutaneous, extracutaneous, and disseminated sporotrichosis ([Box 76-1](#)).

## **CUTANEOUS SPOROTRICHOSIS**

Cutaneous sporotrichosis, the most common form of sporotrichosis, can present in one of two ways. In lymphangitic cutaneous sporotrichosis, lesions appear at the site of direct inoculation of the fungus into the skin. These initial lesions are often raised, erythematous, and warm. The organisms replicate locally, then advance proximally through the lymphatic channels, leading to the development of secondary lesions along these lymphatic channels. In the fixed form of cutaneous sporotrichosis, the organisms replicate locally but do not spread through the lymphatic channels.

Differential diagnosis includes skin infection caused by other fungi, skin infection caused by tuberculosis and atypical mycobacteria, bacterial skin infection, and foreign body granuloma.

## **EXTRACUTANEOUS SPOROTRICHOSIS**

### **INTRODUCTION**

The main extracutaneous sites affected by sporotrichosis are the joints, lungs, and central nervous system. Other less commonly affected sites include the genitourinary tract, ocular adnexa, sinuses, larynx, and vocal cords.

### **1. OSTEOARTICULAR SPOROTRICHOSIS**

The joints commonly affected are the joints of the hand, elbow, ankle, and knee. Onset is insidious, presenting with pain and swelling of a single joint with minimal fever or systemic toxicity. Over time, a sinus tract may develop and, if left untreated, other joints may be involved. Differential diagnosis includes rheumatoid arthritis, gout, and tuberculosis. Joint aspirations and synovial biopsies, often multiple, are required to establish the diagnosis.

### **2. PULMONARY SPOROTRICHOSIS**

Pulmonary sporotrichosis can occur either as a primary lung infection subsequent to direct inhalation of *S schenckii* spores or in the setting of disseminated disease. Onset is insidious and associated symptoms include productive cough, fever, weight loss, fatigue, and malaise. Cavitory or nodular lesions involving the upper lobes, bilateral in about one third of the cases, are noted on chest roentgenograms. Conditions associated with pulmonary sporotrichosis include alcoholism, tuberculosis, chronic obstructive pulmonary disease, diabetes, sarcoidosis, steroid use, and malignancies.

### **3. CENTRAL NERVOUS SYSTEM SPOROTRICHOSIS**

Central nervous system involvement is an uncommon complication of sporotrichosis and has been reported in the setting of alcoholism, AIDS, and Hodgkin's disease. It presents as a chronic meningitis process with headache as the most common feature. Fever and neurologic deficits are unusual. Lymphocytic pleocytosis, a low glucose, and an elevated protein value are noted on cerebrospinal fluid analysis. Repeated lumbar

punctures and cultures of large volume of cerebrospinal fluid are usually required to make a diagnosis.

## **DISSEMINATED SPOROTRICHOSIS**

### **Introduction**

Immunosuppressed individuals, especially those with the acquired immunodeficiency syndrome and those with hematological malignancies, may present with widespread cutaneous disease as well as involvement of multiple organs, including the lungs, joints, and central nervous system. Blood cultures may occasionally be positive. Elevation of the erythrocyte sedimentation rate, anemia, and leukocytosis are noted on routine laboratory evaluation. Culture of skin lesions and joints is usually diagnostic.

### **Diagnosis**

In patients with typical cutaneous syndrome of ascending lymphangitis, demonstration of the characteristic appearance of the microorganism on stains performed on tissue biopsy is highly suggestive of diagnosis. Definitive diagnosis requires recovery of microorganisms from culture. Multiple attempts to isolate the organisms may be necessary.

Several serologic testing procedures such as agglutination tests, ELISA, complement fixation, precipitation, and immunodiffusion tests have been developed to aid in the diagnosis of sporotrichosis. While these may prove to be useful, especially in the diagnosis of meningitis, methodologies have not been standardized, and they have not yet found wide clinical application.

Skin tests are useful only as an epidemiological tool.

### **Treatment**

Several therapeutic modalities such as local treatment, systemic therapy, and surgery have been used for the treatment of sporotrichosis ([Box 76-2](#)).

A saturated solution of potassium iodide (SSKI) is an effective regimen for cutaneous disease. Its mechanism of action is not well understood. SSKI drops are taken orally, and the dose is progressively increased to a maximum tolerated dose. Treatment is continued until the resolution of the skin lesions.

More recently, itraconazole, a triazole antifungal agent, has become the drug of choice for treatment of lymphocutaneous sporotrichosis. As stated above, treatment should be continued until resolution of infection, which usually takes 3-6 months. Itraconazole has been shown to be effective therapy for cutaneous as well as visceral sporotrichosis, with the exception of meningitis.

Osteoarticular sporotrichosis requires treatment with itraconazole or amphotericin B, but relapses can occur. There have been reports of successful treatment of osteoarticular sporotrichosis with intra-articular instillation of amphotericin B. Patients with pulmonary

sporotrichosis should be treated with either itraconazole or amphotericin B, depending on the severity of their infection. Surgical resection may be necessary. Patients with disseminated disease should be treated with intravenous amphotericin B. Itraconazole may be an acceptable alternative if they are not acutely ill.

Terbinafine, an allylamine antifungal agent, has successfully been used to treat both the fixed and lymphatic forms of cutaneous sporotrichosis. Treatment of meningitis caused by *S schenckii* requires the use of intravenous amphotericin B. The addition of 5-fluorocytosine may be necessary. There are no data on the role of azoles in this setting.

Sporotrichosis in the setting of AIDS responds poorly to all therapeutic modalities. Amphotericin B is the drug of choice; itraconazole can be used in less severe cases. After induction therapy with amphotericin B, treatment needs to be continued with itraconazole, indefinitely, to prevent relapse.

Local heat therapy (ie, application of heat, for example, in the form of a warm pack) directly on the affected skin lesion, can be useful either as an adjunct therapy to other forms of therapy or as an alternative treatment in pregnant women, in whom the use of SSKI and azoles is contraindicated.

## Prognosis

Prognosis is variable and difficult to generalize. Disseminated sporotrichosis, if untreated, causes death.

## Prevention & Control

Avoiding direct skin contact with known sources of *S schenckii* (eg, sphagnum moss) and wearing protective gloves and long sleeves in occupational or recreational activities, such as handling of rose bushes, wires, decayed wood, and vegetation, may help prevent sporotrichosis ([Box 76-3](#)).

## 77 . *Fusarium*, *Penicillium*, *Paracoccidioides*, & Agents of Chromomycosis — Michael R. Keating, MD

### **FUSARIUM INFECTION**

#### **Essentials of Diagnosis**

- Worldwide geographic distribution.
- Mold, septate hyphae 3-8 um in diameter.
- A rare infection in severely immunocompromised patients.
- Blood cultures often but not always positive.
- No serologic tests available.
- Cutaneous involvement is common feature.

#### **General Considerations**

**A. Epidemiology.** *Fusarium* spp. is an emerging fungal pathogen. Although long recognized as a cause of local infection involving nails, traumatized skin, or the cornea (eg, in contact lens wearers), deep or disseminated infection was not described until the mid 1970s. Despite its worldwide distribution and its frequent recovery from soil and vegetative material, infection is quite rare. Only ~ 100 cases involving invasive disease in immunosuppressed patients have been described in the medical literature.

Most cases of serious disease occur in patients with hematologic malignancy and chemotherapy-induced neutropenia. Profound neutropenia and prolonged neutropenia increase the risk for infection. The respiratory tract is the most common portal of entry leading to infection, but other sites of acquisition include a disrupted skin barrier, the digestive tract, and a central venous catheter. *Fusarium* onychomycosis also appears to be a potential source of disseminated infection in at-risk patients.

**B. Microbiology.** *Fusarium* spp. are filamentous fungi that are soil saprophytes and plant pathogens. The hyphae range in size from 3 to 8 um and are generally septate. Growth from clinical specimens usually occurs after 4-5 days of incubation in the laboratory ([Figure 77-1](#)). Dichotomous branching is common, and branches usually occur at an angle of 45°. Consequently, *Fusarium* spp. are indistinguishable from *Aspergillus* spp. (see [Chapter 75](#)) when seen in tissue. Although there are many different species, human disease appears to be limited to *F oxysporum*, *F solani*, *F moniliformie*, and *F proliferatum*. Like other filamentous fungi, the different *Fusarium* spp. may be identified by the distinguishing characteristics of their fruiting bodies and microconidia.

**C. Pathogenesis.** The clinical pathogenic pattern of infection caused by *Fusarium* spp. is very similar to that of *Aspergillus* infection. Although much rarer than invasive aspergillosis, the same pathogenic mechanisms that allow *A. conidia* to invade tissue contribute to the development of *Fusarium* infection. Alteration in macrophage function by steroid therapy and neutropenia allow the *Fusarium* microconidia to replicate unimpaired in host tissue. Angioinvasion leads to early dissemination particularly to skin structures. The reason for the marked propensity to disseminate to skin is unknown. Colonization with *Fusarium* spp. without infection is common, particularly among burn patients.

## Clinical Findings

**A. Signs and Symptoms.** Invasive fusariosis usually develops with the abrupt onset of high spiking fevers ([Box 77-1](#)). Although myalgias are a common feature, infection of muscle is uncommon but has been reported. Focal symptoms may depend on the site of infection. Shortness of breath, cough, and hemoptysis are present in patients with pulmonary involvement. Central venous catheter infection may be associated with tunnel tract tenderness or exudation.

Physical findings are also dependent on the extent of invasive disease and sites of dissemination. Almost 80% of patients will have cutaneous involvement. Typically, this will begin as a erythematous indurated maculopapular lesion, which will enlarge and eventually ulcerate, leaving a nodular lesion with a necrotic, often black center ([Figure 77-2](#)). Multiple lesions are commonly seen and may resemble ecthyma gangrenosum. Localization to the extremities is most common. Primary cutaneous fusariosis may present with a single necrotic skin lesion. Multiple skin lesions suggest disseminated disease. A rhinocerebral form of infection has been described that is indistinguishable from rhinocerebral mucormycosis or aspergillosis.

**B. Laboratory Findings.** Neutropenia is usually present at the onset of the signs and symptoms of infection, but there are no other commonly associated hematologic or chemistry abnormalities. Blood cultures are positive in 60% of patients with invasive fusariosis, which is in marked distinction to invasive aspergillosis, where blood cultures are negative. The reason for this difference is unknown. There are no serological tests available for diagnosing *Fusarium* infection.

**C. Imaging.** The chest roentgenogram in a patient with pulmonary involvement may show nonspecific infiltrates, nodular lesions, or cavitary lesions. With rhinocerebral infection, opacification of one or all the sinus cavities and destruction of bony structures can best be imaged with computed tomography. A bone scan may be helpful to determine if there is bone involvement underlying extensive cutaneous involvement.

**D. Differential Diagnosis.** In addition to invasive fusariosis, the differential diagnosis of persistent neutropenic fever includes invasive aspergillosis and other infection with opportunistic filamentous fungi. Although *Candida*, *Aspergillus*, and *Rhizopus* spp. are all capable of causing similar skin lesions in disseminated invasive disease, *Fusarium* spp. are the most likely of these organisms to do this. Histologically and clinically, fusariosis resembles invasive aspergillosis and infection due to *Pseudoallescheria boydii* (see [Chapter 75](#)).

**E. Complications.** Widespread or metastatic cutaneous involvement can develop from a single primary focus of infection. Disseminated disease may involve the heart, liver, kidneys, spleen, brain, and other vital organs.

## Diagnosis

The diagnosis is confirmed by the recovery of *Fusarium* isolates from blood or biopsy specimens. Skin lesions developing in the setting of new fever in a neutropenic patient should be biopsied for histopathology and culture. The recovery of *Fusarium* spp. from sputum can suggest the diagnosis in the appropriate host with a syndrome compatible with invasive fusariosis; however, colonization of the respiratory tract can occur with this organism.

## Treatment

Amphotericin B is the treatment of choice ([Box 77-2](#)). Response to therapy is usually poor, and in vitro susceptibility testing suggests that more than half of the strains tested are resistant to amphotericin B. It is unknown if the lipid preparations of amphotericin B offer any therapeutic advantage, but patients have been successfully treated with lipid preparations of amphotericin B. The use of granulocyte colony stimulating factors and granulocyte transfusions has been reported to be effective in some patients. *Fusarium* spp. are uniformly resistant to 5-flucytosine. The role of treatment with azoles is unknown. The most important factor contributing to successful treatment is recovery of neutropenia.

## Prognosis

Invasive fusariosis is a lethal disease. The overall mortality rate according to the medical literature is > 70%.

## Prevention & Control

Because the skin and nails are potential portals of entry, before chemotherapy-induced neutropenia, patients with significant onychomycosis should be evaluated by a dermatologist for *Fusarium* infection ([Box 77-3](#)). Furthermore, high-risk neutropenic patients with skin trauma and contamination should be carefully examined for potential inoculation with *Fusarium* spp. This may need to include biopsy and culture.

## **PENICILLIUM INFECTIONS**

### Essentials of Diagnosis

- *Penicillium marneffe* infection found in both immunocompetent and immunosuppressed patients.
- *P. marneffe* found in Southeast Asia and southern China.
- Mold, septate hyphae 1.5-5 um in diameter.

- May be cultured from a variety of specimens including blood.
- *Penicillium* spp. other than *P marneffe* occur worldwide.
- Infection with *Penicillium* spp. is rare; occurs in immunosuppressed patients.

## General Considerations

**A. Epidemiology.** *Penicillium* spp. are ubiquitous in nature and may be recovered with ease from a variety of sources within the hospital environment. These molds commonly contaminate clinical specimens and cause contamination in the laboratory. Colonization of nonsterile anatomical sites in humans is common. In most cases where *Penicillium* spp. are recovered from clinical specimens, they represent colonization. Nevertheless, colonization must be distinguished from the possibility of invasive disease.

Unique among the *Penicillium* spp., *P marneffe* is an endemic mycosis that is found in Southeast Asia and southern China. Most of the cases in the world literature have been reported from these areas; however, an increasing number of cases have been reported among individuals, particularly those with AIDS, who have traveled to or resided in the endemic parts of Southeast Asia and southern China. In Thailand, penicilliosis is the third most common opportunistic infection in patients with AIDS. Little is known about the environmental reservoir of *P marneffe*. Infection is acquired via inhalation, inoculation of the skin, and possibly ingestion. Person-to-person transmission does not occur. There is a marked predominance of male cases (~ 90%).

**B. Microbiology.** *Penicillium* spp. are among the most common filamentous fungi found in nature. These blue-green molds grow rapidly in the mycology laboratory and produce fine septate hyphae with 1.5-5  $\mu$ m wide elements. In tissue specimens, the mycelial elements are somewhat larger at 15-20  $\mu$ m in width and exhibit branching at ~ 45° angles. One of the *Penicillium* spp., *P marneffe*, is unique because of its dimorphic characteristic. In tissue specimens, it grows as a small yeast cell that resembles *Histoplasma capsulatum*. In the laboratory, *P marneffe* will grow as a mold with hyphal characteristics similar to the other *Penicillium* spp. The species may be distinguished by their characteristic conidia forms. Except for *P marneffe*, the *Penicillium* spp. are rarely speciated by mycology laboratories.

**C. Pathogenesis.** Infection caused by *Penicillium* spp. other than *P marneffe* occurs almost exclusively among profoundly immunosuppressed patients and is exceedingly rare. *Penicillium* spp. lack the necessary virulence factors to commonly cause human infection, and only in the setting of extreme immunodeficient states can invasive infection occur.

In contrast, *P marneffe* is capable of causing infection in both immunocompetent and immunocompromised patients. In immunocompetent patients, *P marneffe* infection may resemble histoplasmosis with a granulomatous reaction involving the reticuloendothelial system. The organism is capable of surviving within macrophages. On occasion, a more suppurative reaction can occur in immunocompetent patients, resulting in abscess formation in various organs, especially the lung, skin, liver, and subcutaneous tissues. *P*

*marneffe* infection in immunosuppressed patients can be granulomatous or necrotizing and is likely to disseminate.

## Clinical Findings

**A. Signs and Symptoms.** Infections caused by *Penicillium* spp. other than *P marneffe* are very rare, and recovery of *Penicillium* spp. from clinical specimens will almost always represent colonization; however, in the severely immunocompromised host, repeated recovery may represent opportunistic infection. Isolated case reports of invasive penicilliosis, including prosthetic valve endocarditis, peritonitis, endophthalmitis, and infections at other sites, have been reported in the literature.

The most common presentation of *P marneffe* infection is chronic illness with fever and weight loss ([Box 77-4](#)). A nonproductive cough is frequently present. Other specific symptoms may be present depending on the extent of infection. Because skin involvement occurs in nearly two-thirds of patients, skin lesions are usually present and are most commonly found on the face, upper trunk, and arms. They are papular in appearance and resemble molluscum contagiosum. Generalized lymphadenopathy is also often present. Hepatosplenomegaly may be detected on abdominal examination and is more common in children.

**B. Laboratory Findings.** Anemia is the most common laboratory abnormality present and is found in approximately three-quarters of patients. Blood cultures are positive in over half of patients. There are currently no serological tests to diagnose *P marneffe* infection.

**C. Imaging.** In patients with pulmonary involvement, the chest x-ray may show multiple infiltrates, abscesses, and cavitation. Hilar involvement may be present, but there is usually no hilar calcification.

**D. Differential Diagnosis.** *P marneffe* may closely resemble tuberculosis, particularly in patients with HIV infection. The disease also closely resembles histoplasmosis and cryptococcosis as it occurs in HIV-infected patients.

## Diagnosis

The diagnosis of invasive disease by *Penicillium* spp. other than *P marneffe* must be based on histologic evidence of tissue invasion and recovery of the organism from tissue culture. In addition, recovery from a sterile body fluid such as blood or synovial fluid is suggestive of infection but must be interpreted with caution in view of the frequency with which *Penicillium* spp. contaminate laboratory specimens.

Infection with *P marneffe* occurs only in people who have lived or traveled in the endemic areas of Southeast Asia and southern China. An exposure history is critical in considering the diagnosis. Blood cultures will establish the diagnosis, but other specimens including bone marrow, skin, abscess fluid, lymph nodes, sputum, and others may yield the organism. *P marneffe* must be distinguished from *Histoplasma capsulatum*, which it closely resembles in the laboratory.

## Treatment

The drug of choice for treatment of *P marneffe*i infection is amphotericin B, although in vitro resistance has been described ([Box 77-5](#)). The addition of 5-flucytocine appears to enhance the efficacy of amphotericin B therapy especially in more severe cases. Itraconazole also appears to be highly active against the organism; however, it should be reserved for indolent cases or for use following an initial response to amphotericin B. A standard course of therapy is 2 weeks of amphotericin followed by 6 weeks of itraconazole. Relapse rarely occurs in immunocompetent patients but is common among AIDS patients. Chronic maintenance therapy with itraconazole is indicated in patients with AIDS.

## Prognosis

With early diagnosis and initiation of appropriate fungal therapy, the prognosis is very good; however, among patients in whom the diagnosis is delayed, the mortality rate is high.

## Prevention & Control

Because very little is known about the environmental niche of *P marneffe*i, there are no recommendations or guidelines for prevention and control of this infection.

## PARACOCCIDIOIDOMYCOSIS

### Essentials of Diagnosis

- Patients usually immunocompetent.
- Patients in endemic areas with chronic pulmonary and mucocutaneous lesions involving the mouth, nose, larynx, and face; regional or diffuse lymphadenopathy.
- Found in Latin America, from Mexico to Argentina.
- Dimorphic fungus: yeast form in tissue specimens and at 37 °C; mold form when grown at room temperature in the laboratory.
- Thick-walled yeast, 4-40 um, with multiple buds when seen in tissue specimens.
- Complement fixation or immunodiffusion.

### General Considerations

Paracoccidioidomycosis is caused by *Paracoccidioides brasiliensis*. Also known as South American blastomycosis, it is the most prevalent systemic mycosis found in Central and South America and is the most common endemic mycosis in this area.

**A. Epidemiology.** Paracoccidioidomycosis is acquired only in Central and South America and ranges from Mexico to Argentina. Most cases occur in Brazil, and fewer

cases are seen in Colombia, Venezuela, Ecuador, and Argentina. In other Latin American countries, it is considered rare. It has never been reported in Belize, Nicaragua, Suriname, French Guiana, Guyana, Chile, or any of the Caribbean islands. Cases reported in nonendemic areas such as North America and Europe have occurred in patients who have traveled to or lived in the endemic areas. Within the geographic range for *P brasiliensis*, there is considerable variability in endemicity. It is commonly found in tropical or subtropical forests, where there are mild temperatures with little seasonal variation and very high humidity. The precise ecological niche in the environment has not been established. Soil has been postulated to be the reservoir.

Nearly 95% of the cases of paracoccidioidomycosis occur in males. It is also unusual in adolescents and children. There is evidence that estrogen has an inhibitory effect on conidia of *P brasiliensis*, and this may explain the difference in incidence among the sexes. Inoculation of the skin was once thought to be the portal of entry; however, the evidence now suggests respiratory acquisition. There is no evidence of person-to-person transmission.

**B. Microbiology.** *P brasiliensis* is a dimorphic fungus. In clinical specimens, it appears as a thick-walled yeast that ranges in size from 4 to 40  $\mu\text{m}$ . Multiply budding yeast cells (the so-called "pilot wheel" or "mariner's wheel" cells) may be seen from tissue specimens and are a characteristic feature ([Figure 77-3](#)). In the laboratory, when this yeast is grown on enriched media at 37°C, colonies will appear in 5-10 days. In contrast, when grown at room temperatures (19°-28°C), the mycelial form or mold will grow in 20-30 days. The thin septate hyphae can develop a variety of conidia, but induction of conidial growth can be difficult and unequivocal identification of *P brasiliensis* requires documentation of dimorphic growth in the laboratory.

**C. Pathogenesis.** After the conidia of *P brasiliensis* are inhaled, fungal growth begins within the alveoli and small airways of the lungs. The yeast stimulates a vigorous neutrophilic and then macrocytic response. Spread to regional lymph nodes usually occurs early in infection. At the same time, more widespread dissemination may occur, particularly to the reticuloendothelial system. Depending on the host response, the infection may be controlled, may become clinically apparent, or may become dormant. The inflammatory response seen is a mix of granulomatous, suppurative, and necrotizing. Host response and the status of the immune system are critical determinants in the expression of disease. Both humoral and cellular immune responses are required to control the infection. Although serious infection has been reported with increasing frequency in recent years in patients with AIDS or other forms of severe immunosuppression, it is not a common opportunistic infection in these patients despite its endemic nature. The widespread use of prophylactic trimethoprim-sulfamethoxazole in AIDS and transplant patients may explain the relatively infrequent occurrence in these patients.

## Clinical Findings

**A. Signs and Symptoms.** The manifestations of infection with *P brasiliensis* range from asymptomatic or subacute to chronic and focal to disseminated. Although all patients are presumed to have a pulmonary portal of entry, and 80% will have evidence of pulmonary infection, not all will have symptoms that suggest respiratory disease. The

majority of patients present with symptoms involving mucosal surfaces of the mouth, nose, or larynx; a variety of cutaneous lesions; or general or localized lymphadenopathy. Symptoms will vary by the extent of involvement, and sites may include the liver, spleen, central nervous system, gastrointestinal tract, and bones. Of note, like *H capsulatum*, *P brasiliensis* has a particular propensity to involve the adrenal glands. Most patients with any evidence of disseminated disease will have some degree of adrenal involvement; however, overt Addison's disease is very uncommon.

Patients with respiratory symptoms will present with cough, purulent sputum production, and dyspnea ([Box 77-6](#)). Fever may or may not be present. Many patients will have nonspecific constitutional symptoms such as weight loss, weakness, and malaise. Mucocutaneous involvement is characterized by ulcerations in the mouth, cheilosis, and dysphagia.

On physical examination, the pulmonary findings are often less prominent than would be expected based on the radiographic findings. Examination of the mouth may reveal polymorphic ulcerations. The lips may be indurated and painful. Lymphadenopathy is often present, and spontaneous drainage commonly occurs. A variety of cutaneous lesions may be seen including abscesses, nodules, papules, ulcers, and verrucous lesions. It is very common for pulmonary, mucocutaneous, and lymph node involvement to coexist in the same patient.

**B. Laboratory Findings.** Direct examination of sputum or lymph node drainage with a potassium hydroxide smear may reveal the yeast forms. Culture of sputum or drainage will also be positive. Blood cultures may be positive in disseminated disease, particularly among children and young adults. Serologic tests will be positive in most patients with infection.

**C. Imaging.** The chest x-ray will generally show diffuse bilateral interstitial and alveolar infiltrates. Less frequently encountered findings include multiple nodules, cavitation, and hilar lymphadenopathy. Calcification occasionally occurs but not as frequently as in histoplasmosis or tuberculosis.

**D. Differential Diagnosis.** Tuberculosis may coexist with paracoccidioidomycosis in as many as one-quarter of the cases, and care must be taken to distinguish two diseases that can resemble each other. The differential diagnosis also includes histoplasmosis, blastomycosis, lymphoma, leishmaniasis, leprosy, and malignancies.

**E. Complications.** Chronic untreated pulmonary disease may lead to fibrosis, pulmonary hypertension, and cor pulmonale. Chronic symptomatic adrenal insufficiency is a rare complication of disseminated disease, but adrenal function may recover after long-term antifungal therapy.

## Diagnosis

The diagnosis of paracoccidioidomycosis can be suspected when an appropriate clinical syndrome occurs in a patient who has lived or traveled in Latin America. Given the syndrome's strong propensity to become dormant and remain so for years, even a remote history of exposure in the endemic area can be considered significant. The

presence of multiply budding yeast cells on direct examination of sputum or pus is presumptive evidence of paracoccidioidomycosis. These cells may also be seen on histologic examination of a lymph node or other tissue. Definitive diagnosis requires culture from sputum, pus, blood, or a biopsy specimen. Serologic tests will be positive in 95% of cases by the immunodiffusion test and 80-95% by complement fixation. The skin test for paracoccidioides is of no help diagnostically and is suitable only for epidemiological investigation.

## **Treatment**

The azoles are now considered the treatment of choice for paracoccidioidomycosis ([Box 77-7](#)). In clinical trials, 95% of patients responded to a standard ketoconazole regimen, and 8% of patients relapsed. Itraconazole may be superior to ketoconazole, but there is less experience with this agent. A similar response rate has been observed but with a lower relapse rate. Similar findings have been noted with fluconazole.

Paracoccidioidomycosis can also be treated with sulfonamides. Although the response rate is excellent, there is a relapse rate of ~ 15%. Therapy with sulfadiazine can be instituted and continued for 4 weeks until a clear clinical response is detected. The maintenance dose is continued for 3-5 years. Amphotericin B can be used in life-threatening infections or in patients who are intolerant of or have failed sulfonamide therapy. Azole therapy should follow amphotericin therapy for several months. Trimethoprim-sulfamethoxazole can be substituted for sulfadiazine in both the initial and maintenance phases of therapy and should be given lifelong in AIDS patients with a history of paracoccidioidomycosis.

## **Prognosis**

The prognosis for paracoccidioidomycosis is excellent when the diagnosis is established early in the course of the disease and therapy is promptly instituted. In patients with advanced disease and a wasting syndrome characterized by weight loss, fatigue, and malnutrition, the prognosis is less favorable but is enhanced by aggressive supportive care, including nutritional repletion, correction of anemia, and bed rest.

## **Prevention & Control**

Prophylactic trimethoprim-sulfamethoxazole will prevent primary or relapse paracoccidioidomycosis ([Box 77-8](#))

## **CHROMOMYCOSIS**

### **Essentials of Diagnosis**

- Patients are usually immunocompetent.
- Found worldwide but usually in tropical or subtropical areas.
- Mold in culture; forms sclerotic body or muriform cell in tissue.

- Infection results from direct inoculation from contaminated soil or vegetative substances.
- Chronic indolent cutaneous verrucous lesions, most often on the feet.

## General Considerations

Chromomycosis, also known as chromoblastomycosis, is a chronic subcutaneous infection caused by several different fungi. Although rarely seen in the United States, it is common worldwide.

**A. Epidemiology.** Chromomycosis occurs worldwide but is most frequently encountered in tropical and subtropical regions. The most common occurrence is in barefoot individuals, particularly among agricultural workers. The organisms causing chromomycosis are found commonly in soil, rotting wood, and decaying vegetation. Infection follows only after traumatic exposure to soil or other material, and person-to-person transmission does not occur.

**B. Microbiology.** A variety of different agents is capable of producing the clinical syndrome chromomycosis. The most common is *Fonsecaea pedrosoi*. Others that may be encountered include *Fonsecaea compactum*, *Cladosporium carrionii*, *Phialophora verrucosa*, *Botryomyces caespitosus*, *Rhinochrysiella aquaspersa*, *Exophiala spinifera*, and *E. jeanselmei*. These fungi share a number of characteristics. Most are exceedingly slow growing and require 4-6 weeks in the mycology laboratory before growth may be encountered on culture plates. The colonies tend to be dark green to brown or black in color, and the hyphae are septate. Speciation can be difficult and requires an experienced mycologist.

**C. Pathogenesis.** After an incubation period of several weeks following traumatic subcutaneous inoculation, clinical infection begins. Histologically, there is a pyogranulomatous reaction and significant pseudoepithelial hyperplasia yielding the characteristic verrucoid appearance. Sclerotic bodies, also known as muriform cells, are the characteristic histologic finding. These are actually brown, round, fungal elements that are thick-walled and septated. Their presence on histologic examination is pathognomonic. Occasionally, there may be associated branched septated hyphae adjacent to the muriform cells.

## Clinical Findings

**A. Signs and Symptoms.** Chromomycosis is a chronic skin and soft tissue infection that may develop over months, years, or decades ([Box 77-9](#)). Frequently, patients seek medical attention for cosmetic reasons after years of infection. The feet are the most common location after inoculation from being barefoot. The hands, arms, and legs may also be involved. Typically, a lesion will start as a papule and slowly enlarge to develop into a nodule or plaque ([Figure 77-4](#)).

Different morphologic forms of infection have been described. The verrucous form has a bulky, wartlike appearance and can be very disfiguring. It is often described as cauliflowerlike in appearance. Ulceration, crusting, and bacterial superinfection are

common. The annular form tends to be more flattened with a slowly advancing edge of infection with central healing and scarring. This form is more likely to lead to lymphedema, which in its extreme manifestation may resemble elephantiasis. Infection remains localized with satellite lesions and only rarely disseminates.

**B. Laboratory Findings.** Blood chemistries and cell counts are usually normal in patients with chromomycosis.

**C. Imaging.** Plain film roentgenograms of affected sites will show only soft tissue changes. Bony involvement is rarely seen.

**D. Differential Diagnosis.** A wide variety of infections can cause a syndrome similar to that of chromomycosis. Blastomycosis, sporotrichosis, and mycetoma are other fungal infections that may present as chronic skin and subcutaneous infection. Yaws, tertiary syphilis, leishmaniasis, tuberculosis, and infection with atypical mycobacterium are other possibilities. Carcinoma, on rare occasion, may resemble chromomycosis.

## Diagnosis

The diagnosis of chromomycosis requires scraping or biopsy. The presence of the characteristic sclerotic body is diagnostic. These are easily seen with a KOH stain, particularly when collected from verrucous form of infection. Annular infections tend to have a lower number of organisms and may require biopsy. Scrapings and biopsy specimens submitted to culture should be held in the mycology laboratory for = 4-6 weeks to allow sufficient time for growth to occur. There are no serological tests to assist in the diagnosis of mucormycosis.

## Treatment

Treatment of chromomycosis is difficult, and failure to achieve a cure is common ([Box 77-10](#)). Early, localized infection can be treated with wide surgical excision. Cryotherapy with liquid nitrogen has also been successful in eradicating early infection.

More established infection will require antifungal therapy; 5-flucytosine has been extensively used. Many cases will have partial response, but relapse is common, and resistance develops frequently. Retreatment with 5-flucytosine is usually unsuccessful because resistance develops. The role of the azoles in the treatment of chromomycosis continues to evolve. Ketoconazole is ineffective. Both itraconazole and fluconazole have been used with some success. The optimal duration of therapy has not been established, and failures and relapses are common. Amphotericin B has been tried in resistant cases but is generally not recommended. Terbinafine has been used in a very small number of patients with promising results. More experience with this agent is needed before it can be recommended. The optimal therapeutic approach to chromomycosis remains to be determined.

## Prognosis

Untreated chromomycosis leads to a disfiguring, slowly enlarging lesion. Elephantiasis can develop as a result of the disruption and obstruction of lymphatics.

## Prevention & Control

Chromomycosis of the feet can be prevented by wearing shoes ([Box 77-11](#)). Agricultural workers and other at-risk individuals should attempt to limit trauma to their hands and extremities. Because the organisms causing this infection are ubiquitous in soil and vegetative material, control efforts directed at reducing or eradicating the organisms are impractical.

## 78 . Dermatophytes — *D. Scott Smith, MS, MD & David A. Relman, MD*

### Essentials of Diagnosis

- Characteristic pattern of inflammation on glabrous skin surfaces. The active border of infection is scaly, red, and slightly elevated.
- Wet mount preparation with potassium hydroxide (10-20%). Skin scraping of the active border shows branching, translucent, rod-shaped filaments (hyphae) in keratinized material under low-power microscopy (10-40 $\times$ ). Hyphae are uniformly wide and regularly septated.
- Wood's light examination (UV light at 365 nm) shows blue-green fluorescence for *Microsporum canis* and *Microsporum audouinii*. *Trichophyton schoenleinii* is pale green, and tinea versicolor shows white-yellow fluorescence.
- Culture should be performed with hair, nail, and skin specimens from particularly inflammatory lesions, to make a definitive mycologic diagnosis.

### General Considerations

Dermatophytes are molds that infect keratinized tissues including skin, hair, and nails. Whereas 40 dermatophyte species are known to infect humans, only about 15 of these are common causes of disease. These organisms belong to three genera, *Microsporum*, *Trichophyton*, and *Epidermophyton*. Because these fungi have such similar infectivity, morphology, and pathogenicity, they are often categorized according to the clinical syndrome and the preferred anatomic site with which they are associated, such as tinea capitis, tinea pedis, etc. "Tinea" comes from the Latin word meaning worm or moth. These superficial mycoses often create serpiginous skin markings.

Although tinea versicolor (caused by *Malassezia furfur* or *Pityrosporum* spp.) is not formally considered a dermatophytosis, it is also discussed in this chapter, as it also affects superficial skin layers.

**A. Epidemiology.** Dermatophytes are found in three distinct environmental niches and display specific adaptation to these sites: animals, humans, and soil. Therefore, they are classified as anthropophilic, zoophilic, or geophilic organisms. As these names imply, infection occurs following exposure to either infected humans, animals (such as cats, dogs, or cattle), or soil.

Dermatophytoses occur worldwide, and vary in their presentation according to the site of infection. Improved living standards in the United States since the end of World War II have decreased the incidence of tinea capitis. On the other hand, dramatic increases in the incidence of tinea pedis and tinea cruris due to *Trichophyton rubrum*, an anthropophilic dermatophyte, have been observed in recent years in developed nations. *T. rubrum* is the most common dermatophyte pathogen worldwide, affecting up to one-third of the population of industrialized countries. Tinea pedis occurs almost

exclusively among people who wear shoes, because the latter provide warmth and moisture, conditions that are preferred by the causative organisms.

Transmission of zoophilic dermatophytes occurs through direct contact with infected animals or fomites, such as via troughs and stalls used by infected animals. Geophilic dermatophyte infections occur from direct contact with soil and are seen in greenhouse workers, but infections with these organisms are relatively less common than those caused by anthropophilic dermatophytes.

**B. Microbiology.** The dermatophytes belong to three anamorphic (asexual or imperfect) genera, *Epidermophyton*, *Microsporum*, and *Trichophyton* of the Deuteromycota (Fungi Imperfecti). Members of the *Epidermophyton* genus have macroconidia that are smooth-walled and either single or in clusters, but these fungi have no microconidia. Members of the *Microsporum* genus have macroconidia with fusiform or cylindrical and roughened walls. There are fewer microconidia, and they are found alone along the hyphae as pear-shaped structures. *Trichophyton* species have macroconidia with smooth cylindrical walls. Their microconidia are numerous, and spherical or pear shaped; they appear in clusters along the hyphae.

Conidia are used as the basis for dermatophyte speciation. Because dermatophytes form only hyphae and arthrospores in the nonviable keratinized tissue of infected humans, they must be cultivated in the laboratory to develop conidia for purposes of identification. Colonies form at room temperature on Sabouraud's agar, and their color, texture and morphology are also useful in species identification.

**C. Pathogenesis.** Host factors that enhance the development of dermatophytoses include genetic-susceptibility markers; abraded skin; occlusive clothing, footwear, or dressings; and the presence of other cutaneous diseases like atopic dermatitis. The dermatophytes invade the keratinized layers of skin by producing keratinases, enzymes that digest keratin. While adhering to and invading host skin, the dermatophytes elicit a diverse set of clinical responses. Most lesions are contained within a certain anatomic boundary and may even be self-limited, but widespread dermatophyte infection has been observed in patients with AIDS, patients on immunosuppressive drug regimens, and those who have endocrinopathies such as Cushing's disease. The pathogenic features of superficial dermatophyte infections of the skin are illustrated in [Figure 78-1](#).

Trichophyton is also the name of a crude extract from certain dermatophytes that produces a tuberculinlike response in most adults. There are two moieties of the galactomannan peptide responsible for antigenic response. The carbohydrate portion is responsible for an immediate response, and the peptide portion is associated with a delayed response and probably immunity as well. Resistance to infection is T cell mediated and may be acquired after infection, but it varies in duration and degree, depending on host factors, species of the fungus, and site of infection.

## Clinical Findings

The superficial mycoses are named according to the site of infection, which usually corresponds to the site of local inoculation. The degree of inflammation is often dictated by the nature of the environment from which the fungus originates. For example,

anthropophilic dermatophytes elicit a milder immune response in humans than do the zoophilic fungi. The anthropophilic *M audouinii* causes minimal inflammation as compared with the zoophilic *M canis*. [Table 78-1](#) lists the microbiological differential diagnosis for each clinical syndrome discussed below.

**A. Tinea Capitis.** Tinea capitis or scalp ringworm mainly affects prepubertal children ages 4-14 ([Figure 78-2](#)). It is most commonly observed in crowded living conditions and in areas of poverty. Infection of the hair shaft distinguishes this disease from other dermatophytoses that involve the glabrous skin. Tinea capitis is often classified according to one of three patterns of fungal invasion noted microscopically: endothrix, ectothrix, or favus. Endothrix infections invade the inside of the hair shaft, and the cuticle is not destroyed; thus, clinically it appears as simple scaling of the scalp. It may resemble seborrheic dermatitis or dandruff. There may be gray patches of alopecia with minimal or no inflammation or "black dot" alopecia, in which hairs break off at the roots.

The ectothrix infections present with gray or scaling patches of alopecia with minimal or no inflammation. The "black dot" appearance is also seen. Kerions and prominent inflammatory lesions may be observed, as the dermatophytes that cause ectothrix infections invade both the inside and the outside of the hair shaft and follicles. Kerions are boggy, suppurative, and usually painful. Kerions are most commonly seen with *M canis* and rarely with *Trichophyton mentagrophytes* or *Trichophyton verrucosum*.

Favus infection leads to crusting and matted hair on the scalp with such severe invasion that permanent alopecia often results. It is primarily seen in Eastern Europe and Africa.

**B. Tinea Barbae.** Tinea barbae, like tinea capitis, affects the hair follicles and shafts but in the facial area, and it is often diagnosed only after it fails to respond to several courses of antibacterial agents. Affected hairs are easily removed, unlike those in bacterial folliculitis, which resist removal. The zoophilic dermatophytes *T mentagrophytes* and *T verrucosum* are the most common causes of tinea barbae. The condition often begins with a small clump of follicular pustules, then develops into a boggy, erythematous tumorlike abscess.

**C. Tinea Corporis.** Tinea corporis or ringworm refers primarily to lesions affecting the nonhairy or glabrous skin, but this condition may also result from extensions of scalp or groin infections. Lesions are usually sharply demarcated and ringlike with a raised border ([Figure 78-3](#)). The infections can range from mildly to highly inflammatory with pustules, vesicles, and marked erythema. The central area may become brown or hypopigmented and less scaly as the active border progresses.

**D. Tinea Cruris.** Tinea cruris or jock itch is more common in men and may involve the perineum and the perianal and thigh areas, but it rarely affects the scrotum. (*Candida* infections, in contrast, typically involve the scrotum.) Tinea cruris typically presents with bilateral asymmetric erythematous plaques that spread distally from the groin. There is often central clearing and an active erythematous border, which may have vesicles or papules. Pruritis and burning are common complaints.

This infection is usually transmitted from the patient's foot to the groin. Tinea cruris often occurs in the summer months after sweating or wearing wet clothing or in the winter

months after wearing many layers of clothing, leading to the predisposing warm moist conditions conducive to fungal growth.

**E. Tinea Pedis.** Tinea pedis, also known as athlete's foot, is the most common dermatophyte infection diagnosed overall, and it is usually caused by the anthropophilic organism *T rubrum*. Occlusive footwear promotes warmth and sweating which provide an ideal environment for fungal growth. Tinea pedis presents in four general fashions (a) interdigital infection with erythema, maceration, and scale formation; (b) "moccasin foot" with erythema and thick hyperkeratotic scales; (c) inflammatory infection with vesicles usually on the medial foot; and (d) a less common ulcerative infection affecting the web spaces of the toes, sometimes superinfected with bacteria, and often seen in immunocompromised patients. If tinea unguium is present, tinea pedis may persist because of constant reinfection from the nails.

**F. Tinea Unguium.** Tinea unguium or onychomycosis is an infection of the fingernails or toenails. Infections typically begin along the leading edge of the nail or the lateral border and involve the nail plate; the result is opaque, chalky or yellow nail discoloration. The nail may also become thickened and brittle. Inflammatory changes of the skin around the nail including paronychia are not seen with tinea unguium. Toenails are more frequently involved than fingernails, and the incidence of this infection increases with age.

The nondermatophytic molds such as *Scopulariopsis* and *Scytalidium* spp., *Acremonium fusarium*, and *Candida* spp. cause ~ 5% of fungal nail diseases. This prevalence varies by geography, and these molds may account for = 50% of fungal nail infections in Southeast Asia. These fungi are important to distinguish, because not all respond to the same therapy.

**G. Tinea Incognito.** Tinea incognito refers to dermatophyte infections that are disguised, often because they are treated with topical steroids and then lose some of their characteristic clinical features. Steroids may temporarily reduce inflammation, but the fungus is able to grow unchecked by the impaired immune response. The rash changes such that scaling margins disappear, borders become irregular, and a once localized process may expand. The diagnosis is easily made once steroids are stopped for a few days and scaling reappears and hyphae can be seen on microscopy. Tinea incognito is most often observed in the groin, face, and hands.

**H. Dermatophytid.** Dermatophytid or the "id" reaction is an allergic response to tinea processes that causes sterile dermatitis at distant sites. The most common presentation is a patient with tinea pedis who develops itching and burning on the hands, usually on the sides of the fingers near the crease. Vesicles may appear that enlarge to bullae. Desquamation of the palms and soles occurs less commonly, without inflammation. The lesions persist until the primary process resolves.

**I. Tinea Versicolor.** Tinea versicolor is a common fungal infection of the superficial layer of skin caused by members of the *Malassezia* genus, especially *Malassezia furfur*, formerly known as both *Pityrosporum orbiculare* and *Pityrosporum ovale*. These organisms are lipophilic and make use of medium-chain-length fatty acids. They are members of the normal skin flora, but certain conditions promote proliferation, such as

excess heat, humidity, pregnancy, oral contraceptives, malnutrition, burns, Cushing's disease, corticosteroid therapy, or other forms of immunosuppression.

Clinically, tinea versicolor has a characteristic distribution and lesions; it begins as small circular macules of various colors (thus the name "versicolor"), such as white, pink, or brown, that expand radially. The varied color with this rash stems from the pathologic response of the host. For example, reddish macules or patches are related to a hyperemic inflammatory response; the hypopigmented lesions are caused by alterations in melanosome formation and transfer of pigment to keratinocytes; the tan or dark macules or patches are also related to alterations in melanosome formation. The color of the lesions is uniform in each individual. The upper trunk is the area that is most commonly affected, because the organism is found in highest numbers in areas of increased sebaceous activity. The lesions often become more obvious in summer, when the hypopigmented areas contrast more sharply with the unaffected tanned skin. The lesions are usually asymptomatic, but they may itch if there is inflammation.

## Diagnosis

In addition to clinical recognition and diagnosis on clinical grounds, there are three specific techniques that are useful in the work-up and more definitive diagnosis of superficial mycoses: UV light examination, direct microscopy, and culture. Direct examination of the patient's skin in a darkened room by using UV light (a Wood's lamp) is useful only for infections—primarily tinea capitis or corporis—caused by certain species, including *M. audouinii*, *M. canis*, and *T. schoenleinii*. These infections give off a blue-green color.

Specimens for diagnosis by microscope or culture can be collected using a razor or scalpel to scrape keratinized or flaking material from the leading edge of the newest lesion. Nail scrapings are ideal if the nail is scraped underneath the nail plate, initially to clean it and then to collect a specimen onto a microscope slide or to inoculate culture. A few drops of 10-20% KOH solution is placed on the slide to dissolve keratin. Heating accelerates the process. This enables visualization of hyphae seen with dermatophytes or of hyphae and spores seen in candidal and tinea versicolor infections.

Because KOH wet mounts cannot differentiate among dermatophyte species, the organisms should be cultivated to reveal the distinguishing forms of conidia. From a clinical perspective, it is usually not necessary to identify the dermatophyte species, because topical and oral agents are active against all of them. Species identification is important for scalp infections, severe or inflammatory skin infections, and certain nail infections, because systemic treatment is necessary for scalp infections, treatment may be prolonged and expensive, and species identification may enable prevention of zoophilic infections. Some nail infections may be caused by a mold (eg, *Scopulariopsis* spp.), which, despite being indistinguishable from dermatophytoses on a gross visual basis, will not respond to the same therapy. Culture is usually performed using Sabouraud's agar slants, which are incubated at room temperature for 1-3 weeks. The specific dermatophyte is then identified by colony color and texture, as well as by light microscopy, which reveals the specific morphologic patterns.

Diagnosis of tinea versicolor is made by Wood's light examination, which shows

irregular whitish-yellow areas of fluorescence, although some lesions do not fluoresce. Potassium hydroxide wet mount preparations show short, broad hyphae and clusters of budding cells, which are often described as having the appearance of "spaghetti and meatballs" ([Figure 78-4](#)). Cultivation is possible but rarely indicated and requires the addition of oil to the fungal culture media because the organism is lipophilic.

## Treatment

The principles of treatment are outlined in [Box 78-1](#), according to the specific clinical presentation. Most tinea infections involving the skin can be treated with topical agents such as an imidazole twice a day for 2 or 3 weeks. Terbinafine is also available both in topical and oral formulations and appears to be a more potent drug, requiring shorter dosing with longer lasting clinical responses. Terbinafine and newer related drugs block ergosterol synthesis at an earlier step than do the azole drugs.

If the infection is widespread, involving a large surface area, or if it is particularly inflammatory, systemic drugs are indicated. For infections of the hair and nails, debridement is important prior to systemic treatment. Several oral medications including itraconazole, fluconazole, and terbinafine can be dosed on a daily basis or in so-called "pulsed" regimens for effective treatment of infections of the keratinized tissues. The concept underlying pulse dosing takes advantage of drug deposition in the nail so that the total dose can be reduced; elevated amounts of drug are given repeatedly for short intervals corresponding to the length of time for a finger or toenail to grow. For example, a slightly higher daily dose is given for 1 week each month for the length of time estimated for the infected nail to grow again.

Treatment of tinea versicolor is with a 2.5% selenium sulfide suspension applied to the entire skin surface from the lower posterior scalp area down to the thighs for 10 min every day for 7 days. Another common regimen is to apply the lotion and wash it off after 24 h, repeating once a week for a month. Antifungal creams are useful. Single dose oral treatment with ketoconazole, itraconazole, or fluconazole has also been shown to be effective. Other important adjunctive measures to minimize reinfection include discarding or boiling frequently worn garments that are in contact with the skin. The lesions may take months to clear as they result from depigmentation, which persists despite eradication of the fungus.

## Prevention & Control

Several interventions have been shown useful in the prevention and control of dermatophytes, depending on their type and anatomic location ([Box 78-2](#)). In general, ensuring a clean and dry body surface; avoiding occlusive gloves or shoes that may promote tinea unguium, manus, or pedis; and avoiding sweat-dampened clothing that enables tinea versicolor to thrive all control this infection. Regular cleaning of showers and changing areas at public pools with bleach is thought to control some infection, as is the use of chemicals on an individual basis, such as foot powders.

**Figure 78-1.** Pathogenic features of dermatophyte infection of the stratum corneum (from Hernandez AD: Dermatophytoses. Hosp Med 1985:227). A. The normal epidermis undergoes continual shedding of the stratum corneum, protecting it from dermatophytes. B. Inflammatory reaction that accompanies dermatophytoses. (1) Penetration of the stratum corneum by dermatophytes induces a cell-mediated reaction against the fungus; (2) vesiculation occurs in severe cases; (3) the stratum corneum contains nucleated cells; the inflammatory reaction increases epidermal cell division rates, and these cells pass more rapidly through the epidermis, so full differentiation does not occur; (4) loss of normal translucency causes the stratum corneum to appear white and dermal vessels to dilate; (5) mononuclear inflammatory cells infiltrate the dermis.

## **79 . *Pneumocystis carinii* — James J. Chamberlain, MD & Kristen Ries, MD**

### **Essentials of Diagnosis**

- *Pneumocystis carinii*, when examined using molecular techniques, most closely resembles a fungus.
- Stains of either bronchoalveolar-lavage (BAL) or transbronchial-biopsy samples yield a diagnosis in > 90% of patients and should be considered the gold standard in diagnosis.
- BAL with transbronchial biopsy increases diagnostic yield to ~ 100%.
- *P carinii* has not yet been cultured in vitro.
- Polymerase chain reaction (PCR) (especially on sputum) increases sensitivity but reduces specificity.
- The prophylactic use of aerosolized pentamidine reduces the sensitivity of sputum and bronchoscopic samples.

### **General Considerations**

**A. Epidemiology.** In 1983, *P carinii* pneumonia (PCP) was described as the AIDS-defining illness in = 60% of the first 1000 patients diagnosed with AIDS in the United States. Subsequently, the advent of prophylactic measures has reduced the incidence of PCP presenting as the initial diagnosis for AIDS to < 50% of cases. In addition, the hospitalization rate is also declining for patients with AIDS who also have PCP. This decline has presumably been caused by successful use of prophylaxis against the organism. An analysis from Ontario, Canada, demonstrated that hospital admissions caused by PCP decreased from 48% to 29% over a 2-year period with the initiation of prophylaxis with aerosolized pentamidine. Another Canadian study tracked PCP cases over the decade from 1981 to 1991 and showed that PCP episodes peaked in 1989 and subsequently began to decline.

Of AIDS patients who do not receive prophylaxis against *P carinii*, = 80% will develop at least one episode of PCP and ~ 25% of AIDS patients not receiving prophylaxis will die from PCP. Of patients who have experienced PCP as their AIDS-defining illness, = 70% will develop recurrent disease in the ensuing 2 years without the use of prophylactic medication, and 50% of these cases will occur in the 9 months after the initial episode.

CD4 lymphocyte levels in immunocompromised patients have become the most useful factor in predicting risk for developing *P carinii* infections. Retrospective data have demonstrated that PCP rarely occurs in patients with CD4<sup>+</sup> counts of > 200 cells/mm<sup>3</sup> and that > 90% of AIDS patients will have a CD4 count of < 200 cells/mm<sup>3</sup> in the 2 months before becoming infected with *P carinii*. The percentage of lymphocytes that are

CD4 also seems an important prognostic factor because > 95% of patients had a CD4<sup>+</sup> percentage of < 20% in the 2 months before infection.

Although *P carinii* infection in children is clinically similar to that seen in adults, the numbers of CD4 lymphocytes in pediatric patients differ from those of adults and vary by the age of the patient. The relationship of the CD4 count and the age of a child must be understood to ascertain the degree of immunosuppression. Severe immunosuppression in children < 12 months old is seen with a total CD4 count of < 750 cells/mm<sup>3</sup> or a CD4 percentage of < 15%. For HIV-infected children between 1 and 5 years old, a CD4 T-lymphocyte count of < 500 cells/mm<sup>3</sup> or a CD4 percentage of < 15% is indicative of immunosuppression and increased risk for PCP.

New information suggests that PCP occurs as a result of transmission from human hosts and not from reactivation of latent infection as once thought. The organism is probably not maintained in the lungs of immunocompetent humans for any significant period, and it has been difficult to detect in normal individuals at autopsy. Further support for the theory of person-to-person spread is that PCP infections seem to peak ~ 4 months after winter viruses. The organism may be spread via aerosolized secretions by persons in the community with viral infections. Clustered outbreaks of PCP also suggest person-to-person spread.

Mortality in cases of mild to moderate PCP (partial arterial oxygen pressure [PaO<sub>2</sub>] = 70 mm Hg and alveolar-arterial oxygen gradient [A-a] = 35 mm Hg) has substantially decreased as physicians treating the disease have gained experience. The early to mid 1980s saw mortality rates of = 25% in mild to moderate disease. More recent large, multicenter trials have demonstrated mortality rates of < 1%. However, patients with PCP who develop respiratory failure still suffer profound mortality rates (= 45-72%).

**B. Microbiology.** *P carinii* is an obligate extracellular organism that characteristically evolves from a trophozoite of a single cell into a 5- to 10-mm-diameter cyst that contains up to eight sporozoites, each 1 to 2 μm in size. The developed cysts release sporozoites, which evolve into trophozoites. The majority of organisms in pulmonary tissue exist in the trophozoite form.

The molecular biology of *P carinii* is interesting, and new discoveries have led to significant modification in the understanding and classification of this organism. *P carinii* has long been considered a member of the protozoan kingdom. However, in 1988, *P carinii* ribosomal RNA sequences were found to more closely parallel certain fungal ribosomal RNA sequences. More recent inspection of *P carinii* gene sequences and fungal sequences from each of the seven fungal phyla seems to suggest that *P carinii* is a fungal organism. In particular, there appears a noticeable morphologic similarity between *P carinii* and the ustomycetous red yeast fungi, which is evidenced by a striking resemblance in mitochondrial RNA segments by PCR analysis.

It is interesting that the strain of *P carinii* that infects organisms may not be clonal. Within humans, the organism appears to be genetically diverse; isolates from four distinctly different geographic regions of the world show DNA diversity. Different mammalian hosts appear to harbor genetically diverse strains of *P carinii* as well. *P*

*carinii* has been proven unable to grow when organisms from one species are deposited in the lungs of a differing species.

**C. Pathogenesis.** Recent data continue to suggest that *P carinii* infections are acquired via inhalation between hosts. Thus, infectious episodes are thought to occur as a result of reinfection and are not caused by reactivation of latent organisms. Once acquired, the organisms seem to adhere to alveolar cells of the lung. Replication of the organism is slow, and the resultant host immune response is relatively deliberate as well.

Impaired gas exchange at the alveolar level, a hallmark of PCP infection, appears to be caused by both the extensive proliferation of *P carinii* organisms and the subsequent host response. The presence of a foamy alveolar exudate, alveolar macrophages, interstitial edema, and type I alveolar cell destruction has been demonstrated by electron and light microscopy during the course of infection. The efficacy of corticosteroids in moderate to severe PCP infection is presumably caused by blunting of the host immune response. The importance of the correlation between the degree of immune response and the severity of disease is supported by the association between the number of neutrophils seen on BAL specimens and increased mortality.

## CLINICAL SYNDROMES

### *P CARINII PNEUMONIA*

#### Clinical Findings

**A. Signs and Symptoms.** The triad of shortness of breath with exertion, nonproductive cough, and fever describes the typical case of PCP ([Box 79-1](#)). Symptoms are usually slow to progress and typically worsen over several weeks to months. Cough may be productive of purulent sputum, especially if the patient is concomitantly infected with a bacterial pathogen. Shortness of breath at rest occurs late in the course of disease and signals moderate to severe hypoxia.

The physical exam is relatively nonspecific in diagnosing PCP because = 50% of patients may have normal pulmonary examinations. Fine rales may be auscultated in = 40% of patients, most with severe PCP. Patients may have restriction of their inspiratory ability, which is usually not mentioned unless the patient is questioned specifically.

**B. Laboratory Findings.** The serum lactate dehydrogenase (LDH) level has long been considered a useful laboratory value in the diagnosis of PCP. However, although LDH sensitivity may be > 80%, the test lacks specificity. The serum LDH level does appear to be of prognostic value. Serum LDH levels have been shown to portend a poor prognosis and increased mortality if they are elevated at diagnosis or if they persistently rise despite treatment.

**C. Imaging.** The chest radiograph is an important tool in the assessment of patients thought to be infected with PCP. Although nearly any pattern may be seen on chest radiograph, the typical appearance seen in ~ 80% of cases is one of diffuse bilateral interstitial infiltrates. Chest radiographs that show consolidation, nodularity, or cavitations may be seen in < 5% of cases. The finding of pneumothoraces, cysts, or

pneumatoceles is not uncommon in patients with advanced disease. Of patients with PCP, = 10% may have cysts (as seen on chest radiographs) and = 6% may have pneumothoraces. The vast majority of AIDS patients with a pneumothorax have active *P carinii* infections.

## **EXTRAPULMONARY *P CARINII* INFECTIONS**

### **Introduction**

Extrapulmonary *P carinii* infections occur in < 3% of patients and must be diagnosed with histopathologic samples. Primary prophylaxis for PCP with pentamidine may confer a higher risk for extrapulmonary infection. Symptoms of extrapulmonary involvement are nonspecific, usually consisting of fevers, chills, and sweats. Although any area of the body may be involved, splenomegaly with cysts and thyroiditis are most common.

### **Diagnosis**

The practice of diagnosing PCP morphologically by traditional staining methods (silver methenamine and toluidine blue) of induced sputum samples in HIV-infected individuals has fallen out of favor. Although relatively simple and inexpensive, staining of sputum samples induced by hypertonic saline inhalation is clearly dependent on operator and laboratory experience, and sensitivity varies tremendously between centers. These classic staining techniques yield a diagnosis in only 30-90% of patients suspected of being infected with PCP. Subsequently, a large number of patients may continue to be treated with potentially toxic drug regimens without a definitive diagnosis. The practice of indirect immunofluorescent stain with monoclonal antibodies has increased the sensitivity of induced sputum samples to ~ 70% or to > 90% in some reports.

Bronchoscopy with BAL with or without transbronchial biopsy has become the gold standard in the diagnosis of PCP. Several studies have demonstrated a sensitivity of > 90% for both BAL and transbronchial biopsy. The combination of BAL and transbronchial biopsy leads to a sensitivity of ~ 100%. The complications of transbronchial biopsy, including bleeding and pneumothorax, have led most clinicians to use BAL as the initial diagnostic method during bronchoscopy if diagnosis is not obtained by induced sputum.

PCR technology on induced sputum samples has improved sensitivity to ~ 100% but appears to result in diminished specificity. PCR may become a reasonable diagnostic tool as PCR technique improves, resulting in less contamination and fewer false-positive results.

Chemoprophylaxis for PCP with aerosolized pentamidine has led to a considerable reduction in the rate of recovery of PCP in sputum and bronchoscopy samples. Performing BAL bilaterally or on multiple lobes seems to maintain sensitivity at > 90%.

### **Treatment**

The primary treatment of moderate to severe pulmonary or extrapulmonary infection caused by *P carinii* remains the combination of trimethoprim (TMP) and

sulfamethoxazole (SMX), either orally or intravenously (IV).

Several medications (atovaquone, trimetrexate, and pentamidine) and combination regimens (dapson + TMP and clindamycin + primaquine) probably afford nearly equal efficacy to TMP-SMX in mild to moderate PCP and may be better tolerated in specific populations of patients ([Boxes 79-2](#) and [79-3](#)).

**A. TMP-SMX.** TMP-SMX was the first regimen approved for use in the treatment of PCP, and this regimen is still considered the best initial treatment choice for PCP infection. If tolerated, this combination should be regarded as the initial treatment choice for all PCP infections.

In moderate to severe pulmonary infection with *P carinii*, TMP-SMX has been shown to significantly improve survival when compared with IV pentamidine (86% vs 61%) in randomized trials. Several drug regimens subsequently discussed appear to have similar efficacy compared with TMP-SMX in mild to moderate PCP and may be better tolerated. However, the fact that TMP-SMX also has excellent antimicrobial activity against organisms causing community-acquired bacterial pneumonia and *Toxoplasma* infections should be considered when choosing an agent for treating *P carinii* infections.

Treatment with TMP-SMX is often limited by adverse effects, which occur in the majority of patients to some degree (65-100%). A morbilliform rash is the most commonly observed adverse reaction among patients treated with TMP-SMX; the rash occurs ~ 20-45% of the time and limits treatment in = 20% of patients. Antihistamines may be used to reduce the severity of the rash. Additional side effects of TMP-SMX include fever, nausea and vomiting, neutropenia, anemia, thrombocytopenia, and elevated serum aminotransferase levels.

**B. Pentamidine isethionate.** IV pentamidine isethionate is a suitable alternative treatment for PCP if TMP-SMX is not tolerated. Pentamidine appears to be comparable to TMP-SMX in effectiveness in mild to moderate disease. However, a randomized trial comparing IV pentamidine isethionate with TMP-SMX in moderate to severe disease resulted in a significant mortality advantage for patients treated with TMP-SMX (86% vs 61%).

Aerosolized pentamidine isethionate has been used in the treatment of mild to moderate PCP. Unfortunately, although it results in fewer systemic adverse effects, the aerosolized form of pentamidine isethionate has resulted in lower response rates and a higher frequency of relapse. The use of aerosolized pentamidine isethionate is expensive and requires compressed air to be delivered effectively.

The most common adverse effects associated with the use of pentamidine isethionate include nephrotoxicity, hyperkalemia, hypocalcemia, hypomagnesemia, hypoglycemia, and hypotension. The hypotension seems to be related to the rate at which the drug is administered and usually responds to IV fluids. Hyperglycemia and insulin dependence can also occur. Acute pancreatitis has also been reported.

**C. Trimetrexate.** Trimetrexate is relatively new in the spectrum of drugs used to treat PCP. The U.S. Food and Drug Administration approved trimetrexate for use in moderate

to severe PCP in late 1993. Trimetrexate is related structurally to methotrexate and is thought to possess a similar mechanism of action. Trimetrexate presumably inhibits dihydrofolate reductase, which diminishes the production of nucleic acid precursors, resulting in cell death. Thus, a reduced form of folic acid, folinic acid (leucovorin), must be administered with trimetrexate to reduce toxicity to host cells.

Trimetrexate has been compared with TMP-SMX in a randomized, double-blind, multicenter trial in a group of patients with moderate to severe PCP. Trimetrexate was relatively well tolerated; only 8% of patients terminated treatment before 21 days because of adverse effects. By comparison, 28% of patients who received TMP-SMX had discontinued therapy by 21 days ( $P < 0.001$ ). However, by 21 days after initiation of treatment, a significantly larger number of patients receiving trimetrexate had been considered treatment failures as measured either by lack of efficacy or death (38%) vs those receiving TMP-SMX (20%). Thus, trimetrexate should be considered a relatively safe treatment option in patients with moderate to severe PCP who do not respond to or are intolerant of TMP-SMX or in patients in whom TMP-SMX is contraindicated.

Trimetrexate, as mentioned, has been well tolerated, with = 10% of patients discontinuing therapy at 21 days. The principal dose-limiting side effect has been myelosuppression, especially neutropenia and thrombocytopenia, occurring in 10-15% of patients. Elevated serum aminotransferase, alkaline phosphatase, and creatinine levels have been reported as well. Rash and anemia may also occur in patients receiving trimetrexate.

**D. Atovaquone.** Atovaquone is a hydroxynaphthoquinone drug that has proven to be an effective alternative in the treatment of mild to moderate PCP. Several multicenter prospective trials have shown atovaquone to be much better tolerated than either TMP-SMX or pentamidine isethionate. Although atovaquone is somewhat more likely to result in treatment failure, the favorable side effect profile of atovaquone compared with TMP-SMX and pentamidine isethionate has led to equivalent overall clinical success rates of ~ 60-80%. Mortality rates appear similar between atovaquone and pentamidine isethionate = 8 weeks after completion of treatment. However, mortality appeared significantly higher with atovaquone (7%) as compared with TMP-SMX (0.6%) in a randomized multicenter trial ( $P = 0.003$ ).

The adverse effects of atovaquone that lead to termination of treatment seem to occur in < 10% of patients over a typical 21-day course of treatment. Gastrointestinal complications arise most frequently and include nausea, vomiting, diarrhea, hepatitis, and constipation. In addition, an erythematous rash has occurred in = 25% of patients who take atovaquone. Fever and cough are also common side effects.

**E. Clindamycin and Primaquine.** The use of the combination of clindamycin and primaquine has been proven quite effective in the treatment of mild to moderate PCP.

Several prospective trials have proven that clindamycin and primaquine are = 90% effective in treating mild to moderate PCP. No significant difference has been demonstrated between clindamycin and primaquine when compared with either TMP-SMX or dapsone-TMP, in mild to moderate disease.

Adverse effects have occurred in up to one-third of patients receiving clindamycin and primaquine, and they may be related to the dose of primaquine used. When primaquine has been dosed at 30 mg/d instead of the more frequently used dose of 15 mg/d, the incidence of dose-limiting side effects has nearly doubled. The most significant dose-limiting adverse effect observed in patients taking clindamycin and primaquine is a vesicular, desquamating, or ulcerating rash. Anemia is a frequent problem as well, which is likely related to the strong oxidative effects of primaquine that lead to its contraindication in patients with glucose-6-phosphate dehydrogenase deficiency. The primaquine component of this treatment combination may lead to methemoglobinemia as well. Less common side effects include nausea and vomiting, neutropenia, and gastrointestinal complaints.

**F. Dapsone and TMP.** The combination of dapsone and TMP has been shown to possess similar efficacy to TMP-SMX in the treatment of mild to moderate PCP, with significantly fewer treatment-limiting unfavorable effects. Of patients with mild to moderate PCP, > 90% may be expected to respond to treatment with dapsone and TMP.

Adverse reactions to this combination regimen seem to occur at a much lower rate than to either pentamidine or TMP-SMX. Side effects requiring termination of treatment have occurred in < 10% of patients receiving dapsone and TMP. In clinical trials, the major side effects most commonly include rash (occasionally requiring discontinuation of therapy), elevated hepatic transaminases, neutropenia and thrombocytopenia, hemolytic anemia, and methemoglobinemia with serum levels that can exceed 20%. Of note, dapsone is a potent oxidant, an effect that can cause severe hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency, and it should be used with caution in this population of patients.

**G. Corticosteroids.** The use of corticosteroids has unquestionably been shown to reduce mortality by ~ 50% in patients with moderate to severe PCP. In addition, the need for mechanical ventilation is dramatically reduced in this group of patients. Patients with mild to moderate PCP have not demonstrated benefit from the use of adjuvant corticosteroid use. The suppression of the host inflammatory response to the presence of *P carinii* infection is thought to be the mechanism of the beneficial effect of corticosteroids. Corticosteroid use may exacerbate mucocutaneous herpes simplex, cytomegalovirus infections, and the lesions of Kaposi's sarcoma.

## Prognosis

Many clinical markers or scoring systems have been suggested to diagnose and predict outcome in PCP. Most if not all of these factors have been shown to have little value in the management of disease. The degree of hypoxia is an important prognostic factor that affects recommended treatment. The adjuvant use of corticosteroids and choice of treatment regimen should be based on whether the disease is classified as mild to moderate ( $\text{PaO}_2 > 70$  mm Hg and  $\text{P[A-a]O} = 35$  mm Hg) or moderate to severe ( $\text{PaO}_2 < 70$  mm Hg or  $\text{P[A-a]O} = 35$  mm Hg). However, it is probably better to err on the side of using corticosteroids.

## Prevention & Control

Prophylaxis for PCP has clearly been shown to be effective in reducing the incidence of disease and improving survival in patients at risk for developing the disease ([Box 79-4](#)). No chemoprophylactic treatment regimen has been shown to be more effective than TMP-SMX. In addition, TMP-SMX provides protection against the bacteria that cause community-acquired pneumonia, as well as against toxoplasmosis. Aerosolized pentamidine isethionate and dapsone with or without pyrimethamine or TMP should continue to be regarded as second-line agents in the prevention of PCP.

**A. TMP-SMX.** No drug regimen has been shown to be more effective for preventing PCP in immunocompromised patients than TMP-SMX. Several primary and secondary prevention trials have proven that TMP-SMX is superior to aerosolized pentamidine isethionate and dapsone in patients who tolerate the drug. Patients who have experienced an initial episode of PCP have a more than threefold greater risk of developing a subsequent recurrence at 18 months while receiving aerosolized pentamidine isethionate than while receiving TMP-SMX. The use of TMP-SMX three times weekly seems to afford protection against *P carinii* infection that is equal to that from daily treatment.

Of patients receiving prophylaxis against PCP with TMP-SMX, = 75% may not tolerate the drug. Because TMP-SMX is cheaper and more effective than other treatment options, desensitization protocols have been used to allow some patients who were previously intolerant to TMP-SMX to continue taking the drug. Several published reports indicate that the majority of patients with previous mild to moderate adverse reactions and some with severe anaphylactic responses to TMP-SMX may be safely and successfully desensitized with oral protocols. Thus, most patients who were previously thought to be unable to tolerate TMP-SMX for prophylaxis against PCP may be safely and effectively desensitized with oral desensitization protocols and continue to take TMP-SMX. Some physicians have recommended that all patients who started treatment with SMX should use a desensitization protocol, thus preventing many allergic reactions.

**B. Dapsone.** Dapsone with or without pyrimethamine or TMP is as potent as inhaled pentamidine isethionate but less effective than TMP-SMX in the primary prevention of PCP in HIV-infected individuals. Dapsone is also poorly tolerated, with only 25% of patients in one randomized trial who were able to complete the daily treatment regimen. Dapsone does have the advantage over pentamidine isethionate in efficacy against *Toxoplasma* infections.

Twice weekly dapsone and pyrimethamine appears to be an effective and perhaps better tolerated alternative to daily dosing regimens. Toxicities associated with prophylactic dapsone are the same as those listed in the treatment section.

**C. Aerosolized Pentamidine Isethionate.** Pentamidine isethionate delivered once monthly via an ultrasonic nebulizer is a reasonable but less effective alternative to oral systemic therapy in PCP prophylaxis. Aerosolized pentamidine isethionate is very well tolerated, with < 15% of patients being unable to tolerate treatment. Unfortunately, aerosolized pentamidine isethionate is more likely to result in extrapulmonary *P carinii* infection because very little inhaled drug is absorbed systemically. Aerosolized

pentamidine isethionate has been shown to reduce the sensitivity of diagnostic procedures used in the diagnosis of PCP as well.

When adverse effects are encountered with inhaled pentamidine isethionate, they are mainly limited to a dry cough and bad taste in the mouth. Spontaneous pneumothorax is a potentially dangerous effect of aerosolized pentamidine isethionate. The small amount of systemic absorption may occasionally result in rash, renal impairment, and pancreatitis. Use of an albuterol inhaler before the nebulized pentamidine isethionate is recommended as routine by some to prevent bronchospasm and to promote better penetration of the drug.

## Section VII. Parasitic Infections Part A. Protozoa

### 80 . Malaria and Babesia — Gary W. Procop, MD & David H. Persing, MD, PhD

#### ***PLASMODIUM SPP.***

##### **Introduction**

- Exposure history, such as travel, recent transfusion, or living in close proximity to an international airport.
- Nonfalciparum malaria: chills and fever spikes, followed by defervescence and fatigue; symptoms may be cyclic every 48-72 h.
- Falciparum malaria: fever spikes and chills, often noncyclic and associated with rapidly progressive systemic symptoms.
- Detection and identification of a *Plasmodium* species in a thick and thin blood smear, respectively.
- Molecular detection of *P falciparum*'s histidine-rich protein by enzyme-linked immunosorbent assay (ELISA) or *Plasmodium* DNA by polymerase chain reaction (PCR) followed speciation by probe hybridization or DNA sequencing.

##### **General Considerations**

**A. Epidemiology.** Malaria, a disease of antiquity, was recognized by Hippocrates and described possibly as early as 1700 BC in ancient Chinese texts. Malaria is a global disease that occurs most commonly in the tropics; however, transmission may also occur in temperate zones. In the 19th and early 20th centuries, *Plasmodium* species were widely distributed in the United States. This distribution included the southern United States, the Mississippi River Valley, and extensions as far north as Minnesota and Michigan.

Today, primarily in tropical areas, *Plasmodium* parasites continue to cause > 100 million cases of malaria per year. This results in an estimated 1-2 million deaths annually, many of whom are children. In fact, greater than 90% of severe, life-threatening malaria occurs in children. The distribution of the mosquito vector and the prevalence of disease in indigenous populations are the major factors that determine the distribution of the *Plasmodium* parasite.

Mosquito-infested areas, such as swamps, have long been associated with high attack rates of malaria. Environments that support long-standing, stagnant water promote mosquito breeding. Currently, endemic areas include parts of the Caribbean, northern South America, Central America, parts of Africa, India, parts of Australia, Southeast

Asia, and many of the Asian Pacific Islands.

Malaria also occurs sporadically in nonendemic areas. In many instances, this represents imported, latent disease. Malarial relapses may present months after travelers have returned from endemic areas. These patients have usually been incompletely treated or have taken insufficient chemoprophylaxis.

Relapsing malaria is caused by reactivation of the latent hypnozoite phase of *P vivax* or *P ovale*. Patients who develop malaria may be treated with a wide variety of agents. The most commonly used antimalarial drugs, chloroquine and mefloquine, are effective against the symptomatic, erythrocytic phase of *P vivax* and *P ovale* and may result in apparent cures. These drugs, however, are ineffective against the hepatic hypnozoites. Patients treated in such a manner are incompletely treated and are at risk for malarial relapse.

Some patients may report never having had a previous episode of malaria. Specific questioning, however, often reveals a brief lapse in chemoprophylaxis. A lapse in chemoprophylaxis may result in a window period of subprophylactic drug levels. During this window period, sporozoites injected by an infected mosquito during a blood meal may reach and infect the liver. Any parasites (merozoites) that emerge from the liver while the patient is taking chemoprophylaxis are rapidly killed and the patient remains asymptomatic. Hypnozoites, however, may become active months after return from an endemic area, long after the cessation of chemoprophylaxis. The proper identification of *P vivax* and *P ovale* is important because only these species form hepatic hypnozoites and may result in malarial relapse.

In nonendemic areas, the cases of so-called "airport malaria" may occur. It is thought that mosquito vectors from endemic areas may be transported with airline cargo. An individual in a nonendemic area who lives in close proximity to an airport may become infected if bitten by these mosquitos. The propagation of the parasite is usually not sustained in the environment. This is either because of a lack of a suitable mosquito host or because of the low number of parasites in the community. When the prevalence of malaria is low, the probability of a mosquito ingesting gametocytes is very low. Additionally, if infected mosquitos are rare, they may take a nonhuman blood meal and thereby disrupt the parasitic cycle.

Mosquito transmission is the most common route of infection, but other modes of transmission exist. Transmission may result from intravenous drug abuse (shared needles) or blood transfusion. In these instances, only the erythrocytic cycle is established, because hepatocytes can be infected only by the sporozoite form of the parasite.

**B. Microbiology.** Numerous *Plasmodium* species exist; however, only four species are known to infect humans. These species are *P falciparum*, *P vivax*, *P ovale*, and *P malariae*. Worldwide, *P vivax* causes the vast majority of disease (~ 80%), followed by *P falciparum* (~ 15%).

Depending on the infecting plasmodial organism, malaria differs in severity, complications, prognosis, and treatment. Therefore, with the exception of differentiating

*P vivax* from *P ovale*, it is important to promptly and properly speciate the organism. Malaria is typically separated into two disease types: falciparum and nonfalciparum. This distinction emphasizes the severity of *P falciparum* malaria, which is a medical emergency in the nonimmune individual. Among the nonfalciparum species, it is important to distinguish *P vivax* and *P ovale* from *P malariae*. The former two species have a dormant hepatic stage, which requires separate treatment to avoid malarial relapse.

The identification of *Plasmodium* organisms and the differentiation of the various species remain primarily based on parasite morphology in Giemsa-stained blood preparations. Organism detection is the initial task in the laboratory diagnosis of malaria. This is accomplished by the examination of a thick blood preparation. The examination of a thick preparation is an important part of the examination of blood for parasites and should not be bypassed, unless plasmodia have already been detected in a routine peripheral blood smear. The thick preparation increases the diagnostic yield compared with the examination of the thin blood smears. In the thick preparation, a larger volume of blood may be screened more rapidly. This becomes critical in detecting low-grade parasitemia, such as that associated with long-term *P malariae* infections or early in the course of malaria.

Thick preparations are made by placing 1-2 drops of the patient's blood together on a glass slide. The blood is not smeared and allowed to air dry. This slide is then stained by the Giemsa method, without methanol fixation. The unfixed erythrocytes (RBCs) lyse in the hypotonic stain solution. The stained preparation is first examined under 10× magnification, then under 100× oil immersion.

Filariasis is endemic to many of the same regions that harbor the malaria parasites and may cause cyclic fevers. The microfilariae are easily detected in thick blood preparations at 10× magnification. The purpose of the 100× oil immersion examination is to detect *Plasmodium* species.

In Giemsa-stained preparations, the *Plasmodium* parasites have red chromatin and light-blue cytoplasm ([Figure 80-1](#)). The ring forms of any *Plasmodium* species and the gametocytes of *P falciparum* are the structures most easily identified in thick preparations. Practice is required to differentiate *Plasmodium* amoeboid and schizont forms from platelets and debris. Thin blood smears must be examined if the thick preparations demonstrate the presence of a *Plasmodium* species.

The methanol-fixed, Giemsa-stained thin blood smear is used for *Plasmodium* speciation. Useful criteria for the differentiation of *Plasmodium* species are listed in [Table 80-1](#). However, only rarely are all of these morphologic features present in a blood smear. Differentiation must be made on all information available. The morphologic criteria useful in differentiating the *Plasmodium* species are briefly discussed.

The crescent-shaped gametocyte is pathognomonic of *P falciparum* ([Figure 80-2](#)), but, unfortunately, this structure is not always present. Features in the peripheral smear, that in combination may be used to identify *P falciparum*, include the presence of small, delicate-appearing ring trophozoites, infected erythrocytes that remain normocytic, and the presence of predominantly ring trophozoites, with a conspicuous absence or relative

rarity of more advanced forms. A high parasitemia and erythrocytes infected with multiple organisms are more commonly seen in patients with falciparum malaria. Applique forms and two chromatin centers per ring trophozoite are also suggestive of *P falciparum*, but may be present in other *Plasmodium* species.

Unlike *P falciparum*, *P vivax* and *P ovale* produce thicker and larger ring trophozoites, the infected RBCs become macrocytic, and advanced forms, such as amoeboid trophozoites, schizonts, or both are usually present in the peripheral smear ([Figures 80-3](#) and [80-4](#)). In an appropriately pH-balanced Giemsa stain (pH 6.8-7.0), RBCs infected by *P vivax* or *P ovale* may demonstrate fine eosinophilic stippling. This fine stippling should not be confused with larger, coarse, comma-shaped dots (Maurer's dots) that may be present in *P falciparum*-infected erythrocytes. Applique forms are typically not present in *P vivax*- or *P ovale*-infected erythrocytes, and ring trophozoites usually have only a single chromatin dot. Occasionally, more than one trophozoite may be present per erythrocyte. Although *P vivax* and *P ovale* can be differentiated from one another, this is difficult and requires parasitology expertise. Differentiation of *P vivax* and *P ovale* is usually not indicated or performed, because the disease produced by these organisms is similar and the treatment is identical.

*P malariae*-infected RBCs invariably contain some advanced plasmodial forms and, like *P vivax* and *P ovale*, the ring forms produced are thick. Stippling, however, is not observed. Specialized advanced forms, such as the band form and the basket form, are highly suggestive of *P malariae*. Like *P falciparum*, the ring trophozoites may occasionally contain two chromatin dots and the infected RBCs remain normocytic.

It should be noted that there may be coinfections with more than one *Plasmodium* species. Coinfections, especially in individuals who live in areas endemic for more than one *Plasmodium* species, are relatively common. These mixed infections are important to detect because of differences in disease prognosis and therapy.

**C. Pathogenesis.** The definitive host and vector for the *Plasmodium* parasite is the female *Anopheles* mosquito. Asexual reproduction and gametogenesis occur in the human intermediate host. The parasitic life cycle is similar for all *Plasmodium* species. However, important differences do exist.

Infecting sporozoites originate from the salivary gland of the female *Anopheles* mosquito. These are transmitted into the human during a blood meal. The sporozoites then migrate via the bloodstream to the liver where hepatocytes become infected. In the liver, tissue schizonts are formed. These contain numerous, asexually derived merozoites. From a single sporozoite, this phase of asexual reproduction results in a 10,000- to 30,000-fold organism amplification. This portion of the asexual reproduction cycle is common to all *Plasmodium* species.

Unique to the life cycle of *P vivax* and *P ovale* is the production of dormant hepatic hypnozoites. The hepatic hypnozoites may represent a form of parasite adaptation to climate. In temperate zones, this would enable the malarial parasite to "over-winter" in the human host. This strategy would prove advantageous when climatic conditions limit the activity of the mosquito vector. The hypnozoites, after a dormancy period between 6 and 12 months, become active and produce tissue schizonts.

Upon maturation, the tissue schizonts rupture, and the merozoites are released into the bloodstream. The merozoites then infect RBCs wherein occurs the second phase of asexual reproduction. Intra-erythrocytic asexual replication is also common to all *Plasmodium* species. *P. falciparum* and *P. malariae* may invade erythrocytes of any age, whereas *P. vivax* and *P. ovale* selectively parasitize only young RBCs. Younger RBCs still maintain their full complement of cytoplasmic membrane and expand with the growth of the organism. Older RBCs, infected with either *P. falciparum* or *P. malariae*, fail to expand with the growth of the parasite and remain normocytic with respect to uninfected RBCs. These features are useful in the laboratory differentiation of *Plasmodium* species.

After RBC infection, there is another cycle of asexual replication. Initially, a ring form develops (Figure 80-5), followed by differentiation into an amoeboid trophozoite form (Figure 80-3). This is followed by the development of an intra-erythrocytic schizont, which contains many merozoites (Figure 80-4). This phase results in a 6- to 32-fold asexual amplification of the organism for each infected RBC. The number of merozoites produced in the intra-erythrocytic schizont varies between species. Schizonts present in the blood smear are useful for speciation. The developing parasites metabolize glucose and use RBC hemoglobin. The parasitic use of hemoglobin produces the characteristic hemozoin pigment as a waste product.

The erythrocyte-based, asexual reproduction cycle culminates with RBC rupture. The merozoites are released into the bloodstream where erythrocytes are again infected. This cycle of erythrocyte infection, merozoite replication, and RBC rupture is repetitive and may become highly synchronized. This synchronization is most classically seen in benign tertian malaria caused by *P. vivax*. The rupture of the RBCs and release of the merozoites correlate with the clinical symptoms of malaria. The RBC-based reproduction cycle of *P. vivax* and *P. ovale* occurs every 48 h, whereas the erythrocytic cycle of *P. falciparum* occurs between 36 and 48 h. The erythrocytic cycle of *P. malariae* occurs approximately every 72 h.

The RBC-infecting merozoite may alternatively undergo differentiation into either a micro- or macrogametocyte. These gametocytes may be ingested by the female *Anopheles* mosquito during a blood meal. Fusion of the gametocytes takes place within the gut of the mosquito. The diploid zygote matures and invades the gut wall. Meiotic division ensues, which results in haploid sporozoites. The sporozoites migrate to the mosquito's salivary gland to complete the parasitic cycle.

## FALCIPARUM MALARIA

### Clinical Findings

**A. Signs and Symptoms.** Fevers are often continual, with irregular spikes and associated chills and paroxysms. Patients with severe falciparum malaria may disclose central nervous system changes (prostration, convulsions, and impaired consciousness) and develop respiratory distress, abnormal bleeding, and circulatory collapse. Fatigue and malaise are nonspecific symptoms of malaria. These are in part caused by hypoglycemia and anemia. Hypoglycemia results from both decreased oral intake

during illness and plasmodial use of blood glucose by the Embden-Meyerhof pathway. Anemia results from parasite-associated hemolysis and in some instances disseminated intravascular coagulation. *Plasmodium* infections cause elevated tumor necrosis factor alpha (TNF- $\alpha$ ) levels, particularly in individuals with severe disease. This may also contribute to hypoglycemia and anemia.

In situations of hyperparasitemia, intra- and extravascular hemolysis may be severe. Excessive hemolysis and hepatic involvement cause hyperbilirubinemia and jaundice. Free hemoglobin, bilirubin, and malarial pigment are excreted and turn the urine brown to black. This manifestation, although not limited to *P falciparum* malaria, is termed "blackwater fever."

Falciparum malaria, particularly in the nonimmune, constitutes a medical emergency. Although patients with hyperparasitemia have high mortality rates, even those with parasitemias < 5% may suffer severe morbidity and death. Fatalities result from the immediate effects and sequelae of microvascular obstruction and extensive hemolysis. The microvascular obstruction is caused by specific cytoadherence between *P falciparum*-parasitized RBCs and endothelial cells. Obstruction of the cerebral vasculature is the most serious manifestation and may cause mental status changes that range from mild confusion to coma. Similar microvascular compromise in various organ systems may result in renal failure, noncardiogenic pulmonary edema, or gastroenteritis.

**B. Laboratory Findings.** Three thick blood smears (see above), spaced ~ 12 h apart, should detect any of the *Plasmodium* species. High levels of parasitemia in patients infected by *P falciparum* may be obvious in peripheral blood smears examined secondary to an abnormal hematopoietic profile. In such instances, a microbiologist or pathologist with expertise in infectious disease pathology should examine the peripheral smear and determine which of the *Plasmodium* species is present. It should be remembered that the routine Wright stain, which is used in many institutions for the peripheral blood smear exam, is not pH balanced and may not disclose the eosinophilic stippling in *P vivax*- or *P ovale*-infected RBCs. Harbingers of a poor prognosis present in the thin smear include hyperparasitemia, the presence of mature plasmodial forms (indicative of a larger sequestered biomass of parasites), and a high proportion (> 5%) of polymorphonuclear leukocytes which contain phagocytosed malarial pigment (indicative of recent schizogony). Other laboratory findings are nonspecific and reflect the specific organ involvement.

Blood smears may disclose RBC fragmentation, reflecting the hemolytic process. Similarly, the urine may be dark in color, and hemoglobin and bilirubin may be detected. Other abnormal indices may be present in the urinalysis, depending on the severity of renal involvement. Hyperbilirubinemia may be present depending on hepatic involvement and the duration and severity of disease. Abnormal coagulation studies, including decreased fibrinogen levels, elevated D-dimers, and thrombocytopenia, may be present in patients with disseminated intravascular coagulation. Blood gas analysis may reveal hypoxemia, depending on the severity of pulmonary edema and the presence of hyaline membrane disease.

**C. Imaging.** Computed tomography or magnetic resonance imaging may be performed

if mental status changes are present. These may reveal evidence of ischemic injury or edema and nonspecific changes.

**D. Complications.** The microvascular congestion, secondary to adhesion between parasitized RBCs and endothelial cells, results in protean clinical manifestations. Complications generally occur in the tissues most sensitive to hypoxia and ischemia. Alterations in cerebral blood flow cause mental status changes, including disorientation, headache, coma, and death. Hepatic and gastrointestinal involvement may result in jaundice and enterocolitis, respectively. Involvement of the alveolar capillaries causes noncardiogenic pulmonary edema, which may be exacerbated by fluid retention secondary to renal failure. Oxygen exchange may be further compromised with the development of adult respiratory distress syndrome. Acute renal failure is multifactorial and results from the renal overload of free hemoglobin and malarial pigment, as well as the microvascular compromise and associated hypoxia. Microvascular damage may result in activation of the coagulation and thrombolytic cascades. Disseminated intravascular coagulation exacerbates the hemolytic anemia and further compromises an already insufficient microvascular circulation.

Hypoglycemia, common in *Plasmodium* infections, worsens tissue injury. The causes of hypoglycemia are nutritional, immune mediated, parasitic, and iatrogenic. Inadequate oral intake and parasite use of glucose contribute to hypoglycemia. Immune-mediated mechanisms, such as elevations of TNF- $\alpha$ , may also contribute to hypoglycemia. Therapy-induced elevations in blood insulin, secondary to quinine and quinidine, cause hypoglycemia.

In pregnancy, *P falciparum* becomes sequestered in the maternal sinuses of the placenta ([Figure 80-6](#)). This and the aforementioned complications increase the probability of adverse outcomes for the fetus. Obstetric complications include spontaneous abortion, premature labor and delivery, and maternal death. Transplacental infection of the neonate or "congenital malaria" is rare, but may occur. Primiparas (women pregnant with their first child) are at increased risk for adult respiratory distress syndrome. Pulmonary edema and adult respiratory distress syndrome in pregnancy may be due to the physiologic hypervolemia of pregnancy and an increase in the peripheral vascular resistance after delivery. Pregnancy-associated and quinine-associated hypoglycemia may exacerbate that caused by the parasitosis.

## **NONFALCIPARUM MALARIA (*P VIVAX*, *P OVALE*, *P MALARIAE*)**

### **Clinical Findings**

**A. Signs and Symptoms.** Patients with nonfalciparum malaria invariably develop fever and chills that may become cyclic. Initially, patients experience chills, which are followed by fever ([Box 80-1](#)). Patients with malaria often manifest many nonspecific symptoms such as weakness, malaise, headache, and myalgias. As the disease progresses, signs of anemia, such as pale conjunctiva, may be seen. Splenomegaly and mild hepatomegaly may also be present. After hours of fever, defervescence occurs with marked diaphoresis. Patients are weakened and exhausted from the severity of the disease. In established infections caused by *P vivax* and *P ovale*, a periodicity may occur approximately every 48 h. *P vivax* and *P ovale* infections are clinically

indistinguishable. Although similar, disease caused by *P ovale* is usually less severe, relapses less frequently, and more often spontaneously resolves. Both of these *Plasmodium* species produce latent disease and may produce relapses months after the initial infection.

Malaria from *P malariae* has a longer incubation period and possibly more severe paroxysms than are seen with *P vivax* and *P ovale*. The clinical periodicity of *P malariae* may become regular and occur in 72-h intervals. This is termed benign quartan malaria. Some infections with *P malariae* may be subclinical and persist for years, but *P malariae* does not produce latent disease.

**B. Laboratory Findings.** Three thick blood smears, spaced ~ 12 h apart, should detect any of the *Plasmodium* species. In instances of subclinical *P malariae* infection, parasitemia is extremely low and may be difficult to identify even in thick preparations.

Blood smears and urinalysis reveal evidence of hemolysis, but usually to a lesser degree than with infections caused by *P falciparum*. Elevated albumin levels are present in the urine of patients with *P malariae*-associated nephrotic syndrome.

**C. Imaging.** Hepatosplenomegaly and splenic complications, such as rupture, may be visualized by computed tomography scans or magnetic resonance imaging.

**D. Complications.** Complications with *P vivax* are rare, although coma and sudden death have been reported. Individuals with splenomegaly are at higher risk for splenic rupture. Infections with *P malariae* may be indolent and mild, but immune complex-associated glomerulonephritis and nephrotic syndrome may occur.

## Differential Diagnosis

**Nonfalciparum malaria.** Many of the signs and symptoms of nonfalciparum malaria are nonspecific. There are many causes of anemia and hepatosplenomegaly. Malaria is endemic in many underdeveloped areas; indigenous people in these countries may suffer from protein-calorie malnutrition and are exposed to a wide variety of infectious agents. Impoverished children with dietary deficiencies may be anemic, and those with protein deficiencies may have protuberant abdomens. Numerous infectious diseases may present with hepatomegaly, splenomegaly, or both. Liver enlargement, spleen enlargement, or both may be seen in patients with amebic liver abscesses, Chaga's disease, visceral leishmaniasis, schistosomiasis, echinococcosis, clonorchiasis, and typhoid fever. Noninfectious causes of hepatosplenomegaly, anemia, or both include thalassemias and other hemoglobinopathies, myelofibrosis, and hematopoietic malignancies.

The symptoms of nonfalciparum malaria may also be nonspecific and may be present in a wide variety of diseases. This is especially true early in the course of malaria, before any synchronization of the erythrocytic cycle. Many tropical diseases, such as visceral leishmaniasis, filariasis, and dengue fever, may present with nonspecific symptoms similar to those present in malaria. If cyclic symptoms occur, filariasis should be considered. Pneumonia, urinary tract infections, and other less exotic causes of fever and chills must also be considered. Fever, chills, and night sweats are constitutional

symptoms that may be seen with hematopoietic malignancies. *P. malariae* has been associated with nephrotic syndrome, but other etiologies, such as post-infectious immune-complex glomerulonephritis and systemic lupus erythematosus, must be also be considered. The differential diagnosis of nonfalciparum malaria is extensive and may only be successfully narrowed by history, careful physical examination, and laboratory studies.

**Falciparum Malaria.** The differential diagnosis of falciparum malaria is also extensive. The focus of the differential diagnosis is usually based on the most severely affected organ system. If only generalized fever and chills are present, the differential is broad. These symptoms may be seen in a wide variety of infections (see above) or may represent the constitutional symptoms that may accompany some lymphoproliferative disorders. The mental status changes present in cerebral malaria may also be seen in patients with brain abscesses, meningitis, tumor, or cerebral or subdural hemorrhage. Gastrointestinal symptoms, such as abdominal pain and diarrhea, may be present in patients with bacterial or viral gastroenteritis, chronic colitis, or ischemic colitis. Similarly, involvement of the liver may suggest viral hepatitis, typhoid fever, or other hepatic disorders. The pulmonary edema and adult respiratory distress syndrome that may occur in falciparum malaria are clinically indistinguishable from those caused by many other etiologies. The astute cytologist, however, may detect the presence of a *Plasmodium* species in RBCs present in respiratory tract samplings (sputa or bronchoalveolar lavage) and may thereby identify the etiology of the respiratory pathology. The hemolytic anemia present in malaria may be clinically indistinguishable from other causes of hemolytic anemia but is usually readily distinguished by an examination of a peripheral blood smear.

When ring forms are present, the possibility of babesiosis must also be considered. Recent travel to *Plasmodium*- or *Babesia*-endemic areas is important supportive information. *Babesia* species may be excluded by the presence of advanced amoeboid or schizont forms and by the presence of malarial pigment. *Babesia* species do not produce amoeboid forms or schizonts, and they do not metabolize hemoglobin to form pigment. These criteria usually readily differentiate *Babesia* species from *P. vivax*, *P. ovale*, and *P. malariae*. The differentiation of *Babesia* species and *P. falciparum* is more difficult, because RBCs infected with either *Babesia* species or *P. falciparum* usually contain only small, delicate ring forms. Furthermore, infections with both these organisms may show more than one ring form per RBC and high degrees of parasitemia.

A useful approach to the differentiation of *Babesia* and *P. falciparum* is to search for pathognomonic forms, to perform an exhaustive search for advanced plasmodial forms and malarial pigment, and to obtain a detailed clinical and travel history. The pathognomonic forms of *Babesia* spp. and *P. falciparum* are the tetrad of merozoites (Maltese cross) and the crescent-shaped gametocyte, respectively. Unfortunately, these forms are not always present in the blood smear. An exhaustive search may demonstrate a rare amoeboid or schizont form in *P. falciparum* infections, especially in patients with severe disease, but this is not guaranteed. The presence of malarial pigment also differentiates *Plasmodium* species from *Babesia* species. In morphologically indeterminate instances, historical information may be the most helpful information available. Alternatively, molecular methods may be used to differentiate

these organisms. These, however, are not routinely available in many areas.

## Diagnosis

The first clue to clinicians of the possibility of malaria is often from a history of travel to a malaria-endemic area. Patients should be asked about their travel history, and the clinician should probe for any information about travel to malaria-endemic areas in either the recent or distant past. If patients have traveled to malaria-endemic areas, they should be asked if they received chemoprophylaxis and if they ever contracted malaria. Specific questioning concerning any travel to endemic areas in the past may reveal the possibility of infections with nonfalciparum *Plasmodium* species, which may cause disease months to years after the initial infection and return from endemic areas.

Mosquito-based transmission in naturally endemic areas is the most frequent mode of transmission, but less common modes of transmission may also occur. Plasmodial organisms in the erythrocytic phase may also be parenterally transmitted, through intravenous drug abuse (shared needles) or blood transfusion. This mode of transmission is infrequent in the United States and other nonendemic locales and is directly related to the frequency of infected donors. Historical information regarding having contracted malaria and recent travel to malaria-endemic areas is useful for screening potential blood donors. As mentioned earlier in this chapter, another group of individuals who may contract malaria are those who live in close proximity to an international airport.

The signs and symptoms of malaria depend somewhat on the infecting *Plasmodium* species. Early in the course of disease, nonsynchronized fever and chills may be present with other nonspecific symptoms such as fatigue, malaise, myalgia, and headache. The classic, nonfalciparum malarial cycle consists of shaking chills, followed by high, spiking fever, and finally defervescence with exhaustion. This cycle is most commonly seen with infections by *P vivax* but is also common with infections caused by *P ovale* and *P malariae*. The cyclic nature of the symptoms reflects the synchronization of the erythrocytic malarial cycle and is a clinical clue to malaria. When highly synchronized, this cycle occurs approximately every 48 h for infections caused by *P vivax* and *P ovale* and every 72 h for infections caused by *P malariae*.

The erythrocytic cycle of *P falciparum* becomes synchronized less frequently than malaria caused by other *Plasmodium* species. Patients with *P falciparum* infections more commonly demonstrate daily chills and fever spikes. The signs and symptoms of falciparum malaria are highly variable. The ischemic changes produced by the microvascular congestion may manifest in any organ system (see above). Therefore the clinical presentation usually depends on the organ system most severely affected. For this reason, malaria must remain in the differential diagnosis for a wide variety of disorders, especially if patients have recently visited malaria-endemic locales. Most patients demonstrate some degree of anemia and hypoglycemia. Headache, seizures, mental status changes, and coma may be seen in patients with cerebral malaria. Blackwater fever from the excretion of blood, hemoglobin, and malarial pigment is common in patients with renal involvement. The involvement of the gastrointestinal tract may produce nausea, vomiting, diarrhea, and abdominal pain. Hepatic involvement may result in jaundice, with elevations in serum levels of bilirubin and liver enzymes. Not

surprisingly, primary gastrointestinal and hepatic manifestations of *P falciparum* malaria are commonly mistaken for self-limited bacterial or viral enteritis and viral hepatitis, respectively.

Although clinical history and physical examination findings may suggest malaria, the definitive diagnosis is made in the laboratory. Although ELISA and PCR-based assays for the detection of the malarial parasite are available, the examination of thick blood smears remains the most cost-effective method in the United States. Thick blood smears should be performed on the peripheral blood of patients suspected to have malaria. If the first blood smear is negative, two more should be performed at 12-h intervals. When a *Plasmodium* species is detected in a thick blood smear, thin blood smears should be made for plasmodial speciation.

If available, highly sensitive and specific molecular methods may be used for the detection of *Plasmodium* species. Molecular assays used for *Plasmodium* identification include the detection of *P falciparum*'s histidine-rich protein 2 by ELISA and the detection of *Plasmodium* nucleic acid by PCR. Dipstick technology has been applied to the detection of histidine-rich protein 2. This allows for a sensitive and specific molecular detection system to be available in the field. The detection of *Plasmodium* nucleic acids by the PCR may soon become the gold standard. PCR-based detection systems offer excellent sensitivity and specificity. This system is extremely useful for patients with low-grade parasitemia. The use of preamplification immunomagnetic separation of *Plasmodium* species and specific colorimetric detection of PCR products may enhance sensitivity and make this technology more user friendly. The PCR-based assay may use either species-specific DNA primers or broad-range *Plasmodium*-specific primers. When broad-range primers are used, speciation is accomplished by either DNA sequencing or Southern-blotting/microtiter plate hybridization with species-specific nucleic acid probes. In nonendemic areas, the molecular detection of plasmodia may be impractical, because costly reagents and kits may expire with only minimal use.

## Treatment

In the treatment of malaria, specific antiplasmodial therapy and supportive care are essential to reduce morbidity and mortality. The basic principles of antiplasmodial therapy are defined below. Therapeutics and dosages for the most commonly used antimalarial agents are listed in [Box 80-2](#). It should be noted that antimalarial drugs exist in both salt and base formulations, and potentially dangerous dosing errors may occur unless care is taken. Updated information regarding the treatment and prophylaxis of malaria are available through the Centers for Disease Control and Prevention and the World Health Organization.

***P vivax*, *P ovale*, *P malariae*, and chloroquine-sensitive *P falciparum*.** Chloroquine phosphate is given to eradicate the RBC phase. Oral therapy is usually sufficient for infections with *P vivax*, *P ovale*, and *P malariae* and for *P falciparum* infections that are not severe. Intravenous administration of antiplasmodial agents should be used for patients with severe falciparum malaria. Side effects of chloroquine may include gastrointestinal disturbances, pruritis, dizziness, and headache. Chloroquine resistance is widespread among *P falciparum* and rarely has been reported for *P vivax*. Alternative regimens include mefloquine and quinine. Patients infected with either *P vivax* or *P*

*ovale* must also be given primaquine phosphate to eradicate hepatic hypnozoites. The failure to use primaquine may result in malarial relapse at a later date. Primaquine phosphate may cause hemolytic anemia in patients with glucose-6-phosphatase deficiency; additional side effects include gastrointestinal and central nervous system disturbances. In infections caused by these organisms during pregnancy, chloroquine is the drug of choice, and quinine is an alternative. Although not yet approved by the Food and Drug Administration, mefloquine is also probably safe during pregnancy; mefloquine should not be used for severe falciparum malaria, since intravenous therapy is required and there is no parenteral formulation for mefloquine. Although quinine may be used in pregnancy, it may cause uterine contractions and contributes to hypoglycemia. Primaquine and halofantrine are contraindicated in pregnancy.

**Chloroquine-resistant *P falciparum*.** Oral regimens for patients that do not have severe disease or have severe disease and access to only minimal healthcare facilities consist of quinine given with pyrimethamine-sulfadoxine or followed by either tetracycline or clindamycin. Other oral therapies include mefloquine and quinidine gluconate. Injections of artesunate or artemether or suppositories of artemisinin or artesunate may be useful in instances of limited healthcare. If oral therapy is not possible or if severe disease is present, parenteral therapy with quinine hydrochloride or quinidine gluconate may be given. Pregnant women with chloroquine-resistant malaria who do not have severe disease may be treated with intravenous quinine, sulfonamide/pyrimethamine (in areas such as India and some regions of Africa, where *P falciparum* is likely to be sensitive) and mefloquine. Mefloquine should not be used for severe falciparum malaria, since intravenous therapy is required, and there is no parenteral formulation for mefloquine. Exchange transfusion may be lifesaving for patients with hyperparasitemia and should be considered if this option exists. The indications for exchange transfusion are a parasitemia of > 10% combined with severe disease, therapeutic failure, or poor prognostic factors or a parasitemia of > 30%, even in the absence of clinical complications.

## Prognosis

The prognosis of nonfalciparum malaria is generally good. These organisms are usually responsive to therapy. Relapses of *P vivax* or *P ovale* malaria can be avoided with appropriate therapy. *P malariae* responds well to therapy; however, rare renal involvement may contribute to morbidity and mortality.

The prognosis in falciparum malaria, especially for the nonimmune, is guarded. Malaria caused by *P falciparum* constitutes a medical emergency until proven otherwise. Multisystem organ damage may occur with extreme morbidity and high mortality. Death may occur rapidly from microvascular compromise and subsequent hypoxemia. Involvement of the central nervous system, lungs, and kidneys is especially devastating. Prompt administration of appropriate antimalarial agents, possible exchange transfusion and supportive care significantly reduce morbidity and mortality.

## Prevention & Control

**Vector Control.** An understanding of the habit and behavior of the female *Anopheles* mosquito is useful in disease prevention. Marshlike areas and even microenvironments

with standing water serve as breeding areas for the *Anopheles* mosquitos. Avoidance of mosquito-infested areas and elimination of standing water decrease the likelihood of being bitten. If these areas cannot be avoided, insect repellent should be used. *Anopheles* mosquitoes are evening and nighttime feeders; therefore a combination of mosquito netting and insect repellent at bedtime is encouraged. Mosquito netting impregnated with insecticides is optimal for nighttime barrier protection. The large-scale use of insecticides for vector control usually provides only a short-term solution; insecticide-resistant mosquito strains develop rapidly.

**Chemoprophylaxis.** Chloroquine is still a useful chemoprophylactic agent in areas without a high prevalence of chloroquine-resistant strains ([Box 80-3](#)). The emergence of chloroquine resistance in *P falciparum* and more recently in *P vivax* has limited the usefulness of this drug as a chemoprophylactic agent. In areas where chloroquine resistance is found, mefloquine, doxycycline, or chloroquine plus proguanil may be used for prophylaxis.

Months before departure, travelers to endemic areas should consult physicians experienced in tropical disease prevention. Chemoprophylaxis must begin weeks before departure to ensure an absence of drug hypersensitivity and adequate serum levels. Records should be kept during travel of any failure to maintain the dosing schedule. Chemoprophylaxis should continue for 4 weeks after leaving endemic areas. If episodes of noncompliance have occurred and the patient has not become ill, they are still at risk for malaria if they visited *P vivax*- or *P ovale*-endemic areas.

Information regarding various aspects of malaria, including treatment and prophylaxis, is regularly updated by the World Health Organization and Centers for Disease Control and Prevention. Respective World Wide Web sites are <http://www.who.ch/> and <http://www.cdc.gov/cdc.htm>. Information on various aspects of malaria and other diseases is available from the Centers for Disease Control and Prevention via fax, toll free, at 1-888-232-3228.

**Vaccine Development.** A highly effective malaria vaccine is yet to be developed. This will likely remain a difficult task, particularly because of the antigenic variability characteristic of *Plasmodium* species. Vaccine targets currently being studied include the sporozoite, the merozoite, and the gametocyte. The respective goals of these vaccine targets are to prevent infection, to decrease the severity and complications of disease, and to arrest development in the mosquito and prevent the production of infective sporozoites.

## **BABESIA SPP.**

### **Essentials of Diagnosis**

- Nonspecific clinical manifestations.
- Exposure: tick exposure, blood transfusion, or both.
- Morphologic, serologic, or molecular evidence of infection.

## General Considerations

The members of the genera *Babesia* and *Theileria* are protozoan parasites. These organisms are of medical, veterinary, and economic importance. *Babesia* species cause disease in humans and animals. The genus *Theileria* is the etiologic agent of cattle fever in Eurasia and Africa; it has also been implicated in human disease.

Common to both genera is an intra-erythrocytic phase. These organisms develop pear-shaped intra-erythrocytic ring forms and are therefore referred to as piroplasms. An exo-erythrocytic schizont stage has been demonstrated only for *Theileria* species.

*Babesia* species were first discovered in cattle in 1888, and they were subsequently found to be the etiologic agent of Texas cattle fever. Human babesiosis was first definitively demonstrated in a splenectomized Yugoslavian cattle farmer in 1957. *Babesia divergens*, a cattle parasite, was the species implicated in this infection. This particular organism causes severe and fatal infections in Europe, in splenectomized individuals. This is in contrast to babesiosis in the United States.

*Babesia* species are highly endemic in the northeastern portion of North America, but infections have been reported from the southern, midwestern, and western United States. Unlike babesiosis in Europe, infections usually occur in normosplenic individuals and are usually caused by the smaller parasite *B microti*. This parasite is predominately maintained in a white-footed mouse (*Peromyscus leucopus*) reservoir, but other small rodents may also be infected. *B microti* is transmitted from mouse to mouse and from mouse to human by the hard-bodied tick (*Ixodes scapularis*, previously known as *I dammini*). Trans-stadial (stage-to-stage) transmission occurs within the tick, but transovarial passage has not been demonstrated. The larval and nymph stages of *I scapularis* typically feed on small rodents and thereby acquire the *Babesia* parasite. The predominant host for the adult *Ixodes* tick is the white-tailed deer. Deer are not infected by *B microti*, but the expanding deer population may contribute to the distribution of both the tick and parasite. This tick vector and the mouse reservoir also harbor the etiologic agent of Lyme disease, *Borrelia burgdorferi* ([Chapter 65](#)), and the agent of human granulocytic ehrlichiosis ([Chapter 68](#)).

A new species of piroplasm, WA-1, has more recently been associated with human infection in the western United States. This organism is antigenically and genotypically distinct from *B microti*. Genotypic data suggest that this species may be more closely related to *B gibsoni*, a dog parasite, or the *Theileria* species. Presumably, a tick vector is also necessary for natural transmission, but this has yet to be established.

## Clinical Findings

**A. Signs and Symptoms.** In North America, the majority of *Babesia* infections are asymptomatic, but severe and life-threatening infections are documented ([Box 80-4](#)). The symptoms in most mild infections are nonspecific and include myalgia, malaise, low-grade fever with chills, fatigue, nausea with or without vomiting, and headache. Severe manifestations probably reflect host susceptibility rather than parasite virulence. The manifestations of severe infection include exacerbations of the symptoms noted above, as well as hemolytic anemia. These patients may be jaundiced and develop dark

urine secondary to intravascular hemolytic anemia. Severe manifestations occur more frequently in splenectomized, elderly, or immunocompromised individuals.

Coinfection with *B burgdorferi* should be considered in patients with babesiosis. *Borrelia* species, which cause relapsing fever and Lyme disease, are also transmitted by the *Ixodes* tick. There is also extensive geographic overlap in the distribution of *Borrelia* species and *B microti*. Krause et al studied patients infected with either *B microti* or *B burgdorferi* and compared them with patients coinfecting by these organisms. They found that patients coinfecting with *B microti* and *B burgdorferi* have longer and more severe disease than patients infected with *B burgdorferi* alone. In animal models, *Babesia* species are known to cause immunosuppression. Similarly, coinfecting subjects have evidence of elevated spirochetemia. The exacerbation of symptoms found by Krause et al could conceivably result from transient immunosuppression by *Babesia* species and a subsequent increased spirochetemia.

The cattle-associated parasites *B divergens* and *B bovis* cause human babesiosis in Europe. In this region, splenectomized individuals are at increased risk for infection by these organisms. These patients develop a severe hemolytic disease and have a high fatality rate.

**B. Laboratory Findings.** Wright- or Giemsa-stained, thick blood preparations may be used to detect the presence of parasites. Thin blood smears are then used for morphologic studies. Most commonly, nonspecific ring forms are present ([Figure 80-7](#)), which must be differentiated from a *Plasmodium* species (see *Plasmodium* section above). Rarely, the parasites may appear as the characteristic "Maltese cross." This consists of a tetrad of merozoites and is pathognomonic for *Babesia* species.

**C. Imaging.** Magnetic resonance imaging or computed tomography scan of the abdomen may identify nonspecific changes in the spleen.

**D. Differential Diagnosis.** The nonspecific symptomatology seen in patients with babesiosis may also be seen in a wide variety of infectious diseases. Important etiologic agents in the differential diagnosis of tick-borne disease include *Rickettsia rickettsii* and other spotted fever group rickettsiae, *B burgdorferi* and other *Borrelia* species, *Ehrlichia chaffeensis* and *Ehrlichia canis*, and the coltivirus responsible for Colorado tick fever. Infections by these organisms often lack characteristic physical examination findings, and the definitive diagnosis may rely solely on laboratory findings. If the tick is retained, identification may be useful in limiting the differential diagnosis.

**E. Complications.** Most infections are asymptomatic, and complications are rare. Complications are more likely in immunocompromised hosts, the very young, and the elderly. Complications include an exacerbation of an already weakened state, severe hemolytic anemia and the sequelae thereof, or, rarely, adult respiratory distress syndrome. As previously mentioned, coinfecting pathogens transmitted by the same tick bite must be considered. Coinfections may produce more severe clinical manifestations and may contribute to higher mortality rates.

## Diagnosis

Many *Babesia* infections are subclinical and are discovered incidentally. Babesiosis should be suspected in patients with mild, nonspecific symptoms who have recently visited endemic wooded areas and report a tick bite. Babesiosis should be considered in patients who have recently received an RBC transfusion. *Babesia* species, like *Plasmodium* species, may also be transmitted by this blood product. The symptoms of babesiosis are nonspecific. Therefore the definitive diagnosis of babesiosis is made in the laboratory.

As for the detection of *Plasmodium* species, thick and thin blood smears are used for the detection and speciation of *Babesia* species. The thick smear allows for the more rapid screening of greater quantities of blood. This is important because low-grade parasitemia may be present in *Babesia* infections. Species determination is often suggested by the species endemic to the geographic area of exposure. Organism morphology, particularly size, is important for speciation. These should be examined in thin blood smear preparations.

In some instances, the differentiation of *Babesia* species from *P falciparum* may be difficult. When only small ring forms are present in a blood smear, a *Babesia* species must be differentiated from a *Plasmodium* species, particularly *P falciparum*. The absence of hemozoin pigment and applique forms supports the identification of a *Babesia* species. Unfortunately, hemozoin pigment may also be absent in erythrocytes containing young plasmodial (ie, ring) trophozoites. *Babesia* species may also be excluded if the characteristic crescent-shaped gametocytes of *P falciparum* are identified. Similarly, malaria is excluded if the tetrad of merozoites, pathognomonic of *Babesia* species, is identified. Probably most important is historical information, such as a history of travel to an endemic area and exposure to the appropriate tick or mosquito vector.

In most instances, the combination of history, clinical presentation, and morphologic features is sufficient to establish the appropriate diagnosis. In difficult cases, molecular methods may be used to differentiate these organisms. The histidine-rich protein 2 of *P falciparum* may be detected in whole blood by ELISA, and species-specific nucleic acid may be detected for either organism by PCR.

## Treatment

Mild *Babesia* infections in immunocompetent individuals usually resolve without antimicrobial therapy. In cases of severe disease or in immunocompromised patients, the combination of clindamycin and quinine is the treatment of choice ([Box 80-5](#)). The clindamycin may be given orally, intravenously, or intramuscularly. Intravenous quinidine may also be used.

## Prognosis

The vast majority of patients infected by *B microti* have subclinical infections that usually resolve without incident. The prognosis for immunocompromised individuals and the elderly is guarded, because these patients may have a more severe course. Patients who are coinfecting with *B burgdorferi* carry a worse prognosis than do patients infected by either organism alone. Prognostic information is not available for infections caused

by the WA-1 agent because so few cases have been reported. Splenectomized patients who may be infected by *B divergens* in Europe have a grave prognosis.

## Prevention & Control

The avoidance of outdoor activities in tick-infested, *Babesia*-endemic areas is the most effective means of prevention ([Box 80-6](#)). If avoidance of these areas is impractical, tick repellents should be used, and appropriate clothing should be worn. After leaving tick-infested areas, one should perform a thorough body and scalp search for ticks.

## BOX 80-2. Treatment of Malaria

	Children	Adults
<b>P falciparum malaria from areas with chloroquine resistance<sup>1,2</sup></b>		
<b>First Choice</b>	<ul style="list-style-type: none"><li>• Mefloquine, 25 mg/kg, not to exceed the adult dosage, PO, taken with = 8 oz of water (single dose)</li></ul>	<ul style="list-style-type: none"><li>• Mefloquine, five 250-mg tablets (1250 mg) PO, with = 8 oz of water (single dose)</li></ul>
<b>Second Choice</b>	<p>Quinine sulfate, 25 mg/kg/d PO with one of the following:</p> <ul style="list-style-type: none"><li>• Doxycycline,<sup>3</sup> 2 mg/kg/d for 7 d, given with the quinine</li></ul> <b>OR</b> <ul style="list-style-type: none"><li>• Followed by pyrimethamine-sulfadoxine (0.25 tablet: age &lt;1 yr; 0.5 tablet, age 1-3 yr; 1.0 tablet, age 4-8 yr; 2 tablets, age 9-14 yr)</li></ul> <b>OR</b> <ul style="list-style-type: none"><li>• Followed by clindamycin, 20-40 mg/kg/d in 3 divided doses</li></ul>	<ul style="list-style-type: none"><li>• Quinine sulfate, 650 mg PO every 8 h for 3-7 d, with one of the following</li><li>• Doxycycline, 100 mg twice daily</li></ul> <b>OR</b> <ul style="list-style-type: none"><li>• Followed by 3 pyrimethamine-sulfadoxine tablets</li></ul> <b>OR</b> <ul style="list-style-type: none"><li>• Followed by clindamycin, 900 mg twice a day for 5 d</li></ul>
<b>Parenteral Therapy</b>	<ul style="list-style-type: none"><li>• Quinine dihydrochloride, 20 mg of salt/kg IV loading dose in 5% dextrose given over 4 h, followed by 10 mg of salt/kg given over 2-4 h, every 8 h (maximum dose, 1800 mg/d)</li></ul> <b>OR</b> <ul style="list-style-type: none"><li>• Quinidine gluconate, 10 mg salt/kg loading dose in normal saline, with slow infusion lasting 1-2 h, (maximum dose, 600 mg), followed by continuous infusion at 0.02 mg/kg/min</li></ul>	<ul style="list-style-type: none"><li>• Quinine dihydrochloride, 20 mg of salt/kg IV loading dose in 5% dextrose given over 4 h, followed by 10 mg of salt/kg given over 2-4 h, every 8 h (maximum dose, 1800 mg/d)</li></ul> <b>OR</b> <ul style="list-style-type: none"><li>• Quinidine gluconate, 10 mg salt/kg loading dose in normal saline, with slow infusion lasting 1-2 h, (maximum dose, 600 mg), followed by continuous infusion at 0.02 mg/kg/min</li></ul>
<b>Malaria caused by P vivax, P ovale, P malariae, and chloroquine-sensitive P falciparum</b>		
<b>First Choice</b>	<ul style="list-style-type: none"><li>• Chloroquine, 10 mg base/kg PO loading dose (not to exceed 600 mg base), followed by 5 mg base/kg (not to exceed 300 mg base) given 6 h after the first dose and again on days 2 and 3</li></ul>	<ul style="list-style-type: none"><li>• Chloroquine, 600 mg base (1000 mg chloroquine phosphate) PO loading dose followed by 300 mg base given 6 h after the first dose and again on days 2 and 3</li></ul>
<b>Latent disease caused by P vivax/P ovale</b>		
<b>First Choice</b>	<ul style="list-style-type: none"><li>• Primaquine phosphate, 0.3 mg base (0.5 mg salt) /kg/d × 14 d</li></ul>	<ul style="list-style-type: none"><li>• Primaquine phosphate, 15.3 mg base (26.5 mg salt) qd PO × 14 d</li></ul> <b>OR</b> <ul style="list-style-type: none"><li>• 45 mg base (79 mg salt) per week</li></ul>

<sup>1</sup> Severe falciparum malaria should be treated with parenteral therapy; mefloquine should not be used for the treatment of severe falciparum malaria, since there is no parenteral formulation. Options include quinine (see above), quinidine, artesunate and artemether.

<sup>2</sup>Exchange transfusion may be life saving in nonimmune patients with severe falciparum malaria and is indicated if parasitemia is > 30% or if parasitemia is > 10% and poor prognostic factors are present (i.e. schizonts in peripheral blood), there are severe systemic manifestations (i.e. cerebral malaria, pulmonary renal failure) or therapeutic failure.

<sup>3</sup>Do not use doxycycline in pregnant women or in children < 8 years of age.

### **BOX 80-3. Control of Malaria**

#### **Vector Control**

- Avoid mosquito-infested areas.
- Wear protective clothing during evening and nighttime hours.
- Use mosquito repellent (containing 30-35% DEET for adults or 6-10% DEET for children).
- Spray bedclothes and mosquito netting with the insect repellent permethrin.
- Unless absolutely necessary, pregnant women should not travel to *P falciparum*-endemic areas.

#### **Prophylactic Measures**

- Chloroquine remains the drug of choice in areas without known chloroquine resistance.
- Mefloquine is used in areas with known chloroquine-resistant strains.
- Doxycycline should be used when mefloquine cannot be taken, except by pregnant women, children < 8 y old, or those who are hypersensitive to doxycycline.
- Chloroquine & proguanil should be used only for patients who cannot take mefloquine or doxycycline

#### **Emergency Self Treatment of Possible Malaria**

- Individuals using chloroquine prophylaxis in areas where chloroquine-resistant strains may reside must have one or more treatment doses of Fansidar (25 mg pyrimethamine + 500 mg sulfadoxine/tablet) (adult dosage: 3 tablets PO as a single dose; pediatric dosage: 5-10 kg, 1/2 tablet; 11-20 kg, 1 tablet; 21-30 kg, 1 1/2 tablets; 31-45 kg, 2 tablets; > 45 kg, adult dose)

## 81 . *Toxoplasma gondii*— Jose G. Montoya, MD

### General Considerations

**A. Epidemiology.** *Toxoplasma gondii* infection, or toxoplasmosis, is a zoonosis (the definitive hosts are members of the cat family). The two most common routes of infection in humans are by oral ingestion of the parasite and by transplacental (congenital) transmission to the fetus. Ingestion of undercooked or raw meat that contains cysts or of water or food contaminated with oocysts results in acute infection.

In humans, the prevalence of toxoplasmosis increases with age. There are also considerable geographic differences in prevalence rates (eg, 10% in Palo Alto, CA; 15% in Boston, MA; 30% in Birmingham, AL; 70% in France; = 90% in El Salvador). Differences in the epidemiology of *T gondii* infection in various geographic locales and between population groups within the same locale may be explained by differences in exposure to the organism. Occasionally, outbreaks occur within families or certain populations. The possibility of an outbreak should always be suspected with every case of recently acquired acute infection.

The incidence of congenital toxoplasmosis is directly correlated with three factors: (1) the prevalence of primary infection among women during pregnancy, (2) the gestational age at which a pregnant woman acquires the infection, and (3) the types of public health programs available for prevention, detection, and treatment of the infection during pregnancy. Although screening for *Toxoplasma* infection is compulsory during pregnancy in some countries such as Austria and France, routine serological screening is not performed in the United States. Without any therapeutic intervention, the incidence of congenital toxoplasmosis is ~ 15% for a fetus whose mother becomes infected during the first trimester, 30% during the second trimester, and 60% during the third trimester. Spiramycin decreases the incidence of fetal infection by ~ 60%. It has been reported that, if maternal infection is acquired during the first 2 weeks of gestation and spiramycin is administered for the entire pregnancy, the incidence of fetal infection is negligible.

As an opportunistic pathogen in HIV-infected persons, *T gondii* has had a major impact on public health. The incidence of toxoplasmosis in an HIV-infected population is directly correlated with four factors: (1) the prevalence of anti-*Toxoplasma* antibodies, (2) the degree of immunosuppression as estimated by the CD4 cell count, (3) the frequency with which effective prophylactic regimens against *Toxoplasma* reactivation are used, and (4) the frequency with which highly active antiretroviral therapy is used. Of individuals seropositive for both HIV and *Toxoplasma* with CD4 counts of < 100 cells/mm<sup>3</sup>, 30%-50% will develop toxoplasmic encephalitis (TE) if prophylaxis is not used. Genetic factors may also play a role in predisposition of AIDS patients for this disease, based on findings from a murine model of TE and the observation that not all HIV-infected patients with positive *T gondii* serology develop TE. Human lymphocyte antigen DQ3 appears to be a genetic marker of susceptibility to development of TE in AIDS patients, and DQ1 may be a marker of resistance.

Even before the emergence of AIDS, TE had been recognized as a major cause of morbidity and mortality among non-HIV-immunosuppressed patients, especially in those whose underlying disease or therapy caused a deficiency in T-cell-mediated immunity (eg, Hodgkin's disease and heart, lung, kidney, and bone marrow transplantation).

**B. Microbiology.** *T gondii* is an obligate intracellular coccidian protozoan that exists in three forms: the oocyst (which releases sporozoites), the tachyzoite, and the tissue cyst (which contains and may release bradyzoites). The parasite undergoes two cycles, an enteroepithelial sexual cycle in the small bowel of members of the cat family and an extraintestinal asexual cycle in cats as well as in all other infected animals, including humans. Cats shed oocysts after they ingest any of the three forms of the parasite. Humans usually become infected by ingestion of tissue cysts (in meat) or oocysts (in cat feces); the outer walls of both are disrupted by enzymatic degradation, and the parasites are liberated into the intestinal lumen. They become tachyzoites and spread to virtually all cells and tissues of the body.

**1. Oocyst.** Oocysts are formed in the small bowel of members of the cat family and are excreted in their feces for 7-20 days. They are highly resistant to conditions found within the external environment. As many as 10 million oocysts may be shed in a single day and will become infectious (by sporulation) in 1-21 days, depending on temperature and availability of oxygen.

**2. Tachyzoite.** Tachyzoites are crescent or oval shaped and measure 2-4  $\mu\text{m}$  wide by 4-8  $\mu\text{m}$  long. They require an intracellular habitat to survive and multiply despite having their own Golgi apparatus, ribosomes, and mitochondria. Tachyzoites penetrate host cells by an active process involving the components of an "apical complex" (hence the term apicomplexan). They reside and multiply within an intracellular parasitophorous vacuole whose composition (eg, acidity) is dictated in large part by the parasite. In the laboratory, tachyzoites are propagated in the peritoneum of mice and in tissue-cultured mammalian cells. The presence of tachyzoites in human fluids or tissues is the hallmark of acute infection.

**3. Tissue cyst.** After cell entry and replication of the tachyzoite form, encystation and formation of tissue cysts may occur. The precise conditions that promote cyst formation are not known. The tissue cyst is formed within a host cell and may vary in size from those containing only a few organisms (bradyzoites) to those = 200  $\mu\text{m}$  in diameter containing several thousand bradyzoites. Tissue cysts stain well with periodic acid-Schiff reagent, Wright-Giemsa, Gomori-methenamine silver, and immunoperoxidase stains. The cysts are spherical when found in the brain and conform to the shape of muscle fibers when in heart and skeletal muscle tissue. The most common sites of latent infection are the central nervous system (CNS); eye; and skeletal, smooth, and heart muscles. Because of this persistence in tissues, demonstration of cysts in histologic sections does not necessarily mean that the infection was recently acquired or that it is clinically relevant.

**4. Stage conversion.** Tachyzoites and bradyzoites differ phenotypically. Tachyzoites multiply rapidly and synchronously, forming rosettes, thereby lysing the cell, whereas the more slowly replicating bradyzoites form tissue cysts. Major differences in energy metabolism and in antigenic structure of tachyzoites and bradyzoites reflect the

expression of stage-specific pathways and molecules that promote parasite survival in diverse environments and under diverse conditions within the host.

**C. Pathogenesis.** *T gondii* multiplies inside cells at the site of invasion (the gastrointestinal tract appears to be the major route for and the initial site of infection in nature). After host cell disruption, parasites invade adjacent cells from which they spread throughout the body via lymphatics and the bloodstream. Humoral immunity and cellular immunity appear to curtail successfully the parasitemic phase; only those parasites protected by an intracellular habitat or within tissue cysts survive. An effective immune response is also responsible for a significant early reduction in the number of *T gondii* in all tissues. Thereafter, tachyzoites are rarely demonstrated in tissues.

The tissue cyst form is responsible for residual infection and persists primarily in brain, skeletal, and heart muscle, and in the eye. Whereas toxoplasmosis in severely immunodeficient individuals may be caused by primary infection, it most often is the result of recrudescence of a latent infection.

The histopathologic changes of toxoplasmic lymphadenitis are frequently diagnostic in immunocompetent individuals. There is a characteristic triad of findings: a reactive follicular hyperplasia, irregular clusters of epithelioid histiocytes encroaching on and blurring the margins of the germinal centers, and focal distension of sinuses with monocytoïd cells.

Ocular involvement in immunocompetent patients produces acute retinochoroiditis characterized by necrosis and severe inflammation. Granulomatous inflammation of the choroid is secondary to the necrotizing retinitis.

Involvement of the CNS is characterized by multiple enlarging foci of necrosis and microglial nodules. Necrosis is the most salient feature of the disease because of vascular involvement. The presence of multiple brain abscesses is the most typical feature of TE in severely immunodeficient patients and is particularly characteristic in patients with AIDS. At autopsy in most AIDS patients with TE, cerebral hemispheres are involved, with a peculiar predilection for the basal ganglia. Pulmonary toxoplasmosis in the immunodeficient patient may present as interstitial pneumonitis, necrotizing pneumonitis, consolidation, and/or pleural effusion. Chorioretinitis in AIDS patients is characterized by segmental panophthalmitis and areas of coagulative necrosis associated with tissue cysts and tachyzoites.

**D. Immunity to *T gondii*.** After disease in the immunocompetent host, immunity against *T gondii* is lifelong. Cellular immunity appears to be more important than humoral immunity in defense of the brain. A well-orchestrated interaction between CD4 and CD8 T lymphocytes; lymphokine-activated killer, natural killer, and  $\gamma\delta$  T cells; and cytokines such as interferon- $\gamma$ , tumor necrosis factor- $\alpha$ , interleukin-1 (IL-1), IL-2, IL-4, IL-6, IL-7, IL-10, IL-12, and IL-15 appears to determine the outcome of the parasite-human host interaction. Nitric oxide may have a tissue-specific protective role.

## Clinical Findings

Primary infection in any host often goes unrecognized. In ~ 10% of immunocompetent

individuals, it causes a self-limited and nonspecific illness that rarely requires treatment. The most frequently observed clinical manifestation in this setting is lymphadenopathy and fatigue without fever; other manifestations include chorioretinitis, myocarditis, and polymyositis ([Box 81-1](#)). Reinfection occurs but does not appear to result in clinically apparent disease. In contrast to the usually benign course of the initial infection in immunologically intact hosts, the congenitally infected fetus and newborn and immunocompromised patients are at high risk for severe or life-threatening disease caused by this parasite. Congenital toxoplasmosis is the result of maternal infection acquired during gestation. Among immunologically impaired individuals, toxoplasmosis most often occurs in those with defects in T-cell-mediated immunity such as those with hematological malignancies, bone marrow and solid-organ transplants, or AIDS.

## **A. Signs and symptoms.**

**1. Infection in immunocompetent adults and children.** Primary infection with *T gondii* in children and adults is asymptomatic in the vast majority of cases. Lymphadenopathy and fatigue, without fever, are the most common manifestations in the minority that become symptomatic. The lymph nodes most commonly involved are cervical, suboccipital, supraclavicular, axillary, and inguinal. Lymphadenopathy is usually regional; often a single posterior cervical node is enlarged. On palpation, the nodes are discrete, nontender, and nonfluctuant. Occasionally, lymph nodes may become matted. Fever, sore throat, maculopapular rash, malaise, night sweats, myalgias, hepatosplenomegaly, or atypical lymphocytes are variably present. The clinical picture may resemble infectious mononucleosis or cytomegalovirus (CMV) infection; however, toxoplasmosis probably causes < 1% of mononucleosis-like syndromes. In rare cases, lymphadenopathy may persist for months.

Toxoplasmic chorioretinitis can occur either in the setting of acute acquired infection (sporadic and epidemic) or as a reactivation of intrauterine or postnatally acquired infection. Patients who present with chorioretinitis as a late sequela of intrauterine infection are more frequently in the second and third decades of life (it is rare after age 40); bilateral disease, retinal scars, and involvement of the macula are hallmarks of the retinal disease in these cases. In contrast, patients who present with toxoplasmic chorioretinitis in the setting of acute toxoplasmosis are more often in the fourth to sixth decades of life and most often have unilateral involvement. The eye lesions usually spare the macula and are not associated with old scars.

**2. Infection in pregnant women.** Recognition of toxoplasmosis in pregnancy is important only because of the risk of transmission to the fetus. This risk is limited almost exclusively to those fetuses whose mothers acquire the infection for the first time during gestation. Acquisition of *Toxoplasma* infection before pregnancy in an otherwise healthy female does not pose a significant risk of transplacental transmission. On rare occasions, transmission to the fetus has occurred in immunocompetent women infected with *T gondii* within 3 months of conception. In immunocompromised women, such as those with HIV infection, acquisition of *T gondii* before conception (chronic infection) has then led to transmission to the fetus as a consequence of reactivation.

**3. Congenital toxoplasmosis.** Of newborns with congenital toxoplasmosis, ~ 85% appear normal at birth. Thus, one cannot rely on clinical examination alone to raise the

possibility of this disease. However, if untreated, congenital toxoplasmosis will inevitably lead to disease in most infected children.

The earlier in gestation a mother is infected with *T gondii*, the more severe is the disease in the fetus and newborn, despite the lower frequency with which transmission occurs with shorter periods of gestation. Findings include chorioretinitis with blindness, epilepsy, psychomotor disorders and developmental delay, hearing loss, jaundice, rash, hematologic abnormalities, and pneumonitis. The classic triad of hydrocephalus, chorioretinitis, and cerebral calcifications is seen only rarely.

**4. Infection in immunocompromised patients.** In immunocompromised patients, toxoplasmosis almost always occurs as a result of reactivation of previously acquired infection. Toxoplasmosis may also result when a seronegative recipient receives a heart from a seropositive donor. In contrast to the relatively favorable course of toxoplasmosis in almost all immunocompetent individuals, it is a dreadful and often life-threatening disease in immunodeficient patients.

In this population, the brain is the most common affected organ. The clinical presentation of TE varies from a subacute, gradual process that evolves over weeks to an acute state of confusion, with or without focal neurologic deficits evolving over days. Clinical manifestations include alteration in mental status, seizures, motor weakness, cranial-nerve disturbances, sensory abnormalities, cerebellar signs, movement disorders, and neuropsychiatric findings. Constitutional symptoms and signs such as fever and malaise are variable.

The most common focal neurologic findings are hemiparesis and abnormalities of speech. Because *T gondii* causes predominantly encephalitis with little or no meningeal involvement, signs of meningeal irritation are rare. Cranial-nerve lesions develop secondary to brainstem involvement. Seizures, cerebral hemorrhage, and diffuse TE may present acutely and progress rapidly to death. Spinal-cord toxoplasmosis in AIDS patients can present with motor or sensory disturbances of single or multiple extremities, bladder dysfunction, and/or bowel dysfunction. Cervical and thoracic myelopathy and conus medullaris syndromes have also been reported.

Clinical manifestations of toxoplasmosis in immunocompromised patients also include pneumonitis, chorioretinitis, and multiorgan involvement that presents with acute respiratory failure and hemodynamic abnormalities similar to septic shock.

**B. Laboratory findings.** Laboratory approaches for the diagnosis of toxoplasmosis include serology, histology with various stains (hematoxylin and eosin, immunoperoxidase, Wright-Giemsa, and periodic acid-Schiff), isolation of the parasite by mouse or tissue culture inoculation, polymerase chain reaction (PCR), and radiological studies ([Table 81-1](#)). Histologic examination may reveal the characteristic morphology of the parasite in tissues; the presence of tachyzoites or multiple cysts is diagnostic of active infection. The presence of a solitary cyst may reflect chronic infection unless it is associated with inflammation. Almost any tissue can be inoculated into the peritoneal cavity of mice for isolation studies. Several body fluids can be examined by PCR for the detection of *T gondii* DNA, including cerebrospinal fluid (CSF), bronchoalveolar lavage fluid, vitreal fluid, aqueous humor, amniotic fluid, urine, and

peripheral blood. PCR examination of brain tissue is discouraged because a positive result does not distinguish active from chronic infection.

For any individual in whom toxoplasmosis is considered in the differential diagnosis, the most important initial step is to determine whether the patient has been exposed to the parasite. In virtually all situations, a negative serum immunoglobulin G (IgG) test essentially rules out earlier or recent exposure to the parasite. Rarely, cases of documented toxoplasmic chorioretinitis and TE have been reported in seronegative patients. If IgG antibodies are present and clinical suspicion is high, it is important to establish whether the patient's condition is caused by a recently acquired infection or by reactivation of chronic infection. A true negative IgM antibody test essentially rules out acquisition of the infection within the previous 6 months; however, it does not rule out reactivation of chronic infection. A positive *T gondii*-specific IgM antibody test can be interpreted in three ways: (1) as a true positive result consistent with recently acquired infection, (2) as a true positive result in the setting of a chronic infection (IgM antibodies have been shown to persist for as long as 5 years after the acute infection), or (3) as a false positive result. To establish which of these is most likely in a given case, confirmatory testing in a reference laboratory should be performed whenever feasible. Confirmatory tests include the Sabin-Feldman dye test, IgM enzyme-linked immunosorbent assay (ELISA), IgA ELISA, IgE ELISA, and differential agglutination test. These tests are available at the Toxoplasma Serology Laboratory at the Palo Alto Medical Foundation (650-853-4828). If the patient has received a blood transfusion, serologic tests may measure antibody acquired exogenously rather than endogenously. The use of serological tests to evaluate the response to therapy should be discouraged.

Despite the crucial role played by members of the feline family in the life cycle of *T gondii*, a history of cat exposure is not particularly helpful in assessing the likelihood of toxoplasmosis in a given patient. Transmission of *T gondii* almost always occurs without the awareness of the patient and may be unrelated to direct exposure to cat feces (eg, transmission of oocysts by contaminated vegetables or water). On the other hand, cats that remain indoors at all times and that are fed only cooked food do not pose a risk to humans. Serologic examination of cats should be discouraged; seropositivity does not predict shedding of oocysts.

**1. Infection in immunocompetent adults and children.** The diagnosis of toxoplasmosis in the vast majority of immunocompetent adults and children relies on serological tests. Recently acquired toxoplasmic lymphadenopathy is easily diagnosed serologically, but, unfortunately, it is not often suspected until after lymph node biopsy. Acute infection is supported by the documented appearance of IgG or IgM antibodies or by a greater than fourfold rise in antibody titer. Histology of appropriate specimens (lymph node or myocardium) may be helpful.

In most cases, toxoplasmic chorioretinitis is diagnosed by and treatment initiated on the basis of ophthalmologic examination and serology test results. PCR analysis of vitreous fluid or the measurement of intraocular production of *T gondii*-specific IgG antibodies may be useful in patients with presumed toxoplasmic chorioretinitis in whom response to appropriate anti-*Toxoplasma* therapy is considered inadequate or suboptimal and in patients with atypical eye findings.

**2. Infection in pregnant women.** The first step in addressing the possibility of toxoplasmosis in pregnancy is to establish whether acute infection has occurred. In the vast majority of cases, the diagnosis of acute infection during pregnancy is only possible with serological testing ([Table 81-2](#)). A serological diagnosis should be confirmed by a reference laboratory because the reliability of commercial IgM test kits varies considerably and because the presence of IgM antibody does not necessarily establish the diagnosis of the acute infection (see above).

**3. Congenital toxoplasmosis.** Prenatal assessment of fetal infection should be performed when a diagnosis of acute infection is established or highly suspected in a pregnant woman. Amplification of *T gondii* DNA by PCR and/or isolation of *T gondii* from amniotic fluid establishes the diagnosis of fetal infection and has entirely replaced the testing of blood samples obtained by periumbilical fetal blood sampling. Examination of amniotic fluid should be performed at 18 weeks. The reliability of the PCR test before 18 weeks of gestational age is unknown. The sensitivity of amniotic fluid PCR is ~70%. The sensitivity of inoculation of amniotic fluid into mice for isolation of *T gondii* is ~ 60%. The specificity of the PCR test is close to 100%. Ultrasonography is a useful test to establish the severity of the infection; however, it should not be used to confirm or rule out congenital toxoplasmosis. Abnormalities frequently reported with this method in cases of in utero infection include ventricular dilatation, intracranial calcifications, increased placental thickness, hepatic enlargement, and ascites.

The diagnosis of congenital toxoplasmosis in the newborn can be made by detecting specific IgA and IgM antibodies. Serum samples from the newborn should be obtained from peripheral blood and not from the umbilical cord, because it is essential that maternal contamination of blood obtained at birth be excluded. The presence of IgG antibodies in the newborn may reflect passive transplacental transfer of maternal antibodies. Other laboratory tests available for the diagnosis of congenital disease in infants include isolation of the parasite in mice or cell culture (eg, from placental tissue or body fluids) and PCR with body fluids, such as CSF, blood, and urine. Clinical evaluation of infants with presumed *T gondii* infection should always include ophthalmologic examination, radiologic studies (particularly to detect the presence of cerebral calcifications), and examination of CSF.

**4. Infection in immunocompromised patients.** It is important to maintain a high index of suspicion for toxoplasmosis in immunodeficient patients because its clinical manifestations are protean and nonspecific and, if left untreated, toxoplasmosis is a source of major morbidity and mortality.

Because reactivation of chronic infection is the most common cause of toxoplasmosis in AIDS- and non-AIDS-immunocompromised patients, the initial routine assessment of these patients, even in the absence of signs of toxoplasmosis, should include a serum *T gondii* IgG antibody test. Those with a positive result are at risk of reactivation of the infection; those with a negative result should be instructed on how to prevent infection.

The anti-*Toxoplasma* serologic status of heart transplant recipients should be routinely assessed before transplantation, and an appropriate prophylactic regimen should be instituted for all seronegative hosts if they receive a heart from a seropositive donor.

A definitive diagnosis of toxoplasmosis in the immunodeficient patient relies on histologic demonstration or isolation of the parasite or PCR-based detection of its DNA. In AIDS patients, CSF examination by PCR has been found to have a sensitivity of ~ 80% for the diagnosis of TE. CSF PCR for other organisms has also been found to be helpful in patients with AIDS, including amplification of Epstein-Barr virus, CMV, and JC virus DNA for the diagnosis of primary CNS lymphoma, CMV ventriculitis, and progressive multifocal leukoencephalopathy, respectively.

Computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained when clinical manifestations suggest involvement of the CNS or spinal cord. These studies should be performed even if the neurological examination does not reveal focal deficits. MRI is the radiological test of choice and is more sensitive than CT.

A presumptive diagnosis of CNS toxoplasmosis can be made for patients with multiple ring-enhancing brain lesions (usually established by MRI), positive *T gondii*-specific IgG antibody titers, and advanced immunodeficiency (eg, CD4 count < 200 or patients who receive intensive immunosuppressive therapy) and justifies anti-*Toxoplasma* therapy. A clinical and radiologic response to specific therapy within 7-10 days supports the diagnosis.

Brain biopsy should be considered in immunodeficient patients with suspected TE if there is a negative IgG antibody test, a single lesion on MRI, inadequate clinical response to an optimal anti-*Toxoplasma* treatment regimen, or development of disease in the face of an effective prophylactic regimen against *T gondii*.

In heart transplant patients who present with a clinical syndrome that suggests toxoplasmosis, serologic test results may be misleading. Results consistent with chronic infection may be seen in the presence of acute toxoplasmosis. On the other hand, results that suggest apparent reactivation (rising IgG and IgM titers) may be found in the absence of clinically apparent infection. In these patients endomyocardial biopsy is useful.

## Differential Diagnosis

The differential diagnosis of toxoplasmic lymphadenitis includes lymphoma, Epstein-Barr virus-associated infectious mononucleosis, CMV "mononucleosis," cat scratch disease, sarcoidosis, tuberculosis, tularemia, and metastatic carcinoma. For toxoplasmic encephalitis, the differential diagnosis includes primary CNS lymphoma, JC virus-associated progressive multifocal leukoencephalopathy, CMV ventriculitis, tuberculoma, cryptococoma, and bacterial or nocardial brain abscess. None of the signs described in newborns with congenital disease are pathognomonic for toxoplasmosis, and all of them may be mimicked by congenital infection with other pathogens, including CMV, *Treponema pallidum*, herpes simplex virus, and rubella virus.

## Complications

In rare instances, toxoplasmosis causes myocarditis, polymyositis, pneumonitis, hepatitis, or encephalitis in healthy individuals. Early maternal infections sometimes result in death of the fetus in utero and spontaneous abortion.

## Treatment

**A. Infection in Immunocompetent Adults and Children.** Immunocompetent adults and children with toxoplasmic lymphadenitis do not require treatment unless symptoms are severe or persistent. Infections acquired by laboratory accident or transfusion of blood products are potentially more severe, and these patients should always be treated. The combination of pyrimethamine, sulfadiazine, and folinic acid for 4-6 weeks is the most commonly used and recommended drug regimen ([Box 81-2](#)). Treatment should be administered for 2-4 weeks, followed by reassessment of the patient's condition.

The decision to treat active toxoplasmic chorioretinitis should be based on the results of an examination performed by an ophthalmologist. Pyrimethamine and sulfadiazine plus folinic acid are commonly used for this syndrome. Clindamycin has also been used with favorable clinical results. Systemic corticosteroids may be required in addition to the anti-*Toxoplasma* drugs.

**B. Infection in Pregnant Women.** Spiramycin is the drug of choice for pregnant women who have acquired primary *T gondii* infection during gestation ([Box 81-3](#)). It does not eliminate but does appear to decrease the incidence of fetal infection. Because there is usually a delay between acquisition of acute maternal infection, infection of the placenta, and subsequent infection of the fetus, identification of acute maternal infection warrants immediate institution of spiramycin [available from the U.S. Food and Drug Administration (301-827-2335)]. Maternal adverse effects associated with spiramycin include nausea, vomiting, anorexia, diarrhea, vertigo, dizziness, flushing of the face, feeling of coolness, and numbness. There is no evidence that spiramycin is teratogenic. Spiramycin should be continued throughout the pregnancy even if the amniotic-fluid PCR result is negative for fetal infection. If the amniotic-fluid PCR result is positive at = 18 weeks, the institution of pyrimethamine, sulfadiazine, and folinic acid is recommended to treat fetal infection in utero.

Pregnant women with toxoplasmic chorioretinitis from reactivation of infection do not experience a higher risk of parasite transmission to the fetus than do pregnant women with prior infection and no ocular disease. However, when toxoplasmic chorioretinitis is thought to be a manifestation of primary infection acquired during gestation, it should be treated, because of the risks to both the mother and the fetus. The advice of an ophthalmologist should be sought.

**C. Congenital Toxoplasmosis.** The combination of sulfadiazine, pyrimethamine, and folinic acid for = 12 months is a commonly advocated regimen for infants born to mothers with positive results in the amniotic fluid or in whom the disease is highly suspected or proven ([Box 81-4](#)).

**D. Infection in Immunocompromised Patients.** The regimens used to treat toxoplasmosis in immunocompromised patients are basically the same as those used in other clinical settings; however, the doses recommended for immunocompromised patients are usually higher. The standard regimen is the combination of pyrimethamine, sulfadiazine, and folinic (not folic) acid ([Box 81-5](#)). Clindamycin can be used instead of

sulfadiazine in adult patients intolerant to sulfonamides. The recommended duration of treatment is 4-6 weeks after resolution of all signs and symptoms (often for a total of at least several months). The role of other drugs (eg, atovaquone, clarithromycin, azithromycin, trimethoprim-sulfamethoxazole, and dapsone) in the treatment of toxoplasmosis in immunocompromised patients has not been well established. If these drugs are used, they should be given preferably in combination with pyrimethamine. At the present time, monotherapy does not have a role in the treatment of toxoplasmosis.

In patients with AIDS, after treatment of the acute phase (primary or induction treatment), maintenance therapy (secondary prophylaxis) should be instituted. The maintenance regimen is the same as that used in the acute phase but with each drug at one-half the dose. Current recommendations suggest that maintenance therapy be continued for the life of the patient. It is not known at this time whether the immune reconstitution observed as a result of combination antiretroviral therapy in AIDS patients might allow the successful discontinuation of maintenance treatment. Some non-AIDS-immunocompromised patients may also require maintenance treatment as long as their immunosuppressive regimens continue to exert a significant impact on cell-mediated immunity.

## Prevention & Control

Prevention of the primary infection is of paramount importance in pregnant women and immunodeficient patients who are seronegative ([Box 81-6](#)). Tissue cysts in meat are rendered noninfectious by heating the meat to 66 °C (meat should be cooked to "well done" with no pink meat visible in the center), by smoking or curing it, or by freezing it to -20 °C (which is not achieved in most home freezers). Hands should be washed meticulously after handling raw meat or vegetables; eggs should not be eaten raw, and unpasteurized milk (particularly milk from goats) should be avoided. Flies and cockroaches should be controlled. Areas contaminated with cat feces should be avoided entirely. Disposable gloves should be worn while disposing of cat litter (if this task cannot be avoided altogether), working in the garden, or cleaning a child's sandbox. Oocysts are killed if the cat litter container is soaked in nearly boiling water for 5 min. If the litter container is cleaned every day, oocysts will not have a chance to sporulate.

There is no vaccine currently available for prevention of toxoplasmosis in humans; primary prophylaxis against toxoplasmosis in patients with AIDS who are at high risk of developing TE has been shown to be effective. Primary prophylaxis is recommended for seropositive patients whose CD4 count has been < 100 cells/mm<sup>3</sup> (some experts use a cutoff of < 200 cells/mm<sup>3</sup>), regardless of the HIV RNA viral load.

Trimethoprim-sulfamethoxazole and dapsone plus pyrimethamine have been reported to be effective regimens in preventing the first episode of TE ([Box 81-7](#)). Pyrimethamine has been used post-transplantation for primary prophylaxis in seronegative heart transplant recipients whose donors are seropositive ([Box 81-7](#)).

General Considerations
-

**Table 81-1.** Laboratory tests for the diagnosis of toxoplasmosis.

- Serology (IgG) is useful to establish whether the patient has been exposed to *T gondii*.<sup>1</sup> It can also indicate whether the infection is acute or chronic.<sup>2,3</sup>
- Histology (hematoxylin and eosin, immunoperoxidase, Wright-Giemsa and periodic acid-Schiff stains). The presence of tachyzoites is diagnostic of acute infection. Solitary cysts do not necessarily indicate acute or reactivated disease.
- Isolation of the parasite from any tissue by mouse or tissue culture inoculation is diagnostic.<sup>2</sup>
- PCR-based detection of DNA in amniotic fluid, CSF, ocular fluids, bronchoalveolar lavage, peripheral blood, and urine is diagnostic.<sup>2</sup>
- Radiographic studies are helpful when suspecting CNS toxoplasmosis in the fetus or newborn (ultrasound or CT) and immunocompromised patients (CT or MRI).
- In most cases, ocular toxoplasmosis is a clinical diagnosis.

<sup>1</sup>Confirmatory serological tests include the Sabin-Feldman dye test for IgG, IgM ELISA, IgA ELISA, differential agglutination test, and IgE ELISA.

<sup>2</sup>Consultation with a reference laboratory is strongly recommended.

<sup>3</sup>Serological diagnosis may not be useful in immunocompromised individuals.

### **Infectious Form**

### **Preventive Measure**

Tissue cyst (meat)

- Wash hands thoroughly after contact with raw meat
- Avoid mucous membrane contact when handling raw meat
- Wash kitchen surfaces and utensils that have come in contact with raw meat
- Cook meat well done (meat that is cured in brine may be infectious)
- Avoid ingestion of dried meat
- Refrain from skinning animals

Oocyst (cat feces)

- Wash fruits and vegetables before consumption
- Avoid contact with materials potentially contaminated with cat feces
- Wear gloves when gardening or handling cat litter
- Disinfect cat litter with near boiling water for 5 min before handling

## 82 . Pathogenic Amebas — *Christopher R. Fox, MD & Merle A. Sande, MD*

### ***ENTAMOEBA HISTOLYTICA & ENTAMOEBA DISPAR***

#### **Essentials of Diagnosis**

- Patient living in or having traveled to endemic area increases risk.
- Frequent loose stools with blood and mucus.
- Demonstration of cyst or trophozoite on stool wet mount or in biopsy specimen.
- Serology positive within 7-10 days of infection, may remain positive for years after infection resolved.
- Monoclonal antibodies and polymerase chain reaction emerging; may help differentiate *E histolytica* and *E dispar*.

#### **General Considerations**

**A. Epidemiology.** There are numerous distinct species of ameba within the genus *Entamoeba*, and the majority of these do not cause disease in humans. *E histolytica* is a pathogenic species that is capable of causing disease, such as colitis or liver abscess, in humans. *E dispar* is prevalent and is indistinguishable from *E histolytica* by conventional laboratory methods. *E dispar* exists in humans in only an asymptomatic carrier state and does not cause colitis.

It has been estimated that 10% of the world's population is infected with either *E histolytica* or *E dispar*. Of those infected, < 10% will manifest symptomatic disease. Infection is prevalent in Central and South America, southern and western Africa, the Far East, and India. Pregnant women, children, those of lower socioeconomic status, and those who live in crowded conditions or areas with poor sanitation are more likely to be infected.

In the United States, the prevalence of *E histolytica* and *E dispar* is much lower, approximately 4%. The risk factors for infection are the same as those above. In addition, those who travel to an endemic area, homosexual males, and institutionalized persons are at increased risk of infection.

**B. Microbiology.** *E histolytica* exists in one of two forms, a cyst or a trophozoite. Infection is generally through fecal-oral spread with ingestion of the cyst form, which is resistant to killing by the low pH of the stomach. Within the small bowel, the cyst divides into trophozoites, which then colonize the large intestine. The trophozoites may subsequently encyst and be shed into the stool. Once shed, they may remain viable for weeks to months.

During acute colitis, trophozoites may be shed into the stool. Unlike the cyst, the trophozoite cannot live outside the host because it is rapidly killed by poor environmental conditions and, if ingested, is degraded in the acid stomach environment.

**C. Pathogenesis.** *E histolytica* infection is enhanced by the production of several virulence factors. Production of proteolytic enzymes allows the trophozoite to disrupt tissue planes and invade the colonic epithelium. The trophozoite may ascend the portal venous structures to produce hepatic infection, and obstruction of the portal vessels by the trophozoites may produce hepatic necrosis. The trophozoites are able to lyse neutrophils through a contact-dependent mechanism that protects the trophozoite from ingestion and causes local tissue damage by release of the neutrophil's enzymes. Trophozoites are also resistant to complement-mediated lysis and produce adherence lectins that aid in the binding of the trophozoite to colonic epithelium, thereby facilitating invasion of the epithelium. These adherence proteins also aid in the contact-dependent lysis of tissue and white cells.

## CLINICAL SYNDROMES

### INTRODUCTION

Infection with *E histolytica* causes multiple syndromes, which range from asymptomatic intestinal infection to fulminant colitis. In addition, *E histolytica* may cause disease at several nonintestinal sites, including the liver, lung, brain, and genitourinary tract. The clinical syndromes caused by *E histolytica* are outlined in [Box 82-1](#).

### INTESTINAL DISEASE

#### Clinical Findings

**A. Signs and Symptoms.** Of patients infected with *E histolytica*, > 90% are asymptomatic carriers who are colonized with the organism and pass cysts in the stool. This carrier state often resolves without treatment, although relapses and reinfection are common.

Acute amebic colitis usually presents with several weeks of lower abdominal pain and diarrhea with frequent loose to watery stools containing blood and mucus. Most patients are afebrile. Significant volume depletion is uncommon.

Chronic amebic colitis is characterized by low-grade inflammation resulting in intermittent bloody diarrhea and abdominal pain over a period of months to years. It is often difficult to distinguish chronic disease from inflammatory bowel disease, and this distinction must be made before corticosteroid or surgical therapy for inflammatory bowel disease, to avoid worsening amebic infection or to perform surgical therapy for a treatable infection.

Patients with fulminant amebic colitis present with fever, diffuse abdominal pain, and bloody diarrhea. This form of the disease is rare and presents most commonly in children. Colonic perforations frequently develop, and the patient may progress to toxic

megacolon, particularly in the setting of corticosteroid treatment. Liver abscess is common in patients with fulminant colitis. Mortality in patients with fulminant colitis is high, approaching 50%.

Of patients with intestinal disease, ~ 1% will develop an ameboma. Most common in the cecum or ascending colon, ameboma is a chronic, localized amebic infection. The mass may be entirely asymptomatic or may be painful and tender. It is often confused with malignant lesions on imaging studies, and correct diagnosis can be made by biopsy.

**B. Laboratory Findings.** Laboratory findings in intestinal amebiasis are nonspecific, and there are no characteristic laboratory findings that should prompt a search for the organism. The stool is usually positive for erythrocytes. Fecal leukocytes are often not present, secondary to lysis by the parasite, despite invasion of the intestinal mucosa.

**C. Imaging.** The most useful imaging study for amebiasis is endoscopy. Colonoscopy or flexible sigmoidoscopy allows for direct visualization of the intestinal mucosa and provides an opportunity for mucosal biopsy. Endoscopy typically reveals inflamed mucosa with punctate, hemorrhagic ulcers interspersed with normal-appearing mucosa.

**D. Differential Diagnosis.** Acute intestinal amebiasis must be distinguished from bacterial dysentery caused by *Salmonella*, *Shigella*, *Campylobacter*, enteroinvasive *E coli*, and *Yersinia* spp. Amebiasis, particularly chronic infection, may be confused with inflammatory bowel disease.

**E. Complications.** Complications from amebic intestinal disease are rare, because the majority of patients are asymptomatic. Those complications that do occur include peritonitis, colonic perforation, stricture formation, and hemorrhage. Toxic megacolon, a serious complication of amebic colitis, occurs rarely, but its incidence is increased in persons treated with steroids during the course of their infection.

## AMEBIC LIVER ABSCESS

### Clinical Findings

**A. Signs and Symptoms.** Amebic liver abscess is the most common extraintestinal manifestation of amebiasis. Patients may note right-upper-quadrant pain that is either dull or pleuritic in nature. Often pain is referred to the right shoulder. Less than 50% of patients have an enlarged liver. In the acute setting, patients typically manifest fever. If symptoms have been present for > 2 weeks, fever is present in less than half of patients. Respiratory symptoms, such as cough, can occur even in the absence of pulmonary disease and may be the only complaint. In the subacute setting, weight loss is common. Diarrhea is found in less than one-third of patients with amebic liver abscess.

Exam may reveal abdominal tenderness, tender hepatomegaly, and crackles at the right lung base. Jaundice is uncommon.

**B. Laboratory Findings.** Patients with amebic liver abscess may have leukocytosis without eosinophilia, elevated alkaline phosphatase, and mild anemia. The

transaminases are elevated in severe disease. Other findings include a high erythrocyte sedimentation rate and proteinuria.

**C. Imaging.** Ultrasound of the liver may show a round or an oval hypoechoic area contiguous with the liver capsule and without significant wall echoes. This is often a single lesion in the right hepatic lobe. Computer tomographic scanning and magnetic resonance imaging are sensitive studies for hepatic involvement, but the finding of a mass is not specific for amebic abscess. Each of these studies allows definition of the number of lesions as well as their size, and this information may be used to monitor a patient's course.

**D. Differential Diagnosis.** An amebic liver abscess needs to be differentiated from other mass lesions of the liver, which include bacterial abscess, echinococcal cyst, hepatoma, and metastatic cancer.

**E. Complications.** Amebic liver abscesses may rupture and thereby extend into surrounding tissues, including the pleural space, lung parenchyma, and pericardium. Pleural effusion may be present without frank rupture of the abscess.

**Pleuropulmonary amebiasis.** Pleuropulmonary disease is the most common complication of amebic liver abscess and usually presents with cough and pleuritic chest pain. Findings may reveal serous effusion, which does not imply disseminated disease. Amebic empyema, with "anchovy paste" material present upon drainage, occurs with rupture of the abscess into the pleural space and has an increased mortality. Consolidation of the lung parenchyma may occur with contiguous spread from a liver abscess. A patient who develops a hepatobronchial fistula will have a cough productive of large amounts of sputum and necrotic material, with the sputum possibly containing detectable amebas.

**Peritoneal amebiasis.** Peritoneal amebiasis occurs in 2-7% of patients with amebic liver abscess and represents the second most common complication of amebic liver abscess. Presentation may be dramatic enough to simulate a perforated viscus or may be more indolent with a slow leak of organisms into the peritoneal space.

**Pericardial amebiasis.** Pericardial disease is a rare but serious complication of amebic liver abscess. It usually results from the rupture of an abscess in the left lobe of the liver and presents with fever and chest pain and progresses to congestive heart failure, tamponade, and shock.

**Cerebral amebiasis.** Cerebral amebiasis is rare, with reports from clinical series of < 0.1% of patients. Autopsy series of patients with known amebiasis show central nervous system involvement of 1-2%. Cerebral abscess should be suspected in a person with known amebiasis who presents with mental status changes or focal neurologic signs.

**Genitourinary amebiasis.** Renal infection may occur either from direct extension of hepatic disease or by hematogenous or lymphatic spread. Genital lesions typically arise from fistulae from hepatic or colonic disease and present with painful ulcers with profuse discharge.

## Diagnosis

The diagnosis of intestinal infection with *E histolytica* or *E dispar* is made by demonstration of cysts or trophozoites in the stool or by examination of biopsy specimens of mucosal tissue. Amebic trophozoites are destroyed by many agents, including antibiotics, antidiarrheal agents, barium, and tap water. Therefore, stool specimens should be examined by preparing wet mounts of specimens within 20 min of collection and examining immediately. Staining with iodine and trichrome maximizes the yield of positive specimens. Pathogenic trophozoites of *E histolytica* may be distinguished from nonpathogenic species by the presence of ingested erythrocytes within the organism.

Serology is useful in diagnosis of *E histolytica* infection. Antibodies to ameba develop only with infection by *E histolytica* and do not develop with *E dispar* infection. With invasive colitis or hepatic abscess, antibodies may be negative initially but become positive by 7-10 days in > 85-95% of patients. Antibodies cannot distinguish current infection from remote infection, as the antibodies may remain positive for years.

Monoclonal antibodies and polymerase chain reaction technology are newer technologies being used for diagnosis of amebic infection and appear to allow differentiation of *E histolytica* from *E dispar*. An enzyme-linked immunoabsorbent assay with monoclonal antibodies to a region that contains epitopes unique to *E histolytica* has been used to make this distinction in preliminary studies.

Amebic liver abscess should be suspected in any patient with an abnormal abdominal exam and appropriate risk factors, such as recent travel to an endemic area. Once a hepatic fluid collection is demonstrated radiographically, it is important to distinguish amebic abscess from pyogenic abscess. Serology once again is useful but may be negative for the first week of the infection. Often, percutaneous sampling of the fluid is required to look for cysts and trophozoites. Amebas may not be found in the liquefaction center of an abscess, but the results of Gram stain, culture, and serology will usually distinguish amebic abscess from other causes.

Diagnosis of other extraintestinal sites of infection requires clinical suspicion in the appropriate setting, such as a patient with known amebic abscess. Demonstration of amebas in these extrahepatic sites is not universally required but is often obtained, because drainage is required for empyema, peritoneal involvement, and, usually, pericardial involvement.

## Treatment

Treatment of amebic disease requires both the elimination of the trophozoite form from the intestine or extraintestinal sites and the elimination of cysts from the intestine. If a luminal agent is not used to eradicate cysts, disease may recur.

Metronidazole is the agent of choice for treatment of amebic colitis. Doses of 750 mg three times daily for 5-10 days are extremely effective, and the drug can be given orally or intravenously. Side effects are generally gastrointestinal: nausea, vomiting, and abdominal discomfort. If ingested with alcohol, metronidazole produces a disulfiram-like

reaction. The drug carries a potential risk of teratogenicity if used in pregnant women; however, because amebic disease is often more serious in pregnant women, treatment is generally recommended. No teratogenic effects were seen in > 2500 women inadvertently given metronidazole during pregnancy. In Europe, two additional nitroimidazole antibiotics (tinidazole and ornidazole) are available, are effective therapy, and are associated with fewer adverse effects than metronidazole. These drugs are not available in the United States.

Tetracycline or erythromycin is effective therapy for milder cases of colitis. Because these drugs will not eradicate ameba in the liver, their use should probably be restricted to patient who cannot tolerate metronidazole. Emetine and dehydroemetine have relatively high toxicity and must be given in a monitored environment. They offer no benefit over standard metronidazole therapy.

Three luminal agents are available for eradication of cysts after treatment with metronidazole or other agents. Diloxanide furoate has a > 90% efficacy but must be obtained from the Centers for Disease Control and Prevention in the United States. Iodoquinol (diiodohydroxyquin) requires 20 days of therapy and is in limited supply in the United States. Because of its high iodine content, it may interfere with thyroid function tests and should be avoided in those allergic to iodine. Other side effects include gastrointestinal discomfort, fever, and headache. Paromomycin is a nonabsorbable aminoglycoside that may cause loose stools. It is often preferred for circumstances in which systemic absorption is undesirable, such as in pregnancy.

Amebic liver abscess is responsive to medical therapy, and, as with intestinal disease, metronidazole is the preferred agent. Given as a 5- to 10-day treatment, metronidazole has a cure rate of > 95%. The role of aspiration or drainage is unclear but usually is not necessary. Because of the high response rate to medical therapy, aspiration is probably best used only in a few defined circumstances. In the patient who is not clinically improved within 3 days of initiation of therapy, aspiration is used to confirm the diagnosis and to exclude other causes of abscess, such as bacterial infection. Aspiration is also indicated for a ruptured abscess and in an abscess that is in danger of rupture, as characterized by a large fluid collection surrounded by a thin rim of hepatic tissue. If a left-lobe abscess is in danger of involving the pericardium, aspiration should be performed.

Medical therapy is generally sufficient for amebiasis involving the genitourinary tract, central nervous system, and lung parenchyma. Involvement of the pericardium and pleural space may require drainage because of the development of loculations. Treatment of amebiasis is outlined in [Boxes 82-2](#) and [82-3](#).

## Prognosis

Although infection with *E histolytica* can be debilitating, it is generally not life threatening. Once infection is identified, effective treatment exists. Relapse or reinfection is not unusual. Only a small minority of patients develops severe complications, such as colonic perforation, toxic megacolon, ruptured hepatic abscess, or cerebral amebiasis.

## Prevention & Control

Prevention of amebic infection is greatly enhanced by effective sanitation and a clean water supply. Cysts are resistant to destruction by chlorine, but iodine or boiling is sufficient to kill the organism. Health education and public health efforts to identify and treat carriers may limit disease spread ([Box 82-4](#)). Travelers to endemic areas should avoid unpeeled fruits and vegetables and should avoid drinking water unless it has been properly treated. Several vaccines to *E histolytica* are under development and may provide the most effective means of disease control once released.

## PATHOGENIC FREE-LIVING AMEBAS

### ***ACANTHAMOEBA* INFECTION**

Amebas of the genus *Acanthamoeba* live as cysts and trophozoites in soil and in water. They can cause several disease syndromes in human hosts, including encephalitis, keratitis, and infections of the skin that resemble deep fungal infections. In addition, they can infect other human tissues and cause a granulomatous reaction. These amebas may be carried in an asymptomatic nasal carrier state. Immunocompromised patients, such as transplant recipients and HIV-infected persons, are at increased risk of contracting disease. Diving in warm water may increase infection rates.

The encephalitis caused by *Acanthamoeba* is a chronic, focal, necrotizing infection characterized by granuloma formation (granulomatous encephalitis). Patients usually present with the insidious onset of focal neurological deficits, fevers, headache, meningismus, seizures, and mental status changes. Common focal deficits include visual disturbances and ataxia. Diagnosis is difficult and is often made only at autopsy. Tissue biopsy specimens may provide diagnosis. Cerebrospinal fluid lymphocytosis may be present, but the organism has not been isolated from cerebrospinal fluid. Granulomatous encephalitis leads to death, with an average survival from the onset of symptoms of 40 days. No treatment is effective. Imidazole antifungal agents, amphotericin B, neomycin, flucytosine, sulfonamides, pentamidine, and propamidine have been used without success.

*Acanthamoeba* species cause keratitis, and > 200 cases have been described in the United States since the early 1970s. Risk factors include use of contact lenses, exposure to contaminated water, and trauma to the cornea. After exposure, patients typically note a foreign body sensation that is followed by eye pain, visual change, tearing, and conjunctivitis. Progression of disease may lead to blindness. The disease is frequently misdiagnosed initially as herpes simplex virus or bacterial keratitis. Correct diagnosis is made by demonstration of the organism on corneal scrapings or biopsy material. Treatment requires surgical debridement followed by a minimum of 3-4 weeks of medical therapy, which consists of topical treatment with propamidine, Neosporin, and miconazole. Other therapies are topical polyhexmethylene biguanide or the combination of topical miconazole and oral itraconazole.

### ***NAEGLERIA FOWLERI* INFECTION**

*Naegleria fowleri* is a free-living amoeba that causes a primary meningoencephalitis. It

may live in warm water areas, including lakes, hot springs, mud puddles, and swimming pools. Most infections are in children or young adults and manifest 5-15 days after exposure to an infected water source. The organism invades the meninges through the cribiform plate, a process facilitated by diving in deep water. Those infected may have a viral prodrome with nausea, vomiting, headache, and malaise and rapidly progress to coma and death within 2-3 days. Most patients have meningeal signs.

Diagnosis must be suspected early, because, even with prompt treatment, there are only four documented survivors of this infection. Primary amebic meningoencephalitis should be considered in those with a viral prodrome rapidly progressing to coma. Patients typically have leukocytosis. Lumbar puncture should be performed with caution, as increased intracranial pressure raises the risk of herniation. Cerebrospinal fluid will show many erythrocytes and typical leukocyte counts of 400-25,000/uL, with 50-100% neutrophils. Protein may be mildly elevated, and glucose is normal to slightly low. If no bacteria are seen on Gram stain of a purulent cerebrospinal fluid, a wet mount should be examined for amebic trophozoites. The specimen should not be refrigerated or centrifuged, because this reduces the ameba's motility and makes trophozoites difficult to distinguish from the many leukocytes.

Treatment of primary amebic meningoencephalitis is generally unsuccessful. The documented survivors received intravenous and intrathecal amphotericin B. One patient also received miconazole, rifampin, and sulfisoxazole. Laboratory studies with a rabbit model have shown synergy between amphotericin B and rifampin or tetracycline. Intrathecal administration of antinaegleria antibody has also improved survival in animal models.

## **83 . *Cryptosporidium*, *Cyclospora*, & *Isospora* Species & Microsporidia — *Stephanie Boade Silas, MD, & DeVon Hale, MD***

### **INTRODUCTION**

Within the last decade, the AIDS epidemic has heightened awareness of several gastrointestinal spore-forming protozoan pathogens. The genera *Cryptosporidium*, *Isospora*, and *Cyclospora* are members of the subclass Coccidia and phylum Apicomplexa; the microsporidia are a group of organisms belonging to the phylum Microspora. The spectrum of disease caused by these protozoans goes beyond gastrointestinal manifestations, and the significance of these protozoan infections is becoming increasingly appreciated in both immunocompromised and immunocompetent hosts.

### **CRYPTOSPORIDIUM**

#### **Essentials of Diagnosis**

- Key signs and symptoms include dehydration with watery diarrhea of variable quantity.
- Waterborne transmission is the most common mode of oocyst transmission.
- Patients at risk for person-to-person transmission include household contacts, sexual contacts, health care workers, and children in day care.
- Symptoms are prolonged and more severe in immunocompromised patients.
- Acid-fast staining of fixed stool specimens allows identification of oocysts; immunofluorescence and enzyme-linked immunosorbent assay techniques are also available.

#### **General Considerations**

**A. Epidemiology.** *Cryptosporidium* spp. were first described at the beginning of this century but were not reported as human pathogens until 1976. *Cryptosporidium* infection is present worldwide with 250 million-500 million annual cases. Increased infection rates occur during warm, humid months. In industrialized nations, oocyst passage is prevalent in 1-3% of the population, compared with 5-10% oocyst passage in less-developed nations. This difference has been attributed to existence in the developing countries of conditions such as poor sanitation, crowded households, and nearby animal reservoirs. Industrialized nations report an increased prevalence in rural areas, whereas less-developed nations have a higher urban prevalence. The significance of cryptosporidiosis may be underestimated because the seroprevalence in industrialized nations has been reported to be = 35%. In developing nations, seroprevalence has been reported to be = 100%. Patients with AIDS with diarrhea have an 11-21% oocyst passage prevalence in developed nations compared with a rate of =

50% in Africa and Haiti. Chronic intestinal cryptosporidiosis that lasts > 1 month has been classified as an AIDS-defining opportunistic infection.

Transmission of oocysts occurs by person-to-person, animal-to-person, and environmental contacts. Those at risk for person-to-person transmission include household members, sexual partners, health workers, and children in day care. Nineteen percent of household contacts of infected patients have been diagnosed with secondary infection. Household pets, laboratory animals, and farm animals have all been associated with transmission to humans. Nosocomial infection has also been reported.

Waterborne oocyst transmission is considered the most important mode of transmission and is associated with the largest outbreaks. The initial cases of waterborne transmission were described in 1983, in Finnish individuals with diarrhea who had traveled to St. Petersburg (then Leningrad), Russia. Subsequently, other cases of traveler's diarrhea have been attributed to cryptosporidiosis. Many common source outbreaks have been described in Great Britain and the United States, the largest of which occurred in Milwaukee in 1993, affecting 403,000 people. Surface runoff from cow pastures was identified as the contaminating source of oocysts. Unboiled well water has also been implicated in transmission. Cryptosporidiosis related to apple cider has been associated with use of fallen apples in contaminated cow pastures. Oocysts, which survive well in cold, moist environments, are found in 65-87% of surface water. In one study, oocysts were found in 27% of drinking water samples from 66 inspected treatment plants, confirming the resistance of oocysts to current water treatment methods.

**B. Microbiology.** *Cryptosporidium parvum* is the species of this intracellular coccidian protozoan parasite that is responsible for illness in humans. Its life cycle occurs within a single host, beginning as an ingested thick-walled, round oocyst measuring 2-6  $\mu\text{m}$  in diameter. Excystation, induced by enzymes and bile salts found in the small intestine, releases four motile sporozoites that infect the small intestine. Further differentiation and division occur within an intracellular but extracytoplasmic vacuole of the enterocyte. Each sporozoite matures and divides asexually, releasing four to eight merozoites. The merozoite reinfects the small intestine or begins sexual maturation to a zygote and ultimately a fully sporulated oocyst. Approximately one of five oocysts is thin walled and reinfects the host; the remaining thick-walled oocysts are passed in stool to the environment. *C. parvum* is unique in its ability to complete its life cycle within a single host. In particular, the autoinfectivity of the merozoites and thin-walled oocysts allows *C. parvum* to perpetuate infection without subsequent environmental exposures.

**C. Pathogenesis.** The mechanism of disease associated with *C. parvum* infection is unknown. As few as 30 oocysts have been found to cause infection in healthy volunteers, with a mean infective dose of 132 oocysts. The organism is limited to the intestine and appendix in the immunocompetent host, but it may be found throughout the gastrointestinal tract, in the hepatobiliary system, and in the respiratory tract of immunocompromised patients.

The resulting diarrhea is postulated to be either secretory (ie, caused by an unidentified toxin) or osmotic (ie, caused by malabsorption from intestinal villi injury). Histologic

findings include atrophy, blunting, fusion, or loss of villi. Crypt hyperplasia is seen, and the lamina propria of the intestine has an inflammatory infiltrate.

The immune response in cryptosporidiosis is also poorly understood. Patients with a variety of immune deficiencies, including both T-cell abnormalities and  $\gamma$ -globulin deficiencies, have prolonged and more severe infections. Acquired immunity can prevent reinfection and limit primary infection, but the mechanism of protection is not entirely understood. Selective antibodies may inhibit an important attachment step. Bovine colostrum containing anti-*C parvum* antibodies limited infection in immunodeficient patients, but similar colostrum without antibodies did the same in experimental mouse infections. Further, patients with AIDS have been shown to mount an antibody response yet still be unable to clear the infection. This response lends support to other evidence suggesting the importance of adequate CD4 cells in addition to immunoglobulin A antibodies for protection. The presence of particular cytokines may be important in this interaction. Human breast milk does not confer protection from infection.

## CLINICAL SYNDROMES

### INTRODUCTION

Enteric cryptosporidiosis is the most common clinical presentation in patient populations. In addition, immunocompromised patients may present with cholecystitis or respiratory infections attributed to *C parvum* ([Box 83-1](#)). Asymptomatic infection has also been reported.

### 1. ENTERIC CRYPTOSPORIDIOSIS

#### Clinical Findings

**A. Signs and Symptoms.** An average of 5-7 days passes from oocyst ingestion to symptom onset. Symptoms are similar in both immunocompetent and immunocompromised patients but are prolonged and considerably more severe in compromised patients. Patients complain of watery diarrhea in variable quantities of = 25 L/day leading to significant dehydration. Abdominal cramps, malaise, low-grade fever, and anorexia are frequently reported. Nausea, vomiting, myalgia, headache, and weight loss may also occur. Symptoms are usually self-limited in immunocompetent hosts, lasting 5-14 days, although cases lasting several months have been reported in normal hosts. Oocysts can still be found in stool 2 weeks after symptom resolution.

**B. Laboratory Findings.** Stool samples are generally negative for erythrocytes and leukocytes but can be streaked with mucous. Leukocytosis and eosinophilia are rare. After prolonged illness, malabsorption of fat, D-xylose, and B<sub>12</sub> can be measured.

**C. Imaging.** Abdominal films are nonspecific, revealing mucosal thickening and disordered motility. Endoscopy shows only focal nonspecific atrophy.

**D. Differential Diagnosis.** In the immunocompetent host, *C parvum* infection may present similarly to *Shigella*, *Salmonella*, and *Campylobacter* spp., as well as

*Clostridium difficile* and *Giardia* spp., in patients with an appropriate history. Similar presentations occur with *Entamoeba histolytica* and other coccidia, and in immunodeficient patients, diagnoses of cytomegalovirus, *Mycobacterium avium*, and microsporidia should be entertained.

**E. Complications.** Toxic megacolon and reactive arthritis involving the wrists, hands, knees, ankles, or feet have been reported in association with cryptosporidiosis. Pancreatitis has also been reported in both immunocompetent and immunocompromised hosts presenting with cryptosporidiosis.

## 2. CHOLECYSTITIS

### Introduction

Up to 10% of AIDS patients with cryptosporidiosis present with cholecystitis. Cryptosporidial cholecystitis has thus far been diagnosed only in AIDS patients.

### Clinical Findings

**A. Signs and Symptoms.** Patients present with fever, right upper quadrant pain, nausea, and vomiting with or without associated diarrhea.

**B. Laboratory Findings.** Laboratory studies reveal elevated alkaline phosphatase and bilirubin levels.

**C. Imaging.** Imaging with ultrasound or computed tomography usually shows an enlarged gallbladder with thickened walls and dilated ducts but may be normal in 25% of infected patients. Endoscopic retrograde cholangiopancreatography can reveal common bile duct beading or papillary stenosis.

**D. Differential Diagnosis.** Microsporidial and cytomegalovirus infections may have similar presentations in patients with AIDS.

**E. Complications.** Cryptosporidial cholecystitis has been complicated by pancreatitis, cholangitis, hepatitis, and chronic gallbladder carriage.

## 3. RESPIRATORY INFECTION

### Introduction

*C parvum* has rarely been identified in biopsy and lavage specimens of immunodeficient patients who present with dyspnea, hoarseness, wheezing, or cough as well as symptoms of laryngotracheitis and sinusitis. Chest films are generally normal or show modest infiltrates and increased bronchial markings. The respiratory syndrome has not yet been directly associated with *C parvum* diarrheal illness.

### Diagnosis

The majority of diagnoses of *C parvum* infection are made by identification of the organism in stool specimens ([Table 83-1](#)). Stool should be examined while it is fresh or fixed in 10% formalin or polyvinyl alcohol. Oocysts can be identified by light microscopy without specific staining but are more readily seen with modified acid-fast staining. Phase-contrast microscopy reveals birefringent oocysts. Oocysts in duodenal aspirates or respiratory secretions can be similarly identified. Submitting three to four separate stool samples has been recommended for increased diagnostic yield. However, in a study of AIDS inpatients, one stool specimen resulted in 96% sensitivity, increasing to 100% with only two specimens. Orders should specify suspected *C parvum* because most laboratories do not routinely use acid-fast staining.

Immunofluorescence and enzyme-linked immunosorbent assay techniques are more sensitive and specific methods of diagnosis ([Figure 83-1](#)). Sensitivities of 93-100% and specificities of 99-100% have been reported for various direct immunofluorescent-antibody assays. The available enzyme-linked immunosorbent assay techniques have 72-100% sensitivity and 98-100% specificity. The clinical utility of polymerase chain reaction analysis is still developing.

Hematoxylin and eosin staining of intestinal biopsy specimens reveals basophilic organisms on the brush border that appear to project into the lumen because of the intracellular but extracytoplasmic location of the organism. Direct immunofluorescence can also be used on these biopsy specimens, and electron microscopy provides greater detail. However, the invasiveness of biopsy is rarely warranted and is not 100% sensitive.

Serologic antibody identification is available for *C parvum* infection but is still investigational and not clinically useful for diagnosis due to the persistence of antibody after infection. It is valuable as an epidemiologic tool, however.

## Treatment

No reliable treatment is available at this time for cryptosporidiosis ([Box 83-2](#)). Supportive care with fluids and antidiarrheal agents can be offered while awaiting resolution in immunocompetent hosts or while addressing the underlying etiology of immunosuppression in compromised hosts. Paromomycin sulfate is currently the drug of choice for *C parvum*, surpassing spiramycin, for which there are no controlled studies. Paromomycin treatment is well tolerated by patients, but relapse is common even on therapy. For those patients relapsing off of therapy, however, 80% will again have a good response when they are back on paromomycin sulfate. Initial reports on the efficacy of a special lactose-free preparation of azithromycin have been promising. Hyperimmune bovine colostrum has been helpful in decreasing symptoms despite the persistence of oocyst shedding. Bovine transfer factor isolated from infected calf lymph node suspensions has been shown to attenuate symptoms, and octreotide has been similarly helpful. For all of the above therapeutic modalities, large randomized studies are needed for better understanding and documentation of effect.

## Prognosis

Although cryptosporidiosis is self-limited in immunocompetent patients, patients with

AIDS with enteric cryptosporidiosis present with disease, the severity of which is related to the degree of immunosuppression. In one series of patients with AIDS, 29% of cases were transient, 60% chronic, 8% fulminant, and 4% asymptomatic. Mean survival in these patients was 25 weeks.

## Prevention & Control

*C parvum* oocysts are 30-fold more resistant to chlorine than are *Giardia* cysts. Oocysts are killed in water kept above 65°C for 30 min as well as water boiled for 1 min at any altitude. Oocyst death is also reported in water kept at < 20°C for 30 min, although more recent information suggests greater resistance to freezing than previously thought ([Box 83-3](#)).

Enteric precautions and good hygiene should reduce most person-to-person transmission as well as animal-to-human exposures because family contacts account for = 50% of secondary cases. Also, apple juice and cider should be pasteurized or boiled before consumption. No prophylactic regimen for patients with AIDS is yet available, although paromomycin sulfate and azithromycin are being studied. Immunocompromised patients should be instructed to drink bottled or boiled water if water supplies are suspect.

## CYCLOSPORA

### Essentials of Diagnosis

- Patients present with watery diarrhea, which is usually self-limited in immunocompetent patients but may be prolonged in the immunocompromised patient.
- A history of travel to areas such as Nepal, Haiti, and Peru, a history of berry consumption, or community outbreak of diarrhea may increase suspicion of diagnosis.
- Acid-fast stain of stool specimens reveals abundant oocysts.

### General Considerations

*Cyclospora* is a coccidian that had been described as a "large cryptosporidium" or "cyanobacterium-like body" before being confirmed as a member of the phylum Apicomplexa in 1993. The life cycle in humans has not been fully detailed. The organism has been shown to infect jejunal enterocytes. Similar to *Isospora*, the oocysts are excreted unsporulated, requiring 7-13 days of optimal conditions outside of the host to mature. Each spherical oocyst has a diameter of 8-10  $\mu$ m and contains two sporocysts, each of which contains two sporozoites. The oocyst is twice the size of *C parvum* ([Figure 83-2](#)).

*Cyclospora catayensis* infection in humans has been reported worldwide and was first described in Papua New Guinea in 1979. It is endemic in Haiti, Peru, and Nepal, where rainy-season outbreaks of *C catayensis* infection occur. Outside these areas, infection is usually travel related when not associated with an outbreak. Protective immunity is suggested because infection is more common in children and in non-natives. Infection

has been reported in HIV-infected patients, but cyclosporiasis is primarily found in immunocompetent patients. In the United States, *Cyclospora* oocysts were identified in only 3 of 1042 submitted stools. The low prevalence in patients with AIDS in the United States is attributed to possible misdiagnoses as *C parvum*, nonuniform use of the acid-fast stain, trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis in these patients, and the coincident low prevalence in immunocompetent patients in the United States.

Transmission of *Cyclospora* has been linked to contaminated water and food sources. The organism is believed to be host specific to humans. In 1990, a Chicago outbreak was related to stagnant water in a storage tank, and in 1994, in Nepal, a British military unit experienced an outbreak related to water from a chlorinated and filtered tank. More recently, cyclosporiasis related to berry consumption has been in the news. In 1995, unwashed strawberries were related to outbreaks in New York and Florida. In 1996, 1465 cyclosporiasis cases in two Canadian provinces and 20 states in the United States were traced to consumption of Guatemalan raspberries. Lettuce and uncooked meat have been reported culprits as well.

The pathogenesis of cyclosporiasis is not well understood. The parasite is found in the upper small bowel and is associated with villous atrophy, crypt hyperplasia, and inflammatory changes similar to those seen in tropical sprue.

## Clinical Findings

After an incubation of 2-11 days, immunocompetent patients experience a self-limited, but prolonged, relapsing watery diarrhea lasting an average of 19-43 days, although organism shedding may last = 70 days ([Box 83-4](#)). In patients with AIDS, symptoms have been reported for = 4 months. A median of six stools/day is reported. Fatigue, fever, indigestion, abdominal cramps, nausea, and vomiting may occur, as well as weight loss. A prodrome of both myalgia and arthralgia has been reported. Diarrhea may not be the primary complaint, and alternation with constipation is not infrequent. Asymptomatic infection has been reported in a study of immunocompetent Peruvians with documented infection in whom only 11-28% had diarrhea. No specific laboratory findings assist in diagnosis although abnormal D-xylose absorption has been reported.

**A. Differential Diagnosis.** A similar presentation may be found in cryptosporidiosis, isosporiasis, microsporidiosis, and sarcocystosis.

**B. Complications.** Biliary disease has been reported.

## Diagnosis

Diagnosis is made by identification of the *Cyclospora* oocyst in fresh or iodine-preserved stool, duodenal aspirates, or small-bowel biopsies. With acid-fast or safranin O staining, oocysts can be seen as 10 um spheres with clusters of refractile globules. The oocysts autofluoresce blue under UV light with a 365-nm excitation filter ([Table 83-2](#)).

## Treatment

TMP-SMX is the first-line treatment for cyclosporiasis, with symptom resolution noted 2-3 days into therapy ([Box 83-5](#)). Immunosuppressed patients may require long-term suppressive therapy owing to an increased relapse rate. In addition to TMP-SMX, metronidazole, tinidazole, and ciprofloxacin hydrochloride have also been reported to stop oocyst excretion.

## Prognosis

Infection is generally self-limited in immunocompetent hosts, but prolonged diarrhea with possible symptoms of malabsorption may occur in immunocompromised patients.

## Prevention & Control

Reliable means of prevention of *Cyclospora* spp. infection are not yet known ([Box 83-6](#)). Efforts to decrease berry contamination have been directed toward using potable water in all aspects of berry preparation, including water used for insecticide spray and for hand washing by workers. Gamma radiation used on berries is also being studied.

## ISOSPORA

### Essentials of Diagnosis

- Patients are usually either travelers to tropical areas with self-limited diarrhea or immunocompromised patients with a protracted diarrheal illness.
- Unsporulated oocysts are detected on wet mounts of stool samples by acid-fast staining.

### General Considerations

**A. Epidemiology.** *Isospora* infection is endemic in several tropical and subtropical climates in areas of South America, Africa, and southwest Asia. In the United States, *Isospora belli* infection occurs primarily in patients with AIDS but is still quite rare in this population, accounting for = 0.2% of AIDS-defining illnesses. *Isospora* infection is more common in patients with AIDS from developing countries in which the prevalence of spore passage is 15% compared with 5% in industrialized nations.

In immunocompetent patients, *I belli* has been identified in cases of chronic traveler's diarrhea and is present in outbreaks of diarrhea in institutional settings such as day care and mental facilities.

Because sporulation can occur only outside the host, transmission may occur through environmental sources such as food and water. A latency state has been postulated based on increased prevalence of infection in Latin American immigrants. In Los Angeles, Latin Americans account for = 20% of AIDS cases but have 80% of *I belli* infections.

**B. Microbiology.** *I belli*, first described by Virchow in 1860, is a coccidian parasite that is host specific to humans. A 30 um x 12 um oval oocyst is ingested, releasing two

sporocysts, each of which contains four sporozoites, which then infect enterocytes. An asexual cycle produces merozoites, which further infect epithelial cells; a sexual cycle produces immature, unsporulated oocysts that are passed in the feces. Sporulation occurs in a few days resulting in a mature oocyst.

**C. Pathogenesis.** The pathogenesis of *I belli* infection is not fully understood. Small-bowel histology reveals shortened villi, hypertrophic crypts, and inflammatory infiltration of the lamina propria with eosinophils. Symptoms of disease based on these histologic findings are likely caused by malabsorption.

## Clinical Findings

**A. Signs and Symptoms.** After an incubation of < 1 week, immunocompetent patients present with an acute, self-limited diarrheal illness of varying severity resolving in 2 weeks ([Box 83-7](#)). Patients may pass 6-10 stools daily; the stools are foul smelling, watery, and soft. Malaise, anorexia, and abdominal cramps are common. Weight loss, headache, vomiting, and increased flatulence may occur, and occasionally fever may be documented. Oocyst shedding persists for 2-3 weeks beyond resolution of symptoms. Persistence of symptoms for months to years has been reported in some immunocompetent patients. Immunocompromised patients present with the same symptom complex but with increased severity and a protracted course.

**B. Laboratory Findings.** Stool specimens contain no leukocytes or erythrocytes but may contain Charcot-Leyden crystals, which are eosinophilic granules indicative of the peripheral eosinophilia specific to *I belli* infection. Laboratory evidence of malabsorption may be present.

**C. Imaging.** Nonspecific mucosal thickening is seen on abdominal films.

**D. Differential Diagnosis.** Cryptosporidiosis and microsporidiosis can have similar presentations. Also, coinfection with *C parvum*, *Giardia* spp., and *Trichuris* spp. has been reported in AIDS patients.

**E. Complications.** Disseminated isosporiasis in a patient with AIDS has been reported with invasion of the bowel wall, lymph nodes, liver, and spleen. Acalculous cholecystitis and reactive arthritis have also been reported to complicate infection.

## Diagnosis

Diagnosis of isosporiasis depends on identification of the oocyst in stool by wet mount with subsequent confirmation using modified acid-fast or trichrome staining. Colonoscopy aspiration or the duodenal string test may be helpful to obtain the necessary sample. Oocysts autofluoresce in UV light when viewed through a 450- to 490-nm excitation filter ([Table 83-3](#)).

## Treatment

TMP-SMX has been shown to be effective treatment ([Box 83-8](#)). Patients with AIDS have a 50% chance of relapse, and low-dose suppressive treatment with TMP-SMX,

pyrimethamine-sulfadoxine, or pyrimethamine alone is recommended. Alternative treatments include metronidazole, ciprofloxacin hydrochloride, roxithromycin, and diclazuril.

## Prognosis

Untreated isosporiasis in the immunocompromised patient can lead to severe malnutrition and dehydration and may be fatal.

## Prevention & Control

No proven means of prophylaxis for isosporiasis has yet been established due to unknown details of transmission and the possibility of a latency state (see [Box 83-6](#)). The common usage of TMP-SMX for *Pneumocystis carinii* prophylaxis may indeed also play a role in *I belli* prophylaxis. Because *I belli* infection appears to be mediated through water and environmental sources, good fecal-oral hygiene and adequate water treatment are recommended.

## MICROSPORIDIA

### Essentials of Diagnosis

- Most cases of microsporidiosis occur in male patients with HIV infection and CD4 counts of < 100.
- In HIV-infected patients, microsporidiosis most commonly presents as chronic diarrhea, although cholecystitis, respiratory infection, keratoconjunctivitis, and myositis have also been reported.
- Infections in non-HIV-infected patients are rare but include central nervous system infection, corneal infection, and myositis.
- Diagnosis is difficult and depends on identification of 1- to 2-um spores.

### General Considerations

**A. Epidemiology.** Microsporidia were first discovered in 1857, but it was not until 1973 that a human case of microsporidiosis was confirmed from a case described in 1959. Awareness of the diversity of microsporidial infections has heightened, especially in light of the AIDS epidemic. Central nervous system, respiratory, corneal, muscular, and gastrointestinal microsporidial infections have all been identified.

Microsporidiosis has been found worldwide. Before the AIDS epidemic, only 10 cases had been reported. Subsequently, hundreds of cases have been recognized, mostly in the United States. Between 23% and 33% of patients with AIDS with chronic diarrhea have been diagnosed with microsporidiosis, with *Enterocytozoon bieneusi* being the most common culprit. Most cases of microsporidiosis occur in male patients with HIV with severe immunosuppression and CD4 counts of < 100. Of 11 cases reported in non-HIV-infected patients, 4 had other forms of immunosuppression such as earlier liver

and bone marrow transplants, and 4 had infections of the cornea, a site that is considered to be immunoprivileged. Infection in immunocompetent patients may be under-recognized because of transient infection or milder disease. Self-limited diarrhea has been documented in an immunocompetent traveler, and an asymptomatic carrier state has been identified.

Little is known about transmission of microsporidiosis, and there have been no reports of common-source outbreaks. However, microsporidium spores have been identified in respiratory secretions, urine, stool, and duodenal aspirates, suggesting that person-to-person transmission may occur by fecal-oral contacts, aerosolized secretions, sexual transmission, or direct corneal inoculation. Microsporidia infect insects, fish, snails, and mammals and are also present in surface water, which suggests the zoonotic and environmental transmission of these resistant spores. The spores have been shown to survive > 1 year in water kept at 4 °C.

**B. Microbiology.** Microsporidia are obligate intracellular, spore-forming protozoa of the order Microsporidia and the phylum Microspora. Primitive eukaryotes that lack mitochondria, microsporidia undergo a life cycle with three phases. In the first phase, infection, spores are ingested or inhaled. The host environment stimulates eversion of the spore coat, at which time a coiled tubular apparatus anchors the spore to the host cell. After the spore is attached, it allows the injection of sporoplasm into the cell, which begins the second phase, merogony. Within the cell, the parasite proliferates by fission, creating multiple multinucleated plasmodial meronts. Sporogony, the third phase, occurs when the meront cell matures and its membrane thickens to form a mature thick-walled spore with a diameter of 1-2  $\mu$ m. Cell rupture releases ovoid spores that either reinfect the host or are passed into the environment by urine, stool, or respiratory secretions. These resistant spores can be viable for = 4 months.

Five genera from the protozoan phylum Microspora have been implicated in human disease: *Encephalitozoon* (*Encephalitozoon hellem* and *Encephalitozoon cuniculi*), *Pleistophora*, *Enterocytozoon* (*Enterocytozoon bieneusi*), *Septata* (*Septata intestinalis*), and *Nosema*, which was recently reclassified as *Vittaforma*. Unclassified species are placed under a sixth taxon, *Microsporidium*. The genera and species are separated primarily based on the location of the parasite in relation to the host, that is, whether the parasite is in direct contact with host cytoplasm, separated into a vesicle made by the host, or located in a parasitophorous vacuole.

**C. Pathogenesis.** Little is known of the etiology of microsporidia. Spores infect epithelia, mesenchymal cells, endothelia, and macrophages. Spores are found in enterocytes with associated intestinal villi shortening, fusion, and crypt elongation, as well as a lymphocytic infiltrate. *S. intestinalis* spreads by lymphatics and blood vessels whereas *E. bieneusi* spreads to the lungs by aspiration. Corneal infection is associated with ulceration, infected epithelium, and an infiltrate of macrophages and neutrophils.

## CLINICAL SYNDROMES IN NON-HIV-INFECTED PATIENTS

Microsporidial infection in non-HIV-infected patients is rare, with < 20 cases reported. Central nervous system, corneal, muscular, enteric, and respiratory infections have all been identified ([Box 83-9](#)).

Central nervous system infections have been reported in two immunocompetent children presenting with fever, loss of consciousness, headache, and convulsions, as well as hepatomegaly. *E cuniculi* was isolated from the cerebrospinal fluid and the urine. Computed tomography of the brain and electroencephalography were normal. Corneal infection has been caused by *Nosema* spp., *Microsporidium ceylonensis*, and *Microsporidium africanum*. Patients have presented with decreased visual acuity, conjunctivitis, and corneal ulcers. Corneal biopsy reveals the organism.

Patients presenting with generalized muscle weakness have been diagnosed with myositis caused by *Pleistophora* spp. Laboratory tests revealed normal creatine kinase levels, and electromyograms showed myopathy. Muscle biopsies revealed scarring, fibrosis, inflammation, and *Pleistophora* infiltrate. Self-limited diarrhea caused by *E bieneusi* has been reported in an immunocompetent host. A patient with chronic myelogenous leukemia who had undergone allogenic bone marrow transplant was recently shown on autopsy to have microsporidial infection along with *Candida tropicalis* infection within lung sections.

## CLINICAL SYNDROMES IN HIV-INFECTED PATIENTS

### INTRODUCTION

The most common manifestation of microsporidial infection in HIV-infected patients is enteric disease, but other recognized syndromes include biliary infection, pulmonary infection, keratoconjunctivitis, and myositis ([Box 83-10](#)).

## 4. GASTROINTESTINAL INFECTION

### Introduction

*E bieneusi* and *S intestinalis* are the most common etiologic agents identified in patients presenting with chronic diarrhea due to microsporidia. However, there is one case report of *E cuniculi* identified in intestinal infection.

### Clinical Findings

**A. Signs and Symptoms.** Symptoms can persist over months and are associated with anorexia and a 10-20% weight loss. The diarrhea is usually loose and watery, with patients reporting 1-20 stools/day. The diarrhea is worse in the mornings and exacerbated by eating. A crampy abdominal pain can precede defecation. Nausea and vomiting are rarely present, and patients are afebrile.

**B. Laboratory Findings.** Stool specimens are negative for leukocytes or erythrocytes. Serum electrolytes can reveal low potassium, magnesium, and zinc. Malabsorption is indicated by abnormal D-xylose absorption, low B<sub>12</sub> levels, and increased fecal fat.

**C. Differential Diagnosis.** Differential diagnosis includes *C parvum* and other coccidial protozoa. Coinfection with *Mycobacterium avium* complex, *Giardia* spp., and *C parvum* in the small bowel and cytomegalovirus and *C parvum* in the large bowel has been

reported.

**D. Complications.** Complications of gastrointestinal infection include biliary disease by direct extension and respiratory infection from aspiration. Nephritis by hematogenous spread of *S intestinalis* has been documented, and *S intestinalis* has also been identified in a rectal ulcer. Mortality of enteric microsporidiosis has been reported at 56%.

## 5. BILIARY INFECTION

### Introduction

*E bienewsi* and *S intestinalis*, often associated with cryptosporidial coinfection, have been identified in patients presenting with symptoms of cholecystitis.

### Clinical Findings

**A. Signs and Symptoms.** Symptoms include right upper quadrant pain, concomitant diarrhea, and rarely jaundice.

**B. Laboratory Findings.** Laboratory studies reveal elevated alkaline phosphatase and transaminase levels that are twice to three times normal. Bilirubin levels are usually normal. CD4 counts are < 50.

**C. Imaging.** Imaging studies using computed tomography, ultrasound, or endoscopic retrograde cholangiopancreatography reveal dilated ducts and gallbladder thickening with sludge.

## 6. PULMONARY INFECTION

*E bienewsi* has been found in bronchial lavage specimens of patients presenting with cough, dyspnea, wheezing, or sinusitis. Chest x-rays show interstitial infiltrates.

## 7. KERATOCONJUNCTIVITIS

*E cuniculi* and *E hellem* as well as *S intestinalis* have caused corneal infections in HIV-infected patients. Patients present with dry eyes, foreign-body sensation, or ocular pain. Blurred vision, excessive tearing, and photophobia have also been reported. Conjunctival hyperemia may be present, and slit-lamp exam reveals a diffuse, superficial punctate keratopathy. Microsporidial corneal infections have been associated with systemic disease with concomitant bronchiolitis, sinusitis, nephritis, cystitis and ureteritis, hepatitis, and peritonitis.

## 8. MYOSITIS

### Introduction

*Pleistophora* infection in immunocompromised patients presents similarly to that in immunocompetent patients as already described.

## Diagnosis

The small size of the *Microsporidium* spore makes diagnosis difficult ([Table 83-4](#)). The sensitivity and specificity of different identification techniques are not known. Microsporidial spores are gram positive and birefringent, and they have a positive periodic acid-Schiff-staining polar body. Spores can be found in stool, duodenal aspirates, urine, respiratory secretions, and conjunctival scrapings. Diagnostic yield may be enhanced by collecting three stools daily over 3 subsequent days. Spore concentration and sedimentation techniques can increase yield. Weber's modified trichrome, Gram, Giemsa, and chitin-binding fluorochrome stains have all been used successfully to identify spores. Diagnostic yield can be increased by preserving stool in formalin, pretreating in 10% potassium hydroxide, and centrifuging for 5 min before staining with the Weber's modified trichrome stain. Biopsy specimens can be similarly stained, but sensitivity may be decreased due to normal-appearing mucosa. If < 25 spores are identified from a stool specimen per coverslip, the likelihood of identifying organisms by electron microscopy of a biopsy specimen is low. *E. bienewisi* usually involves the distal duodenum and proximal jejunum, and *S. intestinalis* can also involve the colon.

Electron microscopy can more readily identify the small spores and is useful in speciation. Immunofluorescence and polymerase chain reaction techniques are also valuable for speciation.

## Treatment

Microsporidial treatment efficacy is anecdotal at this time ([Box 83-11](#)). Albendazole has had the best success thus far in alleviating gastrointestinal and biliary symptoms. However, eradication of spores is rare, and relapse occurs 1-2 months after completion of 4 weeks of albendazole. Metronidazole was reported to have a transient clinical response only, and atovaquone has had mixed results. Fumagillin, itraconazole, and fluconazole are currently being studied. Palliative treatment with octreotide and nutrition adjustments such as prescribing low-fat and simple carbohydrate diets may be beneficial.

Topical fumagillin and propamidine isethionate (0.1%) have been effective in treating microsporidial keratopathy. One case report suggests that itraconazole may be beneficial in this realm as well.

## Prevention & Control

Control of microsporidial infection will be difficult to address until transmission is better understood (see [Box 83-6](#)). Bodily fluid precautions seem warranted to prevent fecal-oral and urinary-oral transmission. Disinfecting, boiling, and autoclaving may also be of benefit. The necessity of respiratory precautions and isolation is uncertain.

INTRODUCTION
-

**Table 83-1.** Laboratory diagnosis of cryptosporidiosis.

- Oocysts are < 4-6  $\mu\text{m}$  in diameter, round, and thick-walled, containing four sporozoites
- Oocysts are identified in stool, duodenal aspirates, bile, or respiratory secretions
- Stool should be fresh or fixed in 10% formalin or PVA and may be stained with modified acid-fast stain.
- Intestinal biopsy shows intracellular but extracytoplasmic sporozoites on the brush border staining basophilic with H & E staining
- Phase contrast microscopy shows birefringent oocysts
- ELISA and immunofluorescent assays are more sensitive and specific methods of diagnosis
- PCR and serology studies are not clinically useful at this time

## 84 . *Giardia* — Stephanie Boade Silas, MD, & DeVon Hale, MD

### Essentials of Diagnosis

- Key symptoms include initially profuse and watery diarrhea progressing to foul-smelling and often greasy stools that float.
- It is the most common pathogen in waterborne diarrheal illness.
- Patients at highest risk include infants, young children, travelers, and immunocompromised patients.
- In North America, the Rocky Mountains and mountainous regions of the northwest, northeast, and British Columbia are notorious *Giardia* reservoirs.
- Giardiasis is diagnosed either by identification of cysts or trophozoites on wet mounts of fresh stool or duodenal specimens or by antigen detection using enzyme-linked immunosorbent assay or immunofluorescence techniques.

### General Considerations

*Giardia*, a genus of primitive eukaryotes, is a flagellated enteric protozoan of the class Zoomastigophorea. *Giardia lamblia*, also known as *Giardia intestinalis* or *Giardia duodenalis*, is the species known to infect humans. Its name comes from Vilem Lambl, who first reported the organism in 1859. However, the first description of *G lamblia* came from Anton von Leeuwenhoek in 1681, while examining his own stool during an episode of diarrhea.

**A. Epidemiology.** *G lamblia* is a global enteric pathogen. It is the most prevalent enteric parasite in the United States and Canada, and populations at highest risk include infants, young children, travelers, and immunocompromised patients. Between 1965 and 1984, the Centers for Disease Control and Prevention documented 90 outbreaks, making *G lamblia* the most common pathogen in waterborne diarrheal illness. Giardiasis plays a role in malnutrition and growth retardation in the developing world.

In some areas of the developing world, the overall prevalence of *Giardia* infection is as high as 20-30%, whereas prevalence in industrialized nations is 2-5%. Age-specific prevalence increases from infancy through childhood before falling in adolescence, and children < 10 years old in developing nations have a 15-20% prevalence of *G lamblia* infection. The highest giardiasis prevalence is seen in the subtropics and tropics. *G lamblia* accounts for < 5% of traveler's diarrhea, with increased risk after travel to southeast and south Asia, tropical Africa, Mexico, South America, and areas of the former Soviet Union, particularly St. Petersburg. In North America, the Rocky Mountains and the mountainous regions of the Northwest, Northeast, and British Columbia are notorious *G lamblia* reservoirs.

*G lamblia* is ingested orally, and transmission has been associated with contaminated

water, person-to-person spread, and, less often, food-borne transmission. Most outbreaks are related either to untreated water or to inadequately purified water. The *G lamblia* cyst is particularly well suited to survive in cold water and is relatively resistant to chlorine.

Person-to-person transmission is related to poor fecal-oral hygiene. Children in day care facilities have an infection prevalence of = 50%, and sexually active male homosexuals, regardless of HIV status, have a prevalence of 20%. Increased numbers of infections are also found in individuals in custodial situations. Food-borne cases related to infected food handlers have been increasingly reported.

Studies have confirmed the presence of a vast animal reservoir. The first associations involved the beaver as a source of water contamination. Subsequently, DNA similarities have been found in *Giardia* isolates from humans and both domestic and wild animals, including beavers, cattle, cats, coyotes, dogs, gerbils, and sheep.

**B. Microbiology.** The *G lamblia* life cycle has two stages, the trophozoite and the cyst. The pear-shaped trophozoite lives freely in the small bowel lumen and is 9-21  $\mu\text{m}$  long  $\times$  5-15  $\mu\text{m}$  wide ([Figure 84-1](#)). It has a convex dorsal surface, a flat ventral surface with a sucking disk, and four pairs of posterior flagella. Absorption of nutrients occurs through the dorsal surface. The sucking disk is composed of an array of microtubules containing tubulin, microribbons containing the protein giardin, and other contractile proteins. Within the trophozoite is a posteriorly placed median body and two anterior nuclei each with a prominent karyosome, giving *G lamblia* its characteristic facelike appearance. The trophozoite divides by binary fission, doubling in 9-12 h in culture. An aerotolerant anaerobe lacking mitochondria, the trophozoite scavenges phospholipids, fatty acids, cholesterol, and pyrimidine. It metabolizes glucose to ethanol, acetate, and carbon dioxide. In vitro growth is optimized by conditions comparable with those found in the small intestine, including the presence of biliary lipids, intestinal mucus, epithelial cells, and low oxygen tension.

Encystation occurs in the small bowel, possibly because of high concentrations of bile salts and elevated pH. The highly resistant cyst is passed out of the host into the environment where trophozoite division occurs within the cyst. The mature *G lamblia* cyst is an oval structure (8-12  $\mu\text{m}$  long  $\times$  7-10  $\mu\text{m}$  wide) with four nuclei and an acid phosphatase-positive periphery encased in a thin wall that is composed primarily of *N*-acetylgalactosamine ([Figure 84-2](#)). Hundreds to thousands of cysts may be excreted per gram of stool. After ingestion and exposure to gastric acid and pancreatic enzymes, excystation releases two trophozoites to resume the cycle.

**C. Pathogenesis.** *G lamblia* infection requires the oral ingestion of as few as 10 cysts. Excystation, promoted by gastric acid, releases trophozoites, which then multiply and colonize the upper small bowel. Trophozoites attach to the brush border enterocytes by two proposed mechanisms. First, the ventral disk may be involved in attachment by either contractile proteins or flagellum-mediated hydrodynamic forces. Second, a receptor-ligand interaction mediated by lectin has been suggested. The attachment process enables the trophozoite to avoid peristalsis.

The exact mechanism of injury causing disease is uncertain, but several observations

have been made. First, the brush border is disrupted by microvilli injury and villous atrophy, which cause a disaccharidase deficiency. It has been postulated that this injury may be caused by a proteinase or mannose-binding lectin. Second, increased epithelial turnover in the crypts has led to altered absorption, which may be caused by immature enterocytes. T lymphocytes may contribute to this crypt hyperplasia, which is also observed in graft vs host disease. Third, decreased bile salt concentrations with consequent diminished pancreatic lipase activity and impaired solubilization of fat has been reported in giardiasis patients. The trophozoite, although unable to deconjugate bile salts, does have an uptake mechanism for bile salts that, in low concentrations, stimulate growth. Low-bile-salt concentrations in giardiasis patients may also result from deconjugation by simultaneous colonization with *Enterobacteriaceae* or yeasts. This increased colonization of anaerobic and aerobic bacteria in giardiasis has not been uniformly reported, however, with all confirmatory studies coming only from India. Fourth, *G lamblia* infection inhibits trypsin. Thus, disaccharidase deficiency, immature enterocytes, and both lipase and trypsin inhibition suggest that the diarrhea in giardiasis is primarily malabsorptive. Evidence supports neither mucosal invasion nor the presence of an enterotoxin in the pathogenesis of giardiasis.

The immune response to *G lamblia* infection is initiated by antigen uptake into macrophages in Peyer's patches. This action generates both an antibody and a cellular response. Although serum immunoglobulins M and G are lethal to *G lamblia* by the classical complement pathway, secretory immunoglobulin A (IgA) appears to be more important in clearing and preventing infection. Intraluminal IgA can prevent adherence, and chronic giardiasis is associated with the failure to make IgA. *G lamblia* has been found to make an IgA protease that is protective to trophozoites.

A cellular immune response is also generated and shown in mice to be necessary for both cytotoxicity and coordination of IgA secretion. As already mentioned, the T-cell response may also contribute to the pathogenesis of *G lamblia* because the mononuclear cell submucosal infiltrate is associated with flattened villi and crypt hypertrophy.

Protective immunity does not develop after a single infection, possibly because of genomic plasticity and significant antigenic diversity described in *G lamblia* isolates. However, increased prevalence in the young and decreased symptoms in long-term residents of endemic areas suggest at least partial immune protection. Infection in infants < 6 months old is rare, and human milk is protective because of the presence of antibodies and cytotoxicity from free fatty acids generated from milk triglycerides.

Although occurring in immunocompetent hosts, a predisposition to chronic giardiasis is reported in patients with X chromosome-linked agammaglobulinemia, lymphoid nodular hyperplasia, and common variable immunodeficiency with variable levels of hypogammaglobulinemia. Patients with earlier gastric surgery and decreased gastric acidity also have an increased susceptibility to infection. Of interest, patients with AIDS have no more severe illness than patients without AIDS, in contrast to the disparity seen in intracellular protozoal infections such as *Cryptosporidium parvum*.

## **CLINICAL SYNDROMES**

## INTRODUCTION

After ingestion of *G lamblia* cysts, 5-15% of patients will have asymptomatic cyst passage, and 25-50% of patients will have diarrhea. From 35% to 70% of these patients will have no evidence of infection. The three manifestations of infection include asymptomatic cyst passage, self-limited diarrhea, and chronic diarrhea with associated malabsorption and weight loss. Factors related to each of these manifestations are unknown but are believed to be related to specific host factors, parasite load, and virulence variation among *G lamblia* isolates.

### 1. ACUTE GIARDIASIS

#### Clinical Findings

**A. Signs and Symptoms.** After ingestion of cysts, an incubation period of 3-20 days exists before symptom onset. At the time of presentation, patients have generally had symptoms for 7-10 days. The predominant symptom in acute giardiasis is diarrhea, occurring in 90% of patients, accompanied by generalized malaise ([Box 84-1](#)). Patients describe initially profuse and watery stools progressing to foul-smelling and often greasy stools that float. Flatulence, bloating, and abdominal cramps are frequent concerns as are belching, nausea, and anorexia. Weight loss and vomiting are less frequent, and fever is rare. Symptoms are usually self-limited to 2-4 weeks.

**B. Laboratory Findings.** Laboratory studies are notable for a normal peripheral leukocyte count without eosinophilia. Stool studies are negative for the presence of mucus, leukocytes, and blood.

**C. Differential Diagnosis.** *C parvum*, rotavirus, and toxigenic *Escherichia coli* may all have similar presentations.

**D. Complications.** Rare associations with urticaria and reactive arthritis have been reported in giardiasis. Biliary tract disease and pancreatitis have been reported, as have retinal arteritis and iridocyclitis. Gastric infections have been seen in *G lamblia* patients with achlorhydria.

### 2. CHRONIC GIARDIASIS

#### Introduction

From 30% to 50% of individuals with acute giardiasis will progress to have chronic giardiasis.

#### Clinical Findings

**A. Signs and Symptoms.** Profound malaise and lassitude are frequently reported. Patients experience diarrhea alternating with constipation, frequent stools, and abdominal pain associated with eating. Weight loss of 10-20% of body weight is common, with a 10-lb weight loss reported in 50% of patients. Headache has also been associated with the syndrome.

**B. Laboratory Findings.** Laboratory studies are significant for biochemical evidence of malabsorption. D-Xylose, fat, protein, vitamin A, and vitamin B<sub>12</sub> malabsorption have all been reported. Disaccharidase deficiency, particularly lactase, occurs in 20-40% of patients and may persist for several weeks beyond infection. Macrocytic anemia from folate deficiency and hypoalbuminemia has been reported.

**C. Differential Diagnosis.** Similar presentations can be seen in infections caused by coccidians such as *C parvum*, *I belli*, and *Cyclospora* spp., as well as infections caused by *Strongyloides* spp. and *Entamoeba histolytica*. Also, diagnoses of inflammatory bowel disease and irritable bowel syndrome should be considered.

**D. Complications.** Chronic giardiasis may play an important role in growth impairment and nutritional deficiency in the developing world.

## Diagnosis

The key to diagnosis of *G lamblia* infection is the identification of trophozoites or cysts, both of which can be seen in stools by standard ova and parasite exam ([Table 84-1](#)). Trophozoites have a short survival time outside the small bowel when not contained within cysts and are more likely to be seen in fresh wet mounts of liquid stool. Semiformed stool may be preserved in formalin or polyvinyl alcohol. Staining with trichrome or iron hematoxylin reveals cysts. Formalin or zinc flotation concentration techniques may increase the yield of diagnosis. Generally, one stool exam has a 50-70% diagnostic yield, which improves to 85-90% after 3 stools collected over 2-3 days because of cyclic shedding. Purged samples have no effect on diagnostic yield.

Enzyme immunoassay and direct fluorescent-antibody assay kits are commercially available for testing for *G lamblia* infection. Both methods have reported sensitivities of 87-100% and specificities of 99- 100% when compared with microscopic stool examination. Advantages of these techniques include a decrease in both examination time and required technician training. Both direct fluorescent-antibody assay and enzyme immunoassay are particularly valuable when the sole diagnosis or exclusion of *G lamblia* is needed, as may occur during an epidemic or for screening purposes. Although cost of antigen detection techniques is similar to ova and parasite microscopic exams, microscopy allows for diagnosis of other possible pathogens. One commercially available direct fluorescent antibody assay kit does detect both *G lamblia* and *C parvum*, however.

Other, more invasive techniques are rarely used but may contribute to diagnosis. The string test involves swallowing a capsule attached to a nylon string. The capsule sits in the jejunum for 4-6 h while the patient is fasting. The string is subsequently removed and examined for trophozoites by microscopy. A duodenal aspirate can be similarly examined. Also, a duodenal biopsy or endoscopic brushing can be examined for trophozoites, by using Giemsa stain.

Upper gastrointestinal aspirates can be cultured, but this test is generally not available clinically. Serology, too, has little clinical utility but may be helpful epidemiologically. Serum immunoglobulin M or IgA titers are indicative of recent infection as compared

with IgG titers. Polymerase chain reaction and gene probe studies are still in experimental stages, with their most practical limitation being extraction of DNA from the stool sample.

## Treatment

Historically, quinacrine hydrochloride has been the drug of choice for the treatment of giardiasis, with 90% efficacy. However, this drug is no longer produced in the United States. Despite having never received a Food and Drug Administration indication for giardiasis, metronidazole is the first-line treatment, with 80-95% efficacy after a 7-day course ([Box 84-2](#)). Its efficacy is considered to be related to inhibition of attachment. Because of the disulfiram effect of metronidazole, patients should be warned that concurrent use of ethanol could cause flushing, tachycardia, and nausea. Tinidazole is also considered a first-line agent with 90% efficacy, but it is also not available in the United States.

Second-line agents include furazolidone and paromomycin sulfate. Furazolidone, a nitroourea with 80% efficacy, may be particularly useful in children because it comes in a liquid form. Paramomycin sulfate is an aminoglycoside with 60-70% efficacy. Because of its poor oral absorption, it may be beneficial for use in pregnant patients. Ideally, treatment for giardiasis in pregnancy should be delayed until after delivery. Metronidazole may be safe after the first trimester, however. Variable sensitivities of isolates to drug regimens occur, and resistance to metronidazole and furazolidone has been reported.

Other drugs with reported benefit against *G lamblia* infection include some antidepressants, fusidate sodium, D- and DL-propranolol, mefloquine, doxycycline, and rifampin. Albendazole, an anthelmintic benzimidazole derivative, may prove to be effective in treating giardiasis and may be especially useful in developing countries for dual coverage.

## Prognosis

The natural history of untreated giardiasis is unknown. Chronic persistent diarrhea may develop in a small number of patients, some of whom, particularly children, may develop malnutrition and growth impairment. The prognosis of treated giardiasis, however, is excellent.

## Prevention & Control

Because of the worldwide presence of *Giardia* spp., vast human and animal reservoirs, and environmental resilience, total elimination of giardiasis is not expected. Instead, prevention depends on focusing on the primary sources of infection, including water contamination and person-to-person contacts ([Box 84-3](#)). Chlorine kills cysts in warm water, and public water supplies should undergo chlorination, flocculation, sedimentation, and filtration. DNA techniques may be valuable in screening filtered water for cysts.

In the wilderness or in the developing world, water should be boiled before

consumption. Inactivation is immediate at 100 °C, and water need only be brought to a rolling boil. At altitudes of = 10,000 ft, where the boiling point is 90 °C, water can still be safely disinfected by simply bringing it to a boil. The margin of safety is further ensured by the time taken for the water to heat to this level and subsequently cool because keeping water at 70 °C for 10 min also results in 100% inactivation. Halogenation with iodine or chlorine tablets has proven useful but may not be effective in cold water. The questionable efficacy of halogenation is best exemplified by reported cases of giardiasis associated with chlorinated swimming pools. Water filters with pores < 1-2 um may also be effective in preventing giardiasis.

Person-to-person spread of giardiasis could be lessened by improved hygiene, especially in those at high risk. However, evidence is not yet available to support the treatment of asymptomatic patients. Further, no vaccines for giardiasis are available. Vaccine development is limited because the initial infection itself does not confer protective immunity to the patient.

**Table 84-1.** Laboratory diagnosis of giardiasis.<sup>1</sup>

- The trophozoite is 10 µm × 15 µm with a convex dorsal surface, flat ventral surface, and 2 facelike nuclei
- The cyst is 10 µm × 10 µm, thin-walled, and with an eccentric nucleus
- Motile trophozoites are seen on microscopy of fresh stool specimens or on specimens obtained by duodenal aspirate, biopsy, or the string test
- Cysts and trophozoites are observed on wet mounts of fresh stools with or without prior formalin concentration. Cysts can also be found in specimens preserved in formalin or PVA, using trichrome or iron hematoxylin staining
- Antigen detection by ELISA is highly sensitive and specific and comparable in cost to standard stool O & P. It is best used when the sole diagnosis or exclusion of giardiasis is needed
- Antigen detection by IFA has the same sensitivity and specificity as standard O & P, but is advantageous in small labs with less-trained technicians
- DNA probes and PCR techniques are available but not yet useful clinically

## **85 . *Leishmania* & *Trypanosoma* — D. Scott Smith, MD & David A. Relman, MD**

### **INTRODUCTION**

The genera *Leishmania* and *Trypanosoma* are members of the family Trypanosomatidae. These protozoans cause diseases with widely varied clinical presentations as well as geographic distributions, including leishmaniasis, American trypanosomiasis (Chagas' disease), and African trypanosomiasis (sleeping sickness). For example, the endemic zones for African and American trypanosomiasis do not overlap, the diseases are transmitted by different vectors, they involve distinct mechanisms of pathogenesis, and they follow different clinical courses. Nonetheless, the causative agents share important biological features. Each is a hemoflagellate with a kinetoplast containing its own chromosomal DNA with highly conserved and repeated elements, each forms a single flagellum at some point during its life cycle, and each is highly adapted to life within an insect.

### **LEISHMANIA**

#### **Essentials of Diagnosis**

- Epidemiologic factors: time spent in an endemic zone and exposure to sandfly vector.
- Physical exam: nonhealing ulcer (cutaneous infection); nonhealing mucosal membrane lesion, nasal obstruction, epistaxis, nasal septum perforation (mucocutaneous infection); fever, hepatosplenomegaly, emaciation (visceral infection).
- Laboratory examination of affected tissue:
  1. Giemsa stain shows phagosomal cells contain amastigotes at leading edge of biopsied ulcer.
  2. Histological analysis of bone, liver, or spleen tissue shows amastigotes.
  3. Culture of biopsied tissue, ie, skin, spleen, liver, or bone, reveals promastigotes.
  4. Serologic analysis using immunofluorescence assay (available through the Centers for Disease Control and Prevention [CDC]).
  5. Xenodiagnostic analyses of macerated tissue samples injected into animals for specific identification via growth in vivo.
  6. Polymerase chain reaction (PCR) (helpful but not widely available).

#### **General Considerations**

Infections with *Leishmania* spp. occur worldwide, in environments as varied as the semiarid deserts of the Middle East and the tropical rain forests of Central and South America. There are three major clinical forms of disease: visceral (kala-azar), mucocutaneous, and cutaneous. Even though each form tends to be associated with particular *Leishmania* species, some species can cause multiple forms of the disease, and some forms can be caused by multiple species. Leishmaniasis is a zoonosis with sandfly vectors and mammalian reservoirs. *Lutzomyia* sandflies are the primary vectors in the Americas, whereas *Phlebotomine* sandflies transmit the disease in the rest of the world.

**A. Epidemiology.** Leishmaniasis is endemic in = 82 countries, with an at-risk population of 350 million people worldwide. The World Health Organization (WHO) estimates 12 million current cases, with an annual incidence of 600,000 new cases and 75,000 deaths. Reliable estimates are scarce owing to lack of surveillance or active reporting and the large number of asymptomatic or subclinical cases, as well as the challenge of diagnostic confirmation.

Leishmaniasis is endemic to all countries in the Americas except Canada, Uruguay, and Chile. Southern Texas is the only endemic area in the United States. There are often small geographic foci of transmission within endemic areas. Leishmaniasis is seen in the countries surrounding the Mediterranean Sea, as well as in central Africa and across the Middle East to India and China. Of visceral leishmaniasis cases worldwide, 90% occur in India, Bangladesh, southern Sudan, and northern Brazil; and 90% of cutaneous leishmaniasis cases occur in Afghanistan, Brazil, Iran, Saudi Arabia, and Syria. The vast majority of mucocutaneous leishmaniasis cases are found in Brazil and the geographic areas after which the subspecies and complexes are named (eg, *amazonensis* [Amazon region], *panamensis* [Panama], and *guyanensis* [Guyana]).

Leishmaniasis is most commonly observed in humans who live or work at the forest edge, where insect vectors are most abundant. These include rural settlers, farmers clearing forests, and road construction workers, as well as military personnel. Most cases of leishmaniasis in the United States are imported by those who have been exposed in rural areas of endemic regions, including Peace Corp workers, ornithologists, and field workers. Leishmaniasis is more common in adult males, probably in part because of occupational risks. Transmission of leishmaniasis has been associated with blood transfusions and intravenous drug abuse.

Although there are > 600 species of sandflies, only about one-tenth of these transmit leishmaniasis. Among these disease transmitters, both the *Phlebotomine* (found in the Mediterranean and Middle East regions) and the *Lutzomyia* (found in the Americas) sandflies are small and hairy and have a V-shaped wing configuration. They are inactive during daylight hours, and they stay in dark moist places that are rich in organic matter. The animal reservoirs in the Americas are primarily sylvatic and include sloths, opossums, and small forest rodents. Canines also serve as reservoirs for organisms that cause the visceral forms, especially as part of a peridomestic transmission cycle ([Figure 85-1A](#)). With the notable exception of dogs and humans, the mammalian hosts that serve as reservoirs generally do not show signs of disease.

**B. Microbiology and Pathogenesis.** Species of the genus *Leishmania* display a

dimorphic life cycle; in the insect vector they assume a flagellated form (the promastigote), and, in human and mammalian hosts, the parasite takes on the amastigote form (devoid of flagellum) ([Figure 85-1B](#)). Amastigotes survive inside phagosomal cells, such as the histiocytes of the skin and other cells of reticuloendothelial origin. Amastigotes are 2-3  $\mu\text{m}$  in length and can be round or oval. The species are morphologically indistinguishable from each other and from *Trypanosoma cruzi*, but *Leishmania* spp. can easily be differentiated from *T. cruzi* in clinical specimens based on tissue tropism. The amastigotes transform into promastigotes once inside the sandfly gut. They then migrate forward to the proboscis to infect another host. Besides the insect vector, the life cycle usually includes a nonhuman animal reservoir. Humans are incidental hosts for *Leishmania* spp. Promastigotes are passed from the female sandfly to the skin of a vertebrate host during a blood meal. These promastigotes invade the reticuloendothelial cells of the vertebrate host, change into amastigote forms, multiply further, and invade other reticuloendothelial cells. Mammalian blood is essential to the sandfly's life cycle and promotes egg maturation within the female; only female sandflies seek blood meals. Once *Leishmania* amastigotes infect a sandfly, disease transmission to a new mammalian host is delayed for at least 7-10 days while the parasite undergoes differentiation.

The visceral form of leishmaniasis (kala-azar) provides an exception to this cycle from insects to animal reservoirs to humans, because there are no known animal reservoirs but only direct insect-to-human transmission. In India, for example, the organism and disease persist in the human population (anthroponoses) and are maintained by patients with persistent subclinical post-kala-azar dermal leishmaniasis, from whom parasites have been isolated from normal appearing skin.

Interferon gamma and other components of the Th1 cytokine response appear to be critical for host defense against disease. In an apparent attempt to subvert these defenses, *Leishmania mexicana* expresses several cysteine proteinases that down-regulate the Th1 cytokine response and induce the Th2 cytokines such as interleukin-4, thereby enhancing susceptibility of the host to disease progression.

## Clinical Findings

**A. Cutaneous Leishmaniasis.** Cutaneous leishmaniasis begins as papules and, less commonly, as nodules at the site of the vector bite; it then progresses to ulcer formation ([Figure 85-2](#)). It is most commonly caused by *Leishmania major* and *Leishmania tropica* in the Old World and by *Leishmania mexicana*, *Leishmania braziliensis*, and *L. panamensis* in the New World, and the infection exhibits an incubation period of 2-8 weeks. Satellite lesions appear in some cases. Most forms of the disease (> 80%) heal spontaneously within 3 months, although, on occasion, the cutaneous form can be disfiguring. In a more recently described form of cutaneous disease associated with *L. braziliensis*, lymphadenopathy was found in three-fourths of patients and preceded the development of skin lesions; the latter healed spontaneously in only 20% of patients by 3 months after initial infection.

**B. Mucocutaneous Leishmaniasis.** Mucocutaneous leishmaniasis involves the mucosal membranes of the nose and mouth but may also involve the oropharynx and

the larynx. *L. braziliensis* is the cause of most mucocutaneous disease. An estimated 3% of patients with infection by this species develop mucosal disease. The disease begins as a primary cutaneous ulcer at the site of inoculation. During early stages it cannot be distinguished clinically from the more benign cutaneous forms of disease. The time delay from cutaneous disease to development of mucosal involvement can vary from 1 month to 24 years. Mucosal disease may present as nasal obstruction or epistaxis. A slight reddening and swelling in the septum can be seen, which may progress to perforation. Although the disease is termed mucocutaneous, tracheal and genital mucosal involvement is rare.

**C. Visceral Leishmaniasis.** Visceral leishmaniasis or kala-azar is primarily caused by *Leishmania donovani* in the Indian subcontinent and Africa, *Leishmania infantum* in the Mediterranean region, and *Leishmania chagasi* in Latin America. The incubation period is generally 2-6 months. The disease begins with fever, hepatosplenomegaly, and pancytopenia. The onset of fever can be sudden or gradual, and there may be intervals when the patient has low-grade or no fever. Clinically evident disease is usually characterized by progressive weakness, emaciation, and, if untreated, death. Case fatality rates, even with treatment, are = 11%. The ratio of inapparent infection to overt clinical disease varies depending on the age group and the endemic area but ranges from 6.5:1 to 18:1. This feature enables ongoing inapparent transmission of infection. A young age (infants and children) and malnutrition predispose to development of the disease. Viscerotropic (*L. tropica*) disease in US troops who returned from the Persian Gulf was reported among a small number of individuals and resulted in a temporary ban on blood donations from this group.

The combination of visceral leishmaniasis and HIV infection is an increasingly important problem, especially in southern Europe. In general, the clinical presentation of visceral leishmaniasis in HIV-infected patients is similar to that in uninfected persons, but the gastrointestinal tract may be more frequently involved, and sometimes the hepatosplenomegaly is less pronounced or absent.

## Diagnosis

The first step in diagnosis should be to establish an exposure history. It is important to distinguish the more innocuous cutaneous forms of leishmaniasis from the mucocutaneous forms, which are not usually self-limited. Therapy for leishmaniasis is not benign, and, therefore, diagnostic certainty is crucial. The differential diagnosis for each form of leishmaniasis is listed in [Table 85-1](#).

The most common diagnostic approach is demonstration of the presence of parasites by microscopy in Giemsa-stained tissues or by culturing the organisms in specialized media. Aspiration and punch biopsy of the leading edge of a cutaneous or mucocutaneous lesion are the best techniques to obtain specimens for both culture and histology. The tissues of choice for diagnosis of visceral disease are liver, spleen, and bone marrow. Sternal bone biopsy is often the most easily accessible and safest procedure to obtain tissue for culture and smear. Giemsa-stained smears from either the culture (promastigotes) or the tissue biopsy specimens (amastigotes) show the distinctive rod-shaped kinetoplasts of *Leishmania* spp. in the cytoplasm of the parasite. The cytoplasm stains blue with Wright-Giemsa with a large eccentric red nucleus. Small

red kinetoplasts are features of *Leishmania* spp. that distinguish them from other intracellular pathogens with somewhat similar appearance, such as *Toxoplasma* and *Histoplasma* spp.

Many diagnostic techniques, including DNA hybridization, PCR, and monoclonal antibody tests, have been developed. These tests are not widely available or standardized. Xenodiagnostic techniques are also used. Consultation with physicians experienced in the diagnosis of leishmaniasis is available through the CDC by calling (770) 488-7760.

## Treatment

The drugs of choice for leishmaniasis include the organic antimonial compound stibogluconate sodium and meglumine antimoniate ([Box 85-1](#)). Anti-*Leishmania* drugs can be obtained from the CDC by calling (404) 639-3670.

Several alternative regimens and therapies are used, because of increasing resistance and treatment failures including higher dosing and, in some instances, combination therapy to decrease the duration of treatment. The newer drugs include liposomal amphotericin B, pentamidine, as well as paromomycin, and cytokines (eg, interferon gamma), which are used in combination with the antimonials.

**A. Cutaneous Leishmaniasis.** Cutaneous leishmaniasis is usually self-limited, but, if it persists > 6 months or is disfiguring or disabling, then treatment is indicated. The challenge for local therapy is that the disease characteristically involves the dermis and may disseminate to the lymph nodes or mucous membranes. Antimonials are injected with or without steroids initially, on a twice-daily schedule. Infiltration of the lesions in a standardized way is difficult to achieve. Localized controlled heat has also been shown, in a placebo-controlled clinical trial, to be effective for treatment of cutaneous disease.

**B. Mucocutaneous Leishmaniasis.** Mucocutaneous forms of leishmaniasis are treated with stibogluconate. The electrocardiogram (ECG) should be monitored. For resistant cases, stibogluconate plus interferon gamma can be used, or amphotericin B or pentamidine is effective.

**C. Visceral Leishmaniasis.** Visceral leishmaniasis (kala-azar) has successfully been treated with stibogluconate. In immunocompromised patients, such as those with HIV infection, it is necessary to devise a suppressive regimen to minimize recurrence after adequate treatment has been completed. Relapses of clinical disease typically occur after appropriate therapy with either antimony or amphotericin B (which has a higher initial cure rate in this population); therefore, a suppressive regimen has been suggested. Either pentamidine or paromomycin can be used alone as an acceptable choice for suppression, or either one can be combined with one of the following: interferon, ketoconazole, or fluconazole.

## Prevention & Control

Because leishmaniasis is so widely endemic, control of both its reservoirs and its vectors remains a challenge ([Box 85-2](#)). Therefore, primary prevention efforts should

focus on limiting vector contact, by using insect repellents and fine-mesh nets. No vaccine for humans is available. A strategy for preventing transmission of visceral leishmaniasis to humans in Latin America has been suggested, based on vaccination of dogs.

## **TRYPANOSOMA**

### **INTRODUCTION**

Three human pathogens are members of the genus *Trypanosoma*. These are *T cruzi*, the agent of American trypanosomiasis (also known as Chagas' disease), and *T brucei* subspecies *rhodesiense* and *gambiense*, both of which cause African sleeping sickness. Both of these diseases involve persistent circulation of parasites in the blood during some part of the disease course; these organisms are therefore referred to as hemoflagellates.

Trypanosomes have morphologically and physiologically different developmental stages in their insect and mammalian hosts. Like *Leishmania* spp., each stage contains a kinetoplast with highly conserved and repeating DNA sequences. Aside from morphology, the agents of African and American trypanosomiasis have little in common. The endemic zones of disease do not overlap, the organisms use different vectors, and their patterns of transmission are distinct. Furthermore, the clinical courses and response to therapy of these diseases are different.

### **AMERICAN TRYPANOSOMIASIS (CHAGAS' DISEASE)**

#### **Essentials of Diagnosis**

- Epidemiologic factors: time spent in an endemic zone; poor housing conditions, eg, mud or thatched housing; exposure to reduviid insect vector
- History and physical exam: Romana's sign (swollen periorbital mucosal tissues after ocular inoculation); chagoma (skin nodule at the site of acute inoculation); in the chronic phase, congestive heart failure, dysphagia or regurgitation, and constipation
- Laboratory exam:

1. Acute Chagas': trypomastigotes revealed by Giemsa smear of blood or buffy coat; culture of affected tissues, ie, the inoculation site; serologic enzyme immunoassay and enzyme-linked immunosorbent assay (ELISA); xenodiagnosis if available

2. Chronic Chagas': radiological studies show congestive heart failure, megacolon, or megaesophagus; ECG shows right bundle branch block, arrhythmias

#### **General Considerations**

**A. Epidemiology.** *T cruzi* is found only in the Western Hemisphere, where it ranges from the southern United States to Argentina. An estimated 16 million-18 million people in Latin America have chronic *T cruzi* infections and ~ 50,000 die of Chagas' disease

each year. In the United States, there has been concern about transmission of the organism via blood transfusion from unsuspected infected donors who are immigrants from endemic zones. Similar concerns arise for organ transplant recipients.

**B. Microbiology.** The life cycle of *T cruzi* involves an insect vector, the reduviid bug, and a mammalian reservoir. The insect vector, of which there are multiple species, is commonly known as an assassin bug because it preys on other insects; it is also called the kissing bug because it tends to bite the face. After taking a blood meal from an infected reservoir, *T cruzi* organisms multiply in the insect mid gut as epimastigotes and then develop into the infective form, the trypomastigote, in the insect hindgut. There are several nonhuman mammalian reservoirs that enable *T cruzi* to persist in nature, including peridomestic animals such as cats, dogs, and rats, as well as sylvatic animals such as opossums, raccoons, and armadillos.

**C. Pathogenesis.** When an infected reduviid bug takes a blood meal from a human, it defecates, leaving feces on the surface of the skin that is contaminated with the infective metacyclic stage of the trypanosomes. Trypanosomes proliferate at the site of inoculation and then pruritus at the bite wound causes *T cruzi* organisms to be rubbed into the wound or surrounding mucous membranes, introducing the organism to the bloodstream. In the bloodstream, they preferentially infect myocytes and neurons of the peripheral and central nervous system (CNS). After the amastigotes proliferate in the cytoplasm, they differentiate into trypomastigotes. The cell subsequently ruptures, and the newly released trypomastigotes invade local tissues and spread hematogenously. A mononuclear inflammatory response occurs. This intense inflammation leads to destruction of autonomic ganglia in the heart and gastrointestinal tract, and diffuse fibrosis and scarring occur in these organs.

## Clinical Findings

In the acute phase of American trypanosomiasis, an indurated erythematous lesion occurs a few days after inoculation of *T cruzi* into the skin. This is called a chagoma. Periorbital swelling results when trypanosomes are inoculated into the conjunctival mucous membranes, and it is a classic sign of acute infection known as Romana's sign. The patient experiences fever, hepatosplenomegaly, lymphadenopathy, transient skin rash, tender subcutaneous nodules (known as hematogenous chagomas), and nonpitting edema on the face or extremities. The acute phase is more commonly observed in children and is usually self-limited, lasting several weeks to months. Dissemination of organisms is common, regardless of whether chronic disease ultimately develops.

Chronic American trypanosomiasis is usually insidious. There may not be a history of documented acute disease. About 10-30% of infected patients develop chronic disease. These patients progress to have cardiac or gastrointestinal damage that results in clinical disease. Chronic infection may evolve over decades and most often involves the heart. Cardiac disease is manifested by biventricular hypertrophy and electrical disturbances, including premature ventricular contractions, partial or complete atrioventricular block, and right bundle branch block. Death can result from arrhythmia or congestive heart failure. Sudden death occurs in 40% of congestive heart failure patients with Chagas' disease. The second most commonly affected organ system is

the gastrointestinal tract. The autonomic ganglia are destroyed, resulting in functional denervation, impaired motility, and thus dilation, leading to megaesophagus and megacolon.

Congenital Chagas' disease is characterized by hepatosplenomegaly, sepsis, myocarditis, and hepatitis; however, two-thirds of cases of congenital Chagas' disease are asymptomatic. Thus, routine testing for disease in the infants of infected mothers is warranted.

Acute infection and reactivation of infection in immunosuppressed transplant recipients and in HIV-infected patients can result in more severe clinical signs, sometimes involving the CNS. In HIV patients, reactivation has led to cerebral abscesses.

## **Diagnosis**

The diagnosis of acute Chagas' disease is made by detecting parasites in the blood, by using a wet preparation of anticoagulated blood or buffy coat or by using a Giemsa-stained smear of the blood.

Both enzyme immunoassay and ELISA tests are available commercially and are approved by the US Food and Drug Administration for the diagnosis of Chagas' disease. False-positive results using these tests are an ongoing challenge, because there is cross-reactivity among patients with syphilis, malaria, leishmaniasis, and other parasitic diseases. PCR tests are also actively being studied and evaluated, although they are not yet available for routine clinical use. Serum samples can be sent to the CDC for indirect immunofluorescence and complement fixation testing (phone: [770] 488-4414).

## **Treatment**

Acute American trypanosomiasis should be treated with nifurtimox ([Box 85-3](#)). In the United States, this drug is available through the CDC (phone: [404] 639-3670). A parasitologic cure using nifurtimox has been noted in 70-95% of parasitemic patients, but clinical cures are less well defined. Side effects with this drug occur in ~ 40-70% of adult patients and primarily include CNS problems such as disorientation, insomnia, paresthesias, seizures, and polyneuritis, as well as gastrointestinal symptoms including nausea, vomiting, and abdominal pain. Additionally, skin rash has been commonly noted.

Treatment of chronic infections and patients with end-organ damage includes supportive care. For example, pacemakers for cardiac conduction defects are sometimes indicated in this setting. Antiparasitic treatment is not indicated in chronic disease.

## **Prevention & Control**

Disease control is directly related to the control of vectors ([Box 85-4](#)). Because of the potential chronic and insidious nature of this disease, some authorities recommend serologic screening of all persons at high risk who come from endemic areas. Such screening may have two benefits: (1) cardiac disturbances can often be treated with pacemakers, and (2) congenital disease can be prevented or treated.

The safety of the blood supply is a concern in endemic areas and in other regions with immigrants from endemic areas, such as southern California. Two approaches include screening and rejection of donors based on risk factors such as prolonged residence in an endemic area and based on serology. Some endemic countries such as Brazil now use routine serologic screening and reject blood based on positive results.

Travelers to endemic areas are advised to avoid sleeping in structures that may harbor the insect vector and to use appropriate barriers to avoid contact with the insects.

## **AFRICAN TRYPANOSOMIASIS**

### **Introduction**

In Africa, a wide variety of trypanosomes infect wild animals but only two cause significant disease in humans: *T brucei gambiense* and *T brucei rhodesiense*.

### **Essentials of Diagnosis**

- Epidemiologic factors: living or traveling in an endemic zone; exposure to tsetse fly.
- History and physical exam:
  1. General: periodic fevers, wasting, nutritional deficiencies.
  2. Skin: chancre at the site of inoculation, fleeting truncal rash, posterior cervical lymphadenopathy.
  3. Neurologic: disturbed sleep patterns (diurnal somnolence, nocturnal insomnia), mental status changes, cerebellar signs.
- Laboratory:
  1. Blood smear with Giemsa stain shows hemoflagellates.
  2. Aspiration and stain of chancre (may be positive for visible organisms before parasitemia occurs).
  3. Serology: indirect immunofluorescence, ELISA.
  4. Card agglutination test against common variant antigens.
  5. Cerebrospinal fluid (CSF): lymphocytic pleocytosis, elevated protein, motile trypanosomes.

### **General Considerations**

**A. Epidemiology.** An estimated 50 million people are at risk for acquiring African trypanosomiasis worldwide, and there are 20,000 reported new cases annually. This is

likely an underestimate because reporting in endemic countries is incomplete. There are no natural life cycles of *T brucei* outside Africa; thus, the only cases seen outside Africa are imported. Both *T brucei rhodesiense* and *T brucei gambiense* are carried by the tsetse fly vector of the genus *Glossina*, but by different species inhabiting distinct habitats (Figure 85-3). Therefore, because of vector habitat, *T brucei rhodesiense* (the agent of eastern African sleeping sickness) is seen in savanna and drier zones, whereas *T brucei gambiense* (the agent of western African sleeping sickness) is found near rivers and in forested areas. *T brucei gambiense* has primarily a human reservoir, while *T brucei rhodesiense* is an anthroponosis involving ungulates, such as cattle and antelope.

Transmission of *T brucei gambiense* was originally thought to be exclusively person to person, via insect vectors, but several animal hosts have been shown to harbor identical strains of the parasite, including pigs, cattle, dogs, sheep, and wild ungulates such as kob and hartebeest. The importance of these animal reservoirs remains uncertain. West African trypanosomiasis affects primarily rural populations, and the duration of the illness is months to years, which increases ongoing transmission. East African trypanosomiasis, in contrast, has a shorter clinical course, lasting < 9 months, and it primarily affects rural populations in proximity to the animal source and tourists visiting game parks. The animal reservoirs for *T brucei rhodesiense* include several domesticated animals, most importantly cattle, but a large number of wild animals including bushbuck, waterbuck, hartebeest, and lions. Many different domesticated animals become infected, but they succumb to the disease rapidly and are therefore unlikely to be important reservoirs for ongoing transmission. The number of infections in humans fluctuates tremendously depending on migration, land development programs, human conflict, and proximity of animal reservoirs to human populations. In addition to vector-borne transmission, congenital and blood transfusion transmission have been documented.

**B. Microbiology.** Blood-sucking tsetse flies of the genus *Glossina* become infective 18-35 days after taking a blood meal from an infected mammalian host.

Trypomastigotes are ingested and multiply in the midgut of the fly. These migrate to the salivary glands and become epimastigotes, which then turn into short, stumpy infective metacyclic trypanosomes. The fly remains infective for life and transmits by subsequent bites. Both *Glossina* males and females feed on mammalian blood, causing infection if enough organisms are injected. In endemic areas, usually < 1% of flies are infected, whereas during epidemic periods as many as 5% of flies carry parasites.

**C. Pathogenesis.** During the course of the infection with trypanosomes, the number of parasites in the blood and lymph tissues fluctuates according to the host's immune response. An increase in parasite number or parasitemia is related to the proliferation of parasite subpopulations that express an antigenically new or variant glycoprotein coat. A similar phenomenon is observed with *Neisseria* and *Borrelia* species. The declines in parasite number correspond with antibody-mediated destruction of trypanosomes. Each parasite carries genes encoding multiple, variant surface glycoproteins (VSG). Only one VSG is expressed at a single time, except during the switching from one VSG to another. This antigenic switching not only allows evasion of the host's immune system but also poses a major challenge to the development of a vaccine. Acquired immunity does develop, but it is specific for a limited number of VSGs.

Resistance to African trypanosome infections depends on the presence of host interferon gamma and a strong Th1 cytokine response, as is the case for host resistance to *Leishmania* infections. Humoral and cellular immune responses are directed against the VSGs, among other trypanosomal components.

## Clinical Findings

There are three stages of African trypanosomiasis: (1) an initial phase characterized by a skin chancre at the site of inoculation, (2) a blood-borne and lymphatic dissemination phase, and (3) invasion of the choroid plexus and the subarachnoid space, causing meningoencephalitis—hence the term "sleeping sickness." Chancres are reported in about one-third of infections and generally appear on the exposed surface of the skin where the flies have bitten. A chancre lasts ~ 3 weeks. Initially chancres are warm and tender but then scar or infrequently ulcerate. Lymphadenopathy develops in the area draining the ulcer.

Once the ulcer subsides, the hemolymphatic stage appears, with characteristic periodic fevers coinciding with high parasitemia every day or two. Fatigue, arthralgia and headache, and often a fleeting truncal rash are observed with parasitemia. Patients are relatively asymptomatic between febrile periods. Myocarditis is common, and jaundice may occur from either hemolysis or hepatic damage.

In the meningoencephalitic stage, persistent headache, disturbed sleep patterns including nocturnal insomnia and diurnal somnolence, extrapyramidal and cerebellar signs, and behavioral changes are common features of disease. Wasting and nutritional deficiencies are common and may lead to secondary infection due to immunosuppression. The leukocyte count is normal or modestly elevated with a lymphocytosis. Polyclonal hypergammaglobulinemia, especially involving immunoglobulin M, is a striking and constant feature as might be expected from prolonged antigenic stimulation. Anemia and hypoalbuminemia are also observed.

## Diagnosis

A Giemsa or Wright-stained smear of peripheral blood during the acute febrile period is the best means of obtaining a diagnosis ([Figure 85-4](#)). *T brucei rhodesiense* tends to have higher parasite loads and may be easier to detect than *T brucei gambiense*, which may require more frequent repeated blood smears or use of concentration techniques, eg, microhematocrit centrifugation with examination of the buffy coat. If a chancre is present, aspiration and staining may yield a diagnosis before parasitemia is present. Organisms may be demonstrated from aspirates of lymph nodes and bone marrow. The CSF should be examined even if parasitemia is confirmed. This should be done after clearance of the parasites from the blood so that parasites are not introduced into the CSF. In CNS trypanosomal infection, the CSF reveals a lymphocytic pleocytosis, elevated protein, and sometimes motile trypanosomes. Often morular or so-called Mott cells are seen, which are plasma cells with large eosinophilic inclusions containing immunoglobulin G. Several immunodiagnostic tests are available including indirect immunofluorescence, ELISA, and a card agglutination test that uses a commonly occurring variant antigen.

## Treatment

The two forms of African sleeping sickness can be treated in a similar fashion. Eflornithine (difluoromethyl-ornithine) inhibits ornithine decarboxylase, an essential parasite enzyme, and is an effective drug in both the early and later CNS stages of disease ([Box 85-5](#)). The side effects include vomiting, abdominal pain, and diarrhea. Seizures occur in < 5% of cases. Unfortunately, there is a current shortfall in drug supply, with no signs of immediate improvement. Suramin has also been shown to be effective. It is available in the United States only through the CDC. The urine should be checked prior to each dose for protein, and the dose or interval between doses should be altered if the specimen is positive. Pentamidine has been used as an alternative agent, but it is not US Food and Drug Administration-approved for this indication. Drug information is available through the CDC (daytime phone: [404] 639-3670; nighttime, phone [404] 639-2888).

African sleeping sickness tends to relapse, even after appropriate therapy; in this event, treatment should be repeated. Because parasitic confirmation of relapse may not be possible, increasing CSF protein or pleocytosis may be used as a marker of relapse. Infection does not confer immunity, and reinfection presents as new infection, often with chancres. Despite treatment, this disease is fatal in ~ 7% of patients.

## Prevention & Control

One of the most effective public health measures for control of *T brucei gambiense*-associated disease may be recognition and treatment of humans, because they serve as the reservoir for this organism ([Box 85-6](#)). Control efforts that focus on clearance of tsetse fly habitat and destruction of wild game, as well as human population relocation, have not been terribly effective.

Individuals should avoid known foci of disease, wear protective clothing, and use insect repellents and mosquito nets to reduce the risk of infection. Chemoprophylaxis is not generally recommended for travelers to endemic areas. No vaccine is currently available.

## Section VII. Parasitic Infections Part B. Helminths

### 86. Nematodes — *James M. Steckelberg, MD & Walter R. Wilson, MD*

#### Essentials of Diagnosis

- Intestinal nematodes: demonstration of characteristic eggs or parasites in stool.
- Bloodstream nematodes (filariasis): clinical diagnosis can be made; fresh blood smear may be confirmatory.
- Tissue nematodes: clinical diagnosis can be made; skin snip or other tissue examination may show organism.

#### General Considerations

Nematodes (roundworms) are nonsegmented, tapered, bilaterally symmetrical, cylindrical organisms that have complete digestive tracts and reproduce sexually. Although > 500,000 species of nematodes have been described, only a small number are commonly encountered as human parasites. Most nematodes have complex life cycles, sometimes involving several larval forms and intermediate hosts or free-living stages. The pathogenic nematodes may be categorized as primarily intestinal or extraintestinal tissue parasites ([Box 86-1](#)).

## INTESTINAL NEMATODE INFECTIONS

### ASCARIASIS

#### Introduction

Worldwide, more than 1 billion people are infested with *Ascaris lumbricoides*, the causative agent of ascariasis or roundworm. More than 4 million people are estimated to be infected in the United States. Infection occurs predominately in the southeastern states and more commonly in younger children, and it is associated with lower socioeconomic status. The organism is acquired through ingestion of embryonic forms of the worm, which are found in fecally contaminated soil. After ingestion, the embryonic eggs hatch in the small intestine, and the larvae undergo a tissue migration phase. During the migration, the larvae penetrate the intestinal wall and travel intravenously to the pulmonary alveoli. In the lungs, the organisms provoke a cough, are swallowed by the host, and subsequently mature into the adult worm in the small intestine. A single adult female ascarid may produce 200,000 ova daily, which are shed in the feces.

#### Clinical Findings

The majority of ascarid infections are asymptomatic. During larval migration, eosinophilic pneumonia with mild fever, cough, wheezing, pulmonary infiltrates, and

peripheral eosinophilia may be seen. Heavier worm loads may result in intestinal obstruction or symptoms caused by migration of the adult worm outside of the small intestine, most commonly into the common bile duct, causing biliary obstruction and associated complications. Rarely, adult worms may be expelled from the anus, nose, or mouth.

## Differential Diagnosis

During tissue and pulmonary larval migration, other causes of pulmonary infiltrates with eosinophilia, including hookworm and strongyloides infection, as well as Loffler's syndrome, asthma, and allergic bronchopulmonary aspergillosis, should be considered. Heavy intestinal infection may cause obstruction that mimics other mechanical causes of bowel obstruction. Migration into the biliary system or appendix may be confused with acute cholecystitis, appendicitis, acute abdomen, or biliary obstruction caused by other more common causes.

## Treatment

All patients with ascariasis should be treated, even if asymptomatic, to prevent biliary migration and obstruction ([Box 86-2](#)). Ascarids should be treated first in mixed parasitic infections, and they should be treated before general anesthesia because of the risk of inducing migration of hypermotile worms. In some cases, endoscopic removal of worms may be indicated. Stools should be reexamined 2 weeks after therapy and treatment repeated as necessary.

## Prognosis

Prognosis is generally excellent, although reinfection is possible. In rare cases, obstruction of the small intestine by a mass of worms may cause an acute abdominal syndrome. In addition, obstruction of the common bile duct may cause acute biliary colic.

## Prevention

Roundworm infection can be prevented by avoiding ingestion of fecally contaminated soil. Measures to accomplish this include hygienic disposal of fecal waste, avoidance of the use of night soil and proper washing of foods contaminated by soil, hand washing, and avoidance of pica.

## ENTEROBIASIS

### Introduction

Also known as pinworm, infection by *Enterobius vermicularis* is the most common helminth infection in the United States. Enterobiasis is typically found in clusters of individuals living in close proximity, such as families or institutionalized groups. It is particularly common in school-age children. Adult females migrate nocturnally to the perianal areas, where eggs are deposited and subsequently distributed to fingers, fingernails, bedding, nightclothes, and other areas. Ingestion of the embryonated eggs

results in development of intestinal adult worms in 1-2 months.

## **Clinical & Laboratory Findings**

Many infections are asymptomatic. In symptomatic patients, nocturnal anal pruritus and interrupted sleep are typical. Laboratory tests are normal; eosinophilia is not seen with enterobiasis. Although adult worms that resemble small threads may be seen with the naked eye, diagnosis is usually made by documenting eggs in the perianal area in the early morning, before bathing or defecation. This can be done by pressing cellophane tape in the perianal area and examining the tape under the microscope or by using a commercial collection system such as the Swube (Becton Dickinson). Stool examination for eggs is usually not helpful.

## **Differential Diagnosis**

Enterobiasis should be distinguished from other causes of perirectal irritation, including pruritis ani, rectal fissures, moniliasis, hemorrhoids, and strongyloidiasis, among other conditions.

## **Treatment**

Treatment suggestions are given in [Box 86-2](#).

## **Prognosis**

Prognosis is excellent, although reinfection is common in the setting of continued exposure.

## **Prevention**

Reinfection is common in households with an infected person; examination for asymptomatic carriers and simultaneous treatment of all infected household members may be required. Household members should practice hand washing before meals and after defecation and should launder bedding and bedclothes to eliminate environmental eggs.

## **ANCYLOSTOMIASIS & NECATORIASIS**

### **Introduction**

Hookworm infestation is caused by *Ancylostoma duodenale* or *Necator americanus*. After hookworm eggs are passed in stool, the larvae hatch and mature in soil, where they become infective after 1 wk. Human infection occurs after direct penetration by larvae of the host's skin, usually through the feet. The hookworm larvae then enter venules and are carried to the lungs, where they penetrate into alveoli. From the alveoli, the larvae migrate to the trachea. They induce cough and are swallowed by the host. The larvae mature into adult worms in the small intestine. Hookworms attach to intestinal mucosa by means of teeth and a well-developed mouth, and they feed on blood and nutrients sucked from the host. Humans are the only known hosts.

## Clinical & Laboratory Findings

The initial allergic reaction to larval skin penetration and migration is known as "ground itch," and is manifested by intense pruritus and vesicular or maculopapular dermatitis. Patients may experience cough, wheezing, fever, and pulmonary infiltrates during pulmonary migration. Peripheral eosinophilia may be marked. During the intestinal phase, which may last several years, heavy worm burdens may result in protein malnutrition and iron deficiency anemia.

## Differential Diagnosis

Early in infection, strongyloidiasis, cutaneous larva migrans, contact dermatitis, scabies, and other causes of pruritic dermatitis, especially of the extremities, should be considered. Later, other causes of eosinophilic pneumonia should be considered, including *A lumbricoides* and *Strongyloides stercoralis* infections, as well as Löffler's syndrome. Chronic intestinal infestation, with nonspecific gastrointestinal symptoms, may mimic a multitude of gastrointestinal conditions and other causes of iron deficiency.

## Treatment

Re-treatment at 2-wk intervals may be necessary to reduce the worm burden to low levels (see [Box 86-2](#)). Because light infections are usually asymptomatic, complete eradication may not be therapeutically necessary. In patients with iron deficiency, supplemental iron therapy (eg, ferrous sulfate, 200 mg 3 times daily for several months, followed by 200 mg daily until iron stores are repleted) may be necessary.

## Prognosis

Prognosis with treatment is excellent.

## STRONGYLOIDIASIS

### Introduction

Infection by *S stercoralis* (threadworm) is especially notable because the worm is parthenogenetic and larvae mature to an infective stage within the intestinal lumen. As a consequence, sequential generations of worms may persist in a single host over many years. Immunocompromise caused by organ transplantation, corticosteroid therapy, hematologic malignancies, or other conditions may result in massive autoinfection, termed the hyperinfection syndrome. Surprisingly, human immunodeficiency virus infection does not appear to increase susceptibility for hyperinfection.

Like other intestinal nematodes, the life cycle of *S stercoralis* is complex. The initial infection occurs through penetration of the skin by soil-borne free-living infectious larvae. The larvae ultimately reach the proximal intestine via blood-lung migration. Eggs from adult worms hatch in the intestine, producing larvae that may (i) reinfect the same host, (ii) pass to a new host directly via skin penetration, or (iii) give rise to soil-borne free-living adults that may, in turn, produce infectious larvae.

## Clinical & Laboratory Findings

Many patients with chronic but low worm burden infections are asymptomatic or have irregular intestinal symptoms. During initial skin penetration, local skin irritation, pruritic dermatitis, urticaria, and serpiginous tracts ("larva currens") may be seen. During pulmonary migration, symptoms and signs of infection are similar to those of other nematodes that travel through the lung; that is, dry cough, wheezing, low-grade fever, dyspnea, and hemoptysis. Symptoms of chronic intestinal infestation are varied and nonspecific, and they may include bloating, abdominal distension, dyspepsia, epigastric pain, pruritus ani, diarrhea, and flatulence. In immunocompromised patients, hyperinfection syndrome may be manifested by gastrointestinal ulceration, peritonitis, ileus, biliary obstruction, cholecystitis, or hepatic granulomas. Invasion of extraintestinal organs, including meningitis, central nervous system invasion, pericarditis or myocarditis, or pleuritis, may also occur. Gram-negative or polymicrobial bacteremia with sepsis may complicate hyperinfection syndrome.

Diagnosis of strongyloidiasis is made by examination of stool or duodenal aspirate for *S stercoralis* larvae. Larvae may be present in stool only intermittently. Eggs of *S stercoralis* are rarely seen in stool specimens.

## Differential Diagnosis

The myriad of presentations and potential tissue sites of *S stercoralis* requires a high index of suspicion for diagnosis. Chronic intestinal symptoms may mimic dyspepsia, irritable-bowel syndrome, inflammatory-bowel disease, malabsorption, sprue, giardial infection, or other causes of chronic or recurring diarrhea. Epigastric pain may resemble peptic ulcer disease. During tissue migration, eosinophilia, pulmonary infiltrates, wheezing, and cough may suggest nematode or ascarid infections as well as asthma, hypersensitivity pneumonitis, allergic bronchopulmonary aspergillosis, or Loffler's syndrome. Hyperinfection syndrome may mimic sepsis or bacteremia caused by enteric organisms from other causes, such as aortoenteric fistula.

## Treatment

Eradication is the goal of therapy (see [Box 86-2](#)). When immunosuppression can be anticipated, such as in patients being evaluated for organ transplantation, screening for *S stercoralis* and eradication should occur before immunosuppression.

## Prognosis

In immunocompetent hosts, prognosis is good. Severe infection with multiple complications may occur in immunocompromised hosts with hyperinfection syndrome.

## TRICHURIASIS

### Introduction

Trichuriasis or whipworm is caused by *Trichuris trichiura*. These small (30- to

50-mm-length) whiplike nematodes attach to the mucosa of the large intestine, especially the cecum; there is no extraintestinal phase. Infection occurs by ingestion of infective eggs from soil contaminated with feces; 2-4 wk of maturation in soil are required for the larvae within the eggs to become infective; thus, direct person-to-person transmission does not occur.

### **Clinical & Laboratory Findings**

Mild to moderate worm burdens are usually asymptomatic. Heavy infections (> 30,000 eggs/g of feces) may be asymptomatic or cause nonspecific abdominal complaints, including abdominal cramping, bloating, distension, nausea, vomiting, flatulence, diarrhea, or tenesmus. Rectal prolapse and appendiceal obstruction with appendicitis are rare complications of strongyloidiasis. Eosinophilia is common; iron deficiency anemia may be seen with heavy infections that result in chronic occult blood loss.

### **Treatment**

Treatment of symptomatic trichuriasis is outlined in [Box 86-2](#).

### **Prognosis**

Prognosis is excellent.

## **TISSUE NEMATODE INFECTIONS**

### **LYMPHATIC FILARIASIS**

#### **Introduction**

Lymphatic filariasis is a bloodstream and lymphatic infection caused by the filarial nematodes *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*. The disease is endemic in the tropics and subtropics of both hemispheres. A mosquito serves as an intermediate host and vector; the peak blood parasitemia and optimum time of the day or night for obtaining blood smears differ in various parts of the world, corresponding to the feeding pattern of the local mosquito vectors. After deposition by mosquitoes of infectious microfilariae into humans during a blood meal, 6-12 mo are required before adult worms mature and begin producing numerous circulating microfilariae to continue the life cycle. Symptoms of acute disease generally occur 8-16 mo after infection in nonindigenous peoples, but the incubation period may be longer in indigenous peoples.

#### **Clinical & Laboratory Findings**

Indigenous persons with filariasis are often asymptomatic. In the first few years after infection, variably present clinical manifestations include recurrent episodes of lymphangitis, notable for progression proximally to distally, unlike typical bacterial lymphangitis. These episodes may be accompanied by high fever and resolve within 7-10 d. Epididymitis or orchitis may occur intermittently. Other patients, especially travelers, may have allergic symptoms including urticaria, rashes, and eosinophilia. Chronic infection may result in lymphatic insufficiency, with lymphedema involving the

extremities or external genitalia. Hydroceles may also occur. The term elephantiasis refers to advanced changes of chronic lymphedema, including subcutaneous thickening, skin hyperkeratosis, and fissuring.

Tropical pulmonary eosinophilia refers to a syndrome of nocturnal cough and wheezing with diffuse miliary chest x-ray infiltrates, eosinophilia, elevated immunoglobulin E concentrations, and high antifilarial antibody titers. The syndrome is caused by sequestration of *W bancrofti* or *B malayi* microfilariae in the lungs and responds to treatment with diethylcarbamazine citrate (DEC).

Diagnosis of filariasis is usually clinical in endemic areas. Confirmation requires demonstration of microfilaria in filtered blood samples, the timing of which should be adjusted to match the nocturnal or diurnal periodicity of the peak parasitemia in the region in which the infection was acquired. The organisms adapt their periodicity to local time zones, but this requires 10-14 d.

Microfilariae are more commonly seen in the bloodstream during the early stages of disease (1-2 years after infection) and are rare in the bloodstream during the lymphatic obstructive stage of disease. Administration of 50 mg of DEC may result in positive blood smears immediately (within 1 h) after administration in otherwise smear-negative individuals. Serologic testing may also be helpful, but both false positive and false negative test results occur.

## **Treatment**

Symptomatic treatment of acute filarial lymphangitis (eg, antihistamines and aspirin) may be helpful in reducing the intensity of symptoms. DEC is an effective microfilaricidal drug, but the adult worms require a longer course of therapy and sometimes multiple courses of therapy to be eradicated. DEC (2 mg/kg) is administered 3 times daily for 2-3 wk. Allergic reactions (eg, fever, urticaria, or lymphangitis) to injured parasites may occur early in therapy; some authorities suggest smaller doses of DEC (50 mg on the first day, increasing to full dosage over 3-4 d) to minimize these reactions. Antihistamines may also be of benefit. Nonspecific side effects include headache, vertigo or dizziness, malaise, fever, or myalgias. Onchocerciasis should be excluded before DEC treatment. DEC is available in the United States from Lederle Laboratories (800-934-5556).

## **Prevention**

Because transmission depends on mosquito vectors, control measures are directed at reducing mosquito populations and reducing the number of bites by mosquitoes.

## **OTHER FILARIAL INFECTIONS**

### **1. LOIASIS**

#### **Introduction**

Loiasis (African eye worm infection) occurs in rainy areas of central and West Africa.

The filarial parasites are transmitted by the bite of an infected *Chrysops* spp. horsefly. Organisms mature in the subcutaneous tissues, where adult worms may live for more than a decade and release microfilariae into the circulation.

### **Clinical Findings**

Adult worms migrate through subcutaneous tissues at rates = 1 cm/min. This may be asymptomatic, or, especially when migration occurs around or across the eye, noted as conjunctivitis or eyelid edema. Calabar swellings are subcutaneous edematous areas of 3-10 cm that are nonerythematous and do not pit; local pain, pruritus, and mild fever may be present. Calabar swellings are transient, resolving after 2-3 d or 1 wk, only to reappear at irregular intervals in different locations. Calabar swellings do not necessarily contain worms at the time that they appear.

Symptoms of loiasis vary depending on the host. Indigenous populations typically have relatively mild symptoms or are asymptomatic even though they are microfilaremic. Travelers typically have a more symptomatic course, with an increased number and severity of Calabar swellings, marked eosinophilia, leukocytosis, hypergammaglobulinemia, and elevated immunoglobulin E antibodies.

### **Treatment**

Treatment is with DEC, 3 mg/kg 3 times daily for 21 d. Localized inflammatory reactions to dying adult worms in tissues are common. In patients with microfilaremia, reactions may be more severe including severe neurologic complications and death. Gradually escalating doses of DEC and in some patients systemic corticosteroids may be used. Ivermectin and albendazole have been investigated as alternative therapies to DEC.

## **2. ONCHOCERCIASIS**

### **Introduction**

Infection with *Onchocerca volvulus* causes African river blindness, which is the second leading cause of blindness worldwide. Onchocerciasis is transmitted by the *Simulium* spp. blackfly and is found in equatorial West, central, and East Africa and portions of Central and South America. Larval forms penetrate the skin after the bite of the blackfly, where they mature into adults in the subcutaneous tissues. Microfilariae from mature females migrate back to the dermis where they are ingested by blackflies to continue the life cycle.

### **Clinical Findings**

Cutaneous and connective tissue manifestations of onchocerciasis include the formation, usually within a year, of mobile nodules encapsulating the adult worms in a fibrous tissue mass. Multiple nodules may be present in subcutaneous or connective tissues, especially over bony prominences. Depigmentation, wrinkling, and thickening of skin may be seen with chronic infection. Visual loss is the most serious complication. The earliest eye lesions are punctate keratitis associated with microfilariae within the cornea and anterior chamber. Iridocyclitis and posterior synechiae may develop, which

may result in a fixed and distorted pupil. Lesions of the posterior chamber of the eye are less common, including optic atrophy and choroiditis.

Diagnosis is suspected clinically and confirmed by examination of a skin snip obtained without anesthesia from the shoulder or buttock areas, demonstrating microfilariae. Adult worms may be found in biopsied or excised nodules. Slit-lamp examination of the cornea or anterior chamber of the eye may demonstrate microfilariae. Microfilariae are identifiable in urine in 17%-30% of patients > 10 years old.

## **Treatment**

The treatment of choice is ivermectin, 150 µg/kg orally as a single dose, which kills microfilariae but is less effective against adult worms. Treatment is repeated at 3-mo intervals for 2-3 years. Diethylcarbamazine has been used historically but is less effective and more toxic than ivermectin, and it is no longer recommended by the World Health Organization. Cutaneous nodules, especially on the scalp, may be surgically excised.

## **OTHER TISSUE NEMATODE INFECTIONS**

### **1. TRICHINOSIS**

#### **Introduction**

*Trichinella* species are unique among the tissue-dwelling nematodes in that there is no intermediate arthropod vector stage. *Trichinella* nematodes parasitize carnivores. Adult worms parasitize the small intestine; infective larvae are released and migrate from the intestine to muscle tissues in the host, where the larvae encyst and remain viable and infectious for several years. When the host tissues are eaten, the cyst walls are digested and the larvae again mature within several days in the intestine of the new host, perpetuating the life cycle. Normal hosts of *Trichinella* spp. include swine, rats, bears, foxes, walrus, and other carnivorous mammals. Humans are an incidental host. Cooking meat to 55 °C core temperatures or freezing (-15 °C) for 3 wk kills *Trichinella* spp. larvae.

#### **Clinical & Laboratory Findings**

Mild infection is usually asymptomatic. Early (1 wk) after infection, gastrointestinal symptoms predominate, including diarrhea, nausea or vomiting. After the second week, during the muscle invasion stage, systemic symptoms predominate including fever, myalgias, and malaise in most patients. Periorbital edema with conjunctival chemosis and edema of the eyelids is characteristic and common. Symptoms last between 4 and 8 weeks. Rarely, myocarditis or encephalitis may complicate the clinical course. In the laboratory, eosinophilia after the 10th day, sometimes marked, is characteristic, as is elevated immunoglobulin E. Serum creatine phosphokinase and lactic dehydrogenase concentrations reflect myositis. *Trichinella* serology becomes positive at = 3 wk after infection.

#### **Treatment**

Treatment for trichinosis remains controversial and is primarily supportive. If ingestion is known to occur within 24 h, albendazole (400 mg twice daily, (60 days), mebendazole (200-400 mg 3 times daily for 3 days, then 400-500 mg 3 times daily for 10 days), or thiabendazole (25 mg/kg/day for 1 wk) has been proposed to prevent infection. The drug is not beneficial for established infection or muscle larvae. No specific therapy has been unequivocally demonstrated to be of benefit during the muscle invasion stage.

## Prognosis

Spontaneous recovery is the rule, although full recovery may require weeks to months. Death, typically from myocarditis, encephalitis, or pneumonitis, is rare.

## Prevention

The incidence of human trichinosis has declined in developed countries with measures designed to reduce the prevalence of trichinosis in hogs. *Trichina* in wild game (or pork) can be killed by thorough cooking (internal temperature > 62 °C) throughout all parts of the meat or to > 56 °C for > 15 min, freezing < -15 °C for = 20 d, or gamma radiation.

## 3. TOXOCARIASIS (VISCERAL LARVA MIGRANS)

### Introduction

Toxocariasis, or visceral larva migrans, is a syndrome caused by invasion of human extraintestinal tissues by larvae of *Ascaris* spp. for which humans are not the usual host of the adult worms. *Toxocara canis*, commonly found in dogs, is the most commonly implicated species; *Toxocara cati* (cats) and *Belascaris procyonis* (raccoons) have also been implicated. Puppies can be infected transplacentally or transmammarily. Pregnancy in dogs reactivates latent infections in the bitch. Animals harboring adult ascarids in the intestine shed copious numbers of eggs into the environment. The eggs become infectious after 3-4 wk and are highly resistant to harsh environmental conditions. *Toxocara* eggs may remain infectious for months to years. Human infection results from ingestion of eggs from fecally contaminated soil, as may occur for example in children with pica. Direct transmission from pets to humans does not occur, because the eggs require maturation in soil before they become infective.

In young animals, ingested eggs hatch in the intestine and the larvae migrate through extraintestinal tissues, including liver and lung. Larvae induce coughing and are swallowed and then mature into adults in the small intestine to complete the life cycle, which resembles that of *A lumbricoides* in humans. In older animals, humans, and other hosts such as mice or rats, larvae also hatch from ingested eggs and invade extraintestinal tissues, but the larvae are unable to fully mature and may continue to persist and migrate in tissues as "second-stage" larvae for = 6 months. If these second-stage larvae are ingested by a dog or cat, the larvae may complete their life cycle and develop into adult intestinal worms. Eosinophilic granulomas caused by toxocariasis most often involve the liver or lungs; brain, eye, muscle, and skin involvement has also been reported.

## Clinical & Laboratory Findings

Visceral larva migrans is predominately seen in children < 7 years old, and it may be associated with pica. Most cases appear to be asymptomatic. When present, symptoms are variable and depend on the organ systems involved but may include fever, cough or wheezing, and urticarial rash or skin nodules. Hepatomegaly is relatively common. Splenomegaly, lymphadenopathy, and evidence of myocarditis are less common.

Marked leukocytosis, sometimes exceeding 100,000 leukocytes/ul, and hypereosinophilia are common in visceral larva migrans. Polyclonal hypergammaglobulinemia and anti-A or anti-B antibodies to isohemagglutinin antigens (cross-reacting to *T canis* larval antigens) may occur. An eosinophilic spinal fluid pleocytosis may occur with central nervous system involvement. Chest x-ray abnormalities may be seen in one-third of patients. *Toxocara* serology may be helpful in confirming the diagnosis, but it should be remembered that in some populations the background prevalence of seropositivity in patients without clinically apparent visceral larva migrans may be high. Identification of larvae in tissue biopsy samples is diagnostic, but not sensitive. Stool examination is not usually helpful.

Ocular visceral larva migrans deserves special consideration. Infection of the eye with *Toxocara* larvae usually presents as a solitary finding in patients with no known history of visceral larva migrans and without concurrent multifocal, systemic symptoms or signs. The ocular findings are typically a unilateral posterior or peripheral eosinophilic inflammatory mass. Serologies may be negative. The ocular lesion may be mistaken for a retinoblastoma.

## Treatment

No specific therapy has been proven effective. In many cases, symptoms are self-limited and supportive, symptomatic treatment is all that is required. Treatment with a variety of antihelminthic agents has been tried with limited success. These agents include albendazole, thiabendazole, mebendazole, diethylcarbamazine, or ivermectin. Corticosteroids may be of benefit in some patients, especially subconjunctival applications in ocular visceral larva migrans.

## Prevention & Prognosis

Puppies, kittens, and household dogs and cats, especially when pregnant or nursing, should be screened and treated as necessary to prevent transmission to humans. Pica should be prevented. Most cases are self-limited although symptoms may persist for months to several years.

## 4. DRACUNCULIASIS

### Introduction

Dracunculiasis, or guinea worm infection, is caused by infection by the tissue nematode *Dracunculus medinensis*. The parasite has been widely distributed in the Indian subcontinent, the Arabian Peninsula, and certain areas of West and central Africa north

of the equator. Human infection is acquired by drinking water that contains tiny copepods (*Cyclops* spp.; "water fleas") that carry the infectious third-stage larvae. The larvae migrate to subcutaneous connective tissue, usually in the lower extremities, where they develop into adult worms over an extended incubation period that can last up to a year. The adult female may reach 60-80 cm in length. When the extremities are exposed to water, the head of the gravid female protrudes through an ulceration in the host's extremity, a loop of uterus prolapses and discharges large numbers of first-stage larvae into the water. These are ingested by copepods to complete the life cycle.

An active eradication program by the World Health Organization has led to a dramatic reduction in the incidence of dracunculiasis world-wide. Because no nonhuman reservoir is recognized, the disease may be eradicable in the near future.

### **Clinical Findings**

A peripheral chronic cutaneous ulceration, from which the worm may protrude, is the hallmark of dracunculiasis. A local painful, stinging or burning papule may be the first indication of impending ulceration. Generalized symptoms including fever, nausea, vomiting, dyspnea, urticaria or pruritus, or periorbital edema may be associated with development of ulceration. Ulcers on the foot frequently prevent ambulation and may result in long-lasting deformity and secondary infection (including ankle or knee joint infection). Tetanus may also complicate dracunculiasis. Dead or dying worms may result in intense inflammatory reactions. Diagnosis in endemic areas is based on the typical clinical findings.

### **Treatment**

No specific antihelminthic therapy is available to kill adult worms. Mechanical removal of worms has been practiced for centuries. General treatment is focused on controlling complications, including bed rest, elevation of the affected extremity, wound care, and antibacterial therapy for secondary bacterial wound infections. Metronidazole, 250 mg orally 3 times daily, mebendazole, 400-800 mg orally daily, or thiabendazole 25 mg/kg twice daily may be helpful in promoting the expulsion of the worm, as is immersion of the affected limb in water several times daily.

### **Prevention**

Noncontaminated drinking water is the key to prevention of dracunculiasis. The World Health Organization prevention program has focused on provision of clean drinking water by using tube wells, hand pumps, or cisterns, by treating drinking water supplies with temephos (to eliminate the copepods), or by boiling water. Water can also be filtered to remove particles > 100 µm.

## **87 . Cestodes — Andrew D. Badley, MD, James M. Steckelberg, MD & Walter R. Wilson, MD**

### **INTRODUCTION**

Human infections caused by cestodes, or tapeworms, may occur within the lumen of the bowel, where adult cestodes attach themselves to the host intestine ([Box 87-1](#)). Alternatively, human infection may be the result of dissemination of cestodes from the bowel to involve extraintestinal sites, often by larval forms of the parasite. The life cycle of cestodes is determined by definitive hosts, in whom the mature adult worm lives, and intermediate hosts, which harbor the larval forms of the parasite. Humans are a definitive host for six cestodes: *Diphyllobothrium latum*, *Taenia solium*, *Taenia saginata*, *Hymenolepis diminuta*, *Hymenolepis nana*, and *Dipylidium caninum*. In addition, humans may be intermediate hosts for *Echinococcus granulosus* and *Echinococcus multilocularis*. All forms of disease associated with infections caused by cestodes are treatable; therefore, a careful history and physical examination to identify potential patients is warranted.

Cestodes attach themselves to the intestinal mucosa by means of a specialized organ called the scolex, which has a distinctive morphology for each species of cestode. Attached to the scolex are one to several hundred segments called proglottids. Proglottids each contain both male and female reproductive organs and may be classified as immature, mature, or gravid, based on the state of maturation of their sex organs. A gravid proglottid contains a fully developed uterus, full of eggs. The uterine structure of a gravid proglottid helps to differentiate species of cestode.

### **DIPHYLLOBOTHRIUM LATUM INFECTION**

#### **Essentials of Diagnosis**

- Stool examination reveals ovoid, yellow-brown eggs (60-75 um by 40-50 um).
- Chains of proglottids (up to 50 cm long) may be passed in stool.
- Proglottids are wider than long (3 by 11 mm).
- Scolex has no hooklets and two grooves (bothria).
- Gravid proglottid contains rosette-shaped central uterus.

#### **General Considerations**

*D latum* is found worldwide, and infection is acquired by ingestion of contaminated raw or improperly cooked freshwater fish. Because of enthusiasm for raw or undercooked fish, Siberia, Europe, Canada, Alaska, and Japan are endemic regions for *D latum* infection. Once the *D latum* cyst has been ingested, the worm matures within the human intestine and begins to produce eggs after 5 weeks. A mature *D latum* may reach

lengths of several meters and contain = 30,000 proglottids. Eggs and proglottids that are passed in stool hatch after 14 days in fresh water into ciliated coracidium larvae, which are ingested by the intermediate host, the aquatic copepod. Inside the copepod, the larvae develop into a second larval form, the proceroid. Once the copepod is ingested by a freshwater fish, the proceroid larva matures into the plerocercoid larva, which may encyst within fish tissues. Human ingestion of improperly prepared fish initiates infection by the plerocercoid larva cyst. Bears, seals, cats, mink, foxes, and wolves are alternate definitive hosts for *D latum*.

## Clinical Findings

**A. Signs and Symptoms.** Infection with *D latum* is most often asymptomatic, but symptoms such as bloating, abdominal pain, or diarrhea may be present. More rarely, intestinal obstruction may occur. A rare complication of chronic, small-intestinal involvement with *D latum* is the development of Vitamin B<sub>12</sub> deficiency, characterized by anemia with or without neurologic sequelae. This syndrome occurs most often in patients with a genetic predisposition to the development of pernicious anemia, commonly people of Scandinavia.

**B. Laboratory Findings.** Frequently the only abnormal finding in a patient infected with *D latum* is the presence of eggs or proglottids on examination of stool for ova and parasites. Blood examination may reveal a slight leukocytosis with eosinophilia and occasionally a megaloblastic anemia associated with B<sub>12</sub> deficiency.

**C. Imaging.** Contrast studies of the gastrointestinal tract may reveal ribbonlike filling defects corresponding to the adult worm.

## Differential Diagnosis

The most usual manifestation of *D latum* infection is asymptomatic carriage, which is incidentally discovered. If patients present with abdominal pain and diarrhea, the differential diagnosis includes a variety of infectious and noninfectious causes. Diarrhea from *D latum* infection will not be associated with stool leukocytes; this aids in formulating a differential diagnosis. Noninfectious etiologies to consider include osmotic (eg, lactose intolerance) and secretory (eg, villous adenoma) etiologies, malabsorption syndromes (eg, celiac sprue), and motility disorders (eg, irritable bowel syndrome). Infectious etiologies causing diarrhea without stool leukocytes include rotavirus, Norwalk virus, *Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium* spp., and toxigenic diarrhea caused by *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens*, and enterotoxigenic *Escherichia coli*.

## Complications

The complications vary with the clinical syndrome associated with infection. Chronic diarrhea may lead to malnutrition. Megaloblastic anemia secondary to B<sub>12</sub> deficiency results when the parasite disrupts the B<sub>12</sub>-intrinsic factor complex, resulting in B<sub>12</sub> becoming unavailable for absorption by the host. B<sub>12</sub> deficiency may lead to neurologic sequelae including peripheral neuropathy, dementia, and possible severe combined

degeneration of the posterior columns. Also, infection with *D latum* may rarely result in intestinal obstruction caused by a mass of entangled worms.

### **Treatment**

Therapy for infection with *D latum* consists of either praziquantel or niclosamide ([Box 87-2](#)). Follow-up examinations of stool should be performed 1 and 3 months after treatment.

### **Prognosis**

Since the disease is not commonly associated with severe symptoms, the prognosis of infected individuals is excellent. One exception is with patients who manifest B<sub>12</sub> deficiency, in whom the neurologic complications are reversible only if recognized and treated early.

### **Prevention & Control**

Prevention of infection from *D latum* is achieved through adequate cooking of all freshwater fish or freezing of fish for 24-48 h at -18 °C ([Box 87-3](#)). Isolation of infected persons is not required.

## **TAENIA SOLIUM INFECTION**

### **Essentials of Diagnosis**

- Spheroidal yellow-brown eggs (31-43 μm).
- Scolex has hooklets and four suckers.
- Proglottids usually appear as short chains.
- Mature proglottids are square and nonmotile.
- Gravid proglottid has 7-13 lateral branches on each side of uterus.

### **General Considerations**

*T solium* infection occurs worldwide; endemic areas include Mexico, South and Central America, Africa, Southeast Asia, India, and the Philippines. *T solium* infection is commonly linked to the ingestion of undercooked pork, although other animals may harbor the larval form of the parasite. Infection may be intestinal, which is typically asymptomatic, or extraintestinal (called cysticercosis, see below), which is caused by larval forms of *T solium* within the tissues of the human host. Ingestion of encysted *T solium* larvae is followed by the parasite scolex attaching to the intestinal mucosa, which allows the worm to grow into an adult within 12 weeks. There may be one or more adult worms present for = 25 years, and these may reach lengths of 2 to 7 m. Each worm contains < 1000 proglottids. Identification of species is by the number of lateral branches on the side of the uterus within a gravid uterus.

## Clinical Findings

**A. Signs and Symptoms.** Infection with the adult worm of *T solium* is usually asymptomatic, but nonspecific abdominal symptoms including indigestion and nausea may be present.

**B. Laboratory Findings.** Patients with intestinal *T solium* infection will frequently have abnormal results of stool examinations for ova and parasites and occasionally will have a mild leukocytosis with eosinophilia.

## Differential Diagnosis

Since infection with the adult worm of *T solium* is asymptomatic, the main diagnostic concern in a patient with intestinal *T solium* is whether the patient has cysticercosis. If the results of evaluation suggest that there is extraintestinal infection, then specific therapy for cysticercosis is required.

## Complications

*T solium* infection of the intestine is not commonly associated with symptoms; however, in patients with high parasite loads, obstruction may occur.

## Treatment

Therapy for *T solium* infection of the intestine consists of either praziquantel or niclosamide (see [Box 87-2](#)). Follow-up examinations of stool should be performed 1 month after treatment.

## Prognosis

The prognosis for patients with intestinal *T solium* infection is excellent.

## Prevention & Control

Prevention from infection with *T solium* involves adequate cooking of pork and pork products to a > 65 °C core temperature ([Box 87-3](#)). Freezing, pickling, and salting do not prevent infection. Immunization of swine and provision of animal feed that is free of eggs and proglottids are other preventative measures that have been reported to be effective in controlling infection. Since infected humans are capable of transmitting cysticercus to others, enteric precautions should be used, and stool specimens should be handled with attention to decontamination. In addition, adequate facilities for disposal of human sewage should be available.

## CYSTICERCOSIS (CYSTICERCUS CELLULOSEA INFECTION)

### Essentials of Diagnosis

- Surgical excision of involved tissue, with microscopic identification of parasite.

- Frequently calcified cysts present on x-ray or computed tomography (CT) scans.
- Positive serology indicating previous exposure to *T solium*.
- Fine-needle aspiration of cysts (characteristic cytomorphology).

## General Considerations

Cysticercosis is caused by invasion of tissue by the larval forms of *T solium*, which have been referred to as *Cysticercus cellulosea*, although the name is not taxonomically correct and introduces confusion. Within a host infected by the adult *T solium*, eggs or proglottids are passed in the stool. Once eggs or proglottids are ingested by either pigs (intermediate hosts) or humans (definitive and intermediate hosts), eggs hatch in the gastric juice, allowing the cysticercus to migrate from the intestine to disseminated sites, via efferent mesenteric venules. Autoinfection may also occur in humans, wherein eggs produced by the adult intestinal worm hatch and invade the intestinal epithelium.

## Clinical Findings

**A. Signs and Symptoms.** The symptoms associated with cysticercosis relate to the organ that is invaded by cysticerci and to the inflammatory reaction that occurs in response to the larva. Within the brain, cysticercosis may cause arachnoiditis or chronic meningitis, with associated headache, vertigo, vomiting, and cranial neuropathies. Alternate presentations include obstructive hydrocephalus with ataxia and dementia, intracranial vasculitis with focal neurologic signs and neuropsychiatric changes, or mass effect with seizures, headache, or focal neurologic deficits. In addition, cord compression with lower limb weakness and loss of bowel and bladder continence may occur. Cysts outside the central nervous system tend to occur within muscle, are most often asymptomatic, and eventually die, calcify, and may be incidentally detected on radiographs. Occasionally, muscle cysts will cause pseudohypertrophy that may be associated with myositis, high fever, and eosinophilia. Cysts may also occur within critical organs (commonly heart and liver) where they present as mass lesions with pain or obstructive symptoms.

**B. Laboratory Findings.** Patients with cysticercosis may have a mild elevation on leukocyte count, possibly with eosinophilia. In patients with meningitis associated with neurocysticercosis, cerebrospinal fluid examination may show either lymphocytic or eosinophilic pleocytosis, hypoglycorrhachia, and elevated protein. Recently a serologic test for *T solium* has been developed, but its performance characteristics remain to be validated. False positive results have been associated with infections caused by other cestodes. A negative serologic test does not exclude the diagnosis of cysticercosis.

**C. Imaging.** Living cysts associated with cysticercosis are often multiple and have a characteristic appearance on CT scans or magnetic resonance images, both enhancing and nonenhancing unilocular cysts. Patients with extraneurologic cysticercosis may have painless subcutaneous nodules, often on the shins, which are calcified and have a characteristic appearance on plain radiographs.

## Differential Diagnosis

Patients who seek care for symptoms of infection with *T solium* most commonly do so because of the neurologic symptoms associated with neurocysticercosis. The most common neurologic symptoms are mass effect and seizures (related to intraparenchymal lesions), hydrocephalus (related to intraventricular cysts), chronic meningitis (related to subarachnoid cysts), and cord compression (owing to spinal cord cysts). The differential diagnosis of each of these symptoms is beyond the scope of this discussion, but malignancy may present in identical ways, and so it must be ruled out.

## Complications

Visceral cysticercosis is also commonly asymptomatic, but may obstruct local structures (eg, biliary obstruction in hepatic cysticercosis). Neurocysticercosis may lead to permanent neurologic impairment, coma, or even death.

## Treatment

Therapy for cysticercosis includes surgery when feasible and necessary, in combination with praziquantel or albendazole (see [Box 87-2](#)). Therapy of cysticercosis commonly increases the local inflammation, thereby transiently causing a paradoxical worsening of the patient's symptoms. Whether corticosteroids should be used as adjunctive therapy for patients being treated for neurocysticercosis remains in debate.

## Prognosis

The mortality rate for untreated neurocysticercosis approaches 50%, but treatment decreases this rate to 5-15%.

## Prevention & Control

Guidelines for the prevention of cysticercosis are the same as for the prevention of *T solium* infection ([Box 87-3](#)).

## TAENIA SAGINATA INFECTION

### Essentials of Diagnosis

- Stool examination reveals spheroidal yellow-brown eggs (31-43 mm).
- Motile proglottids that appear singly in stool.
- Mature proglottids are square.
- Scolex has no hooklets and four suckers.
- Gravid proglottid has 15-20 lateral branches.

### General Considerations

*T saginata* infection is commonly associated with the ingestion of undercooked beef. This is distinguished from infection with *T solium* because human infection with the larval form (as in cysticercosis) is extremely rare with *T saginata* infection. *T saginata* infection is common in areas of the world with intensive cattle breeding, such as central Asia and central and eastern Africa. Alternative intermediate hosts for *T saginata* include llamas, buffalo, and giraffes. The life cycle for *T saginata* is similar to that of *T solium*; larvae are ingested in infected meat, and the tapeworm attaches to the intestinal epithelium and matures in 12 weeks. Mature tapeworms produce gravid proglottids with characteristic 15-20 lateral branches, which contain numerous eggs. Ingestion of eggs or proglottids by cows leads to hatching of eggs, and larvae that migrate into striated muscle. Case reports exist about *T saginata* cysticercosis in humans, although the incidence is exceedingly uncommon.

## Clinical Findings

**A. Signs and Symptoms.** Infection with *T saginata* is most often asymptomatic, although a minority of patients may report nonspecific abdominal cramps or malaise. The proglottids of *T saginata* are motile, and patients may report seeing moving segments in the stool.

**B. Laboratory Findings.** Examination of the blood in patients with *T saginata* infection typically reveals no abnormalities, although a mild leukocytosis with eosinophilia may be present. Otherwise all laboratory tests except the microscopic stool examination will be normal. The stool examination will frequently reveal eggs and proglottids. The main basis for differentiating *T saginata* from *T solium* is the gravid proglottid, which for *T solium* has 7-13 lateral branches on each side of the uterus, whereas *T saginata* has 15-20 lateral branches.

## Differential Diagnosis

Infection with *T saginata* is usually not associated with clinical symptoms. Patients most often seek medical attention after finding *T saginata* proglottids in stools or on clothing. The main differential diagnosis is to differentiate *T saginata* proglottids from *T solium* proglottids. If no gravid proglottids are present, then differentiation may not be possible, in which case patients should be treated as though they have infection with *T solium*.

## Complications

Usually no complications are associated with *T saginata*; however, regurgitation and aspiration of proglottids may occur.

## Treatment

Therapy for infection with *T saginata* is similar to treatment of intestinal *T solium*, a single dose of either praziquantel or niclosamide (see [Box 87-2](#)). Follow-up examinations of stool should be performed 1 month after treatment.

## Prognosis

The prognosis for patients with intestinal *T saginata* infection is excellent.

## Prevention & Control

Prevention of infection with *T saginata* involves thorough cooking of beef and beef products to > 65 °C core temperature ([Box 87-3](#)). Beef should also be inspected for the presence of cysts, and infected carcasses destroyed.

## HYMENOLEPIS NANA INFECTION

### Essentials of Diagnosis

- Adult worms and proglottids are rare.
- Spheroidal and thin-walled eggs (30-47 mm).
- Eggs contain two polar elements from which 4-8 filaments project (diagnostic).
- Scolex has hooklets and four suckers.

### General Considerations

*H nana* is distributed worldwide and is called the dwarf tapeworm because of its small size (2-4 cm). Endemic areas include Asia, Africa, South and Central America, and southern and eastern Europe. Infection with *H nana* is acquired by the ingestion of eggs, commonly from human stool. The eggs hatch within the stomach or small intestine, and the resultant larvae attach to the bowel wall, where adult worms develop in several weeks. Eggs are released directly from the gravid proglottids while these proglottids are still attached to the adult worm; therefore proglottids are rarely seen on stool examination. Various arthropods such as fleas can serve as alternate intermediate hosts for *H nana*. Eggs produced within infected humans can lead to internal autoinfection, and poor fecal-oral hygiene can cause infection to be passed from one person to another.

### Clinical Findings

**A. Signs and Symptoms.** Infection with *H nana* is most often asymptomatic, yet some patients may complain of headache, dizziness, anorexia, or abdominal pain. Whether these symptoms are related to the infection is uncertain. Children may have headache or sleep and behavioral disturbances, which resolve after successful treatment of the infection.

**B. Laboratory Findings.** As for patients with other cestode infections, examination of blood from patients with *H nana* infection is typically normal, although a mild leukocytosis with eosinophilia may be present. Microscopic stool examination will frequently reveal eggs, but finding proglottids is uncommon with *H nana* infection.

### Differential Diagnosis

Since infection with *H nana* is usually asymptomatic, patients most often discover *H nana* infection as an incidental finding on stool examination done for another reason. In patients with nonspecific gastrointestinal complaints, peptic ulcer disease and malignancy need to be ruled out. Similarly, in children with behavioral symptoms, a variety of neurologic disorders of organic and psychologic origins need to be considered.

## **Complications**

Through a mechanism that is still unclear, seizures have been reported with *H nana* infections.

## **Treatment**

Cysts of *H nana* are more resistant to therapy than adult worms. Therefore higher doses or longer courses of therapy are required to eradicate cysts than with other cestode infections. Therapy for infection by *H nana* consists of a single dose of either praziquantel or niclosamide (see [Box 87-2](#)). Follow-up examinations of stool should be performed at 2 weeks and 3 months after therapy.

## **Prognosis**

Since infection with *H nana* is usually asymptomatic and infection responds to therapy, the prognosis is excellent.

## **Prevention & Control**

Infection with *H nana* can be prevented with good fecal-oral hygiene and adherence to the principles of sanitation (eg, appropriate disposal of human sewage) ([Box 87-3](#)). Incidental ingestion of arthropod hosts may also produce infection, although this mechanism of infection is uncommon.

## ***HYMENOLEPIS DIMINUTA***

### **Essentials of Diagnosis**

- Proglottids are rare in stool, but adult worms may be present.
- Ovoid and thick-walled eggs (70-85 um by 60-80um).
- Eggs contain no polar elements.
- Scolex has no hooklets and four suckers.

### **General Considerations**

*H diminuta* is also distributed worldwide, but the incidence of infection is much less common than with *H nana*. Infection with *H diminuta* is acquired by the ingestion of

eggs, produced from an obligatory arthropod intermediate host. The eggs hatch within the stomach or small intestine, and the adult worms develop in several weeks. Eggs are similar in size to the eggs of *H nana* but may be distinguished by their lack of polar filaments and ovoid shape. In contrast to *H nana*, the life cycle of *H diminuta* requires an intermediate arthropod host, and adult worms may be passed in the stool of humans.

## Clinical Findings

**A. Signs and Symptoms.** Infection with *H diminuta* is not associated with clinical symptoms.

**B. Laboratory Findings.** Microscopic stool examination will frequently reveal eggs and adult worms. Blood examination may demonstrate mild leukocytosis with eosinophilia.

## Differential Diagnosis

The finding of *H diminuta* in human infection is commonly an incidental finding that is asymptomatic.

## Complications

No complications have been reported.

## Treatment

Therapy for infection for *H diminuta* consists of niclosamide in a one-time dose (see [Box 87-2](#)).

## Prognosis

*H diminuta* responds promptly to therapy, so the prognosis is excellent.

## Prevention & Control

Infection with *H diminuta* can be reduced by decreasing exposure to arthropod vectors, such as by rat control measures ([Box 87-3](#)).

## **DIPYLIDIUM CANINUM INFECTION**

### Essentials of Diagnosis

- Motile proglottids 23 by 8 mm.
- Proglottids have genital pores at either end and contain egg clusters.
- Eggs occur in compartmented clusters (diagnostic).
- Scolex has 4-7 rows of hooklets and 4 suckers.

## General Considerations

*D caninum* is distributed worldwide and is associated with wild and domesticated cats and dogs. The life cycle is similar to that of *H diminuta*, with an obligatory arthropod intermediate host. The adult worm lives in dogs, cats, or humans, and gravid proglottids are released from the adult worm either singly or in short chains. Eggs are passed in the stool, and ingestion of eggs by the intermediate host results in the development of the larval form within the arthropod host. Ingestion of the arthropod that contains larvae results in the development of an adult worm in dogs, cats, or humans. Adult worms may reach 10-80 cm in length.

## Clinical Findings

**A. Signs and Symptoms.** Infection with *D caninum* is not commonly associated with clinical symptoms, although indigestion or anorexia may be present. Also anal pruritus has been reported.

**B. Laboratory Findings.** Microscopic stool examination will frequently reveal characteristic egg clusters and proglottids. As with other cestode infections, blood examination may demonstrate mild leukocytosis with eosinophilia.

## Differential Diagnosis

Since *D caninum* infection in humans is often asymptomatic, most patients do not seek medical care. Once eggs are found in the stool, the appearance of egg clusters is so characteristic that no other parasite could be confused with *D caninum*. When a patient does seek the care of a physician for indigestion or anorexia, a variety of gastric pathologies need to be ruled out (eg, peptic ulcer disease and gastric outlet obstruction).

## Complications

No complications are associated with *D caninum* infection.

## Treatment

Therapy for *D caninum* infection is niclosamide in a one-time dose (see [Box 87-2](#)).

## Prognosis

The prognosis for *D caninum* infections is excellent.

## Prevention & Control

Infection with *D caninum* can be reduced by screening domestic dog and cat stools and treating pets found to be infected ([Box 87-3](#)).

## ECHINOCOCCAL INFECTION

## Essentials of Diagnosis

- Radiographic finding of cyst
- Positive echinococcal serology
- Aspiration of cyst revealing echinococcal sand or hooks
- Typical histologic appearance of cyst wall

## General Considerations

The normal life cycle of *Echinococcus* species does not involve humans. Human disease occurs when humans become an accidental intermediate host for the parasite, and tissue invasion is followed by the formation of cysts (hydatid cysts). The definitive hosts for echinococcal species are canines (usually dogs), in whom the adult worms live. There may be several hundred worms within a host, and the worms are small, usually 3-6 mm long.

The scolex is attached to the dog intestine, and to each scolex is attached a single proglottid. As the proglottids mature and become gravid proglottids containing several eggs, they detach and are passed in the stool. The eggs are resistant to desiccation and may remain viable for weeks. Eggs are ingested by intermediate hosts, commonly sheep and cattle but occasionally humans. The eggs hatch in the duodenum, and the larval forms penetrate the intestinal mucosa and disseminate through the blood stream to distant sites, most commonly the liver. Within tissues, the larva develops an encasing cyst composed of an outer layer and an inner fluid-filled layer. Within 1 year, cysts may reach 5-10 cm in diameter.

Inside the inner layer, daughter cysts form which may detach and float within the fluid, and daughter scolices may form. Ingestion of meat containing hydatid cysts leads to infection of definitive hosts, and adult worms develop. Infections with *Echinococcus granulosus* cause the formation of unilocular cysts. In contrast, infections with *Echinococcus multilocularis* are associated with multilocular cysts. *E multilocularis* also differs from *E granulosus* in that definitive hosts include foxes, wolves, cats, and dogs, and intermediate hosts include small rodents. Endemic areas for *E granulosus* include Africa, the Middle East, southern Europe, Latin America, and the southwestern United States. For *E multilocularis*, forested areas of Europe, Asia, and North America are endemic.

## Clinical Findings

**A. Signs and Symptoms.** In humans, the presentation of infection depends on where the hydatid cyst forms. The principle locations for cysts in humans include liver (60%), lung (20%), muscle (4%), kidney (4%), spleen (3%), soft tissues (3%), brain (3%), bone (2%), and other (1%). Within the liver, cysts may be incidentally diagnosed or may present as pain or a visible mass. Pulmonary cysts are usually asymptomatic, but if sufficiently large, may cause cough, dyspnea, or pleuritic pain.

Although rare, hydatid cysts in the brain are potentially the most serious and may cause obstructive hydrocephalus with ataxia and dementia or mass effect with seizures, headache, or focal neurologic deficits. Bony hydatid cysts most commonly involve vertebrae and present with bone pain. Other presentations include soft tissue swelling and bone pain or pathologic fractures secondary to cysts weakening cortical bone. In = 20% of infected patients, cysts will be multiple, so a thorough evaluation is required of all patients in whom the diagnosis is suspected.

**B. Laboratory Findings.** Eosinophilia may be present in = 25% of patients, but it is a nonspecific marker. Serologic testing is available, by a variety of techniques, and, if positive, the results provide supportive evidence of echinococcal infection. However, a negative result of serologic testing does not rule out hydatid cyst disease. More recent serologic techniques may help to differentiate *E granulosus* infection from *E multilocularis* infection. Cross-reaction between cysticercosis and hydatid cyst disease has been noted with some serologic assays. Another potential diagnostic procedure is cyst aspiration, although it poses some risk for anaphylaxis (see complications). This test is potentially useful to diagnose *E granulosus* hydatid cysts. A small volume of fluid is removed and examined microscopically for the presence of hydatid sand (daughter cysts and scolices). If a cyst is old, sand may not be present, in which case a centrifuged specimen should be examined for the presence of hooks.

**C. Imaging.** Radiographically, cysts appear as either unilocular cysts with an air fluid level (*E granulosus*) or as multiloculated cysts with little or no fluid (*E multilocularis*).

### Differential Diagnosis

Since the usual presentation of hydatid cysts is either liver pain or mass, lung mass with irritative symptoms of obstruction, or seizures with focal neurologic symptoms, the primary differential diagnosis is to rule out primary or metastatic malignancy of each of these organs. In a unilocular hydatid cyst, the radiographic appearance is often sufficient to exclude malignancy. In contrast, multilocular cysts caused by *E multilocularis* are slow growing, often with little or no fluid, and frequently have central necrosis, all suggestive of malignancy. Therefore biopsy and histologic examination are necessary for definite differentiation from malignancy.

### Complications

On occasion, hydatid cysts may leak fluid into the systemic circulation of the host, causing sensitization of the host. Subsequent fluid leaks may then be responsible for the induction of an allergic response or even anaphylaxis. In addition, release of cyst tissue may be associated with embolization and the development of additional cysts at distant alternate sites. Cysts also may become secondarily infected, producing abscesses. Mechanical complications of the cyst are also possible, most commonly leading to portal hypertension, ascites, and portosystemic shunting.

### Treatment

Therapy for hydatid cysts caused by infection with *E granulosus* combines surgical and pharmacological interventions (see [Box 87-2](#)). Solitary unilocular cysts at operable sites

are generally treated with surgical excision, percutaneous drainage, or both. Extreme care must be taken to avoid spillage of cyst contents and subsequent seeding of other sites. One approach has been to remove a portion of the cyst fluid and instill a cystocidal agent such as 95% ethanol before removing the entire cyst. Some authorities also recommend pre- and postoperative therapy with either albendazole or mebendazole.

Recent experience with albendazole is a promising alternative. Mebendazole is an alternate therapy but may be less effective than albendazole. Complicated or multiloculated cysts (caused by *E multilocularis*) require surgery, often in association with albendazole as above. An experimental approach to inoperable cysts involves oral therapy with albendazole or mebendazole, combined with percutaneous aspiration and instillation of 95% ethanol. Although promising, this approach has not been validated in large trials.

### **Prognosis**

The prognosis of hydatid disease is variable. With early diagnosis and treatment of simple unilocular cysts, the outlook is excellent; in contrast, advanced multilocular disease at multiple sites with advanced portal hypertension is a potentially lethal condition. Medical therapy of inoperable *E granulosus* cysts is associated with cure in 30% of cases and improvement in 50%. Inoperable *E multilocularis* is associated with a 10-year mortality rate in 90% of cases. In such cases, indefinite treatment with albendazole or mebendazole is recommended by some authorities.

### **Prevention & Control**

In areas endemic for hydatid disease, the disease is commonly transmitted incidentally during activities such as camping and picking berries. Education is the best prevention for transmission in these settings ([Box 87-3](#)). Routine screening of household pets and appropriate treatment of animals found to carry *Echinococcus* spp. is another important control measure. Pet owners should be educated as to techniques of good hygiene to prevent accidental inoculation of eggs from dog stools. Lastly, carcasses of infected hosts must be disposed of in ways that prevent transmission to canines.

## 88 . Trematodes — *Walter R. Wilson, MD & James M. Steckelberg, MD*

### Essentials of Diagnosis

- Blood flukes: demonstration of eggs in feces, urine, or rectal biopsy
- Liver flukes: demonstration of eggs in feces
- Intestinal flukes: demonstration of adult worms or eggs in feces
- Lung flukes: demonstration of eggs in sputum or feces

All trematode species that are parasitic for humans are digenetic. Sexual reproduction in the adult fluke is followed by asexual multiplication in the larval stage. Most species of adult trematodes have an oral and ventral sucker. The life cycles of trematodes that are important human pathogens are similar among all five major species. Eggs are excreted in the feces of the host, hatch in fresh water, and require a primary host in snails before infection occurs in humans. Trematode infection may be classified into four general groups based on the final habitat of the adult flukes in humans as follows: blood flukes, liver flukes, intestinal flukes, and lung flukes ([Table 88-1](#)).

### CLINICAL SYNDROMES

#### BLOOD FLUKE INFECTION (SCHISTOSOMIASIS)

##### General Considerations

The final habitat for blood flukes is the venous system of the bowel mesentery or the urinary bladder.

**A. Epidemiology.** It is estimated that schistosomiasis occurs in > 200 million people worldwide and is endemic in Asia, Africa, South America, and other parts of the world where the population is engaged in freshwater agriculture. The total number of infected individuals in the United States is estimated to exceed 500,000, and these cases are most often in immigrants from South America, Asia, and the Caribbean. The disease cannot spread in the United States because the specific snail that serves as an intermediate host does not yet exist in the United States. Unlike most other trematodes that are pathogenic for humans, adult schistosomes have separate sexes. The female fluke resides within a groove created by the fold of the lateral edges of the male fluke.

Each of the five blood fluke species that are pathogenic for humans has a specific geographic distribution as follows: *Schistosoma mansoni*, Arabian peninsula, Africa, Caribbean, and South America; *Schistosoma haematobium*, Middle East and Africa; *Schistosoma japonicum*, Japan, China, and The Philippines; *Schistosoma mekongi*, Southeast Asia; and *Schistosoma intercalatum*, west and central Africa. The specific geographic distribution depends on the presence of the specific snail intermediate host.

**B. Microbiology and Pathogenesis.** The life cycle of the five major species of blood flukes is as follows: adult flukes (1-2 cm in length) inhabit the venous system of the mesentery or urinary bladder; sexual reproduction results in the characteristically shaped eggs that are excreted in the feces; the eggs hatch in fresh water, releasing ciliated motile miracidia, which penetrate the body of the snail that serves as the intermediate host (a specific snail and geographic distribution exist for each species of blood fluke); within the snail, the miracidia multiply asexually and, 4-6 weeks later, hundreds of fork-tailed cercariae emerge; the cercariae penetrate human skin, lose their tails, and become schistosomes that migrate to the lungs and liver where maturation occurs; and ~ 6 weeks later, the mature adult fluke migrates to its final habitat in the venous systems. The mean life span of adult flukes in humans is estimated to be 5-10 years.

## Clinical Findings

The three different stages (cercariae, mature flukes, and eggs) of the blood fluke in humans result in three major disease syndromes in chronologic order: dermatitis (swimmers' itch), fever and constitutional complaints (Katayama fever), and finally chronic fibro-obstructive disease ([Box 88-1](#)).

**A. Signs and Symptoms.** Dermatitis (swimmers' itch) is the acute form of schistosomiasis and is characterized by a pruritic and papular rash that usually occurs within 1-3 days after penetration of the cercariae. Swimmers' itch rarely occurs after primary exposure and is more common in individuals who have been sensitized by earlier exposure.

Katayama fever occurs 4-8 weeks after penetration of the skin in humans and coincides with the production of eggs by the flukes. Katayama fever is most severe after *S japonicum* infection, but occasionally occurs in patients infected with *S mansoni* and rarely *S haematobium*. Patients experience an acute onset of fever, chills, headache, and cough. Physical findings often include lymphadenopathy and hepatosplenomegaly. Eosinophilia is common. Symptoms usually disappear within a few weeks after onset, but, rarely, death may occur, usually in association with *S japonicum* infection. Katayama fever may be the result of immune complex formation from massive antigenic challenge from exposure to fluke eggs.

In chronic fibro-obstructive schistosomiasis, tissue damage occurs from chronic inflammatory response to the deposition of eggs. This results in chronic granulomatous disease and eventual fibrosis. Liver and bowel are the sites most commonly affected in patients with infection caused by *S mansoni*, *S japonicum*, *S mekongi*, or *S intercalatum*. Patients often experience chronic abdominal pain and diarrhea. In the liver, fibrosis may result in portal hypertension, hepatosplenomegaly, esophageal varices, and variceal bleeding. Liver function tests usually remain normal for an extended period of time after infection. In chronic untreated cases, hepatic dysfunction, jaundice, ascites, and liver failure may occur.

In patients with *S haematobium* infection, the flukes are located in the vesicular plexus, and granulomatous formation occurs in the bladder and ureters. Hematuria is the most common complaint. With prolonged infection, fibrosis, ureteral obstruction, and chronic

renal failure may occur. The frequency of bladder cancer may be higher in patients with chronic *S haematobium* infection.

Pulmonary schistosomiasis may occur in patients with advanced liver cirrhosis and portal hypertension. The development of portosystemic shunts enables fluke eggs to bypass the liver and enter the pulmonary circulation. Patients with *S haematobium* may also develop pulmonary schistosomiasis; the eggs may enter the inferior vena cava from the vesicular plexus and enter the pulmonary venous system.

Of patients with *S japonicum*, ~ 3% develop central nervous system schistosomiasis manifested by space-occupying lesions that may cause focal seizures. Rarely, granulomatous lesions resulting from ectopic eggs in the vasculature of the spinal cord may cause transverse myelitis.

**B. Laboratory Findings.** The most common laboratory findings seen in patients with schistosomiasis include eosinophilia, hematuria, anemia, and—in chronic end-stage infection—abnormal liver function tests, elevated serum creatinine, and uremia. The diagnosis is established by identifying the characteristic schistosomal eggs in the feces, urine, or a rectal biopsy specimen. Skin tests or serologic tests are helpful for epidemiologic studies but are not diagnostic of active infection.

### Differential Diagnosis

Hepatic schistosomiasis may resemble any process that causes chronic hepatosplenomegaly and portal hypertension including alcoholic cirrhosis, Wilson's disease, chronic hepatitis C infection, and many other conditions. *S haematobium* must be differentiated from bladder or ureteral cancer, reflux disease, and other syndromes that cause hematuria or chronic renal failure.

### Treatment

The treatment for patients with schistosomiasis is shown in [Box 88-2](#). Praziquantel is safe and effective therapy for all five species of schistosome that infect humans. Eggs may be shed for some time after treatment, and follow-up stool or urine examination should be obtained several months after therapy to ensure eradication.

### Prognosis

The prognosis of schistosomiasis is excellent among patients who are treated before end-stage hepatic or renal disease develops. In these patients, prognosis depends on the magnitude of end-organ disease.

### Prevention

The only effective means of prevention is to avoid contact with fresh water in areas where schistosomiasis is endemic.

## LIVER FLUKE INFECTIONS (CLONORCHIASIS, OPISTHORCHIASIS, & FASCIOLIASIS)

## General Considerations

The final common habitat for the liver flukes is the bile ducts. The liver flukes that are the most common cause of human infections are *Clonorchis sinensis* (clonorchiasis), *Opisthorchis* spp. (opisthorchiasis), and *Fasciola hepatica* (fascioliasis).

*C sinensis* (Chinese or oriental liver fluke) is a flat, elongated fluke (~ 15 mm ( 3 mm) that inhabits the distal biliary capillaries. Humans are incidental hosts, and the infection is endemic in China, Hong Kong, Korea, and Southeast Asia. Eggs eliminated in the feces are then ingested by the specific snail intermediate host. After ingestion, the eggs hatch into miracidia. The organisms multiply and produce extremely high numbers of cercariae that exit the snail and penetrate the skin of freshwater fish. Once the cercariae are on the fish skin, they encyst as metacercariae, which are infective for humans. Humans and fish-eating mammals acquire infection by ingestion of raw or undercooked fish that contain metacercariae. After ingestion, metacercariae excyst in the duodenum of humans and pass through the ampulla of Vater, where the flukes mature into adults in the bile ducts.

*O felineus* and other species are endemic in Southeast Asia, Eastern Europe, and Russia and are common liver flukes of dogs and cats that may be transmitted to humans. The life cycle is similar to that of *C sinensis*.

*F hepatica* is a common liver fluke in sheep and cattle and is endemic in South America, Europe, Africa, Australia, and China. Humans are incidental hosts. Eggs are deposited in the biliary system and excreted in the feces. In fresh water, the eggs hatch, and the miracidia must reach and penetrate their specific snail host within 8 h. The cercariae emerge from snails and encyst on aquatic plants and sometimes in soil. The plants are consumed by humans, sheep, or cattle. The organisms excyst in the duodenum. The larvae penetrate through the intestinal wall into the peritoneum, enter through the capsule of the liver, and migrate to the bile ducts.

## Clinical Findings

The majority of patients with *C sinensis* and *O felineus* infections are asymptomatic ([Box 88-1](#)). With heavy infection, biliary obstruction and cholangitis may occur. The frequency of cholangiocarcinoma may be increased in patients with chronic *C sinensis* infection. Diagnosis depends on demonstration of the characteristic eggs in the feces.

Unlike clonorchiasis or opisthorchiasis, patients parasitized by *F hepatica* are usually symptomatic, and there are two distinct clinical stages of infection. In the early stage, symptoms correspond to the hepatic migration of the larvae, and patients experience fever, right upper quadrant pain, hepatomegaly, and eosinophilia. Acute symptoms subside as the larvae enter the bile ducts, and most patients become asymptomatic in this later stage of infestation. Biliary obstruction, cholangitis, or biliary cirrhosis may occur rarely with heavy infestation. The definitive diagnosis is made by identifying the characteristic eggs in the feces or bile. A positive serologic test suggests infection. Computed tomography of the liver may show small nodules and tortuous tracts made by the migrating larvae.

## Differential Diagnosis

In the acute phase of *F hepatica* infection, patients may resemble those with acute cholangitis, cholecystitis, liver abscess, or *Neisseria gonorrhoeae* infection (Fitz-Hugh and Curtis syndrome). However, the presence of eosinophilia suggests *F hepatica* infection.

## Treatment

Praziquantel is effective therapy for symptomatic patients with *C sinensis* or *O felineus* infection. Bithionol is the drug of choice for *F hepatica* infection ([Box 88-2](#)).

## Prognosis

The prognosis for treated patients with liver fluke infection is excellent.

## Prevention

Avoiding consumption of raw or undercooked freshwater fish is the only effective means of prevention of *C sinensis* or *O felineus* infection. Individuals should avoid consumption of undercooked aquatic plants and grasses in areas where *F hepatica* is endemic.

## INTESTINAL FLUKE INFECTION (FASCILOPSIASIS)

### General Considerations

The final habitat of intestinal flukes is the small bowel. *Fasciolopsis buski* is endemic in the Far East and southeast Asia. Eggs are excreted in the feces, develop into cercariae in fresh water, and encyst on freshwater plants. After human consumption, the organisms excyst in the bowel and mature into adult flukes that measure 2-8 cm (1-2 mm). They reside in the upper portion of the small intestine where they attach to the mucosa.

### Clinical & Laboratory Findings

Most patients are asymptomatic, but, with heavy infection, abdominal pain, diarrhea, and occasionally malabsorption may occur ([Box 88-1](#)). Diagnosis may be made by the demonstration of the characteristic eggs or adult flukes in the stool.

### Differential Diagnosis

Most patients are asymptomatic, and the differential diagnosis is that of patients with diarrhea and abdominal pain caused by bacteria and other parasites.

### Treatment

Praziquantel is effective therapy for intestinal flukes ([Box 88-2](#)).

## **Prognosis**

The Prognosis is excellent.

## **Prevention**

Individuals residing in endemic areas should avoid consumption of undercooked aquatic plants and grasses.

## **LUNG FLUKE INFECTION (PARAGONIMIASIS)**

### **General Considerations**

*Paragonimus westermani* is endemic in the Far East Indian subcontinent, Central and South America, and West Africa. Human lung flukes produce eggs in sputum that are swallowed, excreted in the feces, and mature in fresh water into miracidia, which penetrate snails. The mature cercariae exit the snail, penetrate into freshwater crayfish and crabs, and encyst. Infection in humans occurs after ingestion of raw, undercooked, or pickled freshwater crustacea. After ingestion, the organisms excyst in the duodenum, penetrate through the bowel wall, enter the peritoneal cavity, pass through the diaphragm into the pleural space, and enter the lungs where they mature into flukes that measure 7-15 mm ( 5-8 mm. Ectopic eggs in the brain may result in space-occupying lesions and focal seizures.

### **Clinical Findings**

Many patients with minimal to moderate infection are asymptomatic ([Box 88-1](#)). With acute infections, symptomatic patients experience cough productive of brown sputum or hemoptysis and eosinophilia. Heavy untreated infection may progress to chronic bronchitis or bronchiectasis with large-volume sputum production, pleuritic chest pain, pleural effusion, and lung abscess. Diagnosis is made by identifying the characteristic eggs in the sputum or feces. A positive serology may be helpful in the diagnosis of ectopic infection. The diagnosis should also be suspected in individuals who do not reside in endemic areas but have a history of consumption of undercooked crustacea imported from endemic areas.

### **Differential Diagnosis**

Pulmonary paragonimiasis resembles chronic bacterial infection, mycobacterial infection, or carcinoma of the lung. The presence of eosinophilia in these patients who reside in or have traveled to an endemic area should suggest the diagnosis of paragonimiasis.

### **Treatment**

Praziquantel is effective therapy ([Box 88-2](#)).

### **Prognosis**

The prognosis is excellent in patients who are treated before the development of chronic bronchitis or bronchiectasis.

### **Prevention**

Individuals should avoid the consumption of raw or undercooked freshwater crustacea from areas where *P westermani* is endemic.

## Section VIII. Miscellaneous Infections

### 89 . Infections in Travelers — *DeVon C. Hale, MD & Caroline Milne, MD*

#### Essentials of Diagnosis

- Fever
- Weight loss
- Diarrhea
- Myalgia
- Headache
- Skin rash

#### General Considerations

International travel has become a normal part of life. Physicians who are knowledgeable regarding common infections encountered in international travel and ways to prevent infection can provide a great service to their patients.

Most travelers will not encounter "tropical disease"; a study of > 10,000 Swiss travelers to developing countries in the early 1980s revealed that the most commonly encountered illness was diarrhea. No persons were infected with cholera or typhoid. The risk of acquisition of disease depends on where one is traveling and the travel conditions. Standards of sanitation and native immunization rates vary, especially in developing countries. In most developed countries, risk of disease is no greater than in the United States. This chapter focuses on pretravel evaluation of the international traveler, including vaccination recommendations and advice to help in prevention of disease. We also discuss post-travel evaluation, with special attention paid to travelers' diarrhea, typhoid fever, and malaria.

#### PRETRAVEL EVALUATION

##### Introduction

It is essential that physicians evaluating international travelers have accurate and current advice. Information for the practitioner can be found in *Health Information for the International Traveler* from the Centers for Disease Control and Prevention (CDC) and *International Travel and Health Vaccination Requirements and Health Advice* from the World Health Organization (WHO). Both titles are available, or on the CDC (<http://www.cdc.gov/>) or WHO (<http://www.who.int/>) web site, respectively. Information

about current outbreaks of disease (only yellow fever and cholera) can be found in the CDC's *Summary of Health Information for International Travel*, which is published biweekly.

The patient's initial pretravel visit should occur at least 6 weeks before departure. At that time, a pertinent medical history should be taken and physical examination performed. The patient's itinerary and travel conditions should also be elicited.

Travel advice should begin with general-safety advice; an estimated 0.5% of travelers will suffer some sort of accident. Motor vehicle accidents are responsible for 25% of all mortality abroad. The traveler should also be aware of where to obtain medical attention. If medical attention is needed abroad, the traveler can contact the American Embassy for names of physicians and hospitals. The primary physician's name and phone number should be carried on the traveler.

Preparation is the key to disease prevention. Travelers should carry a medical kit with necessary supplies and medications for self-treatment when able. Travelers on medications for chronic illnesses need a sufficient supply. Other important medications include commonly used pain relievers such as acetaminophen and aspirin, antihistamines for allergies, decongestants and cough suppressants, antacids, antidiarrheal agents, and laxatives. Topical antibiotics and anti-itch lotions could also be carried. Antibiotics to be used for treatment of specific illness, especially if the traveler will be in remote areas away from medical attention, may be considered. First-aid supplies such as bandages, gauze, tape, syringes, needles, scissors, and tweezers should be included in the medical kit. Other materials such as antimalarial agents, insect repellent, and water purification tablets should be carried when applicable ([Table 89-1](#)).

Travelers' diarrhea is the most common illness suffered abroad. This illness is most often acquired through contaminated food or water. Because of varying sanitation practices abroad, it is important that the traveler be aware of risk of diseases spread through food and water ([Table 89-2](#)). In general, tap water in developing countries is considered unsafe to drink. This includes ice cubes and other nonbottled drinks that may have been prepared by using nonpurified tap water. Boiling is the most effective method of making local water safe from biological hazards. For short trips many travelers rely on carbonated water and reputable brands of bottled water. Water purification pumps are available at most outdoor supply stores. Chemical methods of water purification are listed in [Table 89-2](#). Both were found to be equally effective. Very cold water (< 4 °C) may need to be warmed to room temperature or have prolonged exposure to the purification agent for improved effectiveness. Food should be selected by using common sense. In general, raw and undercooked foods are more likely to be contaminated. Salads and raw fruits and vegetables are more likely to carry diarrhea-producing organisms. It is safest to choose well-cooked, hot foods. Food available from street vendors in developing countries has been associated with an increased risk of disease.

Incidences of diseases carried by mosquitoes and other arthropod vectors can also be decreased by taking preventive measures. ([Table 89-3](#)). *Anopheles* mosquitoes (the vector for malaria) bite between dusk and dawn. Avoidance of outdoor activities during this time is best if possible. Clothing should cover as much skin as possible, and

sandals should be avoided. DEET (*N,N*-dimethyl-*meta*-toluamide)-containing insect repellents are recommended. The CDC recommends solutions containing < 35% DEET for adults and 6-10% DEET-containing solutions for children. Bed nets should be used when windows will be open. For extra protection, clothing and bed nets can be treated with permethrin solutions.

## **Routine Immunization Recommendations**

The CDC Advisory Committee on Immunization Practices meets periodically to make vaccine recommendations based on scientific evidence of benefit versus risk to achieve protection against communicable disease. Routine vaccinations against diphtheria, tetanus, pertussis, measles, mumps, rubella, poliomyelitis, and *Haemophilus influenzae* infections are commonly administered during childhood in the United States. All international travelers should be current on these routine vaccinations. Immunization rates may be much lower in developing countries, and these diseases, which have low incidences in the United States, are more prevalent in these areas. [Table 89-4](#) gives childhood dosing schedules, and [Table 89-5](#) gives the pregnancy dosing schedules.

**A. Diphtheria, Tetanus, and Pertussis.** Diphtheria and tetanus remain health problems throughout the world. The diseases occur almost exclusively in unimmunized or inadequately immunized populations. The primary vaccination series consists of three doses of tetanus-diphtheria toxoid. Doses 1 and 2 are given 4-8 weeks apart. The third dose is given 6-12 months after the second. Although most adult travelers will have received their primary immunizations against these diseases as children, a booster is recommended every 10 years after completion of the primary series. See [Chapter 56](#) for a detailed description of the clinical presentation of these diseases.

Pertussis is quite common in inadequately immunized countries, especially in western areas of the former Soviet Union. Vaccination against this disease is recommended for all travelers under age 7 years who have not received primary immunization against pertussis. Pertussis vaccination is not recommended for people over age 7 owing to greater perceived risk than benefit. See [Chapter 56](#) for a detailed description of the clinical presentation of pertussis.

**B. Measles.** Measles is often a serious disease, especially in adults, because it can be complicated with bronchopneumonia. Vaccination is recommended for all persons born after 1957. Those born before 1957 are considered naturally immune because measles was endemic throughout the world. A 2-dose subcutaneous vaccine is expected to induce immunity. A single adult booster is recommended. See [Chapter 34](#) for a detailed description of the clinical presentation of measles.

**C. Mumps.** Mumps vaccination is commonly completed with combination measles and rubella vaccines (MMR). The combined vaccination is a 2-dose schedule. Vaccination is recommended for all persons born after 1957, because adults born before 1957 are considered naturally immune. See [Chapter 35](#) for a detailed description of the clinical presentation of mumps.

**D. Rubella.** The rubella virus is associated with some morbidity in adults. In pregnant women, there is a high rate of fetal death and deformation. A single dose of rubella virus

vaccine is recommended for all people. This vaccination is commonly given in the two-dose MMR combination series. See [Chapter 36](#) for a detailed description of the clinical presentation of rubella.

**E. Poliomyelitis.** Poliomyelitis remains endemic and epidemic in some parts of the world. The WHO has made a goal for complete eradication. A primary series of oral polio virus vaccine, which includes three doses, or enhanced-potency inactivated polio virus vaccine should be completed before travel. For travelers to developing countries, who have completed a primary series, a single adult booster dose of oral polio vaccine OR inactivated polio vaccine is recommended. Inactivated polio vaccine is recommended to previously unvaccinated adults and immunocompromised hosts owing to the higher risk of vaccine-associated disease in these groups. See [Tables 89-6](#) and [89-7](#) for dosing information. See [Chapter 27](#) for a detailed description of the clinical presentation of this disease.

**F. *Haemophilus influenzae* type b.** *H influenzae* type b causes severe childhood disease including meningitis and pneumonia. Vaccination is recommended for all children under age 5 years, regardless of travel plans. An unvaccinated child 15-59 months old needs only a single dose. The vaccine is not recommended for children over age 5. See [Table 89-8](#) for complete dosing schedules. See [Chapter 56](#) for a detailed description of the clinical presentation of this disease.

### Other Recommended Vaccinations

**A. Hepatitis B.** Hepatitis B infection is associated with a high degree of morbidity and mortality (see also [Chapter 39](#)). It is most often spread via contact with bodily secretions such as blood or by intimate sexual contact. It can cause a fulminant acute hepatitis, a chronic hepatitis, or both, which may lead to increased risk of cirrhosis, hepatocellular carcinoma, and death. In most of the developed world, hepatitis B surface antigen prevalence is low—< 1% of the general population. In Africa, Southeast Asia, the Middle East (except Israel), the Pacific Islands, and certain parts of the Caribbean (Haiti and the Dominican Republic), the prevalence of disease carrier status is as high as 8%, regardless of socioeconomic status. Universal precautions are usually not taken in developing countries, and sterilization techniques may not be adequate; therefore, patient risk of acquisition of disease from medical care is much higher than in the United States. Although a hepatitis B viral vaccination series is now recommended for all health care providers and infants in the United States, many travelers may not be immunized before travel.

Previously unvaccinated persons who will provide health care, who are at risk of having to receive health care, or who might have any exposure to blood or other body secretions abroad are encouraged to receive the vaccination series. Travelers who plan on residing in a given endemic area for > 6 months should also receive the vaccine.

Primary vaccination consists of three intramuscular (i.m.) doses of recombinant DNA vaccine. After the initial vaccination, doses are scheduled at 1 month and 6 months. [Table 89-9](#) gives the dosing schedule. Protection is increased with each dose of the vaccine; thus travelers who cannot complete the 6-month series before travel may still receive benefit from initiating the series. An alternative accelerated schedule is also

available, with dose scheduling at 0, 1, and 2 months, followed by a booster at 12 months.

**B. Hepatitis A.** Hepatitis A virus is transmitted via ingestion of contaminated food or water. It is highly endemic in most of the developing world and in some areas of the developed world (see also [Chapter 39](#)). Risk of acquisition can be decreased by following the recommended food and water practices discussed earlier in this chapter. Hepatitis A vaccine or immunoglobulin protection is recommended for all travelers to areas with intermediate or high endemic rates. This includes all developing countries, eastern Europe, and Russia. For some travelers, screening for hepatitis A virus antibodies may be beneficial before primary immunization. This is indicated in travelers > 40 years old or those born in endemic areas.

Protection from disease can be obtained via two methods, inactivated vaccine or immunoglobulin. Two inactivated hepatitis A vaccines, HAVRIX and VAQTA, are currently approved for use in the United States. The vaccine is administered i.m. in a two- to three-dose series. See [Tables 89-10](#) and [89-11](#) for recommended dose and schedules.

An alternative protection against hepatitis A virus is immunoglobulin. A single intramuscular dose (0.02 mL/kg) offers protection against hepatitis A virus for = 3 months. Protection can be provided for = 5 months with a larger dose (0.06 mL/kg) but must be repeated if protection is required for longer than that time. At present, hepatitis A vaccine is not approved for use in pregnancy or children < 2 years old; therefore, immunoglobulin is currently the prevention of choice in these groups. See [Table 89-12](#) for dosing recommendations.

### Rarely Indicated Vaccinations

**A. Rabies.** Rabies virus causes disease of the central nervous system (CNS), manifested as encephalitis (see also [Chapter 43](#)). It is transmitted by infected secretions of mammal hosts. Almost all exposures are secondary to animal bites; however, there are rare reported cases of nonbite infection. Rabies infection is a significant cause of morbidity and mortality throughout the world. It is estimated to cause = 50,000 deaths each year. Endemic areas of the world include Mexico, parts of South America, India, Nepal, Sri Lanka, Thailand, and Vietnam.

Travelers to rabies-endemic regions, especially those who will have known exposure to animals, should consider preexposure prophylaxis. Preexposure vaccine does not eliminate the need for postexposure treatment; however, it does eliminate the need for immune serum globulin and decreases the number of vaccine booster doses needed.

There are three preexposure vaccinations available: human diploid cell rabies vaccine, rabies vaccine adsorbed, and chicken embryo rabies vaccine. They are given in 1.0-mL doses, i.m., on days 0, 7, and 28. Human diploid cell rabies vaccine can be given via the intradermal route, but this route is not recommended if any drugs interfering with immune response are used simultaneously. Rabies vaccines being used in other countries may contain neural-tissue-derived Semple vaccines or suckling mouse-brain products, which are considered less effective and have more associated side effects.

Postexposure vaccine should be given immediately after exposure. All wounds should be thoroughly cleaned with soap and water. For those not previously immunized, postexposure vaccination consists of five doses of human diploid cell rabies vaccine, rabies vaccine adsorbed, or chicken embryo rabies vaccine, each 1.0 mL i.m., on days 0, 3, 7, 14, and 28. In addition, rabies immune globulin, 20 IU/kg of body weight, is given one-half i.m. and one-half infiltrated into the wound site, on day 0. It can be given = 7 days after exposure if unavoidable. For those previously immunized, two doses of human diploid cell rabies vaccine or rabies vaccine adsorbed (1.0 mL i.m. on days 0 and 3) are administered. Immune serum globulin should not be used.

**B. Japanese Encephalitis.** Japanese encephalitis virus infection affects the CNS (see also [Chapter 7](#)). The illness may present as a febrile headache, meningitis, or encephalitis. Transmission occurs from the bite of the mosquito *Culex tritaeniorhynchus*, which is the major vector species. Risk of acquiring Japanese encephalitis virus is low and of exhibiting clinical manifestations of disease is lower; only 1:300 seroconverters develop encephalitis.

Risk increases with outdoor exposure to mosquitoes during transmission season and with travel to rural areas of endemic countries. Endemic countries include Malaysia, Myanmar, Cambodia, Laos, Nepal, Philippines, Sri Lanka, Taiwan, northern Thailand, and Vietnam.

Vaccination is rarely recommended for short-term tourists. Travelers who plan to live in endemic areas during transmission season should be considered for the vaccine.

The inactivated viral vaccine, JEVax, has an efficacy rate of > 90%. It is given in three separate 1.0-mL doses on days 0, 7, and 28. There is a significant occurrence of systemic side effects including hypersensitivity reactions. Reactions may be delayed up to 72 h; it is therefore recommended that the last dose of the series be administered at least 10 days before departure.

**C. Plague.** Plague is a bacterial illness caused by infection with *Yersinia pestis* (see also [Chapter 60](#)). The disease is spread to humans from the bite of the rodent flea. Human bubonic plague disease is manifested by adenopathy (bubo), sepsis, multiorgan failure, and death. Plague pneumonia can be transmitted via infected cough aerosols. In recent years human plague has been reported in Angola, India, Kenya, Lesotho, Madagascar, Mozambique, Namibia, South Africa, Botswana, Tanzania, Uganda, Zimbabwe, Zaire, Myanmar, China, Mongolia, Vietnam, the United States, the former Soviet Union, Brazil, Bolivia, Ecuador, and Peru. .

Risk to travelers, even those traveling to areas where disease has been reported, is low. Because of this low risk, plague vaccination is recommended only for persons having direct contact with diseased rodents or infected animals. See [Table 89-13](#) for plague vaccine doses and intervals.

**D. Typhoid Fever.** Typhoid fever is a systemic febrile infection caused by *Salmonella enterica* serovar Typhi (see also [Chapter 53](#)). Infection is caused when water or food is contaminated by an infected human carrier. Risk of acquisition of disease depends on

sanitation standards; thus risk is greater for travelers to developing countries. Vaccination should be considered for travelers anticipating prolonged exposure to potentially contaminated food and water. The approved vaccinations may not offer complete protection, and, as always, preventive steps against food and water contamination should be taken.

Three typhoid vaccines are available in the United States, an oral live-attenuated vaccine, a parenteral heat-phenol-inactivated vaccine, and a capsular polysaccharide vaccine. The parenteral heat-phenol-inactivated vaccine is an older vaccine, has more associated side effects, and is no longer commonly used. The vaccines have comparable efficacy rates. See [Table 89-14](#) for doses and schedules.

**E. Yellow Fever.** Yellow fever is caused by a flavivirus that is transmitted via *Aedes aegypti* and *Aedes sylvatic* mosquito vectors (see also [Chapter 43](#)). Clinical manifestations of disease vary from fever and headache to the classic triad of diseases found in severe infections: jaundice, hemorrhages, and severe albuminuria. Risk of transmission is low; however, this is a vaccine-preventable disease that is associated with high mortality and for which there is no treatment.

Yellow fever vaccination is the only required immunization for admission to certain countries including endemic areas of Africa and Central and South America. It is also required in areas where human infection may induce epidemics or cause transmission. Yellow fever vaccine must be administered at an approved yellow fever vaccination center, because International Certificates of Vaccinations are required for country admission. To be valid, the vaccination must occur = 10 days before desired admission to the country.

Yellow fever vaccine is an attenuated live-virus vaccine. It is given to travelers > 9 months of age as a single dose. A booster dose is required every 10 years. Vaccination should not be given to pregnant women, and special consideration should be taken before immunization of immunocompromised hosts.

**F. Dengue Fever.** Dengue fever is caused by the Dengue virus, a member of the family *Flaviviridae*, and it is usually transmitted by *Aedes* mosquitoes. It is a disease most commonly seen in urban areas of the Indian subcontinent, Southern China, Southeast Asia, and South and Central America.

Dengue virus causes a sudden onset of high fever, severe headaches, myalgia, and arthralgia. It is associated with a rash that occurs 3-4 days after the onset of symptoms.

Currently, no vaccine is available. There is, however, a vaccine in development. Because the disease is acquired via mosquito transmission, preventive measures should be taken (see Pretravel Evaluation above). Treatment is primarily supportive. Medication to reduce fever should be avoided.

**G. Cholera.** Cholera is a bacterial diarrheal illness caused by *Vibrio cholera* (see also [Chapters 20](#) and [57](#)). Disease is spread via contaminated food and water. Clinical manifestation of disease ranges from mild, self-limited diarrhea to the voluminous watery diarrhea that quickly leads to dehydration and death.

The risk of cholera to the traveler is very low. The licensed vaccine in the United States offers only 50% effectiveness. Because of the low risk and the low benefit, cholera vaccine is indicated only for high-risk people working and living in endemic areas and in poor sanitary conditions. Endemic areas are present in South and Central America, Africa, and Asia. The vaccine is given as two subcutaneous, intradermal, or intramuscular doses at least 1 week apart. An additional booster dose is required every 6 months. See [Table 89-15](#) for dosing recommendations.

**H. Meningococcal Meningitis.** *Neisseria meningitidis* causes a bacterial meningitis that is responsible for multiple epidemics of disease (see also [Chapters 7](#) and [52](#)). Epidemic areas include sub-Saharan Africa during the dry season (December-June). This area is known as the "meningitis belt." Recent epidemics have also occurred in Kenya, Tanzania, Burundi, and Mongolia. All travelers planning to visit countries in the meningitis belt during the dry season or any of the above-mentioned countries should receive the meningitis vaccine. The vaccination is required for pilgrims to Mecca, Saudi Arabia, for the annual Hajj.

The formulation of meningococcal polysaccharide vaccine available in the United States offers activity against serotypes A, C, Y, and W135. Serotype A is responsible for most of the disease outside the United States and Europe. Serotype C is now the most common cause of *Neisseria meningitidis* and is part of the vaccine. Quadrivalent A/C/Y/W135 vaccine can be given in a single subcutaneous dose, in the volume indicated by the manufacturer.

## DISEASES REQUIRING SPECIAL ATTENTION

### 1. TRAVELERS' DIARRHEA

#### General Considerations

Diarrhea is the most common illness affecting international travelers today (see also [Chapter 20](#)). Disease prevalence varies by destination, from a 5% incidence during travel to the United States and Canada to a 20%-50% incidence upon visiting tropic/subtropic developing countries. Although travelers' diarrhea tends to be a self-limited illness with very few people requiring medical attention (4%), even fewer requiring hospitalization (< 1%), and almost no one dying, the high incidence of the disease makes it exceedingly important. Frequently, travel time is limited, and there is no time for postponement or rescheduling because of illness.

Bacterial agents are most commonly responsible for travelers' diarrhea. The pathogen frequencies change depending on destination and season. Multiple studies conducted in the 1970s found that enterotoxigenic *Escherichia coli* is the major cause of the illness. Viral and protozoan causes of traveler's diarrhea are less frequent. See [Table 89-16](#) for pathogens associated with traveler's diarrhea.

#### Clinical Findings

Clinical symptoms of loose bowel movements, urgency, abdominal pain and cramping,

low-grade fever, and nausea usually start soon after arrival at the travel destination. One study found the highest onset of symptoms on travel day 3. The mean duration of symptoms without treatment is 4.1 days. This can be shortened to 24 h when antidiarrheal medication is used.

## Diagnosis

The diagnosis of traveler's diarrhea is a clinical one. Traveler's diarrhea is caused by a variety of bacteria, viruses, and parasites. The majority of cases are secondary to bacterial agents. Because cultures are time consuming and the natural course of the illness is relatively short, a clinical diagnosis and antibiotic treatment are an appropriate approach to treating this disease.

## Treatment

**A. Oral Rehydration.** Oral rehydration is the cornerstone of therapy for uncomplicated traveler's diarrhea. Parents should be warned that infants and young children who are unable to communicate their thirst and fluid needs are at risk of dehydration. Most often, increased water intake is all that is necessary for otherwise healthy adults. For children or persons with severe dehydration, several oral rehydration formulations are currently marketed, or a rehydration solution can be made with simple ingredients: a half-teaspoon of salt can be mixed with 8 teaspoons of sugar in 1 liter of water.

**B. Antimotility Drugs.** Antimotility drugs such as loperamide (Immodium) are safe to use for relief of symptoms in typical cases of traveler's diarrhea. Loperamide has been shown to decrease intensity of symptoms and shorten the course of the illness. Should the traveler experience prolonged diarrhea, high fevers, or blood or mucoid stools, antimotility agents should be discontinued and medical attention sought.

**C. Antimicrobial Agents.** Antimicrobial agents as presumptive treatment for acute traveler's diarrhea may be beneficial and should be initiated at the onset of abdominal cramps and loose stools. Multiple placebo-controlled trials have shown faster recovery rates in patients who received fluoroquinolones than those who did not. Trimethoprim-sulfa has also been shown to decrease symptoms and duration of diarrhea. Fluoroquinolones are not approved for use in children or pregnant women. Trimethoprim-sulfa is safe to use in children. See [Table 89-17](#) for antimicrobial agents and dosages used in treatment of travelers' diarrhea.

Although most travelers' diarrhea is self limited, travelers should be warned to seek medical attention if diarrhea is severe or does not resolve within several days, diarrhea is bloody or mucoid, diarrhea is associated with high fevers or shaking chills, or the patient is unable to maintain oral fluids, and dehydration becomes an issue.

## Prevention

Because of the large number of agents responsible for this disease, vaccination is not an ideal form of prevention. Although investigation is underway directed at enterotoxigenic *E coli*, the most common pathogen, travelers will remain at risk of infections by the other etiologic agents.

Current forms of prevention can be directed at two routes—careful selection of food and water or chemoprophylaxis. As discussed earlier, it is extremely important for advising physicians to educate their patient regarding selection of food and water (see discussion of general travel advice above). Treatment of water or consumption of bottled carbonated drinks along with careful selection of fully cooked, peeled, or steamed hot foods is essential. Despite good advice, several studies have found that travelers are unable to strictly adhere to recommended water and food choices. In a study of Swiss travelers, 98% consumed food or beverages that they were warned to avoid.

Chemoprophylaxis has been well studied in travelers' diarrhea. It is well accepted that antimicrobial prophylaxis is highly effective. DuPont and Ericsson (1993) found that fluoroquinolone prophylaxis prevents = 90% of disease. If trimethoprim-sulfa is used, prevention is still provided, although to a lesser extent. Despite the effectiveness of antimicrobial agents, most clinicians agree that these should not be routinely provided for prophylaxis. There are numerous problems with routine chemoprophylaxis: (1) adverse drug reactions, such as skin rash, photosensitivity, Steven-Johnson syndrome, or bone marrow suppression; (2) colonic bacterial overgrowth; (3) interference with other medications; and (4), perhaps most importantly, the promotion of resistance to antimicrobial agents.

The decision to provide antimicrobial prophylaxis for travelers' diarrhea should be based on a risk-benefit analysis and recommended only in rare and unusual circumstances. For most travelers, the illness is self-limiting and non-life threatening. A patient who is chronically ill or immunosuppressed may benefit more from prevention, because the risk of acquisition of travelers' diarrhea could be life threatening.

Bismuth subsalicylate (eg, Pepto Bismol) is another consideration in chemoprophylaxis. As with antimicrobial agents, prophylaxis with bismuth subsalicylate has reduced the incidence of travelers' diarrhea. An analysis in the late 1970s of students studying abroad in Mexico revealed that prophylactic use of bismuth subsalicylate reduced the incidence of traveler's diarrhea by 62%. Despite the evidence in this single trial, the CDC does not recommend the use of bismuth subsalicylate as prophylaxis for travelers' diarrhea, based on risk of salicylate toxicity and other uncertain risks.

No antiperistaltic agents are effective in prevention of travelers' diarrhea. In fact, prophylactic use of antiperistaltic drugs may actually increase the incidence of disease.

## **2. TYPHOID FEVER**

### **General Considerations**

Typhoid fever is an enteric fever syndrome caused by *S enterica* serovar Typhi (see also [Chapter 53](#)). At one time, typhoid fever was one of the most common bacterial infections in the United States. With improved sanitation, the incidence of typhoid fever has declined. There is still some risk involved with international travel to developing countries and exposure to contaminated food and water. Acquisition of disease associated with all international travel is estimated to be 1:30,000. Travel to India, Peru, or North and West Africa can greatly increase risk of acquisition.

*S enterica* serovar Typhi infection is caused by contaminated food and water. It is strictly a human pathogen. The bacteria attach and penetrate intestinal mucosa and cause damage to the mucosa directly or via bacterial toxins. The bacteria then invade and multiply within macrophages and therefore reach systemic circulation and cause systemic disease.

## Clinical Findings

Clinical manifestations vary from asymptomatic carriage (eg, as occurred with "Typhoid Mary") to gastroenteritis to enteric fever and bacteremia. Symptoms of enteric fever usually occur 1-2 weeks after exposure. Cough, sore throat, myalgia, and abdominal pain are early symptoms. With time, fever becomes prominent with changes in mental status. The patient may experience diarrhea or constipation. Significant physical findings include bradycardia associated with fever and hepatosplenomegaly.

## Diagnosis

Diagnosis is made by isolation of the bacteria in a blood culture. Stool cultures may be negative both early and late in the illness.

## Treatment

Treatment is different depending on disease manifestations. The treatment of chronic carriers is important because they are the likely source of disease spread. Eradication of the pathogen is difficult. Current therapeutic options are outlined in [Table 89-18](#). If antibacterial therapy is not successful, cholecystectomy may become necessary because the bacteria tend to live in the scarred biliary tree or in the presence of gallstones.

The treatment of choice for enteric fever is a fluoroquinolone. If antimicrobial-agent resistance is a problem, trimethoprim-sulfa can be used.

## Prevention

Prevention of typhoid fever via vaccination ([Table 89-14](#)) is recommended for travelers to developing countries who will have prolonged exposure to contaminated food and water. As always, careful selection of food and drink is strongly encouraged (see Pretravel Evaluation above and [Table 89-2](#)).

## 3. MALARIA

### General Considerations

Malaria is a febrile illness caused by four different species of the genus *Plasmodium*: *P falciparum*, *P ovale*, *P vivax*, and *P malariae* (see also [Chapter 80](#)). These plasmodia infect humans via the bite of the female *Anopheles* mosquito. Rarely, malaria has been linked to blood transfusions and congenital transmission.

The risk of acquisition of these plasmodia depends on the country visited, the type of area visited (ie, rural or urban), the time of year (ie, dry or rainy season), and the duration of the visit. There are 300-500 million cases of acute symptomatic malaria annually and 1.5-2.7 million deaths. The majority of the cases occur in sub-Saharan Africa, with Southeast Asia and Central and South America coming in a very distant second and third, respectively.

The high rate of disease and the continuing emergence of antimicrobial-agent resistance are concerns with malaria treatment. Chloroquine-resistant *P falciparum* is now reported in all countries except the Dominican Republic, Haiti, Central America west of the Panama Canal Zone, Egypt, and most of the Middle East ([Figure 89-1](#)). Pyrimethamine-sulfadoxine (Fansidar) resistance has been reported in Thailand, Myanmar, Cambodia, the Amazon area of South America, and sporadically in sub-Saharan Africa.

## Clinical Findings

Cyclic fevers are the hallmark of plasmodium infection. The fevers occur as the red blood cells lyse, releasing new plasmodium into the bloodstream. Typically, the victim experiences a cold or chilling stage, followed by a febrile stage lasting several hours, followed by a third sweating stage. The timing of the fevers differs depending on the infecting species—48 h for *P vivax* and *P ovale* and 72 h for *P malariae*. *P falciparum* usually causes a continuous fever with intermittent spikes. Most victims also experience shaking chills, hypotension, cough, headache, and back ache. Complications of the illness vary but can include CNS involvement with delirium, seizures, coma, and renal failure. Clinical manifestations vary somewhat depending on species.

*P falciparum* causes the most severe manifestations. The complications are thought to result from diffuse microvascular disease secondary to adherent, parasitized red blood cells that aggregate and obstruct blood flow. Infection with *P falciparum* can lead to severe anemia, renal failure, pulmonary edema, and CNS complications, referred to as "cerebral malaria," which has a range of manifestations from impaired consciousness to seizures.

*P vivax* and *P ovale* typically cause less severe illness. The red blood cells do not aggregate with these infections; thus the microvascular manifestations are not seen. There is a dormant stage in the life cycle of these plasmodia; therefore, a late secondary illness can manifest as late as 12 months or longer after initial infection.

*P malariae* causes a low parasitemic infection, and associated symptoms are typically mild. Parasitized red blood cells do not aggregate; thus, with this infection, as well as with *P vivax* and *P ovale*, no microvascular damage is seen later in the infection. An immune complex glomerulonephritis is sometimes seen. The actual infection may persist for years.

The typical laboratory findings seen with malaria are related to the parasitized red blood cells and cell lysis. Anemia and increased lactate dehydrogenase, bilirubin, and reticulocyte counts are typically seen. Depending on the extent of the disease, increased blood urea nitrogen and creatinine associated with acute renal failure and

thrombocytopenia can also be seen.

## Diagnosis

The standard diagnosis of plasmodium infection is by Giemsa-stained blood smears to visualize the parasite. The infected red blood cells can usually be seen on a Wright's stain as well. If the clinical suspicion is strong, and the initial blood smear is negative, the blood smear should be repeated in 6-12 h.

## Treatment

Successful treatment of malaria requires rapid diagnosis and initiation of treatment. The species responsible should be confirmed via a peripheral blood smear before initiation of treatment. The selection of the antimalarial agent will depend on the infecting species and whether the patient is able to take oral medications.

Patients with *P falciparum* infection should be hospitalized until the physician is certain that serious complications such as cerebral malaria, adult respiratory distress syndrome, and renal failure will not occur. The obvious supportive treatments such as fluid resuscitation and management of complications should be done. Exchange transfusions may be helpful with severe parasitemia. The appropriate drug therapy depends on the *Plasmodium* species involved. Treatment therapies and doses are outlined in [Table 89-19](#).

**A. Treatment of *P vivax* and *P ovale* Infections.** Effective treatment of *P vivax* and *P ovale* infections can be obtained with chloroquine and primaquine. Chloroquine phosphate along with primaquine phosphate is recommended. Chloroquine is the only antimalarial agent approved for use during pregnancy. Primaquine is unsafe for use in pregnant women.

**B. Treatment of Chloroquine-Sensitive *P falciparum* and *P malariae* Infection.** Infection with chloroquine-sensitive plasmodia can be treated with chloroquine. Side effects are minimal.

**C. Treatment of Chloroquine-Resistant *P falciparum* Infection.** Multiple drugs are available for treatment of resistant *P falciparum* malaria. The treatment drug chosen should be different from the drug used for prophylaxis.

Quinine was one of the first drugs used for treatment of malaria. Its use became less frequent with the development of new synthetic antimalarial agents, but, as resistance continues to increase, quinine has again become popular. Lower cure rates have been reported in Southeast Asia, including Thailand, Myanmar, Vietnam, and Cambodia. Quinine is currently a first-line drug for use in chloroquine-resistant *P falciparum* infections.

If the infection was acquired in Southeast Asia, quinine should be extended to 10 days, and doxycycline should be added. Tetracyclines are not safe to use during pregnancy. If a patient in the United States is unable to use oral medications, a continuous intravenous infusion of quinidine gluconate is used.

Malarone (Atovaquone 250 mg plus proguanil 100 mg) has been approved for the treatment of mild to moderate malaria where the patient can take oral medication. It is given as four tablets as a single dose daily for 3 d. It is contraindicated in infants, pregnancy, and while breast feeding. Side effects are rare and include nausea, vomiting, abdominal pain, and headache. It should not be used in patients with severe renal impairment.

## Prevention

Prevention against *Plasmodium* infection is twofold, consisting of personal-protection measures and chemoprophylaxis. Despite complete compliance with both medication and personal-protection measures, infection with *Plasmodium* spp. is still possible. This information should be stressed to the traveler, because a febrile illness after exposure should be taken seriously.

Personal-protection measures include the general arthropod protection steps discussed above. Most importantly, travelers should avoid the outdoors during the feeding time of the *Anopheles* mosquito, which is dusk to dawn. DEET-containing repellent and pyrethroid-containing flying-insect spray should be used in living and sleeping areas during evening and nighttime hours (see [Table 89-3](#)). Additional protection can be provided by treating clothing with permethrin spray.

Chemoprophylaxis is provided to travelers based on information regarding their risk of acquisition, risk of encountering drug-resistant *P falciparum*, and accessibility to medical care. Chemoprophylaxis should be started 1-2 weeks before travel and continued for 4 weeks after leaving the malaria-risk area. There are three chemoprophylaxis regimens. These regimens are outlined in [Table 89-20](#) and described below:

1. For travel to areas where chloroquine resistance has not been reported, chloroquine alone is recommended. Use of chloroquine may be associated with side effects such as mild nausea and skin rash reported in some users.
2. For travel to areas where chloroquine resistance has been reported, if the traveler has no history of mefloquine sensitivity, neuropsychiatric problems, or seizures, mefloquine is recommended. This is a very effective means of malaria prophylaxis. It does have significant side effects that may limit its use. Evidence of CNS toxicity, such as seizures and psychotic behavior, has been reported in 1 European traveler per 13,000. Mefloquine is not recommended for use in combination with beta blockers.

Mefloquine is safe to use in the second and third trimester of pregnancy. Limited data suggest that it may also be safe in the first trimester. Studies are still underway on the use of mefloquine in the first trimester, and women who choose to use the drug are asked to report the use to the CDC for registry in pregnancy outcomes research.

3. Other options include doxycycline, starting on the day of arrival at risk destination and continuing for 4 weeks after leaving the area.

Doxycycline is unsafe for use in pregnancy or in children. Common side effects include

photosensitivity and gastrointestinal toxicity.

4. Malarone (Atovaquone 250 mg plus proguanil 100 mg) is approved for the prophylaxis of chloroquine-resistant malaria and is given as one tablet daily starting 1 d before arriving in a malaria area and continuing for 7 d after leaving the area. Side effects are rare and include nausea, vomiting, abdominal pain, and headache.

Approved by the Advisory Committee on Immunization Practices (ACIP), the principal advisory committee for the U.S. Department of Health and Human Services (DHHS), on October 19, 2001.

\* This vaccine is indicated for immunocompetent children aged 12 months to 19 years. Additional immunization is recommended for children aged 19-23 years who have not received a second dose. Immunocompromised children aged 12 months to 19 years who have not received a second dose should receive a second dose 12 months after the first dose and at least 4 months after the second dose. For children aged 19-23 years who have not received a second dose, a booster dose is recommended 12 months after the first dose.

† This vaccine is indicated for immunocompetent children aged 2 months to 18 years. Additional immunization is recommended for children aged 19-64 years who have not received a booster dose. Immunocompromised children aged 2 months to 18 years who have not received a booster dose should receive a booster dose 12 months after the last dose and at least 4 months after the booster dose. For children aged 19-64 years who have not received a booster dose, a booster dose is recommended 12 months after the last dose.

†† This vaccine is indicated for immunocompetent children aged 4 months to 6 years. Additional immunization is recommended for children aged 7-18 years who have not received a booster dose. Immunocompromised children aged 4 months to 6 years who have not received a booster dose should receive a booster dose 12 months after the last dose and at least 4 months after the booster dose. For children aged 7-18 years who have not received a booster dose, a booster dose is recommended 12 months after the last dose.

††† This vaccine is indicated for immunocompetent children aged 2 months to 64 years. Additional immunization is recommended for children aged 65 years and older who have not received a booster dose. Immunocompromised children aged 2 months to 64 years who have not received a booster dose should receive a booster dose 12 months after the last dose and at least 4 months after the booster dose. For children aged 65 years and older who have not received a booster dose, a booster dose is recommended 12 months after the last dose.

Table 89-4. Recommended Childhood Immunization Schedule United States, January-December, 2001.

**Table 89-5.** Vaccination during pregnancy.

<b>Disease Vaccination</b>	<b>Vaccine Type</b>	<b>Indications for Vaccination During Pregnancy</b>
<b>Live virus vaccine</b>		
Measles	Live-attenuated	Contraindicated
Mumps		
Rubella		
Yellow fever	Live-attenuated	Contraindicated except if exposure to yellow fever virus is unavoidable
Poliomyelitis	Trivalent live-attenuated (oral polio vaccine)	Persons at substantial risk of exposure to polio
<b>Inactivated virus vaccines</b>		
Hepatitis A	Killed Virus	Data on safety in pregnancy are not available. Should weigh the theoretical risk of vaccination against the risk of disease
Hepatitis B	Recombinant produced, purified hepatitis B surface antigen	Pregnancy is not a contraindication
Influenza	Inactivated type A and type B virus vaccines	Usually recommended only for patients with serious underlying disease. Consult health authorities for current recommendations
Japanese Encephalitis	Killed virus	Should reflect actual risks of disease and probable benefits of vaccine
Poliomyelitis	Killed virus (inactivated polio vaccine)	Oral polio vaccine preferred when immediate protection of pregnant females is needed; however, inactivated polio vaccine is alternative if complete vaccination series cannot be administered before exposure
Rabies	Killed virus Rabies immunoglobulin	Substantial risk of exposure
<b>Live bacterial vaccines</b>		
Typhoid (Ty21a)	Live bacterial	Should reflect actual risks of disease and probable benefits of vaccine
<b>Inactivated bacterial vaccines</b>		
Cholera Typhoid	Killed bacterial	Should reflect actual risks of disease and probable benefits of vaccine
Plague	Killed bacterial	Selective vaccination of exposed persons
Meningococcal	Polysaccharide	Only in unusual outbreak situations

Pneumococcal	Polysaccharide	Only for high-risk persons
Haemophilus b conjugate	Polysaccharide-protein	Only for high-risk persons
<b>Toxoids</b>		
Tetanus-diphtheria	Combined tetanus-diphtheria toxoids, adult formulation	Lack of primary series, or no boosters within past 10 years
<b>Immune globulins, pooled or hyper-immune</b>	Immune globulin or specific globulin preparations	Exposure or anticipated unavoidable exposure to measles, hepatitis A, hepatitis B, rabies, or tetanus

## 90 . Zoonotic Infections — *D. Scott Smith, MD & David A. Relman, MD*

### Essentials of Diagnosis

- Occupations such as abattoir worker and hobbies such as hunting, outdoor activities, and fishing.
- History of exposure to animals, birds, fish, and insect vectors such as mosquitoes, ticks, fleas, and lice; history of ingesting uncooked foods.
- Clinical syndromes such as atypical pneumonia, encephalitis, and granulomatous lymphadenopathy.
- Blood smear with visible microorganisms.
- Radiographic evidence of calcified lesions in brain or muscle.

### General Considerations

Zoonoses are infectious diseases of vertebrate animals that are capable of spreading to and affecting humans. This traditional definition is often broadened to include other nonhuman hosts as reservoirs or sources of the infectious agent. Many zoonoses have only historical significance in the developed world; however, they continue to exact a major toll on human health in less-well-developed regions. Of equal or greater concern is that zoonoses are over-represented among diseases that are currently defined as "emerging." Emerging infectious diseases are those that are associated with newly recognized infectious agents or with agents that appear to be spreading and causing more cases of disease or more serious cases than they did previously. One survey has found that 114 of 156 emerging infectious diseases can be classified as zoonoses. The reasons for this important phenomenon are discussed later in this chapter.

**A. Epidemiology.** Zoonoses tend to occur under special circumstances of geography, climate, or human activity that create new opportunities for encounters between humans and zoonotic agents (see Pathogenesis below). As a result, zoonoses are often geographically focal, transient over months or years, and restricted to specific subpopulations. In the case of hantavirus pulmonary syndrome, the disease arises only when humans live or sleep near infected rodents, which in turn are found only in small geographic microenvironments. In general, humans at special risk for acquiring zoonoses are farmers, hunters, and those that handle and work with animals, birds, and fish. In addition, persons with unusual exposure to insect vectors and those that work in and near water are at increased risk for zoonoses. Most often, humans act as "dead-end" hosts for zoonotic disease agents; ie, they do not contribute to overall, long-term persistence or spread of the agent in nature.

**B. Microbiology.** There are numerous diverse pathogenic microorganisms associated with zoonotic disease including viruses, bacteria, fungi, and parasites ([Box 90-1](#)). A reservoir is a host in which a microorganism lives and multiplies. A primary reservoir is a

host on which a zoonotic agent depends for its continued survival in nature. This host does not usually develop disease. As an example, the white-footed mouse is a primary reservoir for *Borrelia burgdorferi*, the agent of Lyme disease, in the northeastern United States. Although an infected mouse does not exhibit signs of disease, it permits prodigious replication of this spirochete and circulation of the organism in the murine bloodstream. As a result, ixodid ticks often acquire the spirochete during a blood meal. A secondary reservoir in contrast, is not necessary for the survival of the microbe in nature but may be important for the transmission of disease to humans. Plague and its causative agent, *Yersinia pestis*, illustrate this concept ([Figure 90-1](#)). Wild rodents serve as primary reservoirs; commensal rodents such as urban rats may serve as secondary reservoirs and as such may play disproportionately important roles in transmission of disease to humans in a peridomestic setting, via their fleas, as was so acutely illustrated during the Middle Ages. Many of the most common reservoirs for human zoonotic diseases are domestic animals or animals adapted to urban and suburban environments. As humans build their homes and move into the habitats of the primary reservoirs, their chances for contact with zoonotic pathogens increase (see below). [Table 90-1](#) lists some of the more common associations of animals with zoonotic agents.

A vector is an organism, usually an arthropod, that carries a zoonotic agent from one host to another. Common vectors include mosquitoes, ticks, and fleas. Vectors can be categorized as mechanical or biological, depending on the degree of intimacy with the microorganism they transmit. A mechanical vector transmits disease agents by means of contamination of its legs, proboscis, or even its gastrointestinal tract. Mechanical transmission requires no multiplication or specific interaction between vector and pathogen to enable disease spread. The common housefly is an example. Biological vectors on the other hand may have a sophisticated and accommodating relationship with the infectious organism, enabling multiplication and cyclic development within vector gut or salivary glands. It is common for pathogens to recognize the distinct environments of a vector and to respond to the relevant cues by expressing a unique set of genes and gene products accordingly. These products facilitate adaptations to the vector. For example, *B burgdorferi* preferentially expresses the surface protein OspA in the tick gut. OspA may play a role in colonization of *B burgdorferi* and its translocation through the tick gut wall. Nocturnal biting patterns of the mosquito vectors that transmit *Wucheria bancrofti*, one of the agents of human filariasis, match the nocturnal periodicity of parasitemia of the microfilariae. Other features of the feeding pattern of the vector may also enhance transmission efficiency or competence; for example, the *Simulium* black fly feeds on subcutaneous pools of blood, enabling it to ingest skin-dwelling microfilaria of *Onchocerca volvulus*.

**C. Pathogenesis.** There are three primary routes of transmission of zoonoses to humans: (1) through the skin, by the bite of a vector or animal (eg, *Pasteurella multocida* from animal bites) or by direct inoculation (eg, cutaneous anthrax from animal skin handling), (2) through inhalation (eg, *Coxiella burnetii* or *Chlamydia psittaci*), and (3) by ingestion (eg, *Giardia lamblia* or *Brucella* or *Salmonella* species). The route of transmission usually determines the nature of the ensuing clinical syndrome in the human host, especially with regard to the sites of disease involvement. Some zoonotic agents are transmitted to humans by more than one route; for example, *C burnetii* is occasionally tickborne, and *Francisella tularensis*, the agent of tularemia, can be

acquired from a tick as well as through direct inoculation of the skin from an abrasion while handling an infected animal. Furthermore, the route of disease transmission to humans may differ from the route between reservoir hosts.

The expression of zoonotic disease reflects an intimate interplay between nonhuman reservoirs, vectors, a human host, and a pathogen. This complex ecosystem is easily disrupted, and when disease emerges in one sector, it often spills over into or has consequences for another sector ([Figure 90-2](#)). A classification of factors responsible for the emergence of zoonotic disease can be organized according to host, vector, and pathogen. Host and vector factors include physical translocation and encroachment by one host into the territory of another, travel, crowding, human conflict, globalization of food supply, and environmental changes such as deforestation, global warming, and El Niño Southern Oscillation events. Pathogen factors include acquisition or expression of genes encoding toxins, adherence factors, or outer surface antigenic structures (antigenic variation) and other genetic events that confer upon the microorganism an improved growth rate or transmissibility, broadened host range, and drug resistance. The spread of Lyme disease in the northeastern United States over the past two decades is attributed to the reforestation of New England, human encroachment on deer and mouse habitats, uncontrolled deer population growth, and climate effects on tick population size.

## **Clinical Findings**

Zoonotic disease should be suspected in the setting of fever and either an unusual history of exposure to a potential reservoir or vector or a more specific clinical syndrome suggestive of zoonotic disease. "Unusual" exposure histories include frequent, prolonged, or intimate contacts with animals, birds, fish, or disease vectors, especially those contacts that involve bites or scratches, or to sick nonhuman hosts. In general, clinical syndromes associated with zoonotic disease reflect the route of transmission. For example, agents that are transmitted by percutaneous inoculation tend to cause local cutaneous disease such as ulcers, cellulitis, or regional lymphadenopathy; airborne agents tend to cause pneumonia or other lower respiratory tract syndromes; and agents that are transmitted by ingestion usually lead to abdominal or intestinal syndromes. Therefore, the differential diagnosis can be limited to the subset of zoonotic agents that use that route of transmission. More specific syndromes that suggest zoonotic disease are fever and cutaneous eschar (eg, Mediterranean and other spotted fevers and scrub typhus); cough, respiratory distress, and widened mediastinum (inhalational anthrax); and fever, preauricular lymphadenopathy, and conjunctivitis or Parinaud's syndrome (tularemia, cat scratch disease, and others).

## **Diagnosis**

The diagnosis of zoonotic diseases depends heavily on a high index of suspicion and a thorough clinical history. A careful series of questions often reveals travel, contacts, or activities that raise the probabilities of zoonosis substantially. Any potential clue should be pursued by acquiring further information about the intensity of the exposure and duration of stay in a particular location and background data on the prevalence of various zoonotic agents in relevant circumstances. In contrast, there are few clues from physical examination that are likely to be helpful. Bite wounds and lesions are certainly

important findings. Cutaneous eschars or certain syndromes such as Parinaud's syndrome (conjunctivitis, preauricular lymphadenopathy, and fever) should suggest zoonoses as part of the differential diagnosis. The laboratory diagnosis of zoonoses relies on serologic testing and thus clinical suspicion of specific disease agents. The finding of microorganisms or poorly explained intracellular inclusions and structures on microscopic examination of a blood smear is a common initial indication of a zoonosis such as malaria, babesiosis, ehrlichiosis, or relapsing fever. Some zoonotic agents require special stains to be visualized under the microscope; for example, *Bartonella* species can be seen reliably only by using the Warthin-Starry silver stain. Agents that enter the body via an oral route may require stool examination and culture for a diagnosis.

## Treatment

The diversity of zoonotic agents precludes any simple protocol for empiric therapy. However, certain clinical syndromes and exposures may be amenable to empiric therapy because of a restricted list of possible zoonotic pathogens that share susceptibility to a few common antimicrobial agents ([Box 90-2](#)). For example, febrile illness in the United States in a person with a recent tick bite can be treated empirically with doxycycline until a specific diagnosis is achieved. Doxycycline provides reasonably good treatment for the following tick-borne diseases: Lyme disease, ehrlichiosis, Rocky Mountain spotted fever, tularemia, and relapsing fever. Some zoonoses such as Rocky Mountain spotted fever and anthrax are medical emergencies and, when suspected, require immediate empiric therapy.

## Control

The complexity that governs the origin and spread of zoonoses also provides an equally diverse and interwoven set of opportunities for disease intervention and interruption ([Box 90-3](#)). Lyme disease is a useful example, in which strategies for disease reduction include tick avoidance, early detection and removal of attached ticks, tick reduction, by making acaricide-impregnated cotton balls available to white-footed mice in their burrows, and vaccination of humans. OspA is a potent immunogen and is the basis of the current Lyme disease vaccine (see Microbiology above). Vaccine programs can be expanded in some cases to other hosts: the spread of rabies in the eastern United States has been limited through vaccination of wild animals (oral vaccine-laden bait) and peridomestic animals that have close contact with potentially infected wild animals.

## 91 . Ectoparasitic Infestations & Arthropod Stings & Bites — *Walter R. Wilson, MD & James M. Steckelberg, MD*

### INTRODUCTION

Ectoparasitic infestation is extremely common worldwide and virtually every human who resides in nonpolar climates is bitten repeatedly by arthropods. Specific infectious diseases transmitted by arthropod bite are reviewed elsewhere in this book. This chapter describes ectoparasitic infestations and toxic reactions to arthropod stings and bites. There is considerable overlap between infestations and bites because ectoparasites either bite or burrow under the skin of their human host.

### ECTOPARASITIC INFESTATION

#### Essentials of Diagnosis

- Ticks: capture of organism
- Mites (scabies): demonstration of organism in pruritic skin lesions, scrapings of burrow, or skin biopsy
- Lice: demonstration of organism or nits (eggs) on hair, skin, or clothing
- Fleas: history of exposure or capture of organism
- Myiasis: demonstration of maggots in tissue
- Leeches: history of exposure, capture of organism

#### General Considerations

Ectoparasites are arthropods or helminths that infest the skin or hair of humans or mammals and feed on blood, serum, or tissue. Ectoparasites attach to skin by mouth parts or burrow beneath skin where they may inflict local tissue injury or necrosis, cause hypersensitivity reactions, or inject pathogens or toxins into the host. [Table 91-1](#) lists common ectoparasitic infestation in humans. [Box 91-1](#) summarizes the signs and symptoms associated with the most common types of infestation.

**A. Tick infestation.** In the United States, the principal ticks that parasitize humans are deer ticks (*Ixodes* spp.), which transmit Lyme disease, babesiosis, and human granulocytic ehrlichiosis; wood ticks (*Dermacentor* spp.) and *Amblyomma americanum*, which transmit tularemia, Rocky Mountain spotted fever, Colorado tick fever, and human monocytic ehrlichiosis; and soft ticks (*Ornithodoros* spp.), which transmit tick-borne relapsing fever.

Because ticks attach and feed on their blood meal painlessly, their presence is often not

readily detected by their host. Tick secretions produce local reactions, fever, or paralysis. The local reactions include small pruritic, papulonodular lesions that may vary in size from a few millimeters to several centimeters, and an eschar may develop. Tick-induced fever and constitutional symptoms disappear within 24-48 h after removal of the tick.

Tick paralysis is an uncommon illness, which is thought to result from toxins found in tick saliva, most often in dog or wood ticks. Children, especially those with long hair where the tick may reside undetected, are most often those affected by tick paralysis. Ascending flaccid paralysis begins 5-6 d after attachment and progresses over several days, resulting in diminished deep-tendon reflexes and cranial-nerve palsies. Sensation remains intact and spinal fluid analysis is normal. Untreated, respiratory paralysis that requires endotracheal intubation may occur. Removal of the tick results in rapid improvement and complete recovery usually within hours to several days. Ticks should be removed by gentle retraction with tweezers or forceps.

**B. Scabies and other mite infestation.** Scabies, caused by *Sarcoptes scabiei*, the human itch mite, is prevalent worldwide and infests 300-500 million people annually. It is one of the most frequent causes of pruritic dermatitis and patient visits to a dermatologist. Female gravid mites 0.3-0.4 mm in length burrow beneath the stratum corneum.

Itching and rash occur as a result of hypersensitivity to the mite excreta deposited in its burrow. Scratching kills the burrowing mite, but symptoms persist as a result of infestation elsewhere. Patients complain of intense pruritus, often worse at night or after a hot shower or bath. A lymphocytic, eosinophilic infiltrate develops around the burrow resulting in a dark wavy line 5-15 mm in length that ends in a small bleb that contains the female mite. Lesions are most commonly located on the wrists, elbows, scrotum, and skin folds and along belt and clothing lines. The face, neck, arms, and soles are usually spared. Papulovesicular eczematous plaques and pustules may develop in untreated patients.

Crusted or Norwegian scabies results from hyperinfestation with thousands or millions of mites and usually occurs in patients with AIDS or other immunocompromised diseases. Crusted scabies is characterized by the presence of thick keratotic crusts, diffuse erythema, scaling, and dystrophic rashes—a condition resembling psoriasis. The characteristic burrow may not be visible in crusted scabies, and pruritus is often minimal or absent. Patients with AIDS and encrusted scabies are at risk of cellulitis and bacteremia resulting from skin fissures.

Transmission of scabies results from close person-to-person contact and is facilitated by crowded unsanitary conditions and sexual promiscuity. Outbreaks of scabies occur in households, hospitals, nursing homes, daycare centers, prisons, mental institutions, and chronic-care facilities. Medical-care personnel are at risk of acquisition. Patients with crusted scabies are highly contagious for others, including health care personnel, and should be placed in strict isolation until treated. Transmission of scabies via sharing of contaminated clothing or bedding is unlikely, because the mite does not survive > 18-24 h without its host.

The diagnosis of scabies should be considered in individuals who have pruritus and rash in the characteristic distribution. Burrows should be unroofed and the scrapings examined microscopically for the characteristic mite or its eggs and fecal pellets. Biopsy or scraping of skin lesions in patients with crusted scabies should be examined microscopically.

Chiggers or other mites commonly infest humans and human habitats. The mouse mite is the vector of rickettsial pox in urban areas of the United States; trombiculid mites transmit scrub typhus in Southeast Asia. The larvae of trombiculid mites reside on grass and other plants and attach to human hosts by contact. The mites penetrate and burrow beneath the skin producing an intense pruritic papule = 2 cm in diameter, which vesiculates, pustulates, and ulcerates. Scratching kills the mite.

House mites (*Dermatophagoides* spp.) are extremely common worldwide. They reside in furniture, carpets, curtains, and elsewhere in the house and feed on shed human dander. Their allergens cause asthma, rhinitis, eczema, and other hypersensitivity conditions in sensitized adults with known house dust allergies. A positive skin test may suggest the diagnosis.

Three species of lice infest humans and feed daily on blood. Their bite results in an intensely pruritic local lesion. In sensitized individuals, a generalized maculopapular, urticarial rash is common and may be associated with fever and constitutional symptoms.

Head lice (*Pediculus humanus* var. *capitis*) are transmitted by human-to-human contact or by shared headgear, brushes, or combs. The prevalence is highest among school children or institutionalized individuals.

Body lice (*P. humanus* var. *corporis*) transmit epidemic typhus, relapsing fever, and trench fever. Body lice inhabit bed or body clothing and emerge to feed on humans. The body louse cannot survive more than a few hours without a human host. Transmission of body lice is the result of human-to-human contact or sharing a bed or body clothing and is facilitated by overcrowding and poor sanitation such as may occur among homeless individuals or during war or natural disasters.

The pubic louse (*Phthirus pubis*) primarily infests the hair in the pubis but may also infest the eyelashes, axillary hair, or other hair. This louse is most often transmitted by sexual contact. Blepharitis occurs with eyelash infestation.

The diagnosis of pediculosis is confirmed by the identification of lice or their eggs (nits) attached to the hair or clothing.

**C. Flea infestation.** Fleas are insects 2-5 mm in body length that feed on blood from humans and other mammals. Body fleas may transmit plague [rat flea (*Xenopsylla cheopis*)], murine typhus, and possibly *Bartonella henselae*. Fleas infest dogs, cats, and other mammals, their nesting areas, carpets, floor mats, bedding, furniture, and other household areas. They possess astonishing leaping ability, and the adult fleas attack humans who enter their proximity. During the blood meal, fleas excrete ingested blood and fecal materials that are often scratched into the bite wound. Erythematous,

intensely pruritic papules and vesicles develop at the bite site. Secondary bacterial superinfection is common. The diagnosis is based on an index of suspicion and a history of contact with fleas, and it is confirmed by the capture of the characteristic creatures.

**D. Myiasis (maggot) infestation.** Maggots are the larvae of screw worm flies or bot flies. The larvae invade healthy or necrotic tissue or body cavities and produce different syndromes depending on the species of fly.

Furuncular myiasis results from human bot fly (*Dermatobia hominis*) larvae. In Central and South America, the adult female bot fly captures a mosquito or other blood-sucking insect and deposits eggs on the abdomen of the insect. When the carrier insect ingests a blood meal, the eggs are deposited on the skin surface and hatch, and the larvae penetrate the skin. The African tumva fly (*Cordylobia anthropophaga*) deposits eggs on wounds or clothing, which hatch on contact with skin and penetrate the skin. Furuncular myiasis results in a characteristic pustular lesion with a central breathing pore that emits bubbles under water. The larvae may be expressed, or surgical excision may be required.

**1. Creeping dermal myiasis.** Eggs of the horse bot fly (*Gasterophilus intestinalis*) are deposited on horses. Riders become infested when the eggs come in contact with bare skin and hatch and the larvae penetrate humans but do not mature. For weeks they migrate in the epidermis, resulting in a serpiginous pruritic lesion. Larvae may be plucked from beneath the skin by a needle.

**2. Wound and cavity myiasis.** Many species of flies are attracted to wounds draining blood, serum, or pus and deposit their eggs in such wounds. The larvae enter wounds or skin, where they penetrate deeply and produce large suppurative cavities. Larvae may also infest normal body cavities, such as the mouth, nares, ears, sinuses, vagina, and eyes. Larvae usually require surgical removal and debridement of tissue.

**3. Leech infestation.** Medicinal leeches (*Hirudo medicinalis*) have been used for centuries for phlebotomy and to reduce edema and venous congestion of surgical flaps or reattached body parts. These leeches may be procured commercially in the United States or elsewhere. Their use has been associated with wound infection and sepsis caused by *Aeromonas hydrophila*, which colonizes gullets of medicinal leeches. Aquatic and land leeches commonly attach to humans and other animals on exposure. Land leeches secrete a potent anticoagulant and bleeding may occur after the leech is removed. Secondary bacterial infection is more common after land leech than aquatic leech infestation. Attached leeches may be removed by gentle traction. Application of heat, alcohol, salt, or vinegar hastens removal.

## Differential Diagnosis

Ectoparasitic infestation must be discriminated from other conditions that cause pruritic, maculopapular, pustulovesicular, or ulcerative dermatitis such as chronic contact dermatitis or neurodermatitis. Tick paralysis must be differentiated from Guillain-Barre syndrome, botulism, or polio. Crusted or Norwegian scabies resembles chronic eczema or psoriasis. Creeping dermal myiasis resembles cutaneous larva migrans caused by

*Ancylostoma braziliense*.

## Treatment

The treatment for ectoparasitic infestation is shown in [Box 91-2](#). Secondary bacterial infections should be treated with appropriate antimicrobial therapy. Tetanus toxoid should be administered as needed in patients with significant cutaneous wounds, such as those caused by myiasis, leeches, or other infestation.

## Prognosis

The prognosis in treated individuals is excellent and is influenced by the transmission of ectoparasite-specific infections, such as plague, typhus, and other serious bacterial infections.

## Prevention

Prevention of tick infestation is facilitated by avoiding brushy vegetation, wearing protective clothing, tucking the trouser cuffs inside socks, and spraying clothing with 0.5 permethrin or an application of repellents containing *N,N*-diethyl-m-toluamide (DEET). Health care workers who treat patients with crusted scabies should wear protective gowns and gloves. Close contacts with patients with scabies should be treated even if they are asymptomatic. Bedding and clothing should be washed with hot soapy water. Combs and brushes belonging to patients infested with lice should be disinfected in hot water (65°C) for 5-15 min or soaked in insecticide for at least one hour. Clothing and bedding may be deloused by washing in hot water and drying in a clothing dryer at 65°C for 30-45 min or by fumigation with insecticide. Thorough cleaning of carpets, furniture, curtains, and other fabrics may reduce house mites. Fleas may be killed by spraying or dusting their nesting sites with insecticide. Myiasis risk may be reduced by good hygiene, including washing with soap and water after horseback riding or fly exposure. Openly draining wounds should be cleaned and dressed regularly. Wearing protective clothing reduces the risk of infestation by land or aquatic leeches.

## ARTHROPOD STINGS & BITES

### Essentials of Diagnosis

- Bees and hornets: painful wheal, flare, edema, history of exposure
- Ants: vesiculopustule, history of exposure
- Brown recluse spider: slowly healing necrotic ulcer, history of exposure
- Black widow spider: fang marks, severe painful muscle cramps, history of exposure
- Scorpions: most species—painful wheal, flare, edema, history of exposure; *Centruoides sculpturatus*—painful wheal, flare, salivation, lacrimation, severe painful muscle cramps, cranial nerve palsy, history of exposure

## General Considerations

Arthropods are ubiquitous pests. The most common arthropod bite of humans is by mosquitoes. Mosquitoes are the vectors for many life-threatening infectious diseases, such as malaria, yellow fever, and viral encephalitis. These infections are discussed elsewhere in this book (see [Chapters 80](#) and [89](#)). This chapter reviews arthropod stings and bites that envenomate or produce local trauma. [Table 91-2](#) lists the common arthropods that sting or bite humans. [Box 91-3](#) summarizes the signs and symptoms associated with arthropod stings and bites.

**A. Hymenoptera sting.** The order *Hymenoptera* includes aphids (bees and bumblebees), vespids (wasps, hornets, and yellow jackets), and ants. Their venoms contain numerous peptides and enzymes that cause localized and systemic reactions. Although the stings are painful and death may occur as a result of multiple stings, most fatalities are the result of hypersensitive anaphylactic reactions. Honeybees and bumblebees attack when their colony is disturbed, lose their stinger during envenomation, and then die. African honeybees (killer bees) were introduced into Brazil in the 1950s, have migrated progressively northward, and now inhabit the southern United States. These bees are highly aggressive, swarm, and may attack without provocation, often inflicting a large number of stings before the victim can escape. Rarely, human death has resulted from killer bee attacks.

Common vespids include yellow jackets, which are distinguished by bright yellow and black abdominal bands, and hornets, which are usually black, brown, or grayish color. Vespids feed on decaying vegetative material, garbage, and especially foods and liquids containing sugar. Vespids become aggressive in late summer and fall when most stings occur. Vespids do not lose their stingers during attack.

The compositions of venom from aphids and vespids vary among species. Toxins include histamine, acetylcholine, kinens, and numerous enzymes such as hyaluronidase phospholipases. Uncomplicated stings cause immediate pain, wheal, and flare reaction and local edema, which subside over a few hours. Multiple stings (100-500) may cause constitutional symptoms, hypotension, generalized edema, rhabdomyolysis, hemolysis, and death. Approximately 0.5%-5% of individuals in the United States have immediate type hypersensitivity and are at risk for mild to life-threatening anaphylaxis.

Ant bites are extremely common in the United States and worldwide. Fire ants are aggressive, red-colored ants that inhabit the southern United States. They excavate areas in fields and urban areas and, when disturbed, mobilize huge numbers of attacking ants that may inflict thousands of stings on a single person. Many other species of ants inhabit the United States, and all that are large enough and capable of biting humans when provoked. Ant venom contains proteins, enzymes, and cytotoxic hemolytic piperidines. The bite is followed by immediate pain, wheal, and flare and then by the formation of a pustule, which ulcerates and may become secondarily infected. Anaphylactic reactions to ant stings occur in ~ 0.5%-2% of sensitized individuals.

**B. Spider bites.** There are > 30,000 species of spiders but < 100 of these have fangs large enough to bite and envenomate humans. Spider venom is intended to immobilize and digest its prey and, when injected into humans, may cause local pain, tissue

necrosis, or systemic toxicity. Two species of spiders in the United States are dangerous to humans—the brown or fiddle spider (*Loxosceles* spp.) and the widow spider (*Latrodectus* spp.).

The brown recluse spider (*L. reclusa*) and at least four other species of *Loxosceles* are distributed throughout the United States and abroad. The brown recluse spider is a species that most commonly bites humans in the United States. This shy spider is 7-20 mm in body length and 2-4 cm in leg span. It has a characteristic dark violin-shaped spot on its dorsal surface. The spider emerges at night to hunt. Usually, it inhabits dark areas, such as basements, closets, attics, clothing, bed clothing, and other similar areas. Bites occur when the spiders are threatened or are involuntarily pressed against the skin such as may occur during sleep or while dressing. Initially, the bite is usually painless or may cause mild stinging. Complex toxins include proteolytic enzymes that cause necrosis. Of these, sphingomyelinase B is the most potent and results in vascular thrombosis and extensive local necrosis. Within hours after the bite, the area becomes painful and pruritic with induration surrounded by a zone of pale ischemia surrounded by erythema. Most lesions resolve spontaneously within a few days. In severe cases, the central area becomes hemorrhagic and necrotic with the formation of a bulla. The bulla ulcerates to form an eschar that leaves a large area of necrosis. Healing may take months to years and may require skin grafting. Rarely, severe systemic reactions including hemolytic anemia and renal failure may occur.

The female widow spider bite envenomates a potent neurotoxin. The black widow (*L. mactans*) is widely distributed throughout the United States (except Alaska) and is most prevalent in the southeast. The spider measures ~ 1 cm in body length and 5 cm in leg span, is shiny black, and has a red-orange hourglass on the ventral abdomen. The black widow webs are most often located in dark places, such as garages, barns, and outdoor privies. The spider bites when the web is disturbed or the spider is provoked. The initial bite may be painless or feel like a pinprick. Two small erythematous red fang marks are visible. The venom does not produce local necrosis. Alpha-latro toxin is the most active toxin, and it binds irreversibly to nerves and causes release and depletion of acetylcholine, norepinephrine, and other neurotransmitters. Painful muscle cramps develop in the area ~ 30-60 min after the bite. Severe pain, muscle cramps, and rigidity may become generalized and may be accompanied by tachycardia, hypertension, muscle weakness, urinary retention, and, in extreme cases, paralysis, respiratory arrest, and rhabdomyolysis. Pain and muscle rigidity usually begin to subside within 12-24 h but may recur over the next days to weeks before resolving.

Tarantulas are large, hairy, nonaggressive spiders that have become popular pets. When threatened, they may bite their owners. Their bite is similar to that of a bee sting, causing localized pain and swelling.

**C. Scorpion stings.** Scorpions are crablike creatures that are widely distributed throughout the United States. They are nocturnal, emerge at night to hunt, and sting with their mobile tail stinger when provoked. Among the > 40 species of scorpions in the United States, only the bark scorpion (*Centruroides sculpturatus*) is potentially lethal. Stings by other species cause symptoms similar to those of bee stings. Anaphylaxis may occur in previously sensitized individuals.

*C sculpturatus* inhabits the southwestern United States and northern Mexico. Scorpions are ~ 7 cm in length and are yellow-brown. Envenomation is with a neurotoxin that affects sodium channels, resulting in nerve excitation. Symptoms include pain and hyperesthesia at the bite, which may progress to cranial and skeletal nerve hyperexcitability, muscle cramps and twitching, increased lacrimation, salivation, and hypertension. In severe cases, respiratory paralysis, rhabdomyolysis, and death may occur. Symptoms maximize within 6 h and usually subside within 1-2 d, but pain and paresthesias may persist for weeks.

## Differential Diagnosis

The pustular ulcerative lesions resulting from ant bites resemble impetigo in children. Severe abdominal pain and abdominal muscle rigidity caused by a black widow spider bite must be differentiated from acute abdominal syndromes such as pancreatitis or peritonitis. However, in black widow spider bites, the abdomen is nontender to palpation. The muscle twitching and cramping from black widow spider and *C sculpturatus* scorpion bites may be confused initially with early tetanus. The increased salivation and hyperexcitability after *C sculpturatus* envenomation may resemble rabies.

## Treatment

Treatment of arthropod stings and bites is outlined in [Box 91-4](#). Administration of antihistamines, topical corticosteroids, and antimicrobial agents for secondary bacterial infection are general therapeutic measures for symptomatic arthropod stings. Anaphylaxis is treated by the administration of subcutaneous or, in severe cases, intravenous epinephrine, fluid resuscitation, bronchodilators, and, if necessary, endotracheal intubation and vasopressors. Patients with a history of severe allergy or anaphylaxis associated with insect stings should carry commercially available kits to treat anaphylaxis and other serious reactions when engaging in activities that place them at risk of arthropod exposure. Desensitization injections reduce the risk of recurrent anaphylaxis in hypersensitized individuals for bee and hornet stings.

## Prognosis

The prognosis for most individuals after arthropod stings is excellent. Most deaths result from anaphylaxis. Deaths are rare in treated patients envenomated by brown recluse spiders, black widow spiders, or *C sculpturatus* scorpions.

## Prevention

Spraying insecticides in dark areas inhabited by spiders reduces the risk of exposure. When camping outdoors, individuals should check their shoes, backpacks, and sleeping bags for scorpions.

## BOX 91-1. Signs and Symptoms of Ectoparasitic Infestation

### Ectoparasite (infestation)

#### Ticks

#### More Common

- Pruritic papulonodule, erythema
- Eschar

#### Less Common

- Fever, malaise, myalgias, paralysis

#### Mites (scabies)

- Erythematous, pruritic maculopapular rash
- Pruritic erythematous burrows

- Crusted thick keratotic lesions, scaling, dystrophic nails

#### Lice

- Head: crusted, pruritic oozing lesions, matted hair
- Body: pruritic, erythematous maculopapular rash
- Pubic: pruritic maculopapular bluish lesions

- Blepharitis

#### Fleas

- Pruritic, erythematous papules, urticaria

- Vesicles, anaphylaxis

#### Flies (myiasis)

- Maggots in furuncles, wounds, or body cavities
- Creeping dermal myiasis
- Secondary bacterial infection

#### Leeches

- Shallow bleeding ulcers

- Sepsis secondary bacterial infection from *Aeromonas hydrophila*

---

## BOX 91-2. Treatment of Ectoparasitic Infestation

### Ectoparasite (infestation) and patient group

	First Choice	Alternative <sup>1</sup>
Ticks (tick paralysis)	See text for treatment of local reactions; remove tick	
Scabies (mites) Immunocompetent patients Immunosuppressed patients (AIDS)	5% Permethrin cream from chin to toes; remove 8 h later with soap and water; repeat in 1 week. Safe for children > 2 mo old. Do not use during pregnancy. Permethrin as above, on day 1; then 6% salicylic acid on days 2-7; then repeat cycles for 3 weeks	Ivermectin, 200 µg/kg, single oral dose
Lice	1% Permethrin to hair, body, or pubic areas kills lice and eggs; comb hair with nit comb after rinsing hair. See text for clothing treatment	0.5% Malathion is less effective. 1% Lindane is less effective and more toxic
Fleas Myiasis Leeches	See text for symptomatic therapy	

<sup>1</sup>Blank fields, No suitable alternative available.

### BOX 91-3. Signs and Symptoms of Arthropod Stings and Bites

#### Arthropod

*Hymenoptera* (bee, wasp, hornet, yellow jacket, ant)

Ant

Spider

Brown recluse

(*Loxosceles reclusa*)

Black widow

(*Latrodectus mactans*)

Scorpion

Most scorpions

*C sculpturatus*

#### More Common

- Immediate pain, wheal, flair

- Immediate pain, erythema, edema, vesicle, pustule

- Minimal initial pain

- Later pain, pruritic lesion central induration surrounded by zones of ischemia, erythema

- Hemorrhagic neurosis, eschar necrosis

- Minimal initial pain, two erythematous fang bites, painful muscle cramps

- Immediate pain, wheal flair erythema, edema

- Pain, paresthesia, muscle cramps, twitching, profuse salivation

#### Less Common

- Anaphylaxis

- Extensive necrosis

- Myalgias, nausea, vomiting, hemolytic, anemia, death

- Extreme rigidity, rhabdomyolysis, respiratory arrest, death

- Anaphylaxis

- Cranial nerve or muscle paralysis, rhabdomyolysis, respiratory arrest, death
