Preface

In the past three decades, enormous strides have been made in our understanding of the relationships between inflammation, immune responses, and degenerative human diseases. Neuroinflammation has grown from a tiny beginning to its current status as the largest field of brain research. Its growth continues to be rapid so this dominance will continue to expand. The field commenced with the obscure identification of activated microglia in the brains of Alzheimer's disease cases. A grant application of ours to the Canadian government to explore the ramifications of this finding was turned down with the terse comment: "This hypothesis is ridiculous!"

To grasp the dimensions of growth in this field, and to gain a perspective of future opportunities, today's neuroscientists only need to read this volume from cover to cover. The developing information has mostly appeared in specialty journals that have dealt only with isolated aspects of these tightly related fields. As a result, contemporary scientists have had a difficult time finding sources, even in review articles, that provide an integrated picture. This updated volume, by assembling chapters that demonstrate the relationship between these historically separated fields, overcome that difficulty. There are 56 chapters which cover a broad spectrum of topics on immunology of the nervous system. Included are diseases that result from immunological dysfunction, current therapeutic approaches, and prospects for the future. Overall, it integrates cutting-edge neuroscience, immunology, pharmacology, neurogenetics, neurogenesis, gene therapy, adjuvant therapy, nanomedicine, pharmacogenetics, biomarkers, proteomics, and magnetic resonance imaging. It is a rich harvest and readers will gain a perspective that has not previously been so readily available. Exposure to such a wealth of ideas is bound to inspire readers to undertake new and productive research initiatives.

The modern era of research into neuroinflammation and its relationship to neurodegenerative diseases began in the 1960s with the elaboration by Ralph van Furth of the monocyte phagocytic system. He injected labeled monocytes into animals and followed their migration and maturation into resident phagocytes in all body tissues. This provided a closure between Metchnikoff's 1882 discovery of mesodermal attack cells in starfish larvae, which he named phagocytes, and del Rio Hortega's 1919 discovery of phagocytic mesodermal cells entering the brain, which he named microglia. Hortega's results had always been questioned, and for more than two further decades, the controversy continued as to whether microglia were truly phagocytes of mesodermal origin or were merely typical brain cells of epidermal origin. Resolving the controversy required development of the techniques of immunohistochemistry and monoclonal antibody production. These tools for exploring brain biochemistry at the cellular level opened new vistas for understanding brain functioning and the pathogenesis of human disease. Using these tools, our laboratory and that of Joseph Rogers in Sun City at that time demonstrated that HLA-DR was strongly expressed on activated microglia. The identification of HLA-DR, a well-known leukocyte marker displayed by antigen-presenting cells, on these cells vindicated both Hortega and van Furth. The way was paved for many productive investigations exploring the properties of microglial cells and their relationship to inflammation and immune responses. This example of a conjunction between a fundamental concept and technical advances to establish its validity has been repeated many times since, as the chapters in this volume illustrate.

For a time, the concept that the brain is immunologically privileged held sway among neuroscientists. This was based on a narrow view that only the invasion of brain by lymphocytes could be taken as evidence of an inflammatory response. But immunohistochemistry, coupled with newly developed molecular biological techniques, revealed that a spectrum of inflammatory mediators, including many known to cause tissue damage, was produced within the brain by resident brain cells. These discoveries required entirely new interpretations as to the nature of neuroinflammation and its relationship to immune responses. The innate immune system, operating at the local level in brain, has clearly proved to be the first line of defense. Indeed, the basic discoveries from studying the response of the brain in a variety of neurological diseases are causing a reevaluation of a number of peripheral degenerative disorders where innate immune responses, which had previously been ignored, have been shown to play a critical role in their pathogenesis. In other words, those studying the brain are providing immunologists with revolutionary new concepts regarding classical peripheral diseases. The insights of this volume need to be interpreted in this broader context.

Major neurologic disorders and details of their pathobiology are presented as individual chapters. They involve disorders where innate immune responses predominate, as in Alzheimer's disease, to others such as multiple sclerosis, where adaptive immune responses predominate, and others which seem to involve both. We have suggested that diseases involving self-damage generated by innate immune responses be defined as autotoxic to differentiate them from classical autoimmune diseases where self-damage is generated by adaptive immune responses. The common theme, however, is the involvement of microglia as the effector cells.

Genetics is well covered. It is a rapidly moving field. The methodology for linking familial disease to DNA mutations commenced in the late 1970s through identification of restriction fragment-linked polymorphisms. By 1983, when James Gusella and his colleagues demonstrated a linkage of the G8 fragment to Huntington disease, only about 18 markers were known. Now over 1,500,000 single-nucleotide polymorphisms have been localized so that every centimorgan of the human genome can be explored. This advance has been coupled with rapid methods for sequencing DNA. The report on genetics must be regarded as the tiny tip of a giant iceberg where much below the surface will soon be revealed.

The ultimate objective of neuroscientists studying human disease is to find more effective treatments. Part 3 covers the pharmacology of existing drugs, as well as describing approaches now in clinical evaluation, and those still at the bench level. Some of these include concepts that depart from established therapeutic approaches, giving the reader much food for thought.

There is an important chapter on the new field of biomarkers. Biomarkers have established that neurodegenerative disorders such as Alzheimer's disease commence at least a decade before clinical signs develop. A window of opportunity is opened up where early anti-inflammatory intervention can arrest disease progression and abort disease development. This can be combined with brain imaging to measure objectively the effects of therapeutic agents in diseases where progressive brain degeneration occurs.

In summary, this is a volume not to be put on the shelf as a reference text, but to be read cover to cover by aspiring neuroscientists.

Introducing Neuroimmune Pharmacology

Neuroscience, immunology, and pharmacology are each of and by themselves broad disciplines that, without argument, impact upon a large component of what we come to know as biomedical science (Elenkov et al. 2000; Gendelman 2002; Holzer et al. 2015; McGeer and McGeer 2004). Each, by themselves and even more so when put together, is multidisciplinary and require, for the student, both a broad knowledge and deep understanding of molecular and cellular biology, neuroimmunity, the functional blood–brain barrier, neurochemistry, neuroinfectious and neurodegenerative disorders, cancer, and neurodevelopment. For many, it is considered a branch of immunology, but that is a start point as the field bridges investigations of drug action and development with nervous system biology and disease pathogenesis. To those engaged in this field, linking of the disciplines is ever more challenging as when they are joined, they come interactive. The bridges between disciplines are what we now call multidisciplinary science and require another level of insight. However, we posit that each need be first understood as a single entity. To this end, we forged chapters that cover the structure, function, and biology of each of the fields independent of one another. Then step-by-step they are each combined one with the other to form the basis of our engagement with the environment, to disease and a means to restore homeostasis by protective immune and pharmacologic means. Indeed, drugs that include immune modulators can certainly influence organ function, aging, and tissue homeostasis and improve clinical outcomes.

Indeed, a special feature of “humankind” among other species is the presence of an extraordinary complex immune system that can be used to protect against a plethora of harmful microbial pathogens, including viruses, bacteria, and parasites, as well as abnormal cells and proteins (Petranyi 2002; Obermeier et al. 2016). This underlies the complexity of the human genome which encodes expansive immune-related genes not found in lower species (Hughes 2002). When the immune system is compromised, disease occurs and often does with ferocity; a wide range of clinical manifestations ensue that follows as a consequence of neurodegenerative, psychiatric, cancer, and infectious diseases, or those elicited by the immune system’s attack on itself. The latter is commonly referred to as “destructive” autoimmunity (Christen and von Herrath 2004). Interestingly enough, the immune system may sometimes be an impediment to therapy. Indeed, modulating its function is required for long-term and successful organ transplantation (Samaniego et al. 2006; Horst et al. 2016). On balance, modulation of the immune system can affect “neuroprotective” responses for certain diseases (Anderson et al. 2014).

Like the immune system, the nervous system contains surveillance functions and also possesses a number of functional roles that include mentation, movement, reasoning, sensation, vision, hearing, learning, breathing, and most behaviors. The nervous system includes defined tissue structures such as the brain, spinal cord, and peripheral nerves. On the cellular level, it includes networks of nerve cells with a variety of functional activities; complex networks and communications; supportive and regulatory cells, called glia; and a protective barrier that precludes the entry of a variety of macromolecules, cells, and proteins. It also possesses connections throughout the body that permits it function. Neuroscience is the discipline used to explore each of the nervous system regions and cells that include their networks and modes of communication in health and disease. As humans, we have ~100 billion neurons that are each

functional units contained within the nervous system. Molecular and biochemical studies along with cell and animal systems were each used alone and together to explore and define neural biology. The task of neurosciences is to better understand the brain's function in the context of ontogeny, organism development, and aberrations during disease. Neuroscience is an interdisciplinary field and evolved as such during the past quarter-century. It includes neurobiology, neurochemistry, neurophysiology, mathematics, psychology, computer neuroscience, and learning and behavior. It also included the field of immunology (Sehgal and Berger 2000). In a historical context, the brain, for a long time, was considered an immune-privileged organ, meaning that its protective shield or barrier, commonly termed the blood–brain barrier, served to protect, defend, and as a consequence exclude ingress of toxins, cells, and pathogens (Streilein 1993; Becher et al. 2000). This has undergone a reassessment of purpose (Louveau 2015). Nonetheless, this is balanced by the fact that resident inflammatory cells do exist inside the brain and are capable of producing robust immune responses. In recent years, we have come to accept that it is the mononuclear phagocytes (MP; perivascular macrophage and microglia) that are disease perpetrators, while the astrocyte serves as “supportive” and “homeostatic” in nurturing neurons and in protection against the ravages of disease (Gendelman 2002; Simard and Nedergaard 2004; Trendelenburg and Dirnagl 2005). The neuron in this neuroimmune model is the passive recipient of the battles that rage between the MP and the astrocyte. Findings that have emerged over the past half-decade have challenged this model. We now know that dependent upon environmental cues and disease, microglia, astrocytes, and other neural cell elements including endothelial cells and oligodendrocytes possess immunoregulatory functions. We also know that microglia and astrocytes dependent upon the environment and stimuli can be supportive, destructive, or both. Even more importantly, neurons can secrete immunoregulatory factors and engage directly into cell–cell–environmental cue stimulations. To make the system perhaps even more complex, local neuroimmune processes can result in the recruitment of T cells and enticement of the adaptive immune response, significantly affecting disease outcomes (Olson and Gendelman 2016). All in all, things appear more complex than once thought even in the past decade.

These three disciplines and the complexities inherent in each academic field is perhaps the most multidisciplinary, serving to bring scientists and clinicians together with knowledge of neurobiology, immunology, pharmacology, biochemistry, cellular and molecular biology, virology, genetics, gene therapy, medicinal chemistry, nanomedicine, proteomics, pathology, and physiology. Even more than immunology and neuroscience, pharmacology integrates a broad knowledge in scientific disciplines, enabling the pharmacologist a unique perspective to tackle drug-, hormone-, immune-, and chemical-related pathways as they affect human health and behavior. Drug actions and therapeutic developments form the basis of such discoveries, but the central understanding of how they act provides vision for further research to improve human well-being and health.

This textbook is unique in scope by serving to investigate the intersection of this new discipline. Neuropharmacologists study drug actions including neurochemical disorders underlying a broad range of diseases such as psychiatric disorders (e.g., schizophrenia and depression) and neurodegenerative diseases (e.g., Alzheimer's and Parkinson's diseases). Drugs can also be used to examine neurophysiological or neurobiochemical changes as they affect brain, behavior, movement, and mental status. Immunopharmacology seeks to control the immune response in the treatment and prevention of disease. Research does include immunosuppressant agents used in organ transplant as well as developing agents that affect bone marrow function and cell differentiation in cancer therapies.

What then defines the field of *neuroimmune pharmacology*? Is it simply a field that intersects the three disciplines of neuroscience, immunology, and pharmacology in seeking to better define the epidemiology, prevention, and treatment of immune disorders of the nervous systems (Fig. 1)? Are these disorders limited in their scope in affecting behavior, cognition, motor, and sensory symptoms, or do they also involve developmental and degenerative disorders? It is clear that the immune system is linked, in whole or in part, to diseases that develop

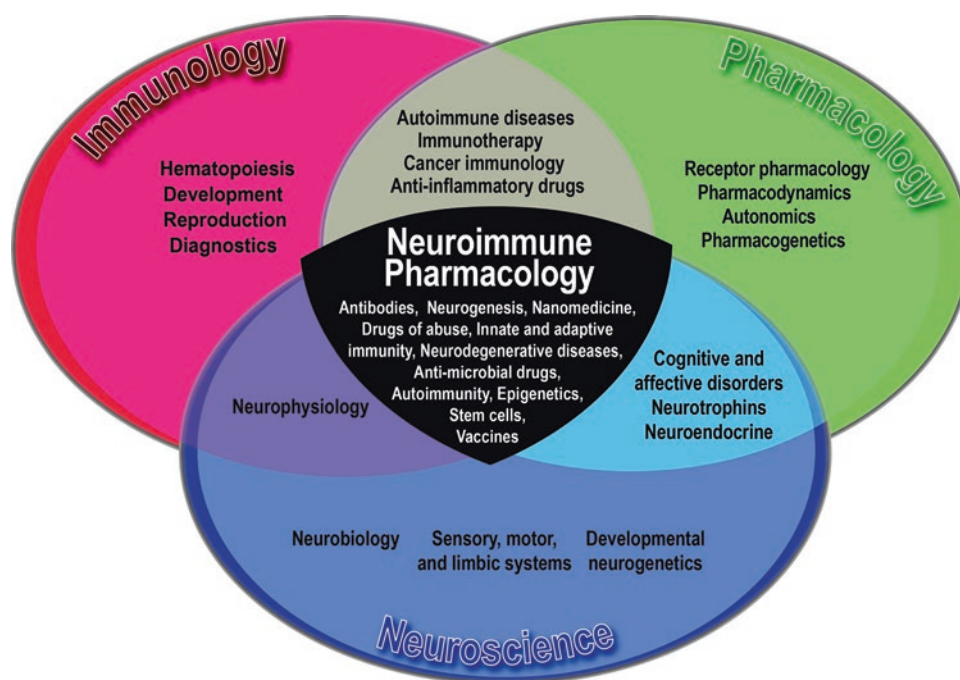

Fig. 1 This Venn diagram pictorially represents the fields of immunology, pharmacology and neuroscience with common elements overlapping into the discipline of neuroimmune pharmacology. The blackened area depicts the diseases and research areas covered in this book and integral to the field of study

as a consequence of genetic abnormalities and a broad range of environmental cues (including microbial infections and abused drugs) and to toxins. So, where does neuroimmune pharmacology find its niche? These can occur, in part, as a consequence of neuropeptides, neurotransmitters, cytokines, chemokines, and abused drugs. Like much in science, we are left with more questions than answers. In the end, we seek avenues for translational research and better understanding of disease mechanisms. Diseases are together linked to microbial agents, by inflammatory processes, by emergence of cancerous cells or tumors, by stress, by environmental cues, and by genetic disturbances. No matter the cause, harnessing the immune processes for pharmacological benefit will, at days end, provide “real” solutions to positively affect some of the most significant and feared disorders of our century.

What do we seek to accomplish by editing such a textbook? First, we would be remiss in not acknowledging the pivotal discoveries made by others when research fields intersect. These include the discovery and characterization of the guanosine triphosphate (GTP) binding and prion proteins (Gilman 1995; Rodbell 1995; Prusiner 1998, 2001), neurotransmission and memory functions (Carlsson 2001; Greengard 2001; Kandel 2001), and odorant receptors (Buck 2000; Axel 2005). We posit that new discoveries can and will be made through the intersections of neuroscience, immunology, and pharmacology and as such sought to define it for the student. The notion that inflammation contributes in significant manner to neurodegeneration and significantly beyond autoimmune diseases is brought front and center and demonstrated without ambiguity for multiple sclerosis, peripheral neuropathies, Alzheimer’s and Parkinson’s disease, and amyotrophic lateral sclerosis as well as for microglial infections of the nervous system including NeuroAIDS where microglial activation is central to disease processes (Hooten et al. 2015; Appel et al. 1995; Toyka and Gold 2003; McGeer and McGeer 2004; Ercolini and Miller 2005; Gendelman 2002; Gendelman and Mosley 2015). Perhaps most importantly, we have laid the groundwork for how the immune system can be harnessed either through its modulation, through altering blood–brain barrier integrity and function, or by drug-delivery strategies that target the brain. This second edition will add on to the success

of the first edition with additional chapters on emerging topics, including but not limited to enteric nervous system, microbiota, innate immunity signaling, exosomes, stress granules, microRNA, autism spectrum disorders, traumatic brain injury, biomarkers, macromolecular therapeutics, and “omics” pharmacology.

No doubt this textbook is an expansive read for the student and scholar alike. To this end, we are humbled by its realization and even more so during this second edition. These words lay only the beginnings to what we believe will be a significant future footprint into the integration between neuroscience, immunology, and pharmacology.

Acknowledgments

These comprehensive volumes would not have been possible without the tireless, dedicated, and determined effort of one very special person, Reed Felderman. Reed is skillful, resourceful, and enthusiastic. Any task offered was never too minor and never left unattended. The linkages between editors, authors, administrators, and publishers flowed seamlessly. He quickly rose to the task of managing editor with aplomb, and it was his attention to detail that was singularly responsible for the success of this text.

Gregory Baer and his staff at Springer USA are already trusted friends, colleagues, and publishing visionaries. Their leadership together with Ms. Robin Taylor and our administrative staff at our own University of Nebraska Medical Center and Boston University School of Medicine has and continues to be a foundation for all we've done and for this textbook, for our *Journal of Neuroimmune Pharmacology* and beyond. We are lucky to have them as partners in this endeavor and so appreciate being able to continue to work with such talented individuals who are so dedicated to the pursuit of excellence.

To our leaders and visionaries, Jeffrey Gold, Harold Maurer, Donald Leuenberger, Dele Davies, and Deb Thomas, a simple thank you is clearly inadequate for all you have done to ensure the success of our mission and so many of our endeavors. To Carol Swarts, a friend, a colleague, a confidant, and a soul mate whose gifts of time and person ensure our sustained academic successes: Carol, you have no parallel. To Susan Leeman, the pioneer of molecular biology in neuroinflammation, our mentor and a friend who always navigate our neuroinflammation research. Your contribution to science is immeasurable. Thank you all for keeping the fire burning very bright for all we do. To Harriet Singer, Frani Blumkin and Jim Roubal who have been steadfast in support for so many years. Your faith in our research and unquestioned faith strengthens us each and every day.

To our chapter contributors and reviewers whose expertise, knowledge, intellect, and dedications proved invaluable in completing the tasks.

To Seiko Ikezu and Bonnie Bloch, our partners in life, life journeys, and always best friends.

To Yohei and Michiko Ikezu and Soffia Gendelman, our parents, navigators, and role models.

To Yumiko Aoyama, for her continuous support of family and friendship, a simple thank you is nearly inadequate.

To our children and grandchildren who are all our life treasures: Clark and David Ikezu and Sierra, Jason and Sacha Tobias and Adam and Jen Wolf-Gendelman and Lesley Gendelman and Emma Ehrenkranz.

We salute *the Journal of Neuroimmune Pharmacology* that provided and continues to be the source of inspiration for this work. To a special friend, Joel Alperson, for the gift of his ears and to our patients, students, mentors, and colleagues who inspire and guide us always, thank you all so much.

48 New Generation of Adjuvants for Protection Against Disease and to Combat Bioterrorism.....	819
Sam D. Sanderson, Joseph A. Vetro, and Bala Vamsi Krishna Karuturi	
49 Medicinal Chemistry and Brain Drug Penetration	831
James Hilaire and Howard E. Gendelman	
50 Polymer Nanomaterials for Drug Delivery Across the Blood Brain Barrier	847
Alexander V. Kabanov and Elena V. Batrakova	

51 Macromolecular Therapeutics: Development and Delivery Engineering	869
Gang Zhao, Xin Wei, and Dong Wang	
52 Application to Gene Therapy and Vaccination	885
Xiaomin Su, William J. Bowers, Michelle C. Janelins, and Howard J. Federoff	
53 Introduction to Imaging in the Neurosciences	907
Michael D. Boska and Matthew L. White	
54 Proteomics and Genomics in Neuroimmunological Disorders	941
Maire Rose Donnelly, Wojciech Rozek, and Pawel S. Ciborowski	
55 Pharmacogenomics of Neurodegenerative Diseases: Roles in Personalized Medicines	959
Ruby E. Evande, Rinku Dutta, Chalet Tan, Jean L. Grem, and Ram I. Mahato	
56 Control of Neuroinflammation for Therapeutic Gain	971
Howard E. Gendelman and Eric J. Benner	
Glossary	979
Index.....	1007

Abbreviations

¹ H	Proton
¹ H-MRSI	Proton magnetic resonance spectroscopic imaging
2D SDS-PAGE	Two-dimensional polyacrylamide gel electrophoresis
3'UTR	3'-Untranslated region
3HK	3-Hydroxykynurenine
5-ASA	5-Aminosalicylic acid
5-HIAA	5-Hydroxyindole acetic acid
5-HT	5-Hydroxy tryptophan
5-HT	5-Hydroxytryptamine
6-OHDA	6-Hydroxydopamine
8-OHdG	8-Hydroxy-2'-deoxyguanosine
γc	Common γ-chain
AAAD	Aromatic L-amino acid decarboxylase
AAV	Adeno-associated virus
Ab	Antibody
Aβ	Amyloid-β
ABD	Adamantiades-Behçet's disease
ABP	Actin-binding protein
AC	Anterior chamber
ACAID	Anterior chamber-associated immune deviation
αCamKII	α-Calcium/calmodulin-dependent protein kinase II
ACh	Acetylcholine
AChE	Acetylcholinesterase
ACTH	Adrenocorticotrophic hormone (pro-opiomelanocortin; POMC)
AD	Alzheimer's disease
ADHD	Attention deficit hypersensitivity disorder
ADI	Acceleration/deceleration injury
ADAM	A disintegrin and metalloprotease
ADCC	Antibody-dependent cellular cytotoxicity
ADEM	Acute disseminated encephalomyelitis
AF	Activation factor
Ag	Antigens
AGE	Advanced glycation end products
AGM	Aorta-gonad mesonephros
AHSCT	Autologous hematopoietic stem cell transplantation
AICA	Anterior inferior cerebellar artery
AID	Activation-induced (cytidine) deaminase
AIDP	Acute inflammatory demyelinating polyradiculoneuropathy
AIDS	Acquired immunodeficiency syndrome
AIF	Apoptosis inducing factor
AIR	Autoimmune retinopathy
AIRE	Autoimmune regulator

AIS	Anterior chamber-associated immune deviation (ACAID)-inducing signal
ALR	AIM2-like receptors
ALS	Amyotrophic lateral sclerosis
AMAN	Acute motor axonal neuropathy
AML	Acute myeloid leukemia
AMN	Adrenomyeloneuropathy
AMPA	α -Amino-3-hydroxy-5-methylisoxazole-4-propionic acid
AMSAN	Acute motor-sensory axonal neuropathy
ANG	Angiotensin II
ANI	Asymptomatic neurocognitive impairment
ANS	Autonomic nervous system
AP	Area postrema
AP-1	Activating protein-1
APAF 1	Apoptotic peptidase activating factor 1
APC	Antigen-presenting cells
aPKC	Atypical protein kinase C
aPL	Antiphospholipid antibody
APO1	Apoptosis antigen 1 (Fas/CD95)
apoE	Apolipoprotein E
APP	Amyloid precursor protein
APPs	Acute phase proteins
AQP4	Aquaporin-4
ARE	AU-rich response element
ARMD	Age-related macular degeneration
ART	Antiretroviral therapy
ASD	Autism spectrum disorders
ASL	Arterial spin-labeled
ASTIN	Acute stroke therapy by inhibition of neutrophils
AT	Adoptive transfer
ATL	Adult T cell leukemia
ATON	Atacicept in optic neuritis
ATP	Adenosine triphosphate
AVE	Anterior visceral endoderm
AVG	Anti-viral granule
AVP	Arginine vasopressin
AV3V	Anteroventral third ventricular
AZT	3'-Azidothymidine/zidovudine
BACE	Beta-site amyloid precursor protein cleaving enzyme
BBB	Blood-brain barrier
BBMEC	Bovine brain microvessel endothelial cells
BCR	B-cell receptor
BCRP	Breast cancer resistance protein
BCSFB	Blood-CSF barrier
BD	Bipolar disorder
BDNF	Brain-derived neurotrophic factor
bFGF	Basic fibroblast growth factor (FGF2)
bHLH	Basic helix-loop-helix
BHV-1	Bovine herpesvirus-1
BLBP	Brain lipid binding protein
BLIMP-1	B lymphocyte-induced maturation protein-1
BLV	Bovine leukemia virus
BM	Bone marrow
BMDM	Bone marrow-derived macrophages

BMP	Bone morphogenetic protein
BMVEC	Brain microvascular endothelial cell
BP	Biological processes
BrdU	Bromodeoxyuridine
BRMs	Biological response modifiers
BSE	Bovine spongiform encephalopathy
BTLA	B and T lymphocyte attenuator
C/EBP	CCAAT box/enhancer binding protein
C3d	Complement C3 fragment d
C4d	Complement C4 fragment d
CA	Cornu ammonis
CA II	Carbonic anhydrase II
CaMKII	Calcium/calmodulin-dependent protein kinase II
CAMs	Cell adhesion molecules
CAPS	Cryopyrin-associated periodic syndromes
CAR	Cancer-associated retinopathy
CARD	Caspase recruitment domain
CARD15	NOD2/caspase recruitment domain 15
CB	Cannabinoid
CB1	Cannabinoid receptor 1
CB2	Cannabinoid receptor 2
CBA	Cytokine bead arrays
CBF	Cerebral blood flow
CBF1	C promoter binding factor 1
CBP	cAMP-response element binding protein (CREB)-binding protein
CBV	Cerebral blood volume
CCI	Controlled cortical impact
CCK	Cholecystokinin
CCT	Central corneal thickness
CD	Cluster of differentiation
CD11b	Complement component 3 receptor 3 subunit (integrin alpha M; ITGAM)
CD40L	CD40 ligand (TNFSF5)
CDP	Common DC progenitor
CDR	Complementarity-determining region
CDV	Canine distemper virus
CEP	Carboxyethylpyrrole
CFT	2- β -Carbomethoxy-3 β -(4-fluorophenyl) tropane
cGMP	Cyclic guanosine 5'-monophosphate
CGRP	Calcitonin gene-related peptide
CHAT	Choline acetyltransferase
CHN	Congenital hypomyelinating neuropathy
Cho	Choline
CIDP	Chronic inflammatory demyelinating polyradiculoneuropathy
CINC1	Cytokine-induced neutrophil chemoattractant-1
CIS	Clinically isolated syndrome
CJD	Creutzfeldt-Jakob disease
CLA	Cutaneous leukocyte antigen
CLL	Chronic lymphocytic leukemia
CLP	Common lymphoid progenitor
CMAP	Compound motor action potential
CMC	Critical micelle concentration
CMP	Common myeloid precursor
CMT	Charcot-Marie-Tooth (disease)

CMV	Cytomegalovirus
CNG	cGMP-gated
CNPase	Cyclic nucleotide 3' phosphohydrolase
CNS	Central nervous system
CNTF	Ciliary neurotrophic factor
CO	Cytochrome oxidase
COMT	Catechol- <i>O</i> -methyltransferase
Con A	Concanavalin A
COP-1	Copolymer-1
COX	Cyclooxygenase (prostaglandin-endoperoxide synthase; PTGS)
CP	Choroid plexus
CR	Complement receptor
CRaBP	Cellular retinal binding protein (retinaldehyde binding protein 1; RLBP1)
CRD	Carbohydrate-recognition domains
CRE	cAMP-responsive element
Cre	Creatine
CREB	cAMP-response element binding protein
CRH	Corticotrophin-releasing hormone
CRID	Cytokine release inhibitory drugs
CRP	C-reactive protein
CRPM	Collapsing response mediator protein
CRVO	Central retinal vein occlusion
CSF	Cerebrospinal fluid
CSF-1R	Colony-stimulating factor receptor
CSPG	Chondroitin sulfate proteoglycans
CT	Computed tomography
CTA	Computed tomographic angiography
CTE	Chronic traumatic encephalopathy
cTEC	Cortical thymic epithelial cell (TEC)
CTL	Cytotoxic T lymphocyte
CTLA-4	Cytotoxic T lymphocyte antigen-4
CTP	Circulating T-cell progenitors
CVF	Cobra venom factor
CVO	Circumventricular organ
Cx	Connexin
cyto c	Cytochrome c
D1R	Type-1 family of dopamine receptors
D9-THC	D9-tetrahydrocannabinol
DA	Daniel's strain of Theiler's virus
DA	Dopamine
DAF	Decay-accelerating factor
DAG	Diacylglycerol
DAMP	Danger-associated molecular patterns
DAT	Dopamine transporter (solute carrier family 6A3; SLC6A3)
D β H	Dopamine- β -hydroxylase
DC	Dendritic cells
DCX	Doublecortin
ddC	Dideoxycytidine
ddI	Dideoxyinosine
DG	Dentate gyrus
dGTP	Deoxyguanosine triphosphate
DHA	Docosahexaenoic acid
Dhh	Desert hedgehog

DHP	Dihydropyridine
DIGE	Difference gel electrophoresis
DIRA	Deficiency of IL-1 receptor antagonist
DISC	Death-inducing signaling complex
DM	Diabetes mellitus
DN	Double/dominant negative
DNA	Deoxyribonucleic acids
Doc2	Double C2 protein
DOR	Delta-opioid receptor
Dox	Doxorubicin
Dox	Doxycycline
DR	Dopamine receptors
DRPLA	Dentatorubral-pallidoluysian atrophy
DSI	Depolarization induced suppression of inhibition
DSPN	Distal sensory peripheral neuropathy
DSS	Dejerine-Sottas syndrome
DTH	Delayed-type hypersensitivity
DTI	Diffusion tensor imaging
DTR	Diphtheria toxin receptor
DWI	Diffusion weighted imaging
E2F	Early-region-2 transcription factor
EAE	Experimental allergic/autoimmune encephalomyelitis
EAN	Experimental allergic/autoimmune neuritis
EAU	Experimental autoimmune uveitis
EBV	Epstein-Barr virus
ECT	Electroconvulsive therapy
EDSS	Expanded disability status scale
EEG	Electroencephalography
EGC	Embryonic germ cell
EGF	Epidermal growth factor
EGFR	Epidermal growth factor receptor
EIAV	Equine infectious anemia virus
ELAVL4	Embryonic lethal, abnormal vision, Drosophila-like 4
ELP	Early lymphoid progenitors
eLTP	Early long-term potentiation
ELVIS	Extravasation through Leaky Vasculature and subsequent Inflammatory cell-mediated Sequestration
EMG	Electromyography
EMP	Erythromyeloid progenitors
EndoG	Endonuclease G
EOAD	Early-onset Alzheimer's disease
EPI	Echo-planar imaging
EPR	Enhanced permeability and retention
EPS	Extrapyramidal symptoms
EPSC	Excitatory postsynaptic currents
EPSP	Excitatory postsynaptic potential
ER	Endoplasmic reticulum
ERK2	Extracellular signal-regulated kinase 2
ESC	Embryonic stem cell
ESCRT	Endosomal-sorting complex required for transport
ESI-MS/MS	Electrospray ionization-mass spectrometry/mass spectrometry
ET	Endothelin
ETP	Early T lineage progenitor

EV	Extracellular vesicles
FA	Fractional anisotropy
FAD	Familial Alzheimer's disease
fALS	Familial amyotrophic lateral sclerosis
FasL	Fas ligand (FASLG)
FcγR-1	Fc receptor IgG, high affinity-1
fCJD	Familial Creutzfeldt-Jakob disease
FcR	Fc receptor
FDA	Food and Drug Administration
FDC	Follicular dendritic cell
FDG	Fluorodeoxyglucose
FDOPA	6-[(18)F]fluoro-L-dopa
FFI	Fatal familial insomnia
FGF	Fibroblast growth factor
FID	Free induction decay
FIRE	Febrile infection-related epilepsy syndrome
FIV	Feline immunodeficiency virus
FR	Fractalkine (CX3CL1)
fMRI	Functional magnetic resonance imaging
Foxp3	Forkhead box P3 transcription factor
FPI	Fluid percussion injury
FR	Folate receptor
FRC	Fibroblastic reticular cell
FRS2	Fibroblast growth factor receptor substrate 2
FS	Fisher syndrome
FSH	Follicle-stimulating hormone
FTD	Frontotemporal dementia
FT-ICR	Fourier transformed ion cyclotron resonance mass spectrometry
FTLD	Frontotemporal lobar dementia
FUS	Fused in sarcoma
Fz/PCP	Frizzled/planar cell polarity
GA	Glatiramer acetate
GABA	Gamma-aminobutyric acid
GAD	Glutamate decarboxylase
GalC	Galactocerebroside
GALT	Gut-associated lymphoid tissue
GAP	GTPase activating protein
GAPDH	Glyceraldehyde 3 phosphate dehydrogenase
GBM	Glioblastoma multiforme
GBS	Guillain-Barré syndrome
GC	Germinal center
GCDC	Germinal center dendritic cell
GCL	Ganglion cell layer
GEF	Guanine nucleotide exchange factor
GL	Granular cell layer
GC-MS	Gas chromatography combined with mass spectrometry
G-CSF	Granulocyte colony-stimulating factor
Gd	Gadolinium
GDF	Growth and differentiation factor
GDNF	Glial-derived neurotrophic factor
GDP	Guanosine diphosphate
GEF	GDP-GTP exchange factor
GFAP	Glial fibrillary acidic protein

GFP	Green fluorescent protein
GI	Gastrointestinal
GKAP	Guanylate kinase-associated protein
GLC1A	Chromosome 1 open-angle glaucoma gene
Gln	Glutamine
GLP-1	Glucagon-like peptide-1
GM-CSF	Granulocyte-macrophage colony-stimulating factor
GMP	Granulocyte monocyte precursor
GnRH	Gonadotropin-releasing hormone
GO	Gene ontology
GO	Graves' ophthalmopathy
GPCR	G-protein-coupled receptor
GPI	Glycosylphosphatidylinositol
GR	Glucocorticoid receptor
GRIP	Glucocorticoid receptor-interacting protein
GRO- α	Growth-related oncogene alpha
GSH	Glutathione
GSS	Gerstmann-Straussler-Scheinker disease
GSTO1	Glutathione <i>s</i> -transferase omega-1
GT	G-protein transducing
GTP	Guanosine triphosphate
GUCY	Guanylate cyclase
GWAS	Meta-genome-wide association study
HAART	Highly active antiretroviral therapy
HAD	HIV-associated dementia
HAM/TSP	HTLV-I associated myelopathy/tropical spastic paraparesis
HAND	HIV-associated neurocognitive disorder
HAT	Histone acetyltransferase
HAV	Hepatitis A virus
HBsAg	Hepatitis B surface antigen
HCV	Hepatitis C virus
HCMV	Human cytomegalovirus
HD	Huntington's disease
HDAC	Histone deacetylase
HDLS	Hereditary diffuse leukoencephalopathy with spheroids
HES	Hairy and enhancer of split homolog
HEV	High endothelial venule
HFS	High frequency stimulation
Hh	Hedgehog
HHH	Hypervolemic-hemodilution and hypertensive
HHV-6	Human herpes virus-6
HIV-1	Human immunodeficiency virus type 1
HIVE	Human immunodeficiency virus encephalitis
HLA	Human leukocyte antigen
HLH	Helix-loop-helix
HMG-CoA	3-Hydroxy-3-methylglutaryl coenzyme A
HNE	4-Hydroxy-2-nonenal
hnRNP-A1	Heterogeneous nuclear ribonuclear protein-A1
HPA	Hypothalamic-pituitary-adrenal
HPMA	<i>N</i> -(2-Hydroxypropyl) methacrylamide
HRP	Horseradish peroxidase
HSC	Hematopoietic stem cell
HSC70	Heat shock cognate protein 70

Hsp	Heat shock protein
HSV	Herpes simplex virus
HSVE	Herpes simplex virus-mediated encephalitis
HT	Huntington's disease
HTLV	Human T-cell lymphotropic virus type
HTRA2	High temperature requirement serine protease 2
Htt	Huntingtin
HUVEC	Human umbilical vein endothelial cells
HveA	Herpesvirus entry mediator A
I-1	Regulatory protein inhibitor-1
IBS	Inflammatory bowel syndrome
ICAM	Intracellular adhesion molecule
ICAT	Isotope-coded affinity tags
ICE	IL-1 β -converting enzyme
ICGA	Indocyanine green angiography
ICH	Intracerebral hemorrhage
iCJD	Iatrogenic Creutzfeldt-Jakob disease
ICOS	Inducible co-stimulatory molecule
ICV	Intra-cerebro-ventricular
Id	Inhibitor of differentiation
IDE	Insulin degrading enzyme
IDO	Indoleamine 2,3-dioxygenase
IE	Immediate early
IF	Intermediate filament
IFN	Interferon
Ig	Immunoglobulin
IGF	Insulin-like growth factor
IgG	Immunoglobulin G
IGIV	Immunoglobulin intravenous therapy
Ihh	Indian hedgehog
IIDD	Idiopathic inflammatory demyelinating disease
I κ B	Inhibitory kappa B
IKK	I κ B kinase
IL	Interleukin
IL1RA	IL-1 receptor antagonist
ILBD	Incidental Lewy body disease
ILK	Integrin-linked kinase
ILM	Inner limiting membrane
ILV	Intraluminal vesicles
IM	Intramuscular
IMAC	Immobilized metal affinity chromatography
IMPDH	Inosine monophosphate dehydrogenase
iNKR	Inhibitory natural killer cell receptor
INL	Inner nuclear layer
INO	Internuclear ophthalmoplegia
iNOS	Inducible nitric oxide synthase (NOS2A)
IOP	Intraocular pressure
IP	Interferon-inducible protein
IPC	Intermediate progenitor cells
InsP3R	Inositol 1,4,5-triphosphate receptor
IPL	Inner plexiform layer
IRAK	IL-1 receptor-associated protein kinase
IRBP	Interphotoreceptor retinoid-binding protein

IRF	Interferon regulatory factor
ISCOM	Immunostimulating complexes
ISH	In situ hybridization
IT15	Interesting transcript 15
ITAM	Immunoreceptor tyrosine-based activation motif
ITGAM	Integrin, alpha M
ITR	Inverted terminal repeat
IVDU	Intravenous drug use
IVIg	Intravenous immunoglobulin
JAK	Janus kinase
JEV	Japanese encephalitis virus
JNK	c-Jun N-terminal kinase
KLH	Keyhole limpet hemocyanin
KO	Knockout
KOR	Kappa opioid peptide receptor
KYN	Kynurenine
KYNA	Kynurenic acid
LAK	Lymphokine-activated killer (cell)
L-AP4	L-2-Amino-4-phosphonobutyric acid
LAT	Latency-associated transcript
LAMP	Lysosome-associated membrane protein
LB	Lewy bodies
LC	Locus coeruleus
LCA	Leukocyte common antigen
LC-FTICR MS	Liquid chromatography Fourier transform ion cyclotron resonance mass
LC-MS	Liquid chromatography combined with mass spectrometry
LC-UV-SPE-NMR	Liquid chromatography, UV detection, solid phase extraction, and nuclear magnetic resonance
LD	Linkage disequilibrium
LDL	Low density lipoprotein
LFA-1	Leukocyte function-associated antigen-1 (integrin beta 2; ITGB2)
LGN	Lateral geniculate nucleus
LH	Luteinizing hormone
LIF	Leukemia inhibitory factor
Lingo-1	Leucine-rich repeat and Ig domain containing Nogo receptor-interacting protein-1
LMN	Lower motor neuron
LOAD	Late-onset Alzheimer's disease
LOS	Lipooligosaccharide
LPA	Lysophosphatidic acid
LPBN	Lateral parabrachial nucleus of the pons
LPS	Lipopolysaccharide
LRP-1	Lipoprotein receptor-related protein-1
LRR	Leucine-rich repeat
LRRK2	Leucine-rich repeat kinase 2
LT	Lymphotoxins
LTD	Long-term depression
LTNP	Long-term nonprogressors
LTP	Long-term potentiation
LTR	Long-terminal repeat
LT-bR	Lymphotoxin beta receptor
MCAO	Middle cerebral arterial occlusion
MCI	Mild cognitive impairment

MG	Myasthenia gravis
MHV	Mouse hepatitis virus
mI	Myoinositol
MIF	Migration inhibitory factor
Mint1	Munc-18 interacting protein 1
MIP	Macrophage inflammatory protein
MJO	Machado-Joseph disease
MME	Membrane metalloendopeptidase (neprilysin)
MMP	Matrix metalloproteinase
MMSE	Mini-Mental State Examination
MNGC	Multinucleated giant cell
MnPO	Median preoptic nucleus
Mn-SOD	Manganese superoxide dismutase
MOAT	Multispecific organic anion transporter
MOBP	Myelin-associated/oligodendrocyte basic protein
MOG	Myelin oligodendrocyte glycoprotein
MOI	Multiplicity of infection
MOR	mu opioid receptor
MOSP	Myelin/oligodendrocyte-specific protein
MP	Mononuclear phagocytes
MPA	Mycophenolic acid
MPL	Monophosphoryl lipid A
MPO	Myeloperoxidase
MPO	Medial preoptic area
MAC	Membrane attack complex
MPP	Multipotent progenitors
MPP+	1-Methyl-4-phenylpyridinium
MAdCAM-1	Mucosal addressin cell adhesion molecule-1
MAG	Myelin-associated glycoprotein
MAML	Mammalian mastermind-like
MAO	Monoamino-oxidase
MAP	Microtubule-associated protein
MAPK	Mitogen-activated protein kinases
Mash1	Mammalian achaete-scute homologue 1
MBGI	Myelin-based growth inhibitor
MBP	Myelin basic protein
MC	Mast cell
MC-1R	Melanocortin-1 receptor
MCMD	Minor cognitive motor disorder
MCP	Membrane cofactor protein (CD46)
MCP-1	Monocyte chemoattractant protein-1 (CCL2)
M-CSF	Macrophage colony-stimulating factor (CSF1)
MD	Major depression
MDA	Malondialdehyde
MDD	Major depressive disorder
MDM	Monocyte-derived macrophages
MDP	Muramyl-dipeptide
MDP	Monocytes and dendritic cell progenitor
MDR	Multidrug resistant
MDSC	Myeloid-derived suppressor cells
ME	Median eminence
MEG	Magnetoencephalography
MEPP	Miniature end-plate potential

MFS	Miller Fisher syndrome
MHC	Major histocompatibility complex
MHC-II	Class II major histocompatibility complex
MHPG	Methoxy-hydroxy-phenylethanolamine
MLR	Mixed lymphocyte reaction
MLV	Murine leukemia virus
MND	Mild neurocognitive disorder
MP	Mononuclear phagocyte
MPMV	Mason-Pfizer monkey virus
MPTP	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MR	Mineralocorticoid receptors
MRA	Magnetic resonance angiography
MRI	Magnetic resonance imaging
MRP	Multidrug resistance protein
MRS	Magnetic resonance spectroscopy
MRSI	Magnetic resonance spectroscopic imaging
MS	Multiple sclerosis
MSA	Multisystem atrophy
MSCs	Myelinating Schwann cells
MSH	Melanocyte-stimulating hormone
MSN	Medium spiny neuron
mSOD1	Mutant Cu ²⁺ /Zn ²⁺ superoxide dismutase 1
MSRV	Multiple sclerosis retrovirus
MT	Magnetization transfer
Mtb	Mycobacterium tuberculosis
MTI	Magnetization transfer imaging
mTEC	Medullary thymic epithelial cell
mTOR	Mammalian target of rapamycin
MTR	Magnetization transfer ratio
MUC1	Mucin type 1 glycoprotein
MuLV	Murine leukemia virus
Munc-18	Mammalian homologue of unc-18
MV	Microvesicles
MVB	Multivesicular bodies
MVE	Murray Valley encephalitis virus
MW	Molecular weight
MZ	Marginal zone
NAA	<i>N</i> -Acetyl-aspartate
NAC	<i>N</i> -Acetyl cysteine
NADPH	Nicotinamide adenine dinucleotide phosphate
NB	Nucleotide-binding domain
NCAM	Neural cell adhesion molecule
NCC	Neural crest cell
NE	Norepinephrine
NEP	Neutral endopeptidase metalloendopeptidase
NET	Norepinephrine transporter
NeuN	Neuronal nuclei
NF	Neurofilament
NF-kB	Nuclear factor-k-B
NFAT	Nuclear factor of activated T lymphocytes
NFL	Nerve fiber layer
NFT	Neurofibrillary tangles
Ng-CAM	Neuronal-glial cell adhesion molecule (L1/NILE)

NGF	Nerve growth factor
NgR	Nogo-66 receptor
NICD	Notch intracellular domain
NK	Natural killer (cells)
NKT	Natural killer T (cells)
NLR	Nod-like receptors
NMDA	<i>N</i> -methyl-D-aspartate
NMDAR	<i>N</i> -methyl-D-aspartate receptors
NMJ	Neuromuscular junction
NMO	Neuromyelitis optica
NMR	Nuclear magnetic resonance
NMSCs	Nonmyelinating Schwann cells
nNOS	Neuronal nitric oxide synthase
NNRTIs	Nonnucleoside analogue reverse transcriptase inhibitors
NO	Nitric oxide
NOD	Nucleotide oligomerization domain
NOD	Non-obese diabetic mice
NOS	Nitric oxide synthase
NOT	Nucleus of the optic tract
NP	Nanoparticle
NPC	Neural progenitor cell
NPY	Neuropeptide Y
NPZ-8	Neuropsychological Z score for 8 tests
NR	Nuclear receptor
NRG	Neuregulin
NRL	Nuclear receptor ligand
NRTI	Nucleoside analogue reverse transcriptase inhibitors
NSAID	Nonsteroidal anti-inflammatory drug
NSC	Neural stem cell
NSE	Neuron specific enolase
NSF	<i>N</i> -ethylmaleimide sensitive factor
NT	3-Nitrotyrosine
NTF	Neurotrophin
NVU	Neurovascular unit
OB	Olfactory bulb
OCB	Oligoclonal band
OCD	Obsessive compulsive disorder
ODN	Oligonucleotides
OE	Olfactory epithelium
OHT	Ocular hypertension
OL	Oligodendrocyte
OLM	Outer limiting membrane
OMgp	Oligodendrocyte-myelin glycoprotein
OMP	Olfactory marker protein
ONH	Optic nerve head
ONL	Outer nuclear layer
OP	Oligodendrocyte progenitors
OPC	Oligodendrocyte progenitor cell
OPCA	Olivopontocerebellar atrophy
OPL	Outer plexiform layer
ORF	Open reading frame
ORN	Olfactory response neuron
OSP	Oligodendrocyte-specific protein

OVA	Ovalbumin
OVLT	Organum vasculosum of the lamina terminalis
P0	Myelin protein zero
p75NTR	p75 neurotrophin receptor (nerve growth factor receptor; NGFR)
PACAP	Pituitary adenylate cyclase-activating polypeptide
PACT	Protein activator of the interferon-induced protein kinase
PAF	Platelet-activating factor
PAG	Periaqueductal gray
PAMP	Pathogen-associated molecular pattern
PANDAS	Pediatric autoimmune neuropsychiatric disorders associated with Streptococcus
PANSS	Positive and negative syndrome scale
PARP	Poly(ADP-ribose) polymerase
PASAT	Paced Auditory Serial Addition Test
PBBS	Peripheral benzodiazepine binding sites
PBL	Peripheral blood lymphocyte
PBMC	Peripheral blood mononuclear cell
PBR	Peripheral benzodiazepine receptor
PCP	Phencyclidine
PCR	Polymerase chain reaction
PD	Parkinson's disease
pDC	Plasmacytoid dendritic cells
PD1	Program death-1
PDE	Phosphodiesterase
PDGF	Platelet-derived growth factor
PDTC	Pyrrolidine dithiocarbamate
PE	Plasma exchange
Pe	Periventricular
PEG	Polyethylene glycol
PEI	Polyethyleneimine
PENK	Proenkephalin
PERG	Pattern electroretinogram
PET	Positron emission tomography
PFS	Periodic fever syndromes
PG	Prostaglandin
Pgp	P-glycoprotein
PHF	Paired helical filament
PI	Phosphatidylinositol
PI3K	Phosphatidylinositol-3-kinase
PICA	Posterior inferior cerebellar artery
PICK1	Protein interacting with C kinase 1
PKA	cAMP-dependent protein kinase
PKG	Protein kinase G
PLGA	Poly(D,L-lactide-co-glycolide)
PLOSL	Polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy
PLP	Proteolipid protein
PMCA	Plasma membrane bound Ca ²⁺ -ATPase
PMD	Pelizaeus-Merzbacher disease
PML	Progressive multifocal leukoencephalopathy
PMN	Polymorphonuclear (leukocyte)
PMP22	Peripheral myelin protein 22
PNS	Peripheral nervous system
POAG	Primary open-angle glaucoma
polyQ	Polyglutamine

POMC	Pro-opiomelanocortin
POU3F2	POU class 3 homeobox 2
PP	Protein phosphatase
PPAR	Peroxisome proliferator activated receptor
PPF	Paired-pulse facilitation
PPG	Poly(propylene glycol)
PP-MS	Primary progressive multiple sclerosis
PR	Photoreceptor
PrPc	Cellular prion protein
PrPres	Protease resistance prion
PrPsc	Disease-associated prion protein
PRR	Pattern recognition receptor
PS	Presenilin (PSEN)
PSA-NCAM	Poly-sialylated form of the neural cell adhesion molecule
PSCs	Perisynaptic Schwann cells
PSD	Postsynaptic density
PSP	Progressive supranuclear palsy
PSW	Periodic sharp wave
Ptc	Patched, a hedgehog receptor
PTM	Post-translational modifications
PTP	Post-tetanic potentiation
PTSD	Post-traumatic stress disorder
PTZ	Pentylene-tetrazol
PVL	Periventricular leukomalacia
PVM	Perivascular macrophages
PVN	Paraventricular nucleus
PYD	Pyrin domain
PYY	Peptide YY
RA	Rheumatoid arthritis
Rag	Recombination-activating gene
RAGE	Receptor for advanced glycation end product
RANTES	Regulated upon activation normal T-cell expressed and secreted (CCL5)
RAS	Renin-angiotensin system
Rb	Retinoblastoma
RBP	RNA-binding proteins
REM	Rapid eye movement
RER	Rough endoplasmic reticulum
RF	Radiofrequency
RFLPs	Restriction fragment length polymorphisms
RGC	Retinal ganglion cell
RISC	RNA-induced silencing complex
RIG1	Retinoic acid-inducible gene 1
RIM	Rab3-interacting molecule
RIP	Receptor-interacting protein
RMS	Rostral migratory stream
RNAi	RNA interference
RNI	Reactive nitrogen intermediates
RNP	Ribonucleoprotein
RNS	Reactive nitrogen species
ROCK	Rho kinase
ROHHAD	Rapid-onset obesity, hypoventilation, hypothalamic dysfunction, and autonomic dysregulation
ROI	Reactive oxygen intermediate

ROR γ	Retinoic-acid-receptor-related orphan receptor- γ
ROS	Reactive oxygen species
RP	Relapsing polychondritis
RPE	Retinal pigment epithelial (cells)
RRM	RNA recognition motifs
RRMS	Relapsing and remitting multiple sclerosis
RSV	Rous sarcoma virus
RTK	Receptor tyrosine kinase
rt-PA	Recombinant tissue plasminogen activator
RT-PCR	Reverse transcription polymerase chain reaction
RyR	Ryanodine receptor
sALS	Sporadic amyotrophic lateral sclerosis
SAP	Synapse-associated protein
SAPAP	SAP-associated protein (discs, large homolog-associated protein-1; DLGAP1)
SAPK	Stress-activated protein kinase (JNK, MAPK8)
sAPP	Secreted β -amyloid precursor protein
SBMA	Spinobulbar muscular atrophy
SCs	Schwann cells
SC	Superior colliculus
SCA-3	Spinocerebellar ataxia-3
scFv	Single-chain Fv antibodies
SCI	Spinal cord injury
SCID	Severe combined immunodeficiency
sCJD	Sporadic Creutzfeldt-Jakob disease
SCPs	Schwann cell precursor
sCrry	Soluble complement receptor-related protein y
SDF-1	Stromal cell-derived factor 1 (CXCL12)
SEC	Sinus endothelial cell
SELDI-TOF	Surface enhanced laser desorption ionization time-of-flight
SER	Smooth endoplasmic reticulum
SERCA	Sarco(endo)plasmic reticulum Ca^{2+} -ATPase
SERT	Serotonin transporter
sFI	Sporadic fatal insomnia
SFO	Subfornical organ
SG	Stress granule
SGLPG	Sulfated glucuronyl lactosaminyl paragloboside
SGZ	Subgranular zone
Shh	Sonic hedgehog
sIg	Surface immunoglobulin
sIL-2R	Soluble IL-2 receptor
SITA	Swedish interactive thresholding algorithm
SIV	Simian immunodeficiency virus
SIVE	Simian immunodeficiency virus encephalitis
SLE	Systemic lupus erythematosus
SMA	Spinal muscular atrophy
SMAC	Second mitochondrial-derived activator of caspase
SMase	Sphingomyelinase
SMN	Survival motor neuron gene
SN	Substantia nigra
SNAP	Sensory nerve action potential
SNAP-25	Synaptosome-associated protein of 25,000 daltons
SNARE	NSF attachment receptor
SNpc	Substantia nigra pars compacta

SNPs	Single-nucleotide polymorphisms
SNS	Sympathetic nervous system
SOCS	Suppressors of cytokine signaling
SOD1	Superoxide dismutase 1
SON	Supraoptic nuclei
SP1	Specificity protein 1
SPARC	Secreted protein acidic and rich in cysteine
SPECT	Single photon emission computed tomography
SPG-II	Spastic paraplegia type II
SR-A	Scavenger receptor type A
SRBCs	Sheep red blood cells
SREBP	Sterol regulatory element-binding protein
SRF	Serum response factor
SSRI	Selective serotonin reuptake inhibitors
STAT	Signal transducers and activators of transcription
STP	Short-term potentiation
SV5	Simian virus 5
SVZ	Subventricular zone
SWAP	Short wavelength automated perimetry
SWATH	Sequential window acquisition of all theoretical mass spectra
SWI	Susceptibility weighted imaging
SYN	α -Synuclein
SZ	Schizophrenia
T	Tesla
Tat	Trans-activator of transcription
TBE	Tick-borne encephalitis virus
TBI	Traumatic brain injury
TBP	TATA-binding protein
TCA	Tricarboxylic acid
TCR	T-cell receptor
TCV	T-cell vaccination
TDO	Tryptophan 2,3-dioxygenase
TE	Echo time
TEC	Thymic epithelial cell
TES	Traumatic encephalopathy syndrome
Teff	T effector cells
TF	Transcription factor
TG	Trigeminal ganglia
TGF	Transforming growth factor
TH	Thyroid hormone
TH	Tyrosine hydroxylase
Th1	T helper type 1 cell
Th2	T helper type 2 cell
TIA	Transient ischemic attack
TIR	Toll/IL-1 receptor
TJ	Tight junction
TLR	Toll-like receptor
TMEV	Theiler's mouse encephalomyelitis virus
TMT	Trimethyltin
TMZ	Temozolomide
TN	Terminal nuclei
TNF	Tumor necrosis factor
TNFR	Tumor necrosis factor receptor

TOR1	Target of rapamycin 1
TRAF	TNF-receptor mediated factor
TRAIL	TNF-related apoptosis-inducing ligand (TNFSF10)
TRANCE	TNF-related activation-induced cytokine (TNFSF11)
TRANCER	TRANCE receptor (TNFRSF11A)
TRE	Tax responsive element
Treg	T regulatory cells
TREM	Triggering receptor expressed on myeloid cells
Trk	Receptor tyrosine kinase
TRP	Transient receptor potential
TRPC	Transient receptor potential canonical channels
TSA	Tissue-specific antigen
TSE	Transmissible spongiform encephalopathies
TSP	Thrombospondins
TULP-1	Tubby-lie protein 1
Tyk2	Protein tyrosine kinase 2
UACA	Uveal autoantigen with coiled domains and ankyrin repeats
UMN	Upper motor neuron
V1	Primary visual cortex
VAMP	Vesicle-associated membrane protein
VCAM	Vascular cell adhesion molecule
VEGF	Vascular endothelial growth factor
VEP	Visual evoked potential
VIP	Vasoactive intestinal peptide
VMAT-2	Vesicular monoamine transporter-2 (solute carrier family 18; SLC18A2)
VZV	Varicella-zoster virus
WDM	Welander distal myopathy
WKAH	Wistar-King-Aptekman-Hokudai
WNV	West Nile virus
X-ALD	X-adrenoleukodystrophy
XIAP	X-linked inhibitor of apoptosis protein
ZO-1	Zonula occludens-1 (TJP1)

Immunology of the Nervous System

Howard E. Gendelman and Eliezer Masliah

Abstract

Neuroinflammatory processes play a significant role in health and disease of the nervous system. These regulate development, maintenance and sustenance of brain cells and their connections. Linked to aging, epidemiologic, animal, human, and therapeutic studies all support the presence of a neuroinflammatory cascade in disease. This is highlighted by the neurotoxic potential of microglia. In steady state, microglia serve to protect the nervous system by acting as debris scavengers, killers of microbial pathogens, and regulators of innate and adaptive immune responses. In neurodegenerative diseases, activated microglia affect neuronal injury and death through production of glutamate, pro-inflammatory factors, reactive oxygen species, quinolinic acid amongst others and by mobilization of adaptive immune responses and cell chemotaxis leading to transendothelial migration of immunocytes across the blood-brain barrier and perpetuation of neural damage. As disease progresses, inflammatory secretions engage neighboring glial cells, including astrocytes and endothelial cells, resulting in a vicious cycle of autocrine and paracrine amplification of inflammation perpetuating tissue injury. Such pathogenic processes contribute to neurodegeneration. Research from others and our own laboratories seek to harness such inflammatory processes with the singular goal of developing therapeutic interventions that positively affect the tempo and progression of human disease.

paracrine amplification of inflammation perpetuating tissue injury. Such pathogenic processes contribute to neurodegeneration. Research from others and our own laboratories seek to harness such inflammatory processes with the singular goal of developing therapeutic interventions that positively affect the tempo and progression of human disease.

As the life expectancy of the human population continues to increase, the possibility of developing neuroinflammatory and neurodegenerative diseases have increased considerably during the past 50 years. Of the neurodegenerative disorders Alzheimer's disease continued to be the leading cause of dementia in the aging population. Traditionally, neurodegenerative disorders have been defined as conditions where there is selective loss of neurons within specific region of the brain accompanied by astrogliosis. However, in the past 20 years, we have learned that the pathological process leading to the dysfunction of selected circuitries in the brain initiates with damage to the synapses rather than with the loss of neurons. In fact, neuronal loss is a late event that is probably preceded by damage to axons and dendrites followed by shrinkage of the neuronal cell body and abnormal accumulation of filamentous proteins.

Therefore, the revised concept of neurodegeneration suggests that neuronal injury initiates at the synaptic junction and propagates throughout selected circuitries leading to neuronal dysfunction which resolves in the classical clinical symptoms characteristic to each of the neurodegenerative disorders (Hashimoto and Masliah 2003). So for example in Alzheimer's disease early damage to the synapses between the entorhinal cortex and the molecular layer of the dentate gyrus (perforant pathway) resolves in the short term memory deficits characteristic of this dementing disorder. Later on disconnection of the cortico-cortico fibers in the frontal, parietal, and temporal cortex resolved in more severe memory deficits, and alterations in executive functions and abstraction. Degeneration of connections between the nucleus basalis of Meynert and the neocortex resolves in attention and memory deficits that usually associated with loss of cholinergic neurons. Other circuitries and neuronal populations are also affected in Alzheimer's disease illustrating the complexity of these disorders and the fact

that the concept of single population is affected is limited. That is the case with several other disorders including Parkinson's disease where degeneration is not limited to the dopaminergic system, but also involves the limbic system, the raphe nucleus, the insula, and other systems.

In response to the injury neurons produce adhesions molecules and trophic factors that recruit astroglial and microglial cells to participate in the process of repair of the damage. In addition the microvasculature and other glial systems might also participate in the process. Thus, neurodegeneration is accompanied by astrogliosis, microgliosis, and microvascular remodeling. While astroglial cells initially produce trophic factors and cytokines that aid in the tissue repair, eventually these factors could amplify the inflammatory response, increase vascular permeability and result in microglial activation, which in turn might lead to the production of more proinflammatory cytokines and chemokines. A critical balance between the repair and proinflammatory factors often determines the future rate and progression of the degenerative process.

The understanding of the mechanisms of neurodegeneration and inflammatory response in these neurological conditions has seen a tremendous progress in the past 10 years. It is now recognized that probably small soluble misfolded protein aggregates denominated oligomers are responsible for the injury. So for example in Alzheimer's disease A β protein oligomers might damage the synapses in neocortical regions and the limbic system while in Parkinson's disease α -synuclein oligomers may damage the axons in the striatum, brainstem and cortical regions. While significant progress has been made in understanding the fundamental mechanisms for the neuronal injury, less is known about the reasons for the selective neuronal vulnerability characteristic to these neurological conditions and the role of the innate immune system in this process.

William A. Banks

Abstract

The blood-brain barriers (BBBs) are mainly located at the levels of the vasculature, choroid plexus, and the circumventricular organs and play multiple roles in neuroimmunology. The ability of the BBBs to separate the blood and its contents from the central nervous system (CNS) is largely responsible for the CNS being an immune-privileged region. However, the BBB then revises this separation in a regulated way by a variety of mechanisms, including the ability to transport cytokines, regulate the entry of immune cells into the brain, and to itself secrete into the blood and into the CNS immunoactive substances. The BBB thereby participates in a number of neuroimmune axes that allow communication between the CNS and the peripheral immune cells. Failure of the highly regulated activities of the BBBs can be both a cause and consequence of immune diseases.

2.1 Introduction

The roles played by the blood-brain barrier (BBB) in neuroimmunology are diverse and ever expanding. Conceptually, the BBB is those processes that restrict, control, or otherwise influence the exchange of substances between the peripheral circulation and the brain interstitial fluid and cerebrospinal fluid (CSF). More concretely, there are multiple BBBs: the barrier formed by monolayers of endothelial cells (the vascular BBB), the barrier formed by ependymal/epithelial cells (the blood-CSF barrier) and a barrier formed by tanycytes interposed between the circumventricular organs and the

adjacent brain tissue. It is the restrictive properties of the BBB that limit and control the trafficking of immune cells and prevent the unrestricted leakage of immune active substances from the blood into the brain that renders the central nervous system (CNS) an immune-privileged area. But the BBB also transports immunoactive substances between the blood and CNS, responds to immunoactive substances secreted into the blood or CNS fluids, and secretes substances into those compartments. These last three processes of transport, responsiveness, and secretion allow the BBB to be in constant cross talk with other cells in both the CNS and periphery in a formation referred to as the neurovascular unit (NVU). The BBB both responds to and influences the CNS and peripheral microenvironment and does so through reacting to immunoactive substances, including cytokines, chemokines, prostaglandins, and nitric oxide. Several consequences arise from this cross talk, including that under physiological conditions the metabolic needs of the brain are met by the BBB. The BBB helps to keep the CNS informed of

peripheral events including immune events and is central to the formation and functioning of neuroimmune axes. When any of these physiological consequences are violated, disease can arise; and the BBB can be a target, a cause, or a conduit to treatment of those diseases.

2.1.1 Structures and Functions of the BBB

Evidence for an interface between the circulation and the CNS dates back to the end of the nineteenth century (Bradbury 1979). The best known of those early studies were done by a young Paul Erlich who found that some dyes did not stain the brain after their peripheral injection. Erlich concluded erroneously that the lack of staining was because these dyes did not bind to brain tissue. Several decades later, Goldmann, a student of Erlich's, found that these dyes could stain the brain when injected intravenously. Thus, these studies were reinterpreted as evidence in favor of some sort of barrier between the CNS and blood.

The location and nature of that barrier was controversial through much of the twentieth century. Elegant studies by Davson and colleagues identified the barrier at the vascular level. However, alternative opinions were held until Reese and coworkers conducted classic studies with the electron microscope in the late 1960s (Brightman and Reese 1969; Reese and Karnovsky 1967). Previous work had shown no difference between vascular beds of peripheral tissues and the CNS when studied grossly or at the light microscope level. However, Reese and coworkers found numerous differences at the ultrastructural level. These included a much-reduced rate of pinocytosis and an absence of intracellular fenestrations. Currently, the most widely discussed finding is the presence of tight junctions between adjacent endothelial cells. The tight junctions, low rate of pinocytosis, and low number of intracellular fenestrations effectively eliminate intercellular gaps and pores. This, in turn, essentially eliminates the production of a plasma-derived ultrafiltrate and hence the leakage of serum proteins into the brain.

From this single change, the lack of a production of an ultrafiltrate, evolves a large number of consequences for CNS function. Obviously, it is the basis of the restriction of protein access, which first defined the BBB in late nineteenth century. The need for an efficient lymphatic system is eliminated, but the lack of a classic lymphatic system means that the CNS needs other methods to rid itself of the free water and wastes produced by metabolism and the secretions of the choroid plexus. Without production of an ultrafiltrate, the CNS depends on other methods to extract nourishment from the blood. The BBB addresses this need with a large number of selective transporters for substances from electrolytes to regulatory proteins (Davson and Segal 1996b, c). Because the CNS is not equipped to handle an ultrafiltrate, the reintroduction of a

leaky BBB, as with hypertensive crisis, can result in increased intracranial pressure and encephalopathy (Al-Sarraf and Phillip 2003; Johansson 1989; Mayhan and Heistad 1985).

2.1.2 The Various BBBs

The BBB is not a single barrier but several barriers, which are in parallel. This contrasts with the testis-blood barrier, which consists of several barriers in series (Holash et al. 1993; Neaves 1977). The most studied of these barriers are the vascular barrier and the choroid plexus. Often, the terms BBB and blood-cerebrospinal (CSF) fluid barrier are used to refer specifically to the vascular barrier and the barrier formed at the choroid plexus, respectively. The least studied barriers are the barriers formed by tanycytes at the circumventricular organs (CVO) and other specialized neural barriers, such as the blood-retinal barrier (Neuwelt et al. 2008).

2.1.2.1 Vascular BBB

The vascular BBB occurs because of the modifications, noted by Reese and co-workers, in the endothelial cells that comprise the capillary bed and line the venules and arterioles of the CNS (upper panel Fig. 2.1). It is likely that these three regions are highly specialized. For example, immune cells primarily cross at the venules, and most of the classic transporters are located at the capillaries (Engelhardt and Wolburg 2004). No CNS cell is more than about 40 μm from a capillary. This means that a substance that can cross the vascular BBB can immediately access the entire CNS. Substances that cross the vascular BBB can be either flow-dependent or not dependent on flow rate. A flow-dependent substance is one in which the BBB extracts from the blood nearly the maximal amount possible (Kety 1987). The only way to increase the amount of a flow-dependent substance entering the brain is to increase the flow rate to the brain. Glucose is an example of a flow-dependent substance (Rapoport et al. 1981). A brain region that is particularly active has its increased demand for glucose met by an increase in regional blood flow. In contrast, transport of a cytokine such as tumor necrosis factor- α (TNF- α) is not flow dependent. Only a small percent of the TNF- α in blood is extracted by the brain via the saturable transporter for TNF- α located at the BBB (Gutierrez et al. 1993). Alterations of blood flow within physiological limits do not alter the uptake of TNF- α from blood by brain. However, extreme changes in the rate of blood flow or capillary tortuosity can result in rheological changes, such as the loss of laminar flow. Such alterations likely occur in stroke, AIDS, and Alzheimer's disease (de la Torre and Mussivand 1993; Nelson et al. 1999). This may result in impaired permeation of flow-dependent and non-flow dependent substances.

Fig. 2.1 The vascular blood-brain barrier: the *upper panel* illustrates the brain endothelial cell. This is the functional and anatomical site of both barrier function and of saturable and non-saturable mechanisms of passage. The major modifications allowing both barrier function and selective penetration of substances are indicated. The *middle panel* illustrates other cell types and structures important in BBB function. Pericytes are embedded in a basement membrane and astrocytes form a structure over the capillary bed above the pericytes and basement membrane. Both cell types are in paracellular communication with the brain endothelial cells. The *lower panel* illustrates the neurovascular unit, a concept that emphasizes integration of peripheral, BBB, and central interactions

The vascular BBB has regional variations in terms of function and susceptibilities to disease. Huber et al. noted that some regions of the brain suffer larger and earlier disruptions to their barriers during diabetes mellitus than others (Huber 2008; Huber et al. 2006). Many peptides and regulatory substances have unique regional variations in their transport rates across the BBB (Banks et al. 1996; Banks and Kastin 1998). It is assumed that these reflect on brain function. For example, the brain region with the highest rate of transport of leptin is the region of the arcuate nucleus, an area important in leptin-mediated control of feeding (Banks et al. 1996; Schwartz et al. 2000).

2.1.2.2 Choroid Plexus

The choroid plexus are bags composed of monolayers of epithelial cells that project into the ventricles and contain a capillary plexus (Johanson 1988). The capillaries do not have barrier function and so produce an ultrafiltrate that fills the bag. The epithelial cells have tight junctions and so prevent the ultrafiltrate from entering the ventricular space. Unlike the capillaries, the epithelial cells of the choroid plexus have a high rate of vesicular turnover that is responsible for the production of the CSF. However, the CSF is not an ultrafiltrate but a secreted substance. The choroid plexus also has many selective transport systems, some of which are specific to it or are enriched in comparison to the vascular BBB. In some cases, the choroid plexus seems not to be a system complementary to the vascular BBB, but one that is contrary to it. For example, efflux of amyloid beta peptide by the vascular BBB is impaired with aging but is increased with aging at the choroid plexus (Pascale et al. 2011). Thus, the choroid plexus should not be thought of as a secondary barrier but as an independent system with its own unique characteristics.

2.1.2.3 Barriers at Circumventricular Organs

The CNS of mammals contains seven regions of the brain where the vasculature does not fully participate in a BBB (Gross et al. 1987). These regions have at least one side that faces a ventricle and so are termed circumventricular organs (CVOs). Together, they comprise about 0.5 % of the brain by weight. Their capillaries allow the production of an ultrafiltrate and so their cells are in more intimate contact with the circulation. They are known to play vital roles as sensing organs for critical peripheral events; for example, they act as emetic centers and are important in blood pressure modulation (Johnson and Deckwerth 1993; Ferguson 1991). They can relay their signals to the rest of the brain by neurons that project from them to distant brain regions or project to them from other brain regions. However, the mixing of their interstitial fluids with that of adjacent brain tissue or CSF has been shown to be limited in most studies (Peruzzo et al. 2000; Plotkin et al. 1996; Rethelyi 1984). Diffusion through brain tissue is poor, and this alone would tend to produce a

limit to mixing within a few hundred microns of the CVO (Cserr and Berman 1978; de Lange et al. 1995). However, the major factor preventing leakage of substances from the CVO into the adjacent CSF and brain tissue is a physical barrier to diffusion. The epithelial cells that line the ventricles form tight junctions when they are next to CVOs, thus limiting CVO-to-CSF diffusion. A functional barrier formed by bands of tanycytes also exists for the diffusion of substances from the CVO to the adjacent brain region (Peruzzo et al. 2000; Plotkin et al. 1996; Rethelyi 1984). These tanycytes themselves can project to the cells and vessels within the CVO and can respond dynamically to relay information to adjacent regions of the brain that have BBBs (Langlet et al. 2013). A recent review by Rodriguez (Rodriguez et al. 2010) has explored the various aspects of the CVO barriers.

2.1.2.4 Other Specialized Neural Barriers

These barriers include the blood-retinal barrier, blood-spinal cord barrier, and blood-nerve barriers (for a full listing, see Neuwelt et al. (2008)). These barriers generally include tight junctions participating in a vascular barrier but exhibit varying degrees of leakiness. They can also vary markedly in transporter activity from the vascular BBB during both health and in response to disease (Pan et al. 2008a; Pan and Kastin 2003; Prockop et al. 1996).

2.1.3 Concept of the Neurovascular Unit and Comparison to Peripheral Vascular Beds

The endothelial cell is the anatomical location of the barrier aspect of the vascular BBB and of its various saturable transporters (Fig. 2.1). Capillary beds from peripheral tissues have numerous intracellular and intercellular pores and fenestrations and high rates of pinocytosis that account for their leakiness. The brain endothelial cell engages in comparatively little macropinocytosis, has few intracellular pores or fenestrations, and intercellular pores or gaps are eliminated because of tight junctions.

However, the brain endothelial cell does not function in isolation. The abluminal (brain side) of the capillary is encased in a basement membrane 40–80 nm thick. This membrane does not act as a barrier to molecules but may restrict viral-sized particles (Muldoon et al. 1999). It also holds pericytes in close approximation to the endothelial cell (Balabanov and Dore-Duffy 1998). The pericyte is a pluripotent cell and a modulator of BBB function (Dore-Duffy et al. 2000; Deli et al. 2005; Dore-Duffy 2008). It, like astrocytes and microglia, secretes cytokines and other immune active substances both constitutively and when induced (Kovac et al. 2011). In the rat hippocampus, astrocytes project endfeet that surround the capillary in what looks at the ultrastructural level like a

complete covering, albeit without intercellular tight junctions (Mathiisen et al. 2010). Astrocytes and pericytes both secrete substances that induce tight junction formation in endothelial cells (Deli et al. 2005; Daneman et al. 2010). All the major cell types of the NVU (pericytes, astrocytes, microglia, and endothelial cells) secrete a variety of substances, including cytokines, into their local environment (Fabry et al. 1993; Nath et al. 1999; Banks 2014). Pericytes and astrocytes play interrelated but distinct roles in BBB function. For example, pericytes are the primary protectors of the blood-retinal and blood-brain barriers during glycemic stress (Romeo et al. 2002; Nakaoke et al. 2007).

It is clear that immune cell trafficking occurs across the normal BBB (Greenwood et al. 2011). One study found that about one in 5000 intravenously injected lymphocytes resided in the brain at any given time and that uptake was affected by strain and immune activation (Banks et al. 2012). The microglia may be at equilibrium with circulating macrophages/monocytes, although whether monocytes cross the BBB of the adult healthy animal to become microglia seems to still be unresolved (Williams and Hickey 1995). Other immune cells also enter and exit the CNS at unknown rates and frequencies as influenced by yet to be determined factors. Clearly, secretions of prostaglandins, nitric oxide, and cytokines from each of these cells are important for intercellular communication and can influence endothelial cell permeability (Chao et al. 1994; Nath et al. 1999; Shafer and Murphy 1997).

The concept of the neurovascular unit (NVU) emphasizes the interactive role that cells and events within the CNS and in the circulation play on BBB permeability as well as the consequences of the permeability itself. The NVU includes other factors long known to influence the penetration of substances across the BBB, such as degradation, sequestration, and serum protein binding. The encompassing concept of the NVU is particularly useful when considering the next section, the mechanisms of transport across the BBB.

2.2 Mechanisms of Transport Across the BBB

Substances can enter or exit the CNS by a variety of mechanisms. Some of these mechanisms are operational in both the blood-to-brain (influx) and the brain-to-blood (efflux) directions; whereas, others are unidirectional.

2.2.1 Blood to CNS

Saturable and nonsaturable modes predominate influx. Within each of these categories are a diverse number of mechanisms. These different mechanisms tend to favor certain groups or types of substances.

2.2.1.1 Nonsaturable Passage

A hallmark of nonsaturable passage is that the percent of material crossing into the CNS is not affected by the amount of material available for transport. The two main mechanisms of nonsaturable passage are transmembrane or transcellular diffusion and the extracellular pathways. The former is much better studied and its principles are widely applied by industry for the development of CNS drugs; the latter has received much less attention.

Transcellular Diffusion

The most studied nonsaturable mechanism by which small molecules cross the BBB is by transmembrane or transcellular diffusion (Rapoport 1976). The major determinant of passage is the degree to which the substance is lipid soluble. A substance that is too lipid soluble will be unable to repartition into the brain's interstitial fluid and so will become trapped in the cell membranes of the BBB. A ratio of about 10:1 in favor of lipid versus aqueous solubility is near ideal for maximal passage across the BBB. The second most important determinant is molecular weight with passage being favored for smaller molecules. Other physicochemical determinants, such as charge, can occasionally become dominant for specific compounds. Work by Lipinski and colleagues in Caco-2 cells, an immortalized cell line derived from a gastrointestinal cancer, clearly shows that smaller, less charged, more lipid soluble drugs are favored in transmembrane diffusion (Lipinski et al. 1997). Many exogenous substances, including many drugs with CNS activity, enter the brain predominantly by way of transmembrane diffusion. Morphine and ethanol are prime examples of common substances that cross the BBB by this mechanism (Oldendorf 1974).

Although higher molecular weight (MW) is an impedance to transmembrane diffusion at the BBB, there seems to be no absolute molecular weight cut-off. A previous study which had thought to define such an absolute limit had discovered, in retrospect, early evidence for an efflux system (Levin 1980). The largest substance to date noted to have a measurable uptake by brain by transcellular diffusion is cytokine-induced neutrophil chemoattractant-1 (CINC1), with a MW of about 7.8 kDa (Pan and Kastin 2001a). A surprisingly large number of small, lipid soluble compounds cross the BBB at a rate considerably greater or lesser than that predicted by their physicochemical characteristics (Oldendorf 1971, 1974). Binding to serum proteins and efflux systems are major factors decreasing influx, and the presence of a saturable blood-to-brain transporter is a major factor increasing influx.

Extracellular Pathways

Albumin derived from serum is present in small amounts in the CSF, showing that the BBB is not absolute. The amount of protein in CSF, however, is very small, being about 0.5%, or 1/200th, of that in plasma. The CSF is not an ultrafiltrate but a

secreted fluid. This means that the relative and absolute concentrations of proteins, electrolytes, minerals, and other substances can differ tremendously to that of plasma. The extracellular pathways are another avenue by which substances can enter the CNS (Balin et al. 1986; Broadwell 1993). These represent what have sometimes been termed “functional leaks” at discreet areas of the brain, including the large vessels of the pial surface and subarachnoid space, the circumventricular organs, the nasal epithelium, the sensory ganglia of spinal and cranial nerves, and some deep brain regions, such as the nucleus tractus solitarius (Broadwell and Banks 1993).

The amount of a substance that enters the brain by the extracellular pathways is small. However, this route may be therapeutically relevant for compounds which have favorable peripheral pharmacokinetics, such as a long serum half-life and a small volume of distribution (Banks 2004). Antibodies, erythropoietin, and enzymes can access the brain by way of the extracellular pathways (Banks et al. 2004a, 2005a, 2007; Kozłowski et al. 1992; Grubb et al. 2008), and this may underlie their therapeutic benefits when given in high doses (Grubb et al. 2008; Alafaci et al. 2000; Ehrenreich et al. 2002; Erbyraktar et al. 2003; Morgan et al. 2000; Janus et al. 2000; Hock et al. 2003; Farr et al. 2003).

2.2.1.2 Receptor-Mediated and Saturable Transports

Saturable processes represent a diverse group of mechanisms. Included in this group are diapedesis and adsorptive endocytosis/transcytosis that share characteristics with the saturable systems.

Active Transport Versus Facilitated Diffusion

Saturable transporters (Yeagle 1987) can be divided into those which require energy (active transport) and those which do not (facilitated diffusion). Both are dependent on a protein which acts as the transporter, may have co-factors, and be modulated by physiologic and disease processes. Energy requiring systems can be unidirectional; that is, they may have only an influx or efflux component. Non-energy requiring saturable transport (facilitated diffusion) is bidirectional; that is, it transports substances in both directions with net flux being from the side of higher concentration to the side of lower concentration.

Most of the classic saturable transporters at the BBB are facilitated diffusion systems (Kaur et al. 1992). For example, GLUT-1, the transporter for glucose, is a facilitated diffusion transporter. If the level of glucose is artificially raised above that of serum (or if radioactive glucose is introduced into the CNS, but not the serum), efflux of glucose can be shown.

Transcytotic Versus Transmembrane Transport

Saturable transporters can also be categorized based on whether they use pores/channels or vesicles to transport their ligands across the BBB. In the pore system, the molecule

crosses from one side of the cell membrane to the other by passing through a cavity in the transporter protein. The substance is thus transported either into or out of the cytoplasm of the BBB cell; a second set of transporters on the opposing cell membrane completes the transfer across the BBB or the substance can rely on transmembrane diffusion. With vesicular transport, the transported substance adheres to a binding site, usually a glycoprotein. Invagination then produces a vesicle that is then routed to the opposite membrane, and the contents of the vesicle are released from the cell surface. A specificity of transport distinguishes these vesicles from the macropinocytosis whose reduction is a defining characteristic of the BBB (Reese and Karnovsky 1967).

Most small molecules, such as glucose, electrolytes, and amino acids, use pores or channels. Pore systems may be either active or facilitated diffusion systems. Vesicular transporters, on the other hand, are energy requiring and so are characterized by unidirectional transport. The best described of these vesicular dependent systems is receptor-mediated transcytosis and is characterized by clathrin- and transglutaminase-dependence (Davies et al. 1980). However, non-clathrin dependent vesicles, such as podocytes, are also likely active at the BBB.

It is reasonable to assume that very large molecules would be required to use vesicles rather than pores and channels to cross, but the molecular weight at which vesicles would be requisite is not known. It has been proposed that interleukin-2 (IL-2) is transported (Drach et al. 1996) by p-glycoprotein (P-gp). As P-gp is a pore system (Begley 2004), IL-2 would be the largest substance currently known to be transported by a pore system. Peptides much smaller than IL-2 are known to cross by vesicular dependent pathways (Shimura et al. 1991; Terasaki et al. 1992). It is clear, then, that the size of the ligand alone does not dictate the need for vesicular transport.

Diapedesis of Immune Cells

A major shift in thinking about the relation of immune cells to the CNS and BBB has occurred over the last few decades. The CNS was once viewed as separate from the immune system and sterile in terms of immune cell occupancy except under conditions of brain infection. As reviewed above, it is now clear that immune cells patrol the normal CNS, although many important questions remain. For example, a major type of brain cell, the microglia, is known to be derived from peripheral macrophages, although the extent to which the pools of peripheral macrophages and microglia mix in the normal postnatal condition is unknown.

Adsorptive Endo- and Trans-cytosis

Adsorptive endocytosis occurs when a glycoprotein on the brain's endothelial surface binds another glycoprotein in ligand like fashion (Broadwell et al. 1988; Broadwell 1989). This second glycoprotein (the ligand) may be free or attached

to the surface of a virus or immune cell (Mellman et al. 1986). The binding can initiate endocytosis with the subsequent vesicle having several potential fates (Banks and Broadwell 1994). In some cases, the vesicle is routed to lysosomes, the glycoprotein destroyed, and the vesicle rerouted to the endothelial cell surface for discharge of contents. In other cases, the vesicle can be routed to the Golgi complex and endoplasmic reticulum. In other cases still, the vesicle can be discharged at the endothelial cell surface opposite to that of uptake. In this case, the vesicle has crossed the width of the endothelial cell, and hence crossed the BBB, in a transcytotic event. What determines the fate of these vesicles is largely unknown, but at least some vesicles can engage in more than one fate (Broadwell 1993). It may be that binding of a large amount of glycoprotein to the endothelial cell can overwhelm the lysosomal pathway and result in the vesicles being routed to the transcytotic or Golgi complex pathways.

Several principles of adsorptive endocytosis and transcytosis (also termed adsorptive-mediated transcytosis) are clear. Many of the glycoprotein ligands are toxic, and endocytosis may represent a mechanism to rejuvenate or repair the membrane (Raub and Audus 1990; Vorbrodt 1994; Westergren and Johansson 1993). Viruses and other pathogens that can infect or cross the BBB have often co-opted adsorptive endocytosis/transcytosis mechanisms (Marsh 1984; Chou and Dix 1989; Schweighardt and Atwood 2001). These processes may also be related to diapedesis as many of the events of immune cell passage across the BBB resemble these endocytic mechanisms. For example, both LFA-1 (leukocyte function-associated antigen-1) and ICAM (intercellular adhesion molecule), important to immune cell passage across the BBB, are glycoproteins. Although adsorptive endocytosis is in some sense saturable because of a finite amount of any single glycoprotein on a cell surface, it is not easy to demonstrate classical saturable kinetics for this process. In fact, excess glycoprotein can sometimes further stimulate endocytosis and so lead to a paradoxical increase, rather than decrease, in the rate of passage across the BBB (Banks et al. 1997). Glycoprotein distribution on brain endothelial cells is polarized; that is, a glycoprotein may be enriched on either the luminal or abluminal membranes (Vorbrodt 1994; Zambenedetti et al. 1996). The tight junctions act as a "fence" to keep the glycoproteins confined to their respective sides of the endothelial cell (Deli et al. 2005). This means that the movement of a glycoprotein molecule (or a virus whose coat displays that glycoprotein) can be unidirectional as its transcytosis can only be initiated from the side of the brain endothelial cell that contains the ligand's complementary glycoprotein (Villegas and Broadwell 1993; Broadwell 1989). The possession and distribution of glycoproteins similarly dictate which viruses can invade the brain; neurovirulent viruses that invade the brain as free virus (as opposed to entering in Trojan horse fashion inside an infected

immune cell) can do so because they possess a glycoprotein ligand capable of binding to the BBB.

Other molecules besides glycoproteins can also induce adsorptive endocytosis/transcytosis type mechanisms. A classic example is polycationic molecules such as the poly-L-lysines and the protamines. Protamines are peptides of about 30 amino acids that contain an abundance of arginine molecules. They can induce adsorptive transcytosis so vigorously as to result in BBB disruption (Vorbodt et al. 1995; Hardebo and Kahrstrom 1985). One of the proofs that viruses co-opt adsorptive transcytosis like mechanisms is that they, like protamine, bind to heparins and heparans; indeed, protamine sulfate blocks viruses such as HIV-1 from binding to the BBB (Banks et al. 2004c; Ramos-Kuri et al. 1996; Bobardt et al. 2004). Many of the highly charged penetrating peptides, such as those derived from Tat, and many of the antibodies that target receptor-mediated transporters likely are taken up by adsorptive endocytosis/transcytosis related mechanisms (Niewoehner et al. 2014; Weissmann 1976; Herve et al. 2008).

2.2.2 CNS to Blood

Traditionally, passage in the brain-to-blood direction (efflux) has been neglected. However, efflux often accounts for the inability of otherwise effective drugs to accumulate in the CNS. Pharmacogenomic studies have suggested that the individual variation in efflux mechanisms may explain why some individuals are less sensitive to the CNS effects of drugs or more sensitive to their toxicities (Loscher and Potschka 2002). Efflux mechanisms are important to the homeostasis of the CNS, ridding the brain of toxins (Taylor 2002). The rate of efflux can be, in addition to synthesis and degradation, an important determinant of the level of a substance produced within the CNS (Chen et al. 1997; Chen and Reichlin 1998; Maness et al. 1998).

2.2.2.1 Nonsaturable

Efflux, like influx, has both saturable and non-saturable mechanisms of entry. Transmembrane diffusion occurs for both influx and efflux. Other mechanisms, such as bulk flow, are unique for efflux.

Transmembrane Diffusion

Many of the principles that govern influx by transmembrane diffusion are also important in efflux. The dramatic role that efflux by transmembrane diffusion can play can be illustrated by comparing the fate of small, lipid soluble molecules to that of a protein after intrathecal administration. Intrathecal application of small, lipid soluble molecules, such as anesthetics, can have a local effect on spinal cord function but have little or no effect on the brain (Bernards 1999). These substances readily cross the brain endothelial

cell by transmembrane diffusion and do this as easily in the brain-to-blood direction as in the blood-to-brain direction. Therefore, they are cleared from the CSF before they are able to reach the brain (McQuay et al. 1989). In contrast, proteins such as leptin and lysosomal enzymes are too large and water soluble to undergo significant transmembrane diffusion (McCarthy et al. 2002; LeBel et al. 1999). Leptin, tetanus antitoxin, and the lysosomal enzyme idursulfase can reach the brain after intrathecal administration in amounts sufficient to produce CNS effects (Calias et al. 2012; McCarthy et al. 2002; Kabura et al. 2006; LeBel et al. 1999).

Efflux by transmembrane diffusion can also contribute to the poor diffusion of substances within brain parenchyma. Diffusion within the interstitial space of the brain is dependent on Brownian motion and the production of metabolic free water as driving forces and so is very slow (Cserr 1984; Cserr and Berman 1978). However, efflux by non-saturable (and saturable) mechanisms can further reduce the distance a substance will ultimately diffuse. For example, the less lipid soluble drug atenolol can diffuse about three times further into brain tissue than can the more lipid soluble drug acetaminophen (de Lange et al. 1993).

Bulk Flow and the Glymphatic System

Bulk flow refers to the reabsorption of CSF into the blood, which occurs at the level of the arachnoid villi (Davson and Segal 1996a) and cribriform plate (Widner et al. 1987; Yamada et al. 1991). Any substance dissolved in CSF will enter the blood by this mechanism (Pollay and Davson 1963; Jones and Robinson 1982). The glymphatic system provides an important mechanism for the mixing of the CSF and brain interstitial fluid, with aquaporin-dependent fluid production at the astrocytes providing the circulant and arteriole pulsations providing the directionality (Iliff et al. 2012). Thus, the glymphatics are important not only for bulk flow, but also for the extracellular pathways, and possibly for the movement of CSF from the spinal cord into the cranium.

The characteristics of this system result in several surprising but important phenomena. For example, CSF drained at the cribriform plate, which is likely the dominant route for CSF drainage at normal CSF pressures (Boulton et al. 1999), can enter into the cervical lymphatic system. This can provide a direct route from the CNS to the cervical lymphatics (Oehmichen et al. 1979), as has been illustrated for gp120, the glycoprotein of the human immunodeficiency virus, HIV-1 (Cashion et al. 1999). This route to the lymphatics may explain why substances injected into the brain can produce a different immune response than when the substance is injected peripherally (Knopf et al. 1995; Cserr and Knopf 1992). Another example is that in some cases, the levels of a substance in blood achieved after injection into the CSF can be sustained longer and at higher levels than after an intravenous bolus (Maness et al. 1998; Chen

et al. 1997; Chen and Reichlin 1998) This is because the central injection acts similarly to an intravenous infusion, slowly delivering drug to the blood. Impairment in glymphatic circulation can result in decreased bulk flow and so may contribute to increased levels of protein and toxins in the CSF (Iliff et al. 2013).

2.2.2.2 Saturable Transport

The last decade has seen a huge increase in the interest of efflux by saturable mechanisms. Just as efflux by transmembrane diffusion can limit diffusion of a substance within the CNS, so can the presence of a saturable efflux transporter (Blasberg 1977). Much of this interest centers on the multi-drug efflux transport systems (Begley 2004), most notably p-glycoprotein (P-gp). However, other efflux transporters for peptides, proteins, endogenous substances, and drugs are known to play important roles in physiology and disease (Martins et al. 1997; Taylor 2002; Drion et al. 1996; Mealey et al. 2001). For example, peptide transport system-1 is a major regulator of brain levels of methionine enkephalin, an endogenous opiate which suppresses voluntary ethanol drinking (Plotkin et al. 1998). Depression and recovery of peptide transport systems-1 with ethanol drinking may relate to alcohol withdrawal seizures (Banks and Kastin 1989, 1994). IL-2 is currently the only cytokine known to be transported by a saturable efflux system (Banks et al. 2004b); some have postulated this transporter may be P-gp. Poor accumulation of protease inhibitors, antibiotics, AZT, anti-cancer drugs, and many other substances occurs because of efflux systems (Glynn and Yazdanian 1998; King et al. 2001; Lee et al. 1998; Loscher and Potschka 2002; Masereeuw et al. 1994; Spector and Lorenzo 1974). P-gp plays a major role in the efflux of intrathecally administered opiate analgesics (Thompson et al. 2000). Brain-to-blood transport of a corticotropin-releasing hormone is sufficient to influence splenic levels of beta-endorphin (Martins et al. 1997). Impaired efflux of amyloid β peptide, the peptide believed to cause Alzheimer's disease, develops with aging in mice which overexpress amyloid precursor protein, thus promoting further accumulation within brain of amyloid β protein (Gherzi-Egea et al. 1996; Banks et al. 2003; Deane et al. 2004). Evidence suggests that impaired transport develops in humans as well and so may be a major mechanism for induction of Alzheimer's disease (Tanzi et al. 2004; Shibata et al. 2000).

2.3 Neuroimmune Interactions

The above discussion of BBB fundamentals is tailored towards understanding the role of the BBB in neuroimmune interactions. Below are specific examples of how the BBB is involved in neuroimmune interactions.

2.3.1 Binding Sites at the BBB: Receptors and Transporters

An important distinction for understanding the function of the BBB is that of receptors vs transporters. The term "receptor" has undergone a transformation of its usage since its introduction in the late nineteenth century when it was first used to denote some physiological function. Eventually, the term receptor was used to denote a physical binding site through which a drug or hormone could exert its effects on a cell. In the 1980s, a distinction was made between "receptor" and "binding site", the former being coupled to intracellular machinery that translated its binding into a cellular effect. Binding sites on the brain endothelial cell can represent transporters, but they can also represent traditional receptors, that is, binding sites coupled to intracellular machinery. For example, brain endothelial cells have both insulin receptors and transporters. As a result, insulin is transported across the BBB to exert effects inside the CNS, but insulin also alters a number of functions of the brain endothelial cell. As examples of the latter, insulin alters the BBB transport of zidovudine (AZT (Ayre et al. 1989), tryptophan (Cangiano et al. 1983), and leptin (Kastin and Akerstrom 2001) and alters brain endothelial cell alkaline phosphatase activity (Catalan et al. 1988). BBB studies have assumed that a binding site represents transporter function and are so designed as to not consider whether receptors as well as transporters may exist at the BBB. However, a great deal of indirect evidence and some direct evidence indicates that the vascular BBB and the choroid plexus probably possess a large variety of receptors that can alter BBB functions. Besides insulin, substances which bind to and alter the function of brain endothelial cells include mu opiate receptor ligands (Baba et al. 1988; Vidal et al. 1998; Chang et al. 2001), cytokines (Ban et al. 1991; Cunningham et al. 1992; van Dam et al. 1996; Vidal et al. 1998; Moser et al. 2004; Khan et al. 2003), leptin (Kastin et al. 2000; Bjorbaek et al. 1998; Hsueh et al. 2013a), acetylcholine (Grammas and Caspers 1991), adrenergics (Walsh et al. 1987; Kalaria and Harik 1989), glutamate (Koenig et al. 1992; Krizbai et al. 1998), and chemokines (Sanders et al. 1998).

2.3.2 Permeability to Cytokines and Related Substances

The BBB is known to transport several cytokines in the blood-to-brain direction. For example, the BBB transports the IL-1s, IL-6, and TNF- α by three separate transport systems. Additionally, nerve growth factor, brain derived neurotrophic factor, interferons, neurotrophins, eotaxin, fibroblast factor 19, and leukemia inhibitory factor (Poduslo

and Curran 1996; Erickson et al. 2014; Hsueh et al. 2013b; Pan et al. 1997b, 1998a, b) are also transported across the BBB. In some cases, the same gene which gives rise to a cytokine's receptor also produces the cytokine's transporter; whereas in other cases, the receptor and transporter are different proteins (Pan and Kastin 2002; Banks et al. 2002). Recently, a BBB transporter for pituitary adenylate cyclase activating polypeptide (PACAP) was found to be the same protein which acts as a neuronal receptor for enterostatin, but not for PACAP, and acts as a lipid transporter in the liver (Martinez et al. 2003; Park et al. 2004; Dogrukol-Ak et al. 2009). In general, BBB transporters occur throughout the CNS, including the spinal cord, although the transport rate across the BBB can vary greatly among CNS regions (McLay et al. 1997; Pan et al. 1997b, 1998b; Banks et al. 1994). Enough cytokine is transported into the brain to affect CNS function. For example, IL-1 α crosses the BBB at the posterior division of the septum where it mediates cognitive impairments (Banks et al. 2001). Similarly, serum TNF- α crosses the BBB to induce CNS release of TNF- α , which in turn can induce apoptosis in the substantia nigra (Qin et al. 2007).

The cytokine transporters are not static but respond to physiological and pathological events. The transport rates of IL-1 and TNF- α each show diurnal variations (Pan et al. 2002; Banks et al. 1998b). The transport rate of TNF- α is altered in animals with experimental allergic encephalomyelitis (EAE), spinal cord injury, or blunt trauma to the brain (Pan et al. 1996, 1997a, 2003b; Pan and Kastin 2001b; Pearce et al. 2003).

2.3.3 Permeability to Other Neuroimmune Substances

Other substances with neuroimmune actions are handled by the BBB in a variety of ways. Monoamines are largely excluded by the BBB (Hardebo and Owman 1990; Kalaria et al. 1987), and opiates and opiate peptides as a rule enter the brain by transmembrane diffusion but are transported by saturable systems in the brain-to-blood direction (King et al. 2001; Banks and Kastin 1990; Elferink and Zadina 2001). Pituitary adenylate cyclase activating peptide, a member of the VIP/secretin/PACAP family, has immune functions (Arimura 1992). Transport of its two major forms across the BBB is complex, involving both brain-to-blood and blood-to-brain components (Banks et al. 1993). Its blood-to-brain transport is altered with CNS injury (Somogyvari-Vigh et al. 2000). Some of the other immune active substances whose passage across the BBB has been investigated are melanocyte stimulating hormone (Martins et al. 1996; Wilson et al. 1984), corticotrophin releasing hormone (Martins et al. 1996), and enkephalins (Banks et al. 1986; Elferink and Zadina 2001).

2.3.4 Permeability to Immune Cells

As discussed above, immune cells cross the BBB by the highly regulated process of diapedesis. The mechanism by which immune cells cross the BBB has also been greatly clarified by recent work. Two major assumptions about how immune cells would enter the CNS has not withstood investigation. The first assumption was that immune cells would enter the CNS by leaking across a disrupted BBB. However, disruptions to the BBB are usually mediated by increased vesicular activity in the endothelial cells (Vorbodt et al. 1995; Lossinsky et al. 1983; Mayhan and Heistad 1985). These vesicles of 100 nm or so could not accommodate the passage of an immune cell 10,000 nm in diameter. Even in diseases where there is both increased immune cell trafficking into the CNS and a disrupted BBB, there is often a mismatch between the site of immune cell entry and BBB disruption (Engelhardt and Wolburg 2004).

The second major assumption is that immune cells would cross between opposing endothelial cells taking the "paracellular route." However, evidence suggests that many immune cells favor a transcellular route and that cells can cross both the vascular BBB and the choroid plexus (Kivisakk et al. 2003; Wolburg et al. 2005). In brief, immune cells tunnel through venular endothelial cells leaving the intercellular tight junctions intact (Engelhardt 2008; Wolburg et al. 2005). This tunneling process is complex and is initiated when LFA-1 on an immune cell binds to ICAM on the brain endothelial cell. Other paracellular messengers, which likely include cytokines, are then released (Male 1995; Persidsky et al. 1997). Protrusions and invaginations of the endothelial cell and protrusions of the immune cell occur, with the immune cell possibly using the tight junction as an initial anchoring site (Lossinsky et al. 1991). Other ligands which have been postulated to play a role in this transcytotic process include PECAM, VE-cadherin, members of the JAM family and CD99 (Engelhardt and Wolburg 2004). Some plasma inevitably accompanies the passage of the immune cells, which can give the appearance of a disrupted BBB (Greenwood et al. 1995; Avison et al. 2004; Persidsky et al. 2000).

The immune processes that induce an immune cell to cross the BBB are complex. Quan has shown that injection of interleukin-1 into brain tissue induces immune cell trafficking, but that such induction can be blocked by injection of lipopolysaccharide (LPS) into the periphery (Ching et al. 2005, 2006; Quan et al. 1994). Although trafficking is a product of a complex interaction between the immune cell and the BBB, the degree to which trafficking occurs can reside primarily with the immune cell or the BBB and genetics or immune events can shift that dominance (Banks et al. 2012). Such events may underlie eufinflammation, the phenomenon by which subclinical activation of the innate immune system renders it increasingly resistant to such activation by increasingly stronger stimuli (Tarr et al. 2014).

2.3.5 Permeability to Viruses

Whether a virus is neurovirulent or not depends largely on its ability to cross the BBB (Chou and Dix 1989). However, viruses can induce neurotoxicity without themselves crossing the BBB by several mechanisms. For example, shed viral proteins might cross the BBB as could circulating cytokines whose release from peripheral sources is induced by the virus. However, most neurovirulent viruses seem to do their major damage directly after entering and replicating within the CNS. Some viruses can replicate within brain endothelial cells and are subsequently shed into the CNS (Cosby and Brankin 1995). Other viruses invade the CNS by crossing the BBB (Nakaoka et al. 2005). Initial uptake by either route involves events reminiscent of adsorptive endocytosis as discussed above. Viral glycoproteins bind to brain endothelial cell (or choroid plexus) glycoproteins to initiate adsorptive endocytosis. As with adsorptive endocytosis, the virus-containing vesicle is subsequently routed to various membrane systems that can include discharge to the original side of uptake or transcytosis. Sialic acid and heparan sulfate are common components of the glycoproteins involved in viral uptake by the BBB (Schweighardt and Atwood 2001; Banks et al. 2004c). In some cases, the functional glycoprotein is known. For example, rabies can bind to acetylcholine and nerve growth factor receptors (Schweighardt and Atwood 2001), and HIV-1 can bind to the mannose-6 phosphate receptor. Without an appropriate luminal or basal glycoprotein with which to bind to the BBB cell, the virus is largely excluded from the CNS.

Other principals reviewed above can play key roles in viral uptake by the brain. Activation of the immune system increases the transport of HIV-1 and other viruses across the BBB (Dohgu and Banks 2008; Chou and Dix 1989; Cosby and Brankin 1995). In the case of HIV-1, this involves inducing secretion of GM-CSF (granulocyte-macrophage colony-stimulating factor) and IL-6 from brain endothelial cells with the cytokines acting in an autocrine fashion to promote the transcytosis of the virus (Dohgu et al. 2011). This process is not dependent on pericytes but is enhanced by it (Dohgu and Banks 2013). Eventually, the immune mechanisms combine to produce the cognitive and behavioral problems seen in AIDS (Hong and Banks 2014).

2.3.6 Secretion of Neuroimmune-Active Substances

The brain endothelial cells and the epithelial cells of the choroid plexus are capable of secreting a large number of neuroimmune active substances. These include interleukins (Fabry et al. 1993; Hofman et al. 1999; Reyes et al. 1999), TNF- α (Lee et al. 2001), nerve growth factor, (Moser et al.

2004), endothelin (Didier et al. 2002), monocyte chemoattractant peptide (Chen et al. 2001), nitric oxide (Mandi et al. 1998), RANTES (Simpson et al. 1998), and prostacyclin (Faraci and Heistad 1998). Some of these substances are secreted spontaneously, and many of them can be stimulated with immunoactive substances such as LPS, bacteria, or viral proteins (Reyes et al. 1999; Hofman et al. 1999; Vadeboncoeur et al. 2003). The unique architecture of the BBB allows it to receive input from one of its surfaces and to secrete substances into the other. For example, LPS applied to the abluminal surface of brain endothelial cells in monolayer cultures will enhance release of IL-6 from the luminal surface (Verma et al. 2006).

2.3.7 Modulation of BBB Function by Neuroimmune Substances

Traditionally, neuroimmune modulation has been thought of in terms of disruption of the BBB. However, as the review above indicates, transporter functions are also vulnerable to manipulation by neuroimmune elements. Alterations in transport function are likely to be more common events than disruption, as the latter is likely seen only with extreme pathology; whereas, the former is likely a physiological, as well as a pathological, aspect of neuroimmune regulation. Other functions of the BBB, such as brain endothelial cell secretions are also clearly affected by neuroimmune events.

2.3.7.1 Agents That Increase Permeability of the BBB

Disruption was the first BBB function noted to be perturbed in neuroimmune disease. However, the review above makes it clear that an increase in BBB permeability can be induced for specific agents by increasing their blood-to-brain transport rate or inhibiting their brain-to-blood efflux rate. An additional observation is that the BBB does not respond to immune activation through a single pathway nor even responds uniformly to an activated pathway. For example, indomethacin blocks the BBB disruption induced by LPS, suggesting that disruption involves prostaglandins (Minami et al. 1998a). In contrast, indomethacin enhances the LPS-induced increase in HIV-1 penetration across the BBB and has no effect on the LPS-induced increase in insulin transport (Xaio et al. 2001; Banks et al. 1999).

2.3.7.2 Regulation of BBB Integrity and Tight Junction Function

The classic example of BBB disruption is that seen in multiple sclerosis and the animal model of that disease, EAE (Pozzilli et al. 1988; Butter et al. 1991; Juhler et al. 1984). LPS and treatment with cytokines such as TNF- α have also been shown to induce BBB disruption (Megyeri et al. 1992). As discussed

above, paracellular (through tight junctions) and transcellular mechanisms of transport exist. Although either can underlie BBB disruption, classic studies have shown that the major cause of increased protein leakage across the BBB for almost every kind of insult to the BBB or to the CNS is mediated by transcytotic mechanisms (Lossinsky et al. 1983; Vorbrodt et al. 1995). Nevertheless, recent advances in understanding tight junction assembly and regulation have encouraged many to investigate paracellular mechanisms. Both tight junction function and transcytosis are regulated events, although it is unclear to what extent protein leakage into the brain may be altered under physiological conditions. To some extent, paracellular and transcytotic routes likely involve some of the same cellular machinery, such as the cytoskeleton. TNF- α is known to induce rearrangements in cytoskeletal architecture. Additionally, cerebral ischemia, diabetes mellitus, and even intense pain are associated with alterations in the expression and cellular distribution of tight junction proteins and opening of the BBB (Brown and Davis 2002; Chehade et al. 2002; Huber et al. 2002). The importance of regulatory processes in BBB disruption is vividly illustrated by the paradoxical finding that maximal disruption does not occur at the time of the CNS injury, even when the event is traumatic but hours or days later (Baldwin et al. 1996). It is thought that it is the peripheral and central responses, such as cytokine release, to CNS injury rather than the CNS injury itself that results in BBB disruption.

2.3.7.3 Regulation of Saturable Transporters

Regulation of both influx and efflux transporters are influenced by neuroimmune events. Additionally, cytokine transporters are also affected by various CNS events.

LPS and Blood-to-Brain Transporters

LPS increases the transport across the BBB of cisplatin, insulin, leukemia inhibitory factor, and the HIV-1 viral coat glycoprotein gp120, but not of TNF- α or pituitary adenylate cyclase activating polypeptide (Banks et al. 1999; Pan et al. 2008b; Minami et al. 1998b; Nonaka et al. 2005; Osburg et al. 2002; Xaio et al. 2001). LPS affects leptin transport (Nonaka et al. 2004) through peripheral mechanisms and increases pituitary adenylate cyclase activating polypeptide binding to receptors on the BBB but does not alter transport. CNS injuries such as ischemia or trauma to the spinal cord induce a cascade of events that can affect the transport of neuroimmune substances across the BBB as discussed below.

LPS, Cytokines, and Brain-to-Blood (Efflux) Transporters

Immune modulators also alter efflux systems. In vitro studies show that LPS, TNF- α , and interferon gamma regulate P-gp (Salkeni et al. 2009; Theron et al. 2003; Hartz et al. 2006; Yu et al. 2007a, b; Stein et al. 1996; Bauer et al. 2007). In vivo studies have shown that LPS down regulates P-gp function at the

BBB (Salkeni et al. 2009). Interestingly, IL-2 appears to be both a substrate for P-gp and a modulator of its activity (Bonhomme-Faivre et al. 2002; Castagne et al. 2004; Drach et al. 1996). Because P-gp regulates the brain concentration of so many drugs and endogenous substances, immunomodulation could affect many other responses. For example, brain levels of exogenous opiate drugs such as morphine (King et al. 2001), endogenous opiates such as β -endorphin (Kastin et al. 2002), and neurotoxins such as cyclosporine (Sakata et al. 1994) would all be expected to be increased in patients given IL-2. Immunomodulation of efflux systems, therefore, could have a major effect on CNS metabolism and the response to drugs.

Activity of low-density lipoprotein receptor-related protein-1 (LRP-1) is also modulated by LPS. LRP-1 at the BBB acts as an efflux pump to amyloid beta protein (Deane et al. 2008), the substance associated causally with Alzheimer's disease. The neurovascular hypothesis states that decreases in LRP-1 activity at the BBB contributes to loss of clearance of amyloid beta protein from brain and so promotes Alzheimer's disease (Zlokovic 2005). Inhibition of LRP-1 activity leads to decreased efflux of amyloid beta protein, increases in levels of amyloid beta protein in the brain, and cognitive impairment (Jaeger et al. 2009b). Mice treated with LPS have decreased efflux of amyloid beta protein, providing a mechanism for connection between inflammatory processes and Alzheimer's disease (Jaeger et al. 2009a).

2.4 Role of the BBB in Neuroimmune Diseases

The above review has emphasized BBB/neuroimmune interactions under normal physiological conditions. However, the BBB is intimately involved in neuroimmune diseases as well. The BBB can be a target of such disease, its functions may be adaptive to disease, or it can be a contributor to the disease process. Below are some examples of the ways in which the BBB is altered in diseases with neuroimmune processes.

2.4.1 TNF- α Transport and EAE

TNF- α has a biphasic effect on many neuroimmune processes, with too little or too much producing harmful effects (Pan et al. 1997c). TNF- α mediates many of its pathological effects through its central receptors, and transport of circulating TNF- α is one source of CNS TNF- α (Pan and Kastin 2002; Gutierrez et al. 1993; Osburg et al. 2002). Induction of EAE is partially dependent on TNF- α and IL-1 (Schiffenbauer et al. 2000). Immune cell invasion in general and during EAE in particular is dependent on TNF-modulated expression of ICAM and VCAM on brain endothelial cells and of LFA-1 on immunocytes (Male 1995; Barten and Ruddle

1994). Finally, the saturable transport across the BBB of TNF- α itself is greatly increased in EAE (Pan et al. 1996).

2.4.2 CNS Injuries and Cytokine Transport

As noted above, CNS injuries can produce a disruption of the BBB, but this disruption is temporally dissociated from the injury (Pan et al. 1997a; Banks et al. 1998a; Baldwin et al. 1996). This dissociation is because the disruption is the consequence of the reactions to injury rather than to injury itself. Not surprisingly, then, CNS injuries can also produce complex alterations in the BBB transport of cytokines. Besides the example of TNF- α in EAE given above, TNF- α transport is also increased in spinal cord injury (Pan et al. 1997a, 2003b; Pan and Kastin 2001b) and after blunt trauma to the brain (Pan et al. 2003a). This increase is neither confined to the site of injury, homogeneous throughout the CNS, nor related to the disruption pattern of the BBB (Pan et al. 1997a; Pan and Kastin 2001b; Xiang et al. 2005). It is also temporally and regionally independent of the changes in BBB transport rates of other cytokines and immunoactive substances whose transport rates are also altered with CNS injury (Banks et al. 1998a; Pan et al. 1998b). The pattern also is dependent on the type of CNS injury (Pan and Kastin 2001b).

2.4.3 Anti-retrovirals and the BBB

A major problem in treating viruses which can invade the CNS, such as HIV-1, is that antiretrovirals often cross the BBB poorly (Thomas 2004). The major problem, however, is not that these substances are especially limited by their rate of transcellular diffusion, but that they are nearly all substrates for efflux systems. For example, AZT is 16 times more lipid soluble than sucrose and so should cross much more rapidly, but actually crosses at the same rate (Wu et al. 1998). AZT is a ligand for at least two efflux systems (Masereeuw et al. 1994; Wang and Sawchuck 1995; Takasawa et al. 1997), and the protease inhibitors are all substrates for P-gp (Lee et al. 1998). P-gp is expressed by immune and other cells as well with three major phenotypic clusters in humans. Those with higher expression of P-gp, and therefore less able to accumulate protease inhibitors in tissues, are more resistant to treatment for HIV-1.

Conditions associated with AIDS further complicate the interaction between efflux systems and the uptake of anti-retrovirals by the brain. P-gp is modulated by inflammation (Yu et al. 2007b, 2008) and by gp120 (Ronaldson and Bendayan 2006). Many of the protease inhibitors induce P-gp expression and function, thus likely further reducing their ability to cross the BBB (Chan et al. 2013).

2.4.4 Immune Cell Invasion

Immune cell trafficking into the CNS is important in mediating neuroimmune diseases. Immune cell invasion is an early event in multiple sclerosis and EAE (Wolburg et al. 2005). Infected immune cells are a mechanism by which HIV-1 (Koyanagi et al. 1997; Nottet et al. 1996) and perhaps prions (Klein et al. 1997) invade the CNS.

Immune cell passage across the BBB is, in turn, affected by immune modulators. LPS and the HIV-1 immunoactive protein Tat increase expression by brain endothelial cells of ICAM and VCAM (Pu et al. 2003; Nottet et al. 1996), and monocytes treated with LPS have an increased rate of passage across the BBB (Persidsky et al. 1997). In vitro studies suggest that these events may be mediated through IL-1 β and IL-6 (De Vries et al. 1994).

2.4.5 Efflux of HIV-1 Proteins and Cytokines

Because the BBB prevents the effective accumulation of many of the antivirals, the CNS can act as a reservoir of virus. This reservoir could potentially reinfect the peripheral tissues. The CNS-to-blood movement of HIV-1 has not been investigated, but movement of two of its proteins has. The coat glycoprotein HIV-1gp120 is cleared through bulk flow (Cashion et al. 1999), being reabsorbed predominately at the cribriform. As a result, it drains by way of lymphatic vessels directly to the cervical lymphatic nodes. If whole virus also takes this route, then that means that lymph nodes could be directly reinfected without the virus having to enter the circulation where it could be exposed to antiviral agents.

A CNS reservoir of virus could affect the peripheral immune system by a mechanism that does not involve reinfection of peripheral tissues. HIV-1 Tat, like HIV-1gp120, is also reabsorbed with the CSF into the blood by a nonsaturable mechanism (Banks et al. 2005b). Proteins which are enzymatically resistant in blood, such as HIV-1 Tat, HIV-1gp120, and cytokines, can achieve high levels in blood even when their only source is the CSF. Production of these proteins within the CNS with subsequent reabsorption with the CSF into blood could be a way in which CNS virus produces toxic effects at peripheral tissues.

To date, IL-2 is the only cytokine known to be transported from the brain to the blood by a saturable transporter (Banks et al. 2004b). This transporter, along with binding to plasma proteins and robust degradation by the BBB or CNS, effectively prevents much IL-2 from entering the brain. Evidence suggests that this transporter is likely P-gp. P-gp activity is decreased with HIV encephalitis (Persidsky et al. 2000), and this could lead to blood-borne IL-2 entering the CNS. Chronically, however, the binding of IL-2 to plasma proteins extends its half-life, allowing time for it to accumulate in

brain by way of the extracellular pathways. Chronic IL-2 administration induces stereotypic behaviors and is used in an animal model of schizophrenia (Zalcman 2001, 2002). Therefore, an enhanced entry of IL-2 is one mechanism by which HIV-1 could induce behavioral changes.

2.5 Summary

The BBB intimately interacts with cells and their secretions that are in both the CNS and periphery. Some neuroimmune substances, exemplified by cytokines, can cross the BBB directly and also have direct effects on the BBB. The BBB is itself a source of neuroimmune substances and can receive signals from one side, for example the brain side, and release substances in response to that signal from its other side. The passage of immune cells across the BBB is a highly regulated event as is the passage of viruses and viral particles. Overall, the BBB is an important component of the neuroimmune axis and the only component that is simultaneously physically in both the peripheral and central compartments of the neuroimmune system.

2.6 Review Questions

- What are components of the blood-brain barriers:
 - vasculature
 - choroid plexus
 - Sertoli cells
 - tanycytes
 - a and c
 - a, b, and d
 - a, c, and d
- Which statement is true about the BBB transport systems for cytokines:
 - The IL-1s and IL-6 share a transport system
 - TNF is not transported across the BBB
 - IL-6 and TNF share a transport system
 - The IL-1s, IL-6, and TNF each have their own transport system*
 - IL-1 is only transported in the brain-to-blood direction
- The circumventricular organs are:
 - Regions of the brain that do express a robust BBB*
 - Are regions outside the brain but inside the skull
 - Completely encircle the ventricles and so prevent cerebrospinal fluid from entering the blood stream
 - Only occur in people who have circumnavigated the earth
- Transcellular diffusion refers to:
 - The mechanism by which immune cells cross the BBB
 - The mechanism by which small lipid soluble substances cross the BBB*
 - The process by which molecules diffuse from one neuron to another within brain interstitial fluid
 - The process by which brain endothelial cells containing two X chromosomes can express testosterone receptors
 - None of the above
- Which statement is true:
 - Receptors on brain endothelial cells never act as BBB transporters
 - Receptors on brain endothelial cells are always the same protein as that which acts as a substance's BBB transporter
 - The brain endothelial cell receptor and the BBB transporter are the same for some substrates and different for others*
 - The brain endothelial cells do not have receptors.
 - BBB transporters are never located on brain endothelial cells
- Immune cells cross the BBB:
 - By leaking across a disrupted BBB
 - By being engulfed by macropinocytotic vesicles
 - By interacting with brain endothelial cells in a complex way*
 - Only in disease states
 - By first binding to astrocytes
- The following statements are true about brain-to-blood transport (efflux):
 - Efflux only occurs for drugs
 - P-glycoprotein is an efflux system
 - All efflux systems require energy
 - A saturable transport system can have an efflux and an influx component
 - A saturable transport system can have only an efflux component
 - b, d, e
 - b, c, e

Regulation of Nervous System Function by Circumventricular Organs

3

Emily A.E. Black, Nicole M. Cancelliere,
and Alastair V. Ferguson

Abstract

In this chapter, we highlight the specialized features of the sensory circumventricular organs (CVO) as central nervous system (CNS) structures located at the blood-brain interface. These structures appear to play critical roles in sensing and integrating information regarding autonomic status derived from circulating signals that do not readily cross the BBB. Intriguingly, while the majority of the original literature highlighting such roles attributed primarily fluid balance and cardiovascular functions to the subfornical organ (SFO) and metabolic function to the area postrema (AP), more recent work as highlighted in this chapter has clearly demonstrated, not only overlap in these physiological roles in SFO and AP, but also additional roles for these CVOs in reproductive and of primary importance to this chapter immune signaling from the circulation to the CNS. Within not only SFO and AP, but also the organum vasculosum of the lamina terminalis, the emerging literature supports the conclusion that single neurons in these CVOs sense, and presumably integrate, signals related to all of these separately classified autonomic functions. In recognizing the potential for such integration in the sensory CVOs, it becomes important to also understand that optimal health is associated with the ability of our physiological systems to regulate these functions in an integrated rather than separate manner.

Keywords

Area postrema • Blood brain barrier • Central autonomic control • Circulating signals • Circumventricular organ • Subfornical organ

3.1 Introduction

It is well accepted that the central nervous system (CNS) is the “command center” of the body, being the system that not only collects and integrates critical autonomic information coming from either the internal or external environment of the organism, but also initiates appropriate physiological responses. Information regarding these autonomic systems comes from a variety of sensors including thermoreceptors,

baroreceptors, chemoreceptors, as well as those monitoring fluid volume, metabolic state, and immune status. It is primarily conveyed in the form of signaling molecules released from one cell to influence the function of another, such as amino acids, peptides, gases, and larger macromolecules, delivered to their site of action in target cells by: the blood (hormones), synaptic terminals (neurotransmitters) or local mechanisms (paracrine). Neuronal systems (autonomic control centers) within the CNS detect these molecules and adjust physiological systems of the body accordingly in order to maintain the critical “milieu interieur” of a well regulated homeostatic system.

Importantly, many of these signaling molecules which originate in the periphery and play important roles in the central regulation of immune function (e.g. IL-1, IL-6,

Fig. 3.1 Anatomical locations of the sensory and secretory circumventricular organs of the rat brain. Midsagittal section of the rat brain. CVOs circumventricular organs, OVLT organum vasculosum of the lamina terminalis

TNF α) are large and/or lipophobic and thus do not readily cross the blood-brain barrier (BBB), an endothelial/glial cell barrier separating the CNS from the periphery. The BBB is comprised of three layers of cells: the endothelial cells of the capillaries (this layer “faces” the interstitial fluid), the epithelial cells of the choroid plexus, and the arachnoid epithelium (an avascular layer of cells surrounding the CNS). The processes of the astroglial cells are also an important component. The cells forming these layers are connected via tight junctions and express transporters for specific molecules, both of which allow the BBB to fulfill its function of selectively excluding macromolecules and polar solutes (Abbott et al. 2006).

3.2 The Circumventricular Organs

In view of this lack of permeability, the BBB would make it difficult for the CNS structures protected by the barrier to detect critical signaling molecules in the general circulation, and thus nearly impossible for these structures to appropriately respond to these signals. How does the CNS then manage to interpret the information provided by the peripheral systems of the body? A few mechanisms of communication between the periphery and CNS exist, such as diffusion and active transport. However, the number of substances that are able to cross the BBB using either method is limited since diffusion only allows small, non-polar molecules to cross this CNS barrier. In contrast, larger lipophobic substances require a suitable transporter to cross the BBB and to date, few specific transporters have been identified.

A solution to this apparent dilemma presents itself in the form of the circumventricular organs (CVOs) of the brain. These specialized structures are highly vascularized areas of the brain whose capillaries do not contain the tight junctions

of the BBB but are instead fenestrated, meaning that gaps exist between the endothelial cells leading to the formation of Virchow-Robin Spaces (Price et al. 2008) that allows circulating blood containing large lipophobic signals to enter and pool, facilitating free exchange between the blood and nervous tissue of the body. The CVOs can be primarily classified as either secretory (neurohypophysis, median eminence, intermediate lobe, and pineal), or sensory (area postrema, subformical organ and organum vasculosum of the lamina terminalis) (Fig. 3.1), while the subcommisural organ does not fit readily into either of the categories and will not be discussed further here.

3.3 The Secretory CVOs

The primary focus of this chapter will be on the sensory CVOs, but we will first very briefly highlight roles of the secretory CVOs in the release of centrally synthesized lipophobic hormones directly into the circulation or cerebrospinal fluid. The secreted products are synthesized in parts of the brain that are protected by the BBB such as the supraoptic, paraventricular, and arcuate nuclei; and thus, these specialized areas of fenestrated capillaries permit the release of synthesized lipophobic products into general circulation. The neurohypophysis is the posterior lobe of the pituitary gland and secretes oxytocin and vasopressin, hormones involved in reproduction and fluid balance, directly into general circulation (Sofroniew 1983; Sofroniew et al. 1981). The intermediate lobe of the pituitary gland, which separates the anterior and posterior lobes of this endocrine gland in humans, synthesizes and secretes melanocyte-stimulating hormone (MSH). The median eminence (ME), perhaps the most important of the secretory CVOs, consists of neuronal terminals which “synapse” on the hypophyseal portal capillaries, the entry point for hypothalamic trophic

hormones controlling the extensive endocrine roles of the anterior pituitary. The hormones secreted by the ME include gonadotropin-releasing hormone, growth hormone-releasing hormone, dopamine, thyrotropin-releasing hormone, and corticotropin-releasing hormone. The pineal gland is the final secretory CVO which produces melatonin, a critical component in the regulation of circadian rhythms. It secretes this hormone not only into the circulation but also into the cerebrospinal fluid (Cassone et al. 1993).

3.4 Sensory CVOs

The sensory CVOs are, in many ways, contrasting structures to the secretory CVOs in that their primary function is to detect, rather than release, signals at the blood-brain interface. The three sensory CVOs are characterized by high expression levels of a variety of receptors and their resulting ability to integrate a multitude of signals. These are: the area postrema (AP), the subfornical organ (SFO), and the organum vasculosum of the lamina terminalis (OVLT). Another defining characteristic of these areas is the minimal afferent input they seem to receive relative to their extensive neural outputs. Additionally, most of the afferent input received by these three CVOs seems to come from the very structures onto which they project, indicating the probability of reciprocal communication between the sensory CVOs and the other structures. They are primarily known for their involvement in cardiovascular regulation and fluid balance; however, these structures have also been shown to be involved in the regulation of other processes such as energy metabolism, reproduction, and immune response.

3.4.1 Neuroanatomy and Connectivity of Sensory CVOs

The anatomy and connectivity of the CVOs provide valuable insight into their roles in the regulation of nervous system function. This section will outline the anatomical location and connections associated with the various sensory CVOs in order to provide a framework for the understanding of their central roles in immune function and regulation of autonomic state.

3.4.1.1 Subfornical Organ

The SFO is a highly vascularized, translucent midline structure protruding from the rostral wall of the third ventricle in the dorsal region of the lamina terminalis. It lies between the columns of the fornix, and its dorsal end is attached to the hippocampal commissure. It consists of a ventral stalk and dorsal crest, which connects to the median preoptic nucleus and the tela choroidea of the third ventricle, respectively (McKinley et al. 2003). The rich capillary network that sur-

rounds the SFO is formed by an anastomosis between branches of the anterior cerebral artery and the posterior choroidea artery. It is so dense that it must be peeled away during microdissection in order to see the SFO. Upon histological assessment, the SFO can be divided into three distinct areas based on morphology: The core region is the largest and is exclusively composed of neuronal cell bodies and glial cells. The rostral and caudal regions surround the core, and contain very few neurons and glial cells, consisting mainly of nerve fibers (Dellmann and Simpson 1979).

The major contributions to the current understanding of the SFO's neurocircuitry can be attributed to the comprehensive studies by the labs of Hernesniemi et al. (1972), Miselis (1981, 1982), and Lind et al. (1982). The earlier study used lesion techniques and Golgi staining methods (Hernesniemi et al. 1972), and the latter investigations used horseradish peroxidase injections to follow anterograde and retrograde transport of labeled proteins through axons (Miselis 1981, 1982; Lind et al. 1982). Evidence for these connections is supported in studies using electrophysiological stimulation (Ferguson and Bains 1996; Bains and Ferguson 1995).

A summary of the major and minor afferent and efferent neuronal connections to and from the SFO are outlined in Fig. 3.2. The major efferents can be grouped into two general areas:

3.4.1.2 The Neuroendocrine and Autonomic Control Centers of the Hypothalamus

Direct (monosynaptic) and indirect (polysynaptic) efferent projections terminate in the anterior and tuberal supraoptic nuclei (SONa and SONt), and the paraventricular nucleus (PVN) including its rostral accessory cluster, respectively. Electrophysiology studies demonstrated excitatory SFO projections to vasopressin- and oxytocin-secreting magnocellular neurons in the SON and PVN, as well as in parvocellular areas of the PVN, which, in turn, project either to the median eminence, the medulla, or the spinal cord. Many efferent fibers to the hypothalamus emerge from the rostral SFO and enter the columns of the fornix, diverge with the ventral stria medullaris to disperse medially and laterally over the columns of the fornix and along their dorsal border at the anterior dorsal level of the columns trajectory through the hypothalamus.

3.4.1.3 The Anteroventral Third Ventricular (AV3V) Area

This includes the median preoptic nucleus (MnPO), the anterior periventricular (Pe) area of the hypothalamus, and the organum vasculosum of the lamina terminalis (OVLT)—another sensory CVO to be discussed later. Many efferent fibers to this area emerge from the rostral SFO, pass anteriorly over the anterior commissure in the midline and either descend along the anterior border of the MnPO or enter the Pe dorsally just beneath the anterior commissure.

Fig. 3.2 Primary neuronal connections of the subfornical organ. A midsagittal section of rat brain representing major afferent and efferent projections of subfornical organ. Afferent pathways are represented by yellow arrows, efferent pathways are represented by blue arrows, and reciprocal projections are represented by purple arrows. *OVLT* orga-

num vasculosum of the lamina terminalis; Hypothalamic structures: *MnPO* median preoptic nucleus, *SON* supraoptic nucleus, *PVN* paraventricular nucleus, *LH* lateral hypothalamus, *Arc* arcuate nucleus; Hindbrain structures: *LPBN* lateral parabrachial nucleus, *NTS* nucleus of the solitary tract

It is important to note that dendritic trees of SFO neurons are relatively compact, and the extent of afferent connectivity is not nearly as elaborate as the efferents (Dellmann and Simpson 1979). These neuroanatomical findings suggest that there is reciprocal communication occurring between these brain regions and that perhaps the SFO's primary afferent information is received from circulating signals in the peripheral circulation as opposed to signals from other brain regions.

3.4.1.4 Organum Vasculosum of the Lamina Terminalis

The organum vasculosum of the lamina terminalis (OVLT) is a midline structure in the anterior wall of the third cerebral ventricle, located ventral to the MnPO and immediately dorsal to the optic chiasm. The OVLT, like the other sensory CVOs, contains a rich arterial blood supply and aggregation of neuronal cell bodies. In 1969, Duvernoy et al. published a detailed study illustrating the four major arterial sources of the human OVLT—a superior median source branching from the anterior communicating artery, two lateral sources from arteries which branch off from each anterior cerebral artery below the anterior communicating artery, and an inferior median source ascending from below the optic chiasm (Duvernoy et al. 1969).

The OVLT can be grouped into two major regions, the dorsal cap and the lateral regions, which each display unique projection

patterns. As is the case for the SFO, much of what is known about the neuronal connections to and from the OVLT can be attributed to a few key tracer studies conducted in the late 1970s and early 1980s that utilized the axonal transport of marker molecules, such as tritiated amino acids and horseradish peroxidase (HRP), in experimental models such as rats and sheep (Camacho and Phillips 1981; Phillips and Camacho 1987; Oldfield et al. 1991; ter Horst and Luiten 1986). The OVLT's main afferent and efferent projections are summarized in Fig. 3.3. Much like the SFO, the OVLT's dominant efferents project to magnocellular neurons of the PVN and SON (either directly or indirectly through the MnPO); and afferents are derived from the MnPO, SFO, and a variety of hypothalamic regions. Efferent connections have also been found to corticotrophin releasing factor-rich neurons in the PVN (Saper and Levisohn 1983). As in the case of SFO, outlined above, there is again a pattern of small dendritic trees of OVLT neurons, minimal afferent neural inputs, and reciprocal communication between afferent and efferent projection sites.

3.4.1.5 Area Postrema

The AP is a midline hindbrain structure located on the dorsal surface of the medulla oblongata, immediately adjacent to the NTS seen protruding into the fourth ventricle (Wislocki and Putnam 1920). The three regions of the AP include the *ventral zone*, which contains mostly glia (McKinley et al. 2003), and

arrows, efferent pathways are represented by blue arrows, and reciprocal projections are represented by purple arrows. *SFO* subfornical organ; Hypothalamic structures: *MnPO* median preoptic nucleus, *SCN* suprachiasmatic nucleus, *SON* supraoptic nucleus, *PVN* paraventricular nucleus

the mantle zone and central zone, which are rich with neuronal cell bodies and axons situated next to ependymal cells. Separating the AP and NTS is a layer of tanycytes called the *funiculus separans* that function much like the BBB. Like the other two sensory CVOs, the AP is one of the most highly vascularized regions in the entire mammalian brain, showing a 150-fold increase in the surface area to permeability ratio when compared with the adjacent regions of the dorsomedial medulla (Gross 1991).

The AP was for decades known as the “chemoreceptor trigger zone” where noxious chemicals in the circulation acted to induce an emetic reflex (Borison and Brizzee 1951; Miller and Leslie 1994). However, despite this well studied functional role, more recent evidence suggests that the AP, like the other sensory CVOs, is also involved in various autonomic functions (to be discussed below).

Much of what is known about the anatomical connections of the AP is derived from retrograde tracing studies performed in the early- to mid-1980s. Using wheat germ agglutinin HRP (van der Kooy and Koda 1983) and cholera-toxin HRP (Shapiro and Miselis 1985), the studies illustrate the connections of the AP to and from various autonomic control centers in the medulla, pons, and hypothalamus. The AP has strong reciprocal connections to and from the lateral parabrachial nucleus of the pons (LPBN) and the NTS—two multifunctional integrative brainstem structures. It also receives

substantial input from the parvocellular regions of the paraventricular and dorsomedial nuclei of the hypothalamus, in addition to peripheral information from vagal and carotid sinus nerve afferents originating from the respiratory, gastrointestinal, and cardiovascular systems (Fig. 3.4).

Despite each sensory CVOs distinct neuroanatomy and afferent and efferent projection sites, the SFO, OVLT, and AP do share various similarities that provide us with a framework for understanding and further investigating their functional roles. Each lack a BBB, are highly vascularized, efficaciously located at an interface between the brain and the circulation, display elaborate efferent connections with few afferents, and express receptors for numerous circulating signals. Additionally, the main projection sites are reciprocated and target various secretory and integrative nuclei in the hypothalamus and brainstem that are involved in the regulation of broad ranging autonomic functions including cardiovascular control, body fluid homeostasis, reproductive function, energy homeostasis, and immune regulation. This neuroanatomical data suggests that the sensory CVOs are integrative structures involved in communicating various autonomic signals from the circulation to the central nervous system.

This concept has developed over the last few decades as a consequence of data derived from various experimental methods including electrophysiological whole-cell recordings from individual neurons both in vitro and in vivo

tions are represented by purple arrows. Hypothalamic structures: *DMH* dorsal medial hypothalamus, *PVN* paraventricular nucleus; Hindbrain structures: *LPBN* lateral parabrachial nucleus, *Amb* nucleus ambiguus, *NTS* nucleus of the solitary tract, *DMN* dorsal motor nucleus of the vagus

recordings, behavioral studies using intraperitoneal injections of various circulatory signaling peptides or immune modulators, as well as electrical stimulation or lesion/ablation techniques to manipulate or disrupt signaling pathways originating in these CVOs. The following section will highlight these data to emphasize the critical role CVOs play in the regulation of autonomic and immune function.

3.5 CVO Functional Roles

Autonomic state is a term we have used to describe the combined physiological status of an organism, which results from the collective integrated homeostatic processes regulating multiple controlled variables at any one point in time. This incorporates metabolic rate, fluid levels, cardiac regulation, glucose levels, and immune function, to name a few, as our physiological systems work to maintain the aforementioned parameters at set values that are ideal for optimal physiological function. As variables deviate from ideal values, there is a systemic response, which activates or inhibits the appropriate functions, returning those variables toward the homeostatic value. In order to correctly respond to a deviation from regulated set points, systems for detection of such changes are clearly essential, and it is here that the importance of the sensory CVOs becomes evident. Many circulating signaling

molecules provide continuously updated information indicating the state of the peripheral systems. Leptin levels in circulation, for instance, will increase or decrease according to the metabolic status, angiotensin II (ANG) with fluid balance, and cytokines with immune function of the body. As previously discussed in this chapter, the majority of the CNS is protected by the BBB and therefore cannot detect changing levels of any of these signals that do not readily cross the BBB. However, neurons in the specialized sensory CVOs are able to detect such fluctuations and transmit this information to autonomic control centers protected by the BBB by CVO efferents. Of course, there are numerous signaling molecules circulating in the periphery at any given time, and the ability of the three sensory CVOs to each detect many of these signals allows them to collect and integrate such complex information; thus, they are ideally positioned as critical enablers for communication between the periphery and the CNS.

3.5.1 Cardiovascular Regulation and Fluid Balance

Cardiovascular function and fluid balance are two systems; the homeostatic regulation of which are so clearly integrated that it perhaps serves no function to attempt to separate them. They are also the functions in which the sensory CVOs are

primarily known to be involved, and thus it is in this area that many of the initial discoveries regarding sensory CVO functions were made. It is now well established that activation of SFO neurons causes rapid increases in blood pressure (Ferguson and Renaud 1984) as well as drinking (Smith et al. 1995), while activation of AP neurons also rapidly changes blood pressure (Ferguson et al. 1988), and also modulates baroreflex sensitivity (Bishop and Sanderford 2000). These two systems are dependent on appropriate balance of osmolarity, fluid volume, and electrolytes in combination with cardiac output and vascular tone, all of which can be regulated by a combination of AP, OVLT and SFO efferents. Many circulating signals provide information regarding the integrated cardiovascular and fluid balance status of an individual, and a number of these are known to be monitored by specific neurons in the sensory CVOs, some of which will be discussed below.

ANG, a peptide hormone, the concentrations of which in the circulation are regulated by BP and $[Na^+]$ does not cross the BBB. Despite this fact, circulating ANG very clearly exerts effects on autonomic output through action of the CNS, causing vasoconstriction, water intake, vasopressin, and ACTH secretion all of which contribute to an increase in BP. The SFO and AP in particular are known to express very high levels of the ANG receptor AT_1 (Gehlert et al. 1990), and single neuron recordings have clearly demonstrated that ANG excites the majority of neurons in these areas (Ferguson and Bains 1996). *In vivo* experiments performed by directly injecting ANG into the SFO result in increases in BP. What is even more convincing are the experiments in which effects of circulating ANG on drinking, BP, and hormone release are abolished by lesion of the SFO, while effects on baroreflex sensitivity are lost following AP destruction (Liu et al. 1999; Ferguson and Bains 1997). Finally, it should also be emphasized that ANG receptors have also been demonstrated in many CNS sites protected by the BBB, and it has been suggested that ANG may even be synthesized in certain areas of the CNS. Such observations clearly suggest that the CNS also uses ANG as a neurotransmitter in specific ANGergic pathways. Such a scenario only remains functionally viable where the BBB protects these areas of the CNS from circulating ANG, which would otherwise continuously activate such ANGergic synapses. Many other circulating peptides known to play critical roles in the regulation of blood pressure and body fluids have also been shown to act in the SFO and/or (Hasser and Bishop 1990) AP including vasopressin (Washburn et al. 1999b; Bishop and Hay 1993), atrial natriuretic peptides (Saavedra et al. 1987; Brown and Czarnecki 1990), endothelin (Wall et al. 1992; Ferguson and Smith 1991), and obestatin (Samson et al. 2007).

SFO and OVLT neurons have also been demonstrated to be intrinsically osmosensitive; and thus, both represent sites at which changes in circulating osmolarity can act to regulate the complex circuitry controlling integrated cardiovascular

and fluid regulation. SFO neurons have also been shown to sense calcium through the calcium sensing receptor (Washburn et al. 1999a) and sodium through modulation of the Na_x channel (Hiyama et al. 2004).

As reviewed in this section of the chapter, the three sensory CVOs are essential in the homeostatic regulation of cardiovascular function and fluid balance. Their unique ability to detect multiple peripheral signals describing the body's fluid and vascular status allows them to be a critical first step in the integrated regulation of cardiovascular function and fluid balance.

3.5.2 Reproduction

The sensory CVOs have also been shown to play roles in the regulation of reproductive function, presumably again as a consequence of their ability to detect reproductive hormones in the circulation, thus closing the loops in critical feedback control circuitry. Hamster food deprivation suppresses the normal progression of the estrous cycle, and lesion of the AP has been shown to abolish this effect (Panicker et al. 1998). Similarly, destruction of both the SFO or OVLT cause a disruption in the secretion of reproductive hormones, with OVLT lesion reducing the luteinizing hormone (LH) surge which normally induces ovulation (Piva et al. 1982), while SFO lesions have been shown to influence the proestrous follicle stimulating hormone (FSH) surge, and perhaps more importantly block normal estrous cyclicity in 50 % of animals (Limonta et al. 1981).

All three sensory CVOs have been found to express multiple signaling molecules and receptors associated with reproductive function including gonadotropin-releasing hormone (GnRH) and oxytocin, as well as estrogen, prolactin and relaxin receptors (Summerlee and Wilson 1994), further supporting their involvement in reproductive function. Activation of estrogen (Pamidimukkala and Hay 2003), prolactin (Black et al. 2014), and relaxin (Sunn et al. 2002) receptors have all also been shown to influence the excitability of neurons in these CVOs. Collectively, these data support important roles for the sensory CVOs in the regulation of reproduction and the potential integration of reproductive function with other homeostatic variables.

3.5.3 Feeding and Metabolism

Before, after, and between meals exists a complex system of hormonal signaling that aids in the digestion and regulation of food intake and metabolism. Production and secretion of various blood-borne peptides are stimulated by specific physiological events or conditions, each of which has the potential to be influenced by physiological state. For example, ghrelin is a peptide produced by ghrelin cells in the gas-

trointestinal (GI) tract when the stomach is empty and increases gastric acid secretion and GI motility to prepare the body for food intake. During meal consumption, the introduction of chyme (containing fatty acids, certain amino acids, and nutrients) from the stomach into the small intestine stimulates the I- and L-cells in the mucosa of the gastrointestinal tract to release various gut hormones such as cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), and peptide YY (PYY). These peptides then enter the bloodstream and travel to effector organs to perform a multitude of functions including signaling the release of various digestive enzymes and bile from the pancreas and gallbladder (role of CCK), stimulating the release of peptide hormones such as insulin or glucagon from the pancreas (role of GLP-1), or inhibiting gastric motility (role of PYY). Insulin and amylin are co-secreted from pancreatic beta cells in response to rising glucose levels and function to prevent post-prandial spikes in blood glucose levels. Between meals, adipocytes, or fat cells, release the protein hormones adiponectin and leptin that are responsible for regulating metabolic processes involved in energy homeostasis such as glucose regulation and fatty acid oxidation.

Interestingly, in addition to their unique roles in digestion and energy metabolism, these blood-borne peptides all possess the ability to act as hunger or satiety signals in the central nervous system. They can be simplistically categorized into two types: orexigenic—causing a sensation of hunger and promoting food intake (only known GI peptide to date is ghrelin), or anorexigenic—causing a sensation of satiety and inhibiting food intake (i.e. CCK, GLP-1, PYY, adiponectin, and leptin). However, due to the lipophilic nature of these peripheral signals, they are unable to cross the BBB; and therefore, alternative methods through which they communicate with the brain have been proposed, one being by actions in the sensory CVOs.

Over the past few decades there has been growing evidence to support the idea that sensory CVOs, initially the AP and more recently the SFO, are involved in the neural circuitry underlying hunger and satiation, specifically by acting as an integrative ‘gate keeper’ that senses various circulating hormones and transmits the information to areas of the hypothalamus and brainstem.

The presence of receptors in the AP and SFO for these various gastrointestinal hormones involved in energy homeostasis has been confirmed using various scientific approaches including *immunostaining*, *in situ hybridization*, as well as *pharmacological* approaches. Many of these peptide hormones cause increased c-fos expression (an indirect marker of neuronal activity) in the AP and SFO when injected intraperitoneally, and/or have been shown to cause changes in the excitability of AP and SFO neurons in dissociated or slice preparations. The AP expresses receptors for and can respond to: adiponectin, leptin, amylin, ANG, CCK, ghrelin, GLP-1,

oxyntomodulin, vasopressin and PYY (Baraboi et al. 2010a); while the SFO can sense and respond to ANG, calcitonin, amylin, ghrelin, leptin, adiponectin, CCK, and PYY (see Fig. 3.3) as described in reviews (Cottrell et al. 2004; Hoyda et al. 2009; Smith et al. 2010). These data are important as they show that the receptors expressed by these sensory CVOs are in fact able to continuously monitor these circulating signals involved in energy homeostasis.

Behavioral studies have also demonstrated critical roles for the sensory CVOs in regulation of energy balance. Lesioning the AP results in significant hypophagia and loss of body weight (Hyde and Miselis 1983; Bird et al. 1983; Contreras et al. 1982), while Potes et al. demonstrated that lesioning noradrenergic AP neurons abolished subcutaneously injected amylin induced hypophagia (Potes et al. 2010). Jordi et al. assessed the effect of oral ingestion of 20 amino acids and found that food intake was most potently reduced by L-arginine (Arg), L-lysine (Lys), and L-glutamic acid (Glu), effects that were accompanied by increased neuronal activity in the AP and NTS. Interestingly, when the AP was surgically lesioned, the anorectic response and increased neuronal activity in the AP and NTS, in response to Arg and Glu, was abolished suggesting that the AP is not only a sensor of circulating GI peptide hormones released when food is ingested, but also a sensor of metabolic food products themselves (Jordi et al. 2013). Although the majority of work involving lesioning the SFO has focused on effects on fluid balance, a recent study has shown that, while lesion of just the SFO has no effect on body weight, combined lesion of SFO and AP has long lasting effects on body weight gain (Baraboi et al. 2010b). In addition, we have recently shown that electrical activation of SFO neurons in satiated rats induces feeding as well as drinking (Smith et al. 2010). Collectively, these data support the conclusion that the AP and SFO, through their connections to the brainstem and hypothalamus, play an important role in central nervous system control of energy homeostasis as components of an integrated network.

3.5.4 Immune Function and Temperature Regulation

The continuous crosstalk between the nervous and immune systems is critical to the integrated mechanisms through which the nervous system can regulate specific immune system functions through the production of neuroregulators (neurotransmitters, neuromodulators, and neuropeptides). Additionally, the peripheral immune system has the ability to regulate specific nervous system functions through the production of immunoregulators (immunomodulators and immunopeptides) (see Fig. 3.5). For example, classical neurotransmitters such as norepinephrine and serotonin are able

Fig. 3.5 Communication between the nervous and immune systems. The nervous system and immune system communicate and influence one another via neuro-immune and immuno-neural pathways utilizing neuroregulators and immunoregulators, respectively. Microbial products, toxins, and inflammation can trigger synthesis and release of immunoregulators from immune or CNS cells, signals that are integrated at the circumventricular organs

to induce immunosuppression (Walker and Codd 1985), while lymphocytes and leukocytes express receptors for and can synthesize biologically active neuroendocrine peptide hormones (i.e. growth hormone and adrenocorticotrophic hormone), which can not only influence nervous system function, but can also modulate the proliferation and differentiation of T-lymphocytes [for review see (Weigent and Blalock 1987)].

Immunomodulators, such as interleukin 1 (IL-1) and tumor necrosis factor (TNF), are important regulators of immune responses and inflammatory reactions. Bacterial endotoxins, such as lipopolysaccharide (LPS), can bind to

immune cells, such as monocytes and macrophages, and promote secretion of these pro-inflammatory cytokines. Interestingly, the biological actions of IL-1 and TNF are not restricted to the immune system. They have been found to have various actions in the nervous system, including pyrogenic, thermogenic, and somnogenic effects, influence on growth and differentiation, as well as suppression of food intake [for review see (Plata-Salaman 1991)]. This seems logical seeing as sickness is often associated with fever, tiredness, and decreased appetite. While the way in which these two systems communicate to coordinate integrated responses is not yet fully understood, the CVOs, with their

IL-1 β interleukin 1 beta, TNF tissue necrosis factor, LPS lipopolysaccharide

lack of a BBB, represent an access point for circulating cytokines and endotoxins to directly influence the CNS (see Table 3.1). Furthermore, because of their connections to critical autonomic control centers, the CVOs have been suggested as integrators for the multiple components of these coordinated responses.

Using in situ hybridization, receptors for IL-1 β (IL-1R) (Ericsson et al. 1995), TNF (p55) (Nadeau and Rivest 1999), and bacterial LPS (mCD14 and toll-like receptor 4 (TLR-4)) (Laflamme and Rivest 2001) have been shown to be expressed by the sensory CVOs. The SFO also expresses receptor mRNA for ciliary neurotrophic factor (Hindmarch et al. 2008), another mediator of the immune response.

In vitro and in vivo techniques that examine neuronal activity have been used to examine the effects of activation of these receptors. Peripheral administration of IL-1 β increases *c-fos* expression in the AP, OVL, SFO, PVN, NTS, and PBN (Brady et al. 1994; Day and Akil 1996), and has also shown to induce phosphorylation of extracellular signal-regulated protein kinase 1 and 2 (ERK1/2) in the CVOs, PVN, and SON (Nadjar et al. 2005). Peripheral administration of TNF- α has been shown to cause upregulation of mRNA for both TNF receptors (p55 and p75) in the CVOs, while also increasing *c-fos* expression in the CVOs, PVN, and NTS (Nadeau and Rivest 1999). Additionally, one hour after intravenous TNF- α administration, PVN expression of corticotropin-releasing factor increased, an effect that was associated with increases in the plasma corticosterone levels (Nadeau and Rivest 1999). Systemic administration of LPS has been shown to rapidly stimulate transcription of IL-6 mRNA and biosynthesis of IL-6 receptor (IL-6R) in the sensory CVOs (Vallieres and Rivest 1997). Pretreated OVL and AP microcultures with IL-10 antibodies before incubation with LPS show significantly enhanced LPS-induced increase

in TNF- α and IL-6 in the microculture supernatant (Harden et al. 2013), which suggests that the CVOs may have a key role to play in both the initiation and modulation of neuroinflammation. An in vivo example of CVO involvement during the development of neuroinflammation can be seen when Wuerfel et al. demonstrated increased signal intensity in the SFO and AP on gadofluorine M-enhanced MRI scans during autoimmune encephalomyelitis (Wuerfel et al. 2010).

Gerstberger et al. have shown that AP and OVL neurons respond to LPS, TNF- α , and IL-1 β with increases in intracellular calcium (Wuchert et al. 2008, 2009; Ott et al. 2010). Interestingly, the 2008 study also showed that LPS-induced calcium signaling can be suppressed by pre-incubating AP microcultures with LPS for 18 h, suggesting that AP cannot only sense circulating LPS but also has the capacity to develop endotoxin-tolerance. Patch clamp recordings from dissociated SFO neurons have also shown that physiological (subseptic) bath application of IL-1 β cause depolarization with increased spike frequency due to activation of a non-selective cationic current (Desson and Ferguson 2003). Additionally, OVL neurons in slice preparations have been shown to increase firing frequency in response TNF- α and interferon α -2 (Shibata and Blatteis 1991).

Finally, we turn our attention to CVO ablation and lesion studies that present evidence for CVO involvement in fever production and neuroendocrine activation during the immune response. The OVL was originally hypothesized to be involved in the febrile response due to its proximity and reciprocal neuronal connections to the median preoptic nucleus (MnPO) and the medial preoptic area (MPO), both critical hypothalamic sites for central thermoregulation and fever production (Nakamura and Morrison 2008; Lazarus et al. 2007). Blatteis et al. ablated the anteroventral third ventricular (AV3V) area, which included the

OVLt, in guinea pigs and sheep and found that these animals were no longer capable of developing a fever in response to systemic endogenous pyrogens (Blatteis et al. 1983, 1987). Conversely, Stitt (1985) found OVLt (not AV3V) lesion-induced fever enhancement in rabbits and rats; whereas, Takahashi et al. (1997) found that lesioning the OVLt or AP had no effect on fever while SFO lesion significantly reduce LPS-induced fevers. As might be expected, the cause for such discrepancies between results was then sought. A more recent study, which reappraised these previous experiments, demonstrated that lesioning the OVLt resulted in many “side effects,” which were not properly controlled for, including acute adipisia and gross emaciation, and chronic hypernatremia, hyperosmolality, a suppressed drinking response to hypertonic saline, and previously unrecognized long lasting hyperthermia (2 °C for >3 weeks) (Romanovsky et al. 2003). After recovery from acute, but not chronic, side effects, rats were still unable to elicit a febrile response to injected IL-1 β . The authors note, however, that rats were in a hyperthermic state at the time of injection, and that this may have been the underlying explanation for the lack of febrile response, not a disruption of a febrigenic-signaling pathway.

The previously described SFO ablation induced reduction of febrile response seen by Takahashi et al. in 1997 gained support in 1999 when Cartmell et al. who demonstrated that microinjection of the IL-1 receptor antagonist into the SFO attenuated LPS induced fever (Cartmell et al. 1999) also showed that antagonist injection into the OVLt had no effect on febrile response. This further supports the hypothesis that the attenuation of febrile response seen in previous studies may not have been attributed to a disruption in the febrigenic-signaling pathway, as was previously suggested.

Studies examining the neuroendocrine response to IL-1 β have suggested roles for the AP as the large elevations in adrenocorticotrophic hormone (ACTH) and corticosterone levels in the plasma in response to systemic IL-1 β and increases in fos expression in AP, NTS, and PVN are attenuated by AP lesion (Lee et al. 1998). This suggests that the AP and adjacent NTS play a critical role in sensing and transducing this circulating cytokine signal to the hypothalamic-pituitary-adrenal axis thereby indirectly influencing the release of ACTH and corticosterone into the bloodstream. Peripherally administered IL-1 β has also been shown to increase extracellular norepinephrine concentration in the PVN of the hypothalamus, an effect that is also attenuated in AP-lesioned rats (Ishizuka et al. 1997).

3.6 Review Questions

1. What are some defining characteristics of sensory CVOs?
2. What makes the sensory CVOs ideal integrative sites?
3. Can most cytokines and peptides cross the blood-brain barrier?

4. What are ways in which the peptides and cytokines can access the CNS?
5. Name two critical neuroendocrine nuclei in the hypothalamus onto which CVOs project.
6. (a) What are the differences between sensory and secretory CVOs?
(b) Why is it important that these areas lack a normal blood-brain barrier?
7. A female rat that is a subject in your study does not display the usual increase in blood pressure in response to ANG injection. Her estrous cycle has been disrupted and her febrile response to lipopolysaccharides (LPS) is much smaller than expected. Based on these observations, which CVO would you say has been damaged in the subject?

3.7 Answers

1. Lack a blood-brain barrier (fenestrated capillaries) High expression of peptide and hormone receptors. Extensive efferent projections, fewer afferent
2. The defining characteristics of: lack of a blood-brain barrier, high receptor expression and extensive efferent projections enable the sensory CVOs to interpret information from different systems, whether it be electrical or chemical, and convey this integrated information to autonomic control centers protected by the BBB.
3. No, many are too large or lipophobic
4. Diffusion across the BBB; Active transport across the BBB; Binding to receptors in the sensory CVOs, which aren't protected by the BBB
5. Paraventricular Nucleus (PVN); Supraoptic Nucleus (SON)
6. (a) Sensory CVOs detect signals circulating in the periphery; whereas, secretory CVOs secrete hormones directly into the circulation.
(b) In order to detect peripheral signals, sensory CVOs need direct access to the circulatory system. Similarly, secretory CVOs need direct access in order to secrete their respective hormones into circulation.
7. Subfornical Organ (SFO)

Anterior Chamber and Retina (Structure, Function and Immunology)

4

William Rhoades, Leila Kump, and Eyal Margalit

Abstract

The goals of this chapter are to review the anatomy of the eye and its immune response, focusing on the anterior and posterior segments. Anterior segment diseases with known immune system involvement include keratitis, uveitis, dry-eye syndromes, uveal melanoma, and allograft rejection following corneal transplantation. Posterior segment diseases with immune system involvement include age-related macular degeneration, glaucoma, chorioretinal disorders and autoimmune retinopathies including cancer and melanoma associated retinopathies.

Keywords

Age related macular degeneration • Anterior chamber associated immune deviation • Autoimmunity • Complement • Immune deviation • Ocular immunology • Ocular inflammation

4.1 Anatomy and Physiology: The Eye

The eye is a sensory organ which uses its lens system to focus light from the surrounding environment onto the retina. The cornea, iris, and crystalline lens cooperate to form a focused image on the retina. The neurons of the retina capture the image and encode it for accurate transmission via the optic nerve to the visual centers in the brain. Figure 4.1 shows a horizontal cross-section of the human eye. Light

entering the eye is refracted by the cornea and the crystalline lens, and is aperture-limited by the iris. The lens is suspended by a ring of thin fibers (zonules) that are attached to a membrane encapsulating the lens. The refractive power of the lens can be adjusted by contraction or relaxation of a muscle ring called the ciliary muscle, which thickens the lens to allow accommodation.

The eye contains three compartments: the anterior chamber (AC), posterior chamber, and vitreous cavity. The AC is a space between the iris and the cornea, which is filled with aqueous humor. On average, it is 3 mm deep, with a volume of about 250 μ L. The posterior chamber is also filled with aqueous humor; its location is posterior to the iris and ciliary body and anterior to the lens and the vitreous face. The largest compartment of the eye is the vitreous cavity, which is filled with vitreous gel. Its average volume is 6 mL. This compartmental division is a practical one. It is used extensively in clinical practice of ophthalmology. Differential diagnosis of a large number of infectious and inflammatory disorders is based on the anatomic location of the process.

4.2 Anterior Chamber

4.2.1 Anatomy and Physiology

The cornea serves as the most anterior structure of the AC. Its exterior is covered by the precorneal tear film, which lubricates, nourishes and protects the corneal surface. The iris and

the pupil represent the posterior border of the AC. The AC angle is an important structure which is comprised of: Schwalbe's line, Schlemm's canal and trabecular meshwork, scleral spur, anterior border of the ciliary body and the iris (Fig. 4.2). Aqueous humor that fills the AC is produced by the ciliary epithelium located in the posterior chamber. The fluid flows through the pupil and is drained by the trabecular meshwork into Schlemm's canal and subsequently into the

episcleral vessels. This passage is named *the conventional pathway*. Aqueous humor is also drained by *the uveoscleral pathway* across the ciliary body into the supraciliary space.

4.2.2 Anterior Chamber Associated Immune Deviation (ACAID)

The phenomenon of immune privilege was initially described by Dutch ophthalmologist van Dooremal 1873. He noticed that tumor cells injected into the AC formed growing tumors unlike tumor cells injected into skin or other organs. Medawar discovered that transplants between genetically different individuals were usually destroyed. However, skin grafts placed in the AC and in the brain of rabbits survived much longer. Medawar called the AC and the brain “immune privileged sites.” Medawar explained that immune privilege was a special circumstance where the laws of transplantation immunology did not apply (Medawar 1948). Immune privilege was later defined as a prolonged, sometimes indefinite, survival of organ or tissue grafts at special body/organ sites (Barker and Billingham 1977). Additional examples of such immune privileged sites would be the cornea, lens, vitreous cavity and subretinal space; testis, ovary, adrenal cortex, pregnant uterus and certain tumors.

Anatomic structures were originally considered key elements of immune privilege in early studies. The existence of a blood-tissue barrier and the absence of afferent lymphatic drainage pathways led to the belief that antigens of the grafts placed in immune privileged sites remained physically sequestered from the immune environment. As such, the immune system never became aware of them. However, later studies demonstrated that the maintenance of immune privilege is actually a dynamic process combining immunoregulatory forces combined with anatomic structure to allow the survival of grafts in privileged sites (Niederhorn et al. 1980; Niederhorn 1990; Ksander and Streilein 1993; Tompsett et al. 1990; Streilein 1995). In other words, the blood-brain and blood-ocular barriers exist, but their creation and exis-

tence are actively maintained. The list of factors responsible for the ocular immune privilege is presented in Table 4.1.

It is now recognized that both active and passive factors contribute to sites with immune privilege. It has been known for over 100 years that the AC possessed qualities allowing a long-term survival of tissue and tumor grafts (Van Dooremal 1873). In the late 1970s Kaplan and Streilein discovered that antigenic cells placed into the AC were not only detected by the immune system, but also elicited a down-regulation of alloimmune responses (Kaplan et al. 1975; Kaplan and Streilein 1977).

It became clear that antigens are not physically sequestered from immune recognition in the AC, but that the consequence of their detection is a deviation from the expected immune response. Although AC injection of allogeneic lymphoid cells aroused the humoral arm of the immune response resulting in the production of antibodies against donor histocompatibility antigens, the cell-mediated component was impaired. Studies in the early 1980s led to the knowledge that a wide variety of antigens (alloantigens, tumor-specific antigens, soluble protein antigens, haptens, viral-encoded antigens) placed in the AC of mice produced a similar deviant pattern of systemic immune responses. Niederhorn, Streilein and Shadduck coined the term Anterior Chamber Associated Immune Deviation (ACAID) to designate this unusual response (Niederhorn et al. 1980). ACAID is an antigen-specific systemic immune response to eye-derived antigens, a response that represents a selective deficiency of T cell functions that mediate delayed hypersensitivity to the antigen Th1 cells and B cells that secrete complement-fixing antibodies. However, this systemic immune response retains primed, clonally expanding cytotoxic T cell precursors and B cells that secrete IgG1, a noncomplement-fixing antibody. Lymphoid tissues of mice with ACAID contain three populations of regulatory T cells: CD8⁺ T cells suppressing expression of delayed hypersensitivity; CD4⁺ T cells suppressing the induction of Th1 cell responses; and CD8⁺ T cells that inhibit B cells from switching to IgG isotypes that fix complement.

Table 4.1 Factors responsible for ocular immune privilege

Passive	Active: soluble factors	Active: cell-surface factors
Blood-tissue barrier	Transforming growth factor- β 2	CD95 ligand
Tissue fluids drain IV	Alpha-melanocyte stimulating hormone	CD55, CD59, CD46
Deficient lymphatics	Vasoactive intestinal peptide	
Reduced expression of major histocompatibility class I and II molecules	Calcitonin gene-related peptide	
Reduced antigen presenting cells with altered function	Somatostatin	
	Thrombospondin	
	Macrophage migration inhibitory factor	
	IL-1 receptor antagonist	
	Free cortisol	

In late 1980s experiments with samples of aqueous humor showed that it possessed some immunomodulatory properties, but these properties were not global, i.e. aqueous humor does not inhibit all immune reactions (Kaiser et al. 1989). Suppression of the following phenomena by aqueous fluid was found:

1. Activated macrophage production of nitric oxide and reactive oxygen intermediate (Taylor et al. 1998).
2. Neutrophil-mediated lysis of target cells (Miyamoto et al. 1996).
3. Lysis of target cells by natural killer (NK) cells (Apte and Niederkorn 1996).
4. Conventional antigen-presenting cell (APC) activation of Th1-type cells in-vitro (Takeuchi et al. 1999).
5. C1q from binding to antibody-coated erythrocytes.
6. C3 cleavage to C3b via the classical or the alternative complement pathways (Goslings et al. 1998).

Streilein and Kaplan have discovered that the spleen plays a crucial role in the immune deviation effects in rats (Streilein and Kaplan 1979). This was confirmed in later experiments in mice (Streilein and Niederkorn 1981; Wilbanks et al. 1991). Following an injection of the heterologous protein antigen ovalbumin (OVA) into the AC, an ACAID-inducing signal (AIS) is released to the blood stream. For example, when naïve mice received intravenous injection of blood from mice that had been injected with OVA into the AC 48 h prior, the naïve mice acquired OVA-specific ACAID. It was postulated that eye-derived antigen-bearing antigen presenting cells (APCs) escaped through the trabecular meshwork, and cells migrated via the bloodstream to the spleen. In the spleen, the regulatory cells that mediate ACAID eventually emerged. This hypothesis suggests that the eye contains nascent APCs that pick up the antigen and deliver it to the spleen via the blood. The spleen induces ACAID, without which, immune privilege in the AC cannot be sustained.

Further understanding of the ACAID phenomenon is attributed to Hara et al. who developed an in-vitro generated ACAID-inducing signal (Hara et al. 1992). These investigators incubated conventional APC (from peritoneal exudate) overnight in the presence of acid-treated aqueous humor and then pulsed with OVA. When injected into naïve mice these APCs induced ACAID. Since then, it became possible to perform experiments with ACAID-inducing APCs that could be grown in vitro. Takeuchi and Streilein conducted series of experiments that led them to conclude that ACAID-inducing APCs were formed by pulsing active-TGF β -2-pretreated-peritoneal-macrophages with OVA. The principal action of TGF-beta is to inhibit activation and proliferation of lymphocytes. It is a family of molecules named TGF β -1, TGF β -2 and TGF β -3. Cells of the immune system mostly produce TGF β -1. This family inhibits immunologic, inflammatory

responses and has immunosuppressive effect. The above-mentioned APCs were capable of activating T-cell receptors (TCR), transgenic OVA-specific CD4 cells, and CD8 T cells in vitro (Takeuchi et al. 1998, 1999).

A universal property of ACAID-inducing APCs created in vitro is the capacity to deviate naïve CD4+ and CD8+ T cells away from their typical differentiation pathway toward a pathway that might enable them to be regulators. Normal aqueous humor contains large amounts of thrombospondin (a glycoprotein involved in the clotting cascade). The gene controlling the formation of this protein is constantly active in ocular parenchymal cells. Thrombospondin and TGF β -2 may be the key players in creating immune deviation when antigens are introduced into immune-privileged sites.

Unique qualities of ACAID-inducing APCs have been analyzed by many researchers in order to understand their ability to alter the function of responding T cells (Takeuchi et al. 1998; Faunce et al. 2001; Masli et al. 2002). TGF β -2 treated peritoneal macrophages usually activate Th1 cells, and express normal levels of class I and II major histocompatibility proteins. However, TGF β -2 exposed APCs fail to upregulate CD40, and they secrete only small amounts of IL-12. IL-12 serves as a mediator and an inducer of innate immune responses to intracellular microbes. It also activates NK cells, promotes their cytolytic activity and development of Th1 cells. CD40 plays various roles in macrophage, dendritic cell and endothelial cell activation. Expression of IL-12 and CD40 is not upregulated even in the presence of responding T cells. Interestingly, the supernatants of TGF β -2-treated APCs contain active TGF β -1, which is usually produced by bone-marrow-derived cells.

In addition, treatment with active TGF β -2 has a profound effect on the genetic arrangement of APCs, as discovered by a study of macrophage hybridoma #59, which is a laboratory-created cell line for immunologic studies (Wetzig et al. 1982). It is apparent that the thrombospondin gene is an early target of TGF β -2 and is upregulated. Thrombospondin has a number of actions that promote the ACAID-inducing properties of TGF β -treated APCs listed here:

1. It binds to CD36 on APCs and tethers latent TGF β to the APC surface;
2. It binds to CD47 on APCs and on responding T cells, potentially forming a cellular bridge that stabilizes the APC/T cell interaction;
3. With CD47 on T cells, thrombospondin alters signaling through the TCR in a manner that deviates the cell's functional program; and
4. It promotes conversion of latent TGF β to its active form in the environment between APC and T cells.

As mentioned above, the spleens of mice that receive OVA into the AC acquire three populations of regulatory T

cells. These cells are produced within 7 days (Wetzig et al. 1982; Niederkorn and Streilein 1983; Waldrep and Kaplan 1983; Wilbanks and Streilein 1990). One population is CD4+. When it is adoptively transferred into naïve recipients, it suppresses the induction of OVA-specific delayed hypersensitivity. A second population of regulatory cells is CD8+, which inhibits the expression of delayed hypersensitivity. So, generation of ACAID correlates with regulatory T cells that suppress the induction and expression of delayed hypersensitivity. A third population of regulatory CD8+ cells arises following AC injection of OVA. This population prevents OVA-specific B cells from class-switching their immunoglobulin isotype to the isotypes that fix complement: IgG2a, IgG2b, and IgG3.

The second population of regulatory cells, efferent CD8+ T cells that suppress delayed hypersensitivity expression, has gained a lot of attention because of its uniqueness to ACAID. These cells are relatively easy to detect and evaluate. They can be evaluated systemically by transferring large numbers of spleen cells intravenously into mice previously sensitized to OVA and challenged for delayed hypersensitivity a few hours later. The regulator cells can be also evaluated locally in a “local adoptive transfer reaction” in which putative regulator cells are mixed with OVA-specific T cells and antigen, and the mixture is injected intradermally into the ear pinnae of naïve mice. Thus, researchers have been able to elucidate a mechanism of ACAID by demonstrating the production of T regulatory cells that inhibit the local expression of delayed hypersensitivity.

In order to induce immune deviation only two cells need to interact: the “tolerogenic” APC and the T cell. These two cells interact under the influence of innate immune cells within the lymphoid organs. It has been found that ACAID does not occur in the absence of gamma/delta T cells (Skelsey et al. 2001; Xu and Kapp 2001), natural killer T (NKT) cells (Sonoda et al. 1999), or B cells (D’Orazio and Niederkorn 1998b). The innate cells that have been most exclusively studied are the APC and NKT cells. The NKT cell is important in peripheral tolerance induction in association with the AC (Sonoda et al. 1999). The antigen-transporting cells may direct the multicellular organization of the innate cells (specifically, NKT cell) with the appropriate adaptive immune cell precursors. The soluble factors secreted by the antigen-transporting cell recruit specific cell types and factors to create an immunosuppressive environment favorable to the induction of tolerance. The antigen that is injected into the AC is carried from the eye by the indigenous APCs. These transporting APCs are unique, possibly because they are bathed in eye-specific immunosuppressive factors that induce their special phenotype. It has been shown that the eye-derived macrophages selectively increased the chemokine MIP-2 (Faunce et al. 2001). While MIP-2 was previously thought to be a neutrophil

chemoattractant, it was found that MIP-2 was a strong chemoattractant for NKT cells as well. NKT cells are absolutely required for the development of the efferent T regulator cell in ACAID. When NKT cells were removed by use of antibodies *in vivo*, or when NKT deficient mice were used, the efferent T regulator cells were not generated (D’Orazio and Niederkorn 1998a).

4.2.3 ACAID and Other Forms of Immune Regulation and Tolerance

Immunologic tolerance is defined as unresponsiveness to an antigen and it is induced by prior exposure to that antigen. When specific lymphocytes encounter antigens, three possible outcomes may follow: the lymphocytes are activated, leading to immune responses; the lymphocytes are inactivated or eliminated, leading to tolerance; or the antigen is ignored. Different forms of the same antigen may induce an immune response or tolerance or may elicit no response. Tolerance comes in many forms. Central tolerance ensures that the repertoire of mature lymphocytes cannot recognize ubiquitous self antigens, which are antigens most likely to be present in the degenerative lymphoid organs. This mechanism is mainly responsible for the elimination of self-reactive lymphocytes from the mature repertoire, and thus for self/nonself discrimination and therefore suppression of autoimmune disease. Peripheral tolerance, also called “active tolerance,” is induced by recognition of antigens without adequate levels of the costimulators that are required for lymphocyte activation. T cell activation requires not only the recognition of antigen, but also the recognition of costimulators. These are also called “signal 2.” If costimulators are not present while the antigen is being recognized, T cell anergy occurs. This also occurs in response to persistent and repeated stimulation by self-antigens in the peripheral tissues.

ACAID is a special form of peripheral tolerance. About 98% of the antigen that is inoculated into the eye is carried into the bloodstream within 6 h of injection (Wilbanks and Streilein 1989). It was initially suggested that ACAID is just a manifestation of intravenously induced tolerance. However, ACAID was demonstrated to be distinctly different from intravenously induced tolerance. Intravenous tolerance is mediated by a CD8+ afferent T suppressor/regulator cell, and in intravenous tolerance no regulatory efferent T cell is generated (Heuer et al. 1982). In ACAID, the afferent regulatory T cell is CD4+ and the efferent regulator is CD8+. Further, ACAID does not occur in mice that are deficient in NKT cells. Intravenously induced tolerance to the same antigens can be induced readily in NKT cell knockout (KO) mice (Sonoda et al. 1999).

Both ACAID and oral tolerance produce efferent CD8+ T regulator cells that are dependent on intact NKT cells. While

low dose oral tolerance and ACAID correlate with the presence of efferent CD8+ regulatory cells, the cells are not functionally identical. The efferent T cells of oral tolerance respond to antigen by secreting IL-10 and TGF- β , whereas the efferent T suppressor cells of ACAID secrete TGF- β only (Weiner 1997). However, NKT cells are needed for both forms of CD8+ T regulatory cell-mediated tolerance.

T helper cells were found to comprise two functionally distinct types (type 1 and 2) (Mosmann and Coffman 1989; Mosmann 1992). Th1 cells responded to antigen stimulation by secreting IL-1 and IFN γ . Th1 cells mediate delayed hypersensitivity reactions, and promote the switch of B cells to Ig isotypes that fix complement (IgG2a/b, IgG3 in mice). Th2 cells respond to antigen stimulation by secreting IL-4, IL-5, IL-6, IL-10, and IL-13, but they fail to secrete IFN γ . Th2 cells promote humoral responses rich in noncomplement-fixing IgG1, IgA, and IgE antibodies. Also, Th1 and Th2 cells are able to cross-regulate each other: Th1 cells suppressing Th2 cells and vice versa. Cross-regulation of Th1 and Th2 cells has been called “immune deviation.” It was speculated that ACAID is a Th2 response evoked by an unusual route of antigen delivery (the eye). It has been reported that mice genetically deficient in IL-10 production fail to acquire ACAID (D’Orazio and Niederkorn 1998a). Some experiments dispute the idea that ACAID is a Th-2 mediated response (Streilein et al. 2001). It is currently thought that ACAID represents a unique form of tissue-dependent regulation of systemic immunity that resembles, but is mechanistically different from tolerance induced by some other routes and procedures. ACAID is a form of peripheral tolerance, unlike central tolerance, where clonal deletion and/or anergy occur within the thymus. Once induced, ACAID persists for a very long period of time. ACAID is an actively acquired and actively maintained manifestation of ocular immune privilege.

4.2.4 ACAID, Ocular Immune Diseases and Implications for Therapy

ACAID may have either beneficial or deleterious effects on ocular inflammatory disease. Ocular inflammation that is elicited by T cell-mediated delayed hypersensitivity and by complement fixing antibodies. ACAID tries to protect the eye from inflammation related injury by selectively suppressing innate (production of phagocytic cells and NK cells, blood proteins and cytokines) and adaptive (lymphocyte and antibody production) immune responses of the intense proinflammatory type (when large amounts of proinflammatory cytokines are present and are ready to excite inflammation). For certain infectious pathogens the entire array of immune defense mechanisms is mobilized in order to eliminate the exciting agent. Because of immune privi-

lege and ACAID, resistance to infectious agents cannot be mediated by delayed hypersensitivity T cells and by complement-fixing antibodies because these components are not active in such an environment. Thus, immune privilege and ACAID could have both positive and negative effects in the eye. ACAID might play a role in protecting the eye against autoimmune attack directed at strong ocular autoantigens such as arrestin, interphotoreceptor retinol binding protein, and rhodopsin.

Some speculate that ACAID-based immunotherapy may be beneficial in immune-mediated diseases of the eye and a variety of other organs. This is due to the fact that the immune deviation of ACAID produces T regulatory cells that are effective in inhibiting both Th1 and Th2 responses (both primary and secondary responses). Cd1d-reactive NKT cell-dependent tolerance or ACAID induced by inoculation of antigen into the eye may contribute to self-tolerance and prevention of autoimmune responses in organs and tissues in general.

There are reports of correlations of defective or deficient NKT cells in a number of autoimmune diseases in mice and humans (Sumida et al. 1995; Baxter et al. 1997; Wilson et al. 1998; Illes et al. 2000; Mieza et al. 1996; Zeng et al. 2000; Shi et al. 2001; Nagane et al. 2001). In humans, diabetes, systemic sclerosis, myasthenia gravis, and multiple sclerosis and in mice, a lupus model, are associated with NKT cell deficiencies. It was demonstrated that the adoptive transfer of NKT cells prevented diabetes in NOD mice. However, it is not clear whether the effectiveness of this treatment was actually due to the establishment of immune deviation of T cell-mediated active tolerance.

It is known that ACAID contributes to ocular tumor survival and long-term survival of orthoptic corneal allografts. Some experiments showed that removal of NKT cells prevented the continued acceptance of ocular tumors and caused the elimination of the immune privilege of the eye. Without functioning NKT cells, mice were not able to accept orthoptic corneal allografts for prolonged periods of time (Sonoda et al. 2002). This data demonstrates the essential role of NKT cells in the generation of ACAID. New information about ACAID may lead to application of ACAID mechanisms in prevention and treatment of immune-mediated inflammatory diseases in humans.

4.2.5 Corneal Transplantation and Ocular Immune Responses

Corneal transplantation is the most common form of solid organ transplantation today. While very successful in patients without corneal neovascularization, it can be less effective in patients with highly vascularized corneal beds (Maguire et al. 1994). T cell mediated graft rejection can be promoted

by chemotactic cytokines and receptors to antigen presenting cells in the cornea in highly vascularized eyes, indicating that when physical barriers are altered and neutrophils are recruited to the allogenic graft, ACAID processes may not be able to prevent rejection. Recent experiments have also shown that neutralizing certain chemokines can lead to prolonged graft survival (Amescua et al. 2008). These experiments show that transplant rejection in the AC can also be mediated by chemotactic factors that have a role in ocular immune responses to allogeneic transplantation. Further research may provide more insight into ocular transplant outcomes.

4.3 Retina

4.3.1 Anatomy

A more complete coverage of this topic appears in Sect. 4.4 of this book. In short, the retina is a thin transparent layered structure lining the posterior eye wall. The main cell types include photoreceptors (rods and cones), which capture the light; bipolar and ganglion cells, which pass the visual signal on towards the optic nerve, and horizontal and amacrine cells, which provide lateral interactions among cells in neighboring locations. Figure 4.3 demonstrates a diagram of cross-sectioned retinal layers (A), a preparation of normal donor retina (B), and tissue from a donor who suffered from a retinal degeneration, causing the disappearance of the photoreceptor layer (C).

The layers of normal cross-sectioned retina (from outer to inner retina in Fig. 4.3a) are:

1. Retinal pigment epithelium (RPE) and its basal lamina
2. Rod and cone inner and outer segments
3. External limiting membrane
4. Outer nuclear layer
5. Outer plexiform layer
6. Inner nuclear layer
7. Inner plexiform layer
8. Ganglion cell layer
9. Nerve fiber layer
10. Internal limiting membrane

A single layer of RPE cells fulfills the role of sustaining the metabolism of the photoreceptors: The metabolic level of the photoreceptor outer segments is among the highest in the human body. RPE cells supply nutrients and oxygen, regenerate phototransduction products, and digest debris shed by the photoreceptors.

Photoreceptors, the cells capturing the incoming light, come in two classes: rods, which allow vision at low light levels, and cones, in short, medium, and long wavelength types to allow color perception. In both classes of cells the actual light capture and conversion takes place in the outer segment—visible as a band with long/thin elements (rods) in Fig. 4.3b. The cell's inner segment provides the transduction to secondary neurons and regulates cell function.

The outer plexiform layer (OPL) contains the contacts between photoreceptors, horizontal and bipolar cells, allowing

Fig. 4.3 (a) Schematic representation of the cell layers in the retina. Light entering the retina passes through the nerve fiber (9), ganglion cell (8), inner nuclear (6)—containing bipolar cells (B), and outer nuclear (4) layers, before being absorbed in the outer segments of the rods (R) and cones (C). (b) Cross section through the retina near the fovea, showing healthy photoreceptor outer segments (POS), multiple layers of photoreceptor cell nuclei in the outer nuclear layer (ONL; labeled black), bipolar cell nuclei in the inner nuclear layer (INL) and ganglion cell bodies in the ganglion cell layer (GCL). (c) Retina of a patient with retinal degeneration, and poor vision, showing lack of photoreceptor outer segments and cell bodies in comparison with B

the first stage in retinal image processing to take place. This processing provides coupling between neighboring rods and/or cones, allowing for the smooth transition between rod and cone function during light/dark adaptation and for dealing with differences, and rapid changes, in illumination.

The inner nuclear layer (INL) contains the cone and rod bipolar cells. Cone bipolar cells form the first stage of image processing in the visual system, combining output from different cone types for color processing. In the periphery, they gather information from multiple cones, and save image transmission bandwidth by reducing resolution. All rod bipolar cells receive input from multiple rods, allowing reliable signal processing at very low light levels. Also located in the INL are the cell bodies of horizontal and amacrine cells.

In the inner plexiform layer (IPL), extensive interactions take place through synaptic contacts: between bipolar cell axons and retinal ganglion cell dendrites; between rod and cone on-bipolar cells through rod amacrine cells (thus merging the rod output signals into the cone pathway); between amacrine, ganglion, and bipolar cells (providing inhibitory feedback to strengthen ganglion cell properties); and between bipolar cells and interneurons (performing a feedback function between neighboring bipolar cells).

The ganglion cell layer (GCL) contains the cell bodies of retinal ganglion cells, with their axons running across the retinal surface (nerve fiber layer) towards the optic nerve head, and on through the optic nerve to the lateral geniculate nucleus in the mid-brain. The nerve fiber layer and a thin membrane (the inner limiting membrane) form the most superficial retinal structures.

In addition to the neuronal cell types responsible for visual signal transmission the retina has several types of supporting cells, similar in function to the RPE cells supporting the photoreceptor outer segments. The most important of these are the Mueller cells, whose principal role appears to be to buffer and balance electrolyte concentrations in the extracellular space, in response to the activity of the retinal neurons, especially photoreceptors.

Figure 4.3c shows a cross-section of the retina, but this tissue came from a donor who had lost useful vision due to a retinal degeneration. There is a complete loss of photoreceptor outer segments, the almost complete absence of cells in the ONL. However, the inner retinal cells are preserved in substantial numbers.

4.3.2 Anatomy and Physiology: Retino-cortical Pathway

The eye and the central nervous system are connected through the fibers of the optic nerve. These fibers, with a diameter of about 1 μm , are actually the axons of retinal gan-

glion cells. Inside the eye, the fibers run along the retinal surface towards the optic nerve head in a characteristic pattern, such that fibers of the upper and lower retinal halves remain separated, and fibers close to the horizontal meridian, but far from the nerve head, arc away from this line to allow room for fibers originating closer to the nerve head. This orderly arrangement causes the fibers from the foveal area (which form 15–20 % of all nerve fibers) to be located in the temporal quadrant of the optic nerve, at least for the initial portion of its trajectory.

After the axons enter the optic nerve, each fiber is encapsulated with a myelin sheath, formed by oligodendrocytes; this sheath decreases the membrane conductance of the axons, increasing the conduction velocity and the length over which impulses can be conducted without severe attenuation. Only at the so-called Ranvier nodes is the myelin sheath interrupted, allowing the impulses to be reinforced by virtue of the gating properties of the local membrane.

A cross-section through the human visual pathways can be seen in Fig. 4.4. One may note that the predominant pathway leads from the eye to the lateral geniculate nucleus (LGN) of the thalamus, and from there to the occipital cortex, while less important numbers of fibers branch off to a tectal area, the superior colliculus (SC), and to a number of pre-tectal nuclei. We will briefly discuss these subcortical pathways below.

The LGN and cortical areas exist in duplicate in the two halves of the brain. Each deals with one half of the visual world: the optic nerves from the two eyes meet at the optic chiasm, where fibers from the two nasal retinas cross over to combine with those from the temporal retina of the fellow eye; consequently each LGN and cortical hemisphere receive visual information from two corresponding retinal halves on their own side, and thus from the contralateral half of the visual field.

The LGN has a layered structure, with layers devoted to nerve fibers coming from each eye, and subsequent pairs of layers receiving axons of different ganglion cell types. Significant interaction between layers does not occur; therefore, binocular interactions such as those required for stereopsis do not take place until the level of the visual cortex. The gateway function of the LGN, which in other mammals such as the cat appears to play a crucial role in adaptation and attention, and through which signals from the two eyes can mutually inhibit each other, is thought to be less prominent in primates, including humans. Yet anatomical feedback connections from a number of subcortical nuclei onto the LGN are as extensive in monkey as in cat, and gating functions related to circadian rhythms and other systemic conditions are therefore plausible in primates as well. Forward pathways from the LGN lead to the primary visual cortex (V1, also called striate cortex; these fibers form the optic

Fig. 4.4 Structure and location of the human primary visual pathways, in relation to other major brain structures. The left cerebral hemisphere, with the exception of the occipital cortex, has been removed; the left LGN is hidden by the optic radiations (arrow)

radiation), but also to higher visual cortical areas and to subcortical areas such as the superior colliculus (SC). The role of the extrastriate cortical pathways is still a topic of study; patients with lesions to the visual cortex suffer vision loss. The roles of the tectal pathways, including mutual connections between cortical areas, the SC and the pulvinar, are also not completely understood.

4.3.3 Anatomy and Physiology: Visual Cortex

The visual cortex occupies the occipital and parts of the parietal and temporal lobes of the cerebral cortex. Like the entire cortex, it forms a highly folded structure, with a thickness of approximately 1.5 mm. It is surrounded by the cerebrospinal fluid, several layers of meninges—pia mater, arachnoid, dura, and the skull.

Like the retina, the visual cortex is a layered structure, in which different cell groups perform different tasks. Along its two-dimensional surface, one finds an orderly mapped representation of the outside world. Unlike the retina, the cortex consists of multiple areas, hierarchically organized, each of which performs a partial processing task in the analysis of the scene around us. Over 30 visual cortical areas per hemisphere are recognized in monkey, and a smaller number of more expanded areas are thought to exist in humans.

The first cortical representation, in the striate cortex, is shown schematically in Fig. 4.5. It presents a straightforward map of the visual world, but contains four major transformations.

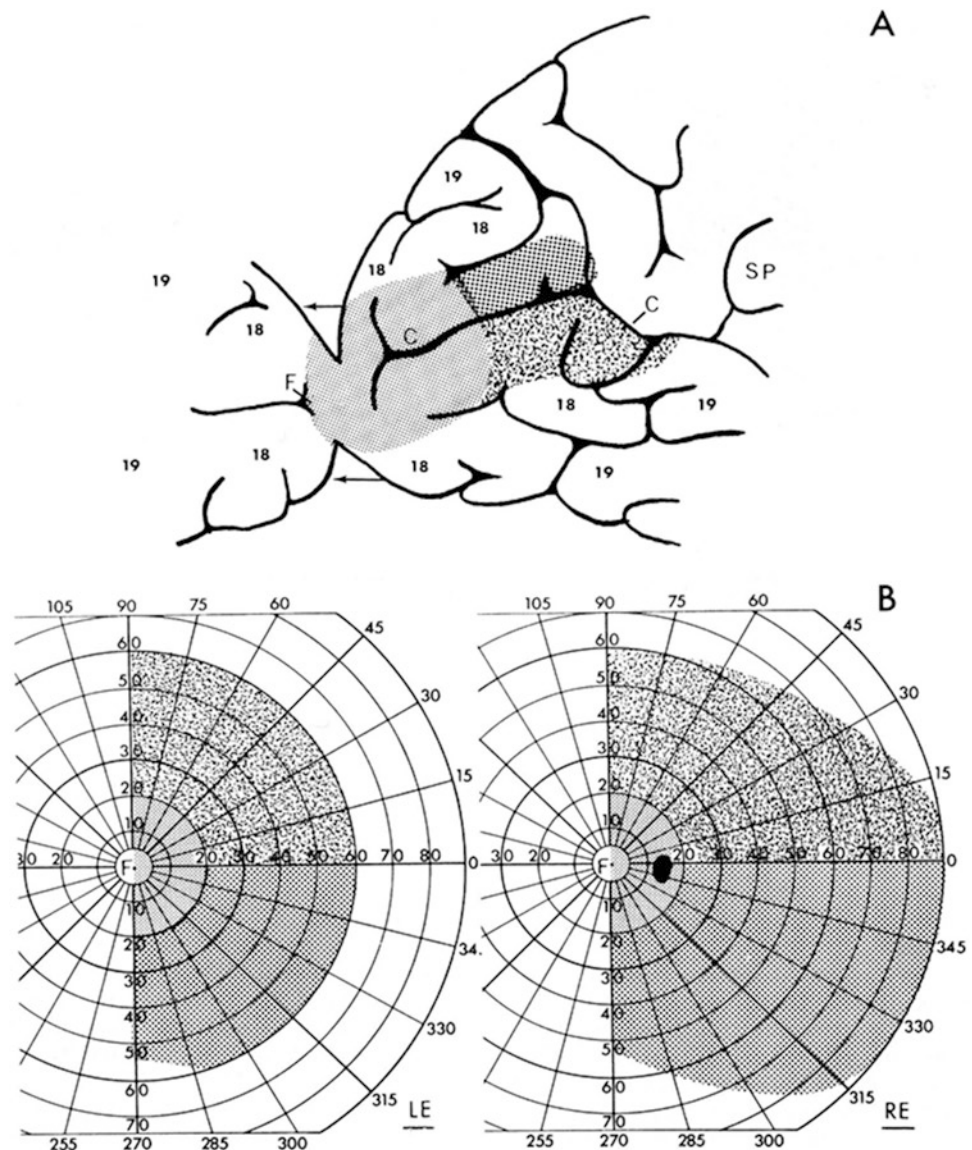

The projection from the LGN (and thus retinal ganglion cells) onto V1 input cells has approximately constant density, which means that the central visual field is highly over-represented in the visual cortex: Roughly 20% of V1 represents the retinal fovea, and thus the central 1–2° of the visual field, with rapid drop-off of the density towards the periphery.

As explained previously for ganglion cell and LGN characteristics, even the signals arriving in the cortex do not carry simple point-to-point representations of the visual field. From the complex processing network in V1 hypercolumns emerge feed-forward signals to higher cortical areas. In turn, feedback signals from these higher areas further influence local signal processing. Moreover, subcortical signals modulate the activity level in response to state changes such as sleep and arousal.

4.3.4 Anatomy and Physiology: Subcortical Pathways

While the visual pathway to the LGN and striate cortex receives the great majority of retinal ganglion cell axons, subcortical pathways exist as well, formed by optic nerve fibers projecting to pretectal nuclei and to the pulvinar. In primates, the projections to the pregeniculate nucleus and pulvinar are thought to be of minor importance, and may be thought of as anatomical evolutionary remnants. For example, in lower mammals, ablation of striate cortex at birth allows these projections to greatly increase in density, leading to the development of crude functional vision, but simi-

Fig. 4.5 V1 projection of the visual field. The medial wall and part of the occipital surface of the left cerebral hemisphere (A) and the corresponding visual fields for the two eyes (B) are shown. Note that the projection of the fovea (*F*) and a narrow surrounding hemicircle of the visual field project onto the occipital cortex, with the projection of the vertical meridian adjacent to area V2, whereas more peripheral areas—including most of the macula—projects to the medial wall of the cortex, with much of the projection buried in the calcarine fissure (*C*). Also note that the left hemisphere receives information from the right visual hemifield, that the superior visual field projects to the inferior part of V1—i.e., gross localization is preserved from retina to V1, and that corresponding retinal locations in the two eyes project to the same cortical location. No such locations exist for the far nasal segment of the right retina (60° – 90°), as the bridge of the nose blocks the corresponding area in the left eye

lar experiments in newborn monkeys show neither the proliferation of projections nor appreciable acquisition of visual function (Cowey et al. 1994, 2001).

However, other projections in primates, in particular those to the pretectal nucleus of the optic tract (NOT) and the terminal nuclei (TN) of the accessory optic system, have been demonstrated to play an important role in the rapid control of eye position through vestibulo-ocular reflex, saccades, and sustained fixation.

Detailed studies of anatomy and physiology of the primate eye movement system over the last several decades in awake, trained animal models have shown that the NOT receives information on “retinal slip,” i.e., generalized displacement of the retinal image (Mustari and Fuchs 1989). This retinal slip signal is encoded as a velocity signal, and serves as input to the neural integrator in the nucleus prepositus hypoglossi

(Mustari and Fuchs 1989). Pathways between the NOT and primary visual cortex (as well as multiple similar projections between cortical and subcortical structures) are also known to exist, and have been shown to compensate in part for lesions to the NOT or its retinal input (Mustari and Fuchs 1989; Hoffmann 1996).

4.4 Retinal Immunology

Distinctive immunologic characteristics of the eye were well documented and led to the concept of immunologic privilege. The success of corneal transplantation established the eye as a site for tissue transplantation (von Hippel 1888). Later, the harvesting and transplanting photoreceptors or retinal pigment epithelial (RPE) cells into subretinal space

further demonstrated this characteristic (Silverman et al. 1992; Silverman and Hughes 1989; Kaplan et al. 1997). This is influenced by the existence of immunologic privilege in the subretinal space and immunogenicity of the transplanted tissue.

As mentioned above, immune privilege in the eye is thought to be the result of a combination of anatomic features with a special molecular environment. As inflammation can cause tissue damage, tissues with limited regenerative capacity such as the neurons in the brain and retina use immune privilege for protection. An absence of lymphatic drainage, blood-ocular barrier, the presentation of antigen to the host via the circulation (camero-splenic axis), and the reduced expression of MHC class I and II molecules on resident cells in the AC are the anatomic features that contribute to immune privilege (Streilein et al. 1997). In a similar manner, the subretinal space is protected by a blood-retina barrier, via tight junctions between RPE cells, as well as the vascular endothelium of the retinal circulation. The subretinal space has no lymphatic drainage and has reduced expression of MHC class I and II molecules on parenchymal cells of the neurosensory retina (Wang et al. 1987).

Some of the molecular mechanisms necessary to achieve and maintain immune privilege in the AC also exist in subretinal space.

1. Complement inhibition: There have been several complementary regulatory proteins identified immunohistologically in the eye. Their role is to protect intraocular tissue from complement-mediated destruction. There is a selective expression of CD59 (inhibiting formation of complement) in the neurosensory retina, but not membrane cofactor protein (MCP or CD 46) or decay-accelerating factor (DAF or CD55), which are expressed within the AC, and both of which participate in the regulation of complement activation (Bora et al. 1993).
2. Fas ligand-mediated apoptosis: Fas-ligand is a membrane protein that is a member of the TNF family of proteins expressed on activated T cells. Fas ligand binds to Fas, thus stimulating a signaling pathway leading to apoptotic cell death of the Fas-expressing cell. Fas ligand is expressed in various ocular tissues, including the RPE and neurosensory retina. Experiments in vivo and in vitro suggest that constitutive expression of Fas ligand in a tissue leads to a deletion of Fas+ T cells that enter the tissue (Griffith et al. 1997; Jorgenson et al. 1998).
3. Immunosuppressive molecules: Aqueous humor contains several immunomodulatory substances, including TGF- β_2 , free cortisol, IL-1 receptor antagonist, substance P and vasoactive intestinal peptide. It has been shown that RPE secretes TGF- β_2 as well. This immunosuppressant is found in the vitreous gel of the eye.

Thus, the existence of a limited immune privilege in the subretinal space is the result of antigen-specific inhibition of cellular and humoral responses. After the introduction of an antigen into the subretinal space, a suppression of delayed-type hypersensitivity to soluble-protein antigens and a delayed rejection of allogeneic RPE cells are seen. These phenomena are the result of the inhibition of cell-mediated immunity. In the AC, delayed-type hypersensitivity is inhibited while the cytotoxic antibody response is exaggerated. In the subretinal space, both antibody production and delayed-type hypersensitivity are inhibited. This is an important difference between the immunologic privilege process within the AC and the subretinal space.

Most of the experimental studies involving placement of alloantigens in the subretinal space have been performed in rodents, and much about the nature of the immune privilege in the subretinal space remains unknown. Also, the immunogenetic disparity between donor and host is not known, so naturally, a question arises, whether immunosuppression is necessary at the time of allogeneic transplant. The survival of the allogeneic transplant is dependent on the presence of immune privilege at that site, as well as the immunogenicity of the transplanted tissue. There are studies demonstrating that RPE cells express MHC class I but not class II molecules. They can express class II molecules when stimulated with interferon- γ (Liversidge et al. 1988, 1998). The RPE also express ICAM-1, a molecule necessary for T-cell activation (Liversidge et al. 1990). The expression of MHC class II and ICAM-1 on the apical plasma membrane of cultured RPE suggests that these molecules may play an important role in the presentation of antigen to the host (Percupo et al. 1990; Osusky et al. 1997).

4.4.1 Retinal Antigens and Autoimmunity

In 1968 Wacker and Lipton developed an excellent animal model of experimental autoimmune uveitis (EAU) (Wacker and Lipton 1968). The EAU model has been used for several decades in eliciting immune mechanisms, the identification of pathogenic epitopes of autoantigens in the eye in animals, and the evaluation of therapeutic strategies.

Retinal antigens, such as S-antigen (arrestin), interphotoreceptor retinoid-binding protein (IRBP), rhodopsin, recoverin, and phosducin, appear to hold uveitogenic properties. Immunization with these antigens or their fragments can induce ocular inflammation in susceptible strains of laboratory animals. New eye autoantigens have been discovered, such as uveal autoantigen with coiled domains and ankyrin repeats (UACA) in patients with Vogt-Koyanagi-Harada disease (Yamada et al. 2001).

EAU models using S-antigen and IRBP (peptides derived from these proteins) contributed mostly to our knowledge of

retinal autoimmunity. S-antigen, a 48-kDa protein (arrestin), is one of the antigens used to induce EAU (Singh et al. 1988). It is the first retinal autoantigen that has been implicated in the pathogenesis of uveitis (Hirose et al. 1989; Merryman et al. 1991). The main action of arrestin is blocking the interaction of rhodopsin with the G-protein transducin in the phototransduction cascade. Immunization of susceptible animals with S-antigen induces a predominantly CD4+ T-cell-mediated inflammatory response in the retina, uveal tract, and the pineal gland. S-antigen has been implicated in the pathogenesis of uveitis through molecular mimicry. It has been demonstrated that several exogenous antigens, such as baker's yeast, *Escherichia coli*, hepatitis B virus, streptococcal M5 protein, Moloney murine sarcoma virus, and baboon endogenous virus, and several endogenous antigens, such as human leukocyte antigen B-derived peptide, tropomyosin antigens share sequence homology with uveitogenic peptide M of S-antigen (Shinohara et al. 1990). Antistreptococcal monoclonal antibodies were found to recognize several uveitogenic peptides of S-antigen, thus suggesting that immunological mimicry between self and exogenous antigens from an infectious agent may be a potential mechanism in the pathogenesis of uveitis in humans (Lerner et al. 1995).

IRBP is a major protein (1264 amino acid residues) of the interphotoreceptor matrix. It functions as a transporter of retinoids between the retina and RPE. It is found in both the eye and the pineal gland. A spectrum of disease ranging from hyperacute to chronic relapsing disease could be induced with variable doses of this antigen. The inflammation is located at the photoreceptor layer, producing histopathology similar to that seen in uveitis, retinal vasculitis, granuloma, focal serous detachments, loss of photoreceptors, and formation of sub-RPE infiltrates resembling to Dalen-Fuchs nodules (Caspi et al. 1988). The relatively long duration of disease activity in the murine IRBP EAU model makes it a good model for evaluation of therapeutic strategies in established disease (Chan et al. 1990).

Retinal autoimmunity is a complex mechanism that has previously been thought to be always pathological. However, retinal autoimmunity appears to have certain neuroprotective qualities. One such study showed that vaccination with peptides derived from IRBP resulted in protection of retinal ganglion cells from glutamate-induced death or death as a consequence of optic nerve injury (Mizrahi et al. 2002). It is evident that the immune system not only protects the body against invading pathogens but also protects it from toxic substances released by the body's own tissues during stress and trauma. So, the autoreactive cells that induce neuroprotection and those that induce autoimmune disease may share the same qualities, indicating their potential to be protective and destructive at the same time (Kipnis et al. 2002). Lymphocytes reactive to retinal antigens have been found in

healthy individuals (Mizrahi et al. 2002; Nussenblatt et al. 1980). The presence of circulating autoreactive cells in healthy humans suggests that immunoregulatory mechanisms are probably in place to prevent retinal autoimmunity. It appears that the ability to protect the eye from inflammation and injury does not purely depend on mechanisms of immune privilege but instead on a precise regulation of autoimmunity.

4.4.2 Autoimmune Retinopathy (AIR)

AIR is an umbrella term for several disorders with common clinical findings. AIR patients experience acute and progressive vision loss without other known causes in the setting of circulating anti-retinal antibodies in the patient serum. These antibodies can cross the blood-retina barrier and can be found in intraocular fluids as well (Adamus 2008). AIR patients have damage throughout the retinal layers, including Muller cells, bipolar cells, and photoreceptor cells. There is vision loss, electroretinographic changes, and often family history of autoimmune disease. In a recent case series, Heckenlively and colleagues have shown that many patients respond to immunosuppressive regimens (Ferreira et al. 2009). AIR disorders include cancer associated retinopathy (CAR), melanoma associated retinopathy (MAR), and non-paraneoplastic autoimmune retinopathy (npAIR). CAR and MAR are rare paraneoplastic diseases thought to be caused by homology between tumor and retinal proteins with resultant autoimmunity. npAIR share a similar phenotype with CAR and MAR, but is not related to underlying malignancy. There are many retinal antigens associated with AIR. Recoverin, α -enolase, and Carbonic anhydrase II (CA II) are associated with CAR and npAIR. Tubby-like protein 1 (TULP-1) and Heat shock cognate protein 70 (HSC70) have been associated with CAR. Arrestin (S-antigen) and Transducin have been associated with MAR. Collagen II, Cardiolipin, and Phosphatidylinositol have been associated with npAIR. The mechanisms involved in AIR are currently under further study.

4.4.3 Age Related Macular Degeneration (ARMD) and the Ocular Immune Response

The retinal pigment epithelium (RPE) cells have many tasks, including phagocytosis of damaged photoreceptors and metabolic waste material, and support of the photoreceptor cells. They help form the blood-retina barrier to keep the systemic immune system from retinal antigens, and inhibit immune cells to prevent inflammation. Recent studies have indicated that at least in a subset of patients, age related macular degeneration involves autoimmune processes. Complement proteins

have been found in drusen, autoantibodies to retinal proteins have been discovered in ARMD (de Jong 2006), and certain polymorphisms in genes encoding complement proteins (e.g. Complement factor H (CFH) and others) have been associated with the presence of disease (Haines et al. 2005).

Recent research has also shown a link between oxidative stress and the formation of lipid peroxidation products such as malondialdehyde (MDA). Weismann and colleagues have shown that the pro-inflammatory MDA is bound by CFH, and that mutations in CFH lead to impaired binding by the immune system, allowing oxidative stress to accumulate and potentially cause damage and inflammation (Weismann et al. 2011). There is also evidence that oxidative stress can alter lipid peroxidation products into retinal antigens capable of setting off an autoimmune reaction. Carboxyethylpyrrole (CEP) is a product formed from docosahexanoic acid (DHA) under oxidative conditions. In the highly oxidative milieu of the retina, proteins become adherent to CEP forming antigenic moieties which have been shown capable of inducing anti-CEP autoantibodies in a systemic adaptive immune response (Hollyfield et al. 2008). Although the exact mechanisms of ARMD pathology are as yet not completely clear, there is evidence that proinflammatory macrophages (M1 macrophages) may be involved with retinal damage, and it is hypothesized that complement deposition in the setting of oxidative damage may play a role in guiding these destructive cells toward the RPE.

Current research in animal models is focused on elucidating the role of T cells and the adaptive immune response in ARMD. It is hoped that further understanding of the humoral and adaptive immune responses in relationship to ARMD may lead to novel prevention and treatment strategies. In humans, there have been several clinical trials to assess complement inhibitors as a treatment for the dry form of ARMD. Clinical trials are still ongoing to assess if they can be effective in treating or preventing ARMD (Perez et al. 2008).

4.5 Summary

The eye has been recognized as an immune-privileged site for more than 100 years. Medawar demonstrated this by showing a prolonged, often indefinite, survival of organs or tissue grafts in the anterior chamber of the eye (Medawar 1948). Immune privilege is a dynamic process in which immunoregulatory mechanisms combined with anatomical factors maintain the vitality of grafts in privileged sites. ACAID is the best-studied immune-privilege phenomenon in the eye. Although it is an anterior-chamber phenomenon, there is enough evidence to show that there are some of the same mechanisms at work in the vitreous and sub-retinal space (Jiang et al. 1993). Therefore understanding

ACAID could possibly further our knowledge of retinal autoimmunity.

Historically retinal autoimmunity has been considered pathogenic. However, later studies have demonstrated the presence of retinal autoantibodies in normal controls (Yamamoto et al. 1993). Animal optic nerve injury studies suggested possible beneficial roles of retinal autoimmunity in controlling collateral damage to the retinal ganglion cells (Kipnis et al. 2002). Thus, retinal autoimmunity can be viewed as both protective and destructive phenomenon.

Current research is focused on the role of immunity in ARMD, AIR, and corneal transplantation. Subretinal embryonic stem cell research is another field made possible by the eye's unique immune status. Recent research has also shown progress in the field of stem cell transplantation in patients with ARMD and Stargardt's macular dystrophy (Schwartz et al. 2015). Ocular immunology will likely play a major role in the next set of breakthroughs for some of the most vexing eye diseases.

4.6 Review Questions

1. How many compartments the eye contains?

- (a) Three: cornea, anterior chamber and posterior chamber.
- (b) Two: anterior and posterior chamber.
- (c) Four: cornea, anterior chamber, posterior chamber and vitreous cavity.
- (d) *Three: anterior chamber, posterior chamber and vitreous cavity.*

2. What is the volume of vitreous cavity on average?

- (a) 2 mL
- (b) 4 mL
- (c) *6 mL*
- (d) 8 mL
- (e) 10 mL

3. Anterior chamber angle includes all of the following structures except:

- (a) Schwalbe's line
- (b) Sclera
- (c) Ciliary body
- (d) *Lens*
- (e) Iris
- (f) Schlemm's canal
- (g) Trabecular meshwork

4. Aqueous is produced by:

- (a) *Ciliary epithelium*
- (b) Corneal endothelium
- (c) Schlemm's canal
- (d) Trabecular meshwork
- (e) Iris roots

5. **All of the following are immune privileged sites except:**
 - (a) Cornea
 - (b) *Conjunctiva*
 - (c) Lens
 - (d) Vitreous cavity and subretinal space
 - (e) Testis and ovary
6. **Which statement is not true regarding immune privilege?**
 - (a) The phenomenon of immune privilege was initially described in the nineteenth century.
 - (b) Immune privilege is defined as a prolonged, sometimes indefinite, survival of organ or tissue grafts at special body/organ sites.
 - (c) Immune privilege is a dynamic process maintained by anatomic structures and immunoregulatory forces.
 - (d) *Grafts placed in immune privileged sites remain sequestered from the immune environment.*
 - (e) Both active and passive factors of immune privileged sites and tissues contribute to the privileged status.
7. **All the following is true about anterior chamber immune associated deviation (ACAID) except:**
 - (a) ACAID is an antigen-specific systemic immune response to eye-derived antigens
 - (b) ACAID is an actively acquired and actively maintained manifestation of ocular
 - (c) *In ACAID aqueous humor possesses immunomodulatory properties and inhibits all immune reactions*
 - (d) ACAID is a form of peripheral tolerance, unlike central tolerance, where clonal deletion and/or anergy occur within the thymus
 - (e) Once induced, ACAID persists for a very long period of time.
8. **Visual cortex occupies the following structures:**
 - (a) *Occipital and parts of the parietal and temporal lobes of the cerebral cortex*
 - (b) Parietal and parts of occipital and temporal lobes of the cerebral cortex
 - (c) Lateral geniculate body, occipital and frontal lobes of the cerebral cortex
 - (d) Frontal and parts of occipital and temporal lobes of the cerebral cortex
 - (e) Occipital and parts of frontal and parietal lobes of the cerebral cortex
9. **Which substance found in the eye is not uveitogenic?**
 - (a) S-antigen (arrestin)
 - (b) *TGF- β*
 - (c) Interphotoreceptor retinoid-binding protein (IRBP)
 - (d) Recoverin
 - (e) Phosducin

10. **Which antigen is not associated with AIR?**

- (a) Recoverin
- (b) TULP-1
- (c) HSC70
- (d) α -enolase
- (e) *Vasoactive intestinal peptide*

Wallace B. Thoreson

Abstract

The retina is an outpost of the central nervous system (CNS) with neuronal structures and proteins specialized for the transduction of light signals into a neural code that the brain can interpret. Mutations of proteins involved in phototransduction or synaptic transmission through the retina produce visual deficits ranging from subtle color vision defects to complete blindness. Although normally isolated from blood-mediated immune responses by the blood-retinal barrier, inflammatory responses, including gliosis and those mediated by the complement system, are important contributors to retinal degeneration, particularly age-related macular degeneration (ARMD). Studying immune responses in the retina and their pharmacological manipulation therefore presents a promising avenue for the treatment and prevention of retinal degeneration.

Keywords

Amacrine cell • Bipolar cell • Choroid • Cone • Fovea • Horizontal cell • Magnocellular ganglion cells • Melanopsin • mGluR6 • Müller cells • Opsin • Outer segment • Parvocellular ganglion cells • Photoreceptor • Retina • Retinal ganglion cell • Retinal pigment epithelium • Ribbon • Rod • Transducin

5.1 Introduction

The retina, like other parts of the Central Nervous System (CNS), derives embryologically from the neural tube. Retinal neurons and glia therefore have many properties in common with other CNS tissue, but they also exhibit specialized response properties and proteins that have evolved to serve the retina's function in transducing light energy into nerve signals and analyzing the visual image. For example, to encode small changes in light intensity, many retinal neurons respond to light with graded changes in membrane potential and do not exhibit sodium-dependent action potentials. In

addition to possessing the specialized proteins needed for phototransduction (e.g., rhodopsin and transducin), the retina contains a number of proteins specialized for the transmission and processing of visual information such as the metabotropic glutamate receptor, mGluR6, in ON type bipolar cells; type C γ -aminobutyric acid (GABA_C) receptors (Lukasiewicz et al. 2004); and CaV1.4 calcium channels in photoreceptors. This chapter summarizes some of the special features of retina that help it to transduce and process light.

5.2 Anatomy

The retina is a thin sheet of neural tissue (150–400 μ m thick) at the back of the eye upon which the visual image is focused by the cornea and lens (Fig. 5.1a). Behind the neurosensory retina is a layer of pigmented epithelial cells known as the retinal pigment epithelium (RPE, Fig. 5.1) and beyond the RPE is a dense bed of capillaries within the choroid.

e-mail: wbthores@unmc.edu

Surrounding the choroid is the sclera, made up of densely woven collagen fibers that help to encase and protect the globe.

The retina has a highly organized laminar structure that is similar in all vertebrate species (Fig. 5.1b; Dowling 2012; Rodieck 1998). It is oriented so that photoreceptors lie at the back, adjacent to the RPE. Thus, to reach the photoreceptors light must generally pass through overlying layers of the retina. The photoreceptor (PR) layer consists of the outer and inner segments of rod and cone photoreceptors. Separating the inner segments and photoreceptor cell bodies is the outer limiting membrane (OLM) formed from apical processes of glial Müller cells. The outer nuclear layer (ONL) contains the cell bodies of photoreceptors. Photoreceptors make synaptic contact with horizontal and bipolar cells in the outer plexiform layer (OPL). The inner nuclear layer (INL) contains cell bodies of horizontal, bipolar, and amacrine cells. Synaptic contacts among bipolar, amacrine and retinal ganglion cells are made in the inner plexiform layer (IPL). Anterior to the IPL, closer to

the front surface of the retina, is the ganglion cell layer (GCL), which contains cell bodies of retinal ganglion cells. Axons from retinal ganglion cells create a nerve fiber layer (NFL) at the inner surface of the retina. The axons join together as they exit the eye to form the optic nerve, which projects to higher visual centers. The absence of retina and photoreceptors at the optic nerve head creates a small blind spot (Fig. 5.1a). The vitreal surface of the retina is bounded by an inner limiting membrane (ILM) formed by Müller cell endfeet.

The retina contains >60 types of retinal neurons grouped into five major classes: photoreceptors (3–4 types), horizontal cells (generally two types), bipolar cells (12–13 types), amacrine cells (~30 types), and ganglion cells (~20 types) (Masland 2012; Euler et al. 2014). Photoreceptors release L-glutamate to stimulate bipolar cells, which in turn release L-glutamate onto ganglion cells forming a throughput pathway for the transmission of light signals through the retina (Fig. 5.2). Horizontal and amacrine cells are predominantly

Fig. 5.1 (a) Schematic diagram of a primate eye. (b) Cross section of primate retina showing the different layers

Fig. 5.2 The five major retinal cell types (photoreceptors, bipolar cells, horizontal cells, amacrine cells, and ganglion cells) and their synaptic connections

inhibitory interneurons with processes extending laterally in the outer and inner plexiform layers, respectively. As light signals are transmitted from photoreceptors to bipolar cells to ganglion cells, they are modified by inhibitory synaptic feedback from horizontal cells onto photoreceptors and bipolar cells in the outer retina and from amacrine cells onto bipolar and ganglion cells in the inner retina. Photoreceptors and second order retinal neurons (bipolar and horizontal cells) respond to light with graded changes in their membrane potential (Dowling 2012). Action potentials are typically observed only in third order neurons of the retina (amacrine and ganglion cells). The use of graded responses by cells early in the visual pathway is likely related to the ability of graded responses to transmit more information than a spike code (Laughlin 2001). By contrast, the use of action potentials by ganglion cells is necessary to propagate information over the greater distances needed to reach higher visual centers.

5.3 Cell Types

5.3.1 Rod and Cone Photoreceptor Cells

5.3.1.1 Outer Segments and Phototransduction

There are two major types of photoreceptors cells: rods and cones (Ebrey and Koutalos 2001). The structure and phototransduction proteins of rods are specialized to allow them to respond to dim lights. Cones are less sensitive to light, but provide high acuity and color vision. Rods and

cones are named for their rod- and cone-shaped outer segments, respectively. The outer segments of both cell types contain the proteins necessary for phototransduction, packaged into disc-shaped organelles. Cone discs are formed by invaginations of the outer segment plasma membrane whereas rod discs are completely sequestered within the outer segment.

The principal job of photoreceptors is to transduce light into an electrical signal. Phototransduction involves a cascade of enzymes in the outer segment (Arshavsky et al. 2002) (Fig. 5.3). It is initiated by absorption of a photon by rhodopsin (or cone-specific opsins). Rhodopsin is a G-protein coupled receptor with homology to other G-protein coupled receptors (GPCRs) (e.g., beta-adrenergic, muscarinic, etc.). However, unlike GPCRs that are activated by the binding of a neurotransmitter ligand, the activating ligand of opsin is a light-sensitive chromophore molecule, vitamin A aldehyde (or retinal), bound within a pocket of the opsin protein. Absorption of a photon by this chromophore initiates a conformational transition of 11-cis-retinal, which is bent around the 11-cis carbon position, into all-trans retinal, which has a straight chain configuration (Fig. 5.3). The conformational change in retinal produces conformational changes in the seven trans-membrane domains of rhodopsin, causing it to assume an active configuration known as metarhodopsin. The activated GPCR, metarhodopsin, stimulates exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on the associated G-protein, transducin (G_T). Activated alpha subunit of transducin (α_T) stimulates the activity of a cGMP-specific phosphodiesterase, which

Fig. 5.3 The enzymatic cascade responsible for phototransduction

hydrolyzes cGMP. The plasma membrane of outer segments contains non-selective cation channels permeable to Na^+ , K^+ , and Ca^{2+} that are opened by the binding of cGMP to their intracellular face. Light-induced reduction in cytoplasmic [cGMP] causes some cGMP-gated cation (CNG) channels to close. When open in darkness, Na^+ and Ca^{2+} influx through CNG channels causes photoreceptors to depolarize. Conversely, light-induced closure of these channels causes photoreceptors to hyperpolarize. Because brighter lights cause a larger number of CNG channels to close, the amplitude of membrane hyperpolarization is graded with intensity.

The enzymatic transduction cascade initiated by photon absorption is terminated by two key mechanisms: (1) Light-activated meta-rhodopsin is inactivated in a process that begins with its phosphorylation by rhodopsin kinase. Following phosphorylation of rhodopsin at three sites by rhodopsin kinase, the protein arrestin binds to rhodopsin and arrests further activity. The actions of rhodopsin kinase are analogous to the regulation of beta-adrenergic receptors by beta-adrenergic receptor kinase. (2) Light activated transducin is also shut down by its intrinsic GTPase activity, which converts GTP into GDP and thereby de-activates the G protein. The intrinsic GTPase activity of transducin is accelerated by binding of the accessory proteins, RGS/G β 5, to the transducin alpha subunit.

Tremendous amplification of the light signal by phototransduction in rods allows them to detect absorption of a single photon (Field et al. 2005). To accomplish this feat, each activated metarhodopsin molecule catalyzes hundreds to thousands of transducin molecules and although each transducin activates only a single phosphodiesterase (PDE) molecule, every PDE molecule hydrolyzes thousands of cGMP molecules. The net result is that activation of a single rhodopsin molecule by a single photon of light causes the degradation of 10^5 – 10^6 cGMP molecules causing many cGMP-gated cation channels to close and producing a small but detectable change in membrane potential.

Mutations in phototransduction proteins are a major cause of retinitis pigmentosa and other photoreceptor degenerations (Kennan et al. 2005). Mutations in rhodopsin, phosphodiesterase and cGMP-gated cation channels can all produce retinitis pigmentosa. Mutations in rod-specific transducin produce night blindness whereas mutations in cone-specific transducin produce achromatopsia (rod monochromacy). Similarly, by preventing cones from responding to light, mutations in cone-specific cGMP-gated cation channels also lead to achromatopsia. For an updated list of genes involved in retinal diseases, consult the “Retinal Information Network” (<http://www.sph.uth.tmc.edu/Retnet/>).

5.3.1.2 Light Adaptation

Photoreceptors can respond to only a limited range of intensities before their responses saturate. To maintain responsiveness over the large range of intensities encountered in the world, the phototransduction apparatus adapts its sensitivity to increased light levels to maintain a constant relative response to increments in illumination ($\Delta I/I = \text{constant response}$) (Fain et al. 2001; Burkhardt 2001). This process of light adaptation is largely due to calcium-sensitive adjustments of the phototransduction enzyme cascade. As mentioned above, cGMP-gated cation channels are permeable to Ca^{2+} allowing Ca^{2+} to enter the outer segments when these channels are open in darkness. This steady Ca^{2+} influx is countered by the extrusion of Ca^{2+} from outer segment by $\text{Na}^+/\text{Ca}^{2+}$ exchangers. The closing of cGMP-gated channels in response to light diminishes the influx of Ca^{2+} but its efflux via the $\text{Na}^+/\text{Ca}^{2+}$ exchanger continues. The concentration of Ca^{2+} in the outer segment therefore diminishes in light. This decrease in $[\text{Ca}^{2+}]$ enhances the activity of guanylyl cyclase stimulating the production of cGMP. The resulting increase in cGMP opens cGMP-gated channels leading to depolarization of the photoreceptor membrane potential. In cones, decreased $[\text{Ca}^{2+}]$ also increases the affinity of cGMP for cGMP-gated cation channels to further promote their opening. The membrane depolarization that results from re-opening of cGMP-gated cation channels restores the operating range of the photoreceptor cell, allowing it to hyperpolarize in response to another flash of light.

While calcium-dependent adaptation is sufficient to maintain the sensitivity of cones over a large range of intensities, at extremely high intensities there is also a contribution from photochemical adaptation in which a significant fraction of unbleached chromophore (11-cis-retinal) is bleached to all-trans-retinal (Burkhardt 1994). At most light levels, there is a sufficient reservoir of 11-cis-retinal in the outer segments so that the bleaching of chromophore molecules does not appreciably limit the sensitivity of the opsin molecule, as long as levels of 11-cis-retinal are soon restored. (As presented later, restoration of chromophore levels after bleaching involves participation of the RPE and Müller cells.) However, at extremely high light levels, the rate and amount of bleaching is sufficient to limit the availability of chromophore and thereby limit the sensitivity of opsin to light.

The combined effects of calcium-dependent and photochemical adaptation allow cones to maintain constant incremental sensitivity to light over 10^7 -fold changes in intensity (Burkhardt 1994). Rods, sensitive to dimmer lights, maintain relatively constant sensitivity over a 1000-fold change in intensity. Rod and cone systems together therefore allow the visual system to perform the impressive feat of maintaining relatively constant incremental sensitivity to light over a ten billion-fold range of intensities. For comparison, pupillary constriction or dilation contributes a 16-fold change in

sensitivity, although it has the advantage of being relatively rapid, occurring within a couple hundred ms compared to minutes for full light adaptation.

5.3.1.3 Photoreceptor Inner Segment, Soma, and Synaptic Terminal

The inner segments of photoreceptors are packed with mitochondria that fuel their tremendous metabolic demands. Sodium ions continuously entering the outer segments through cGMP-gated cation channels in darkness are extruded by Na/K-ATPases in the inner segments. The continuous consumption of adenosine triphosphate (ATP) by these pumps makes photoreceptor cells among the most metabolically active in the body.

Below the inner segment is the soma and nucleus, which connects at its base to the axon and synaptic terminal. Photoreceptors release glutamate at ribbon synapses (Heidelberger et al. 2005). Synaptic ribbons are specialized for sustained release of neurotransmitter and are also found in the terminals of retinal bipolar cells, as well as vestibular and cochlear hair cells. Synaptic ribbons receive their name because of their planar structure in photoreceptor terminals, but bipolar and hair cell ribbons are more spherical in shape.

The ribbon is composed mainly of the structural protein, Ribeye, but also includes other proteins such as a kinesin motor protein KIF3A, Rab3-interacting protein RIM, and Munc13. Ribbons are attached to the synaptic active zone by bassoon, and its structural relative piccolo, through interactions with “cytomatrix at the active zone” or CAST proteins. Although the ribbon appears to anchor a readily releasable pool of vesicles, molecular motors do not appear to be involved in vesicle movements near the active zone. RIM protein mutations have been implicated in an autosomal dominant rod-cone dystrophy (Johnson et al. 2003).

Glutamate release from synaptic terminals of photoreceptor and bipolar cells is regulated by calcium influx through L-type calcium channels (Heidelberger et al. 2005). The use of L-type channels at ribbon synapses contrasts with the reliance on N, P and Q type channels for neurotransmission at conventional synapses of spiking neurons. A retina-specific L-type channel, CaV1.4, is localized to rod terminals. Mutations in this channel produce congenital stationary night blindness (Bech-Hansen et al. 1998).

5.3.1.4 The Fovea

In humans, the center of the visual image is focused on the fovea in the macula lutea, the region of highest acuity in the retina (Kolb et al. 2005). Although primates are the only mammals with a fovea, many birds and lizards also possess a fovea. Unlike more peripheral retina where light must pass through overlying retinal layers to reach the photoreceptors, overlying neurons are displaced at the fovea to diminish light

scattering. At the center of the resulting foveal pit, the only structures between the outer segments and vitreal surface are cone axons. Cone axons contain xanthophyll pigments that give the macula lutea its characteristic yellow color. The fovea contains only cones and, at its very center, is even free of blue-sensitive cones. Visual acuity, the ability to resolve fine spatial details, is limited by the spacing between cones in the fovea and the density of cones parallels visual acuity in the retina. Acuity can be as high as 20/10 at the foveal center, but falls off rapidly towards the retinal periphery. Although we are not typically conscious of these movements, the eye is constantly in motion, making small microsaccades to allow the high acuity fovea to scan various points and thus construct a high-resolution image at higher visual centers. Loss of the macular region (e.g., in macular degeneration) thus leads not only to a loss of central vision but also to a general loss of high acuity vision.

5.3.1.5 Cones and Cone Opsins

The retinas of Old World primates have three cone subtypes with different spectral sensitivities: short wavelength (S or blue-sensitive), middle wavelength (M or green-sensitive), and long-wavelength (L or red-sensitive) cones. Trichromacy evolved in Old World primates 40 million years ago with duplication of a single M/L ancestral pigment gene followed by divergence into separate M and L pigments. Differences in spectral sensitivity among different cone types arise from the presence of different cone opsins. Cone opsins are 40 % homologous to rhodopsin, S cone opsins are 40 % homologous with M and L cone opsins, and M and L cone opsins are 97 % homologous with one another. The differences in spectral absorbance among different opsins result from differences in a small number of amino acid residues that alter the position of hydroxyl groups close to 11-cis-retinal. The 30 nm difference in spectral absorbance between primate M and L cones is determined primarily by only three amino acids: alanine vs. serine at position 180 (~4 nm), phenylalanine vs. tyrosine at position 277 (~10 nm) and alanine vs. threonine at position 285 (~16 nm) (Deeb 2005).

Different photopigments are encoded by genes located on different chromosomes (Deeb 2005). The gene for rhodopsin is found on chromosome 3, the S cone pigment gene on chromosome 7, and M and L cone pigment genes on the X chromosome. M and L cone pigments are found in a tandem array on the X chromosome. Recombination between these genes on adjacent X chromosomes is the most frequent cause of color vision anomalies. For this reason, most color vision defects involve red–green color vision and are X-linked recessive. Males with anomalous M or L cone pigments are most common (anomalous trichromats), with a frequency of ~6 % among European males, while 2 % are entirely lacking in one pigment or the other (dichromats).

5.3.2 Horizontal Cells

Horizontal cells are laterally arborizing interneurons in the outer retina that receive excitatory synaptic inputs from photoreceptors and make inhibitory synapses onto cones and bipolar cells. The neurotransmitter released from horizontal cells is predominantly GABA. A light-evoked reduction of glutamate release from photoreceptors causes horizontal cells to hyperpolarize by reducing the activation of AMPA-type glutamate receptors. With the exception of certain fish retina, there appear to be no N-methyl-D-aspartate (NMDA) receptors in horizontal cells of adult retina (Thoreson and Witkovsky 1999). Rats and mice have only one type of horizontal cell, but most other mammals have two types (Masland 2012). Because both types hyperpolarize to light of all visible wavelengths, they are sometimes referred to as luminosity-type horizontal cells. Many non-mammalian vertebrates have additional chromaticity or color-opponent horizontal cell types that depolarize to certain wavelengths and hyperpolarize to other wavelengths.

Horizontal cells have large receptive fields due to extensive gap junction coupling among cells. Large receptive fields allow horizontal cells to measure illumination from a wide area. Inhibitory feedback from horizontal cells to cones and bipolar cells subtracts the mean luminance level measured over a wide area from signals transmitted to the inner retina about local luminance changes (Thoreson and Mangel 2012). As discussed later, this negative feedback contributes to formation of the center-surround arrangement of visual receptive fields, important for the detection of edges.

5.3.3 Bipolar Cells

Bipolar cells transmit signals from photoreceptors to ganglion cells. They receive glutamatergic input from photoreceptors and inhibitory inputs from amacrine cell contacts at their terminals in the inner retina. Some may also receive inhibitory influences from horizontal cell contacts at their dendrites in the outer retina. Bipolar cells release L-glutamate at ribbon synapses that contact amacrine and ganglion cells in the inner plexiform layer. There are 12–13 types of cone bipolar cell and a single type of rod bipolar cell in mammalian retina (Masland 2012; Euler et al. 2014). The different cone bipolar cells can be grouped into two major physiological subtypes: cone ON bipolar cells that depolarize to light and cone OFF bipolar cells that hyperpolarize to light. Rod bipolar cells in the mammalian retina are a single ON, depolarizing type. In lower vertebrates, ON and OFF bipolar cells receive a greater mixture of rod and cone inputs.

ON and OFF responses of bipolar cells result from the presence of different glutamate receptors in the two cell types. OFF bipolar cells possess KA and AMPA-type iono-

tropic glutamate receptors, but not NMDA receptors (Thoreson and Witkovsky 1999). Thus, like horizontal cells, the synapse from cones to OFF bipolar cells is sign-conserving, i.e., light-evoked hyperpolarization of the cone reduces the depolarizing influence of AMPA/KA receptors thereby causing the OFF bipolar cell to hyperpolarize.

ON bipolar cells do not possess ionotropic glutamate receptors but are instead activated by a metabotropic glutamate receptor, mGluR6 (Slaughter and Awatramani 2002). mGluR6 is a G-protein coupled receptor that acts via the G protein, G_o , to close TRPM1 non-selective cation channels (Koike et al. 2010; Morgans et al. 2010). Thus, light-induced cessation of glutamate release from photoreceptors causes these cation channels in ON bipolar cells to open and thereby depolarizes the cell. By contrast with OFF bipolar and horizontal cells, the synapse from photoreceptors to ON bipolar cells is therefore sign-inverting. Mutations in mGluR6, TRPM1, and other proteins associated with the mGluR6 receptor complex such as nyctalopin disrupt rod bipolar cell function and thus cause a complete form of congenital stationary night blindness. In addition to ON bipolar cells, TRPM1 (“melastatin”) channels are expressed in melanocytes and their expression declines in metastatic melanoma. Circulating autoantibodies to TRPM1 can cause night blindness in melanoma-associated retinopathy by inhibiting rod bipolar cell function (Xiong et al. 2013).

ON and OFF bipolar cells excite ON- and OFF-type ganglion and amacrine cells, respectively. ON and OFF pathways remain segregated into the lateral geniculate nucleus of the thalamus suggesting this segregation has important functional significance. Saturating mGluR6 with the selective agonist, L-2-amino-4-phosphonobutyric acid (L-AP4), produces an acute deficit in the perception of positive contrast (i.e., bright spots on a dark background) (Schiller et al. 1986). It has therefore been suggested that ON bipolar cells preferentially encode information about positive contrast and OFF bipolar cells preferentially encode information about negative contrast. However, ON and OFF bipolar cells can respond equally well to positive and negative contrast steps (Burkhardt 2001). Furthermore, loss of cone ON bipolar cell function by mutations in mGluR6, TRPM1, or nyctalopin does not produce obvious deficits in contrast perception at photopic light levels (Dryja et al. 2005). Thus, the role played in contrast perception by the segregation of different ON and OFF pathways remains unclear.

5.3.4 Amacrine Cells

Amacrine cells are laterally interconnecting interneurons and most contain the inhibitory neurotransmitters GABA, glycine or both. Amacrine cells are excited by glutamate released from bipolar cells. This glutamate acts principally

on KA and AMPA receptors although many amacrine cells also possess NMDA receptors (Thoreson and Witkovsky 1999). By anatomical and neurochemical criteria, amacrine cells can be classified into ~30 different types (Masland 2012; Wässle 2004). Almost every type of neurotransmitter is present in at least one type of amacrine cell. Physiological responses of amacrine cells include transient and sustained depolarization at light onset (ON cells), light offset (OFF cells), or both (ON/OFF cells). By contrast with the graded light responses of bipolar, horizontal and photoreceptor cells, many amacrine cells exhibit sodium-dependent action potentials making their responses much more transient.

Many amacrine cells have relatively dedicated functions. Some examples include:

1. Large, radially symmetric starburst amacrine cells help create directional selectivity in directionally selective ganglion cells (Taylor and Vaney 2003).
2. Dopaminergic amacrine cells with widespread dendritic arborizations increase release of dopamine in response to increases in global illumination. Dopamine diffuses throughout the retina to influence cells as far away as the RPE. The increased release of dopamine by light modifies cell function to optimize retinal responses in daylight (Witkovsky 2004).
3. All amacrine cells transfer rod signals from rod bipolar cells to ganglion cells (Bloomfield and Dacheux 2001).

5.3.5 Ganglion Cells

Retinal ganglion cells are the output cells of the retina. Their axons course along the vitreal surface of the retina and bundle together to exit the eye as the optic nerve. Ganglion cells are excited by glutamate released from bipolar cells acting on both NMDA and non-NMDA (KA- and AMPA-type) glutamate receptors (Thoreson and Witkovsky 1999).

There are about 20 types of ganglion cells in mammalian retina (Masland 2012; Wässle 2004). The two most common types in primate retina are M (magnocellular) cells and P (parvocellular) cells. The various types of ganglion cells generally remain segregated in their projections to the lateral geniculate nucleus (LGN): M ganglion cells project to M cell layers of the LGN, P cells to the P cell layers, and bistratified cells project predominantly to the koniocellular (interlaminar) regions. Primate M and P cells are analogous to Y and X cell types in cat retina.

M cells have large cell bodies and large dendritic arborizations resulting in large receptive fields (Rodieck 1998). M cells are classified anatomically as parasol ganglion cells. The large receptive fields of M cells limit their contribution to fine feature analysis. Instead, their output is primarily related to motion and other changes in illumination.

In contrast to M cells, P cells have small cell bodies with small dendritic arborizations resulting in small receptive fields. P cells are also wavelength-selective. P cell output thus contributes to fine feature analysis and color vision. Small P cells are classified anatomically as midget ganglion cells.

S cones do not provide direct inputs into M and P-type ganglion cells, which receive inputs only from M and L cones. S cones instead provide inputs into two different types of ganglion cells: blue OFF cells and small bistratified blue ON cells.

There is also a population of ganglion cells that are intrinsically light sensitive. These cells do not require photoreceptor inputs in order to respond to light (Berson et al. 2002; Fu et al. 2005; Lucas 2013), although they do receive rod- and cone-driven synaptic inputs. The intrinsic light-sensitivity of these cells is conferred by the presence of a photopigment, melanopsin. Intrinsic light responses of these cells are slow and show minimal adaptation. Although the mechanism of phototransduction employed by melanopsin remains under investigation, it appears to involve transient receptor potential (TRP) channels similar to those employed in invertebrate phototransduction. Melanopsin-containing ganglion cells are large but few in numbers. They project to areas responsible for controlling non-visual responses to light such as the suprachiasmatic nucleus for circadian rhythm entrainment and the olivary pretectal nucleus for controlling pupil constriction. Recent work indicates that melanopsin photosensitivity also contributes to vision (Schmidt et al. 2014; Estevez et al. 2012; Ecker et al. 2010).

5.4 Circuitry

In addition to transducing the incoming light, the retina plays an important role in the initial process of analyzing visual information. In the following section, we consider the retinal circuitry employed for analysis of edges, color, directional selectivity, and scotopic vision.

5.4.1 Edge Detection and Center-Surround Receptive Fields

The detection of contrast edges is enhanced by the center-surround arrangement of receptive fields in cones, bipolar cells, and ganglion cells (Kuffler 1953; Baylor et al. 1971). How does this center-surround organization improve edge detection? Consider an ON type ganglion cell (Fig. 5.4) in which the circular center of the receptive field is excited by light. Its center-surround arrangement is imparted by the presence of an annular inhibitory region flanking this central excitatory region. A small spot of light illuminating only the excitatory center strongly excites this cell but an annulus of

Fig. 5.4 Center-surround receptive fields in the retina enhance responses to small spots, edges, and bars of light. (a) Cross section of the center/surround receptive field of an ON center cell. Light falling on the center of the receptive field excites the cell whereas light falling in the periphery produces inhibition. (b) Overhead view of the center/surround arrangement of a receptive field of an ON center ganglion cell illustrating differences in the trains of action potentials evoked by a small spot or full field illumination

light falling only on the inhibitory surround strongly inhibits it. Full field illumination, which stimulates both the excitatory center and the inhibitory surround, thus produces smaller changes in ganglion cell output. A bar or edge of light illuminating the entire excitatory center along with small portions of the inhibitory surround evokes a stronger response than full field illumination, but not as strong as a spot of light illuminating just the excitatory center. The net result of this center-surround receptive field arrangement is that cells respond more strongly to spots, bars and edges than to full field illumination. These same kinds of considerations can be extended to OFF type cells that are excited by light decrements in the center and inhibited by light decrements in the surround. Another way to think about center-surround inhibition is that inhibitory feedback from the broad receptive fields of horizontal and amacrine cells subtracts the mean luminance level from signals transmitted to ganglion cells about local luminance changes. In machine vision, the mathematical equivalent of the center-surround receptive field is implemented to spatially differentiate the image and thus enhance the detection of edges.

5.4.2 Color

The retina initiates the process of analyzing color in the world. The presence of three spectrally distinct types of cones in the primate retina (L, M, and S) provides the physiological basis for trichromatic vision (R, G, B). The responses of an individual cone do not vary with wavelength, but only with the number of photons absorbed. Thus, one can obtain an identical response from a green-sensitive cone using either green or red light as long as one adjusts the intensities of the two lights to provide equivalent photon capture by the

green-sensitive cone. For this reason, color discrimination requires comparisons between inputs from different classes of cones. Synaptic comparisons between different types of cones produce responses that are color opponent, i.e., cells that respond to one wavelength by depolarizing but to another wavelength by hyperpolarizing. In non-mammalian vertebrates, color opponency is evident in horizontal and bipolar cells (Twig et al. 2003). In mammalian retinas, color opponency is first detected in ganglion cells (Dacey and Packer 2003).

There are red/green and blue/yellow opponent cell types in the retina. These two classes of opponent neurons contribute to the perception of color opponent after-images (e.g., the illusory appearance of red produced after gazing steadily at a field of green). In primate retina, the red/green hue axis of color vision utilizes separate retinal circuits and ganglion cell types from the blue/yellow axis. Red/green opponency in primate P-type ganglion cells arises from the selective segregation to center and surround of M and L cone inputs via distinct bipolar cells (Dacey and Packer 2003). Via specialized S cone bipolar cells, S cones provide the input for responses to blue light in the receptive field center of blue ON bistratified and blue OFF-type ganglion cells. Responses to yellow light in the receptive field surround are generated from a sum of L and M cone signals.

5.4.3 Directional Selectivity

Some ganglion cells are excited by stimuli moving along one axis of the receptive field (e.g., upward) but show little response to stimuli moving in the opposite direction (e.g. downward). ON directionally-selective retinal ganglion cells cluster along three preferred axes of motion that correspond to the three axes

of the semicircular canals (Wei and Feller 2011; Borst and Euler 2011). These cells project to the accessory optic system in the midbrain where they drive optokinetic reflex eye movements that, together with vestibuloocular reflexes, can correct for mismatches between head and eye motion (“retinal slip”) that blur the image on the retina. While directional selective cells mediate eye reflex control, conscious motion perception appears to be largely computed in visual cortex by comparing temporal delays between spatially offset receptors.

ON directionally-selective ganglion cells receive synaptic inputs from bipolar cells and symmetrically radiating starburst amacrine cells (Vaney et al. 2012). While still not fully understood, it appears that the directional selectivity in ganglion cells arises from multiple mechanisms including asymmetric inhibition from starburst amacrine cells involving differences in the number of GABAergic synapses in different parts of the cell (Briggman et al. 2011) and asymmetric excitation from bipolar cells.

5.4.4 Rod Pathways

Scotopic or low-light vision is mediated by rod photoreceptors. The mammalian retina has a duplex organization in which rods communicate with ganglion cells using a largely separate circuit from cones. The primary rod circuit begins with rods communicating with ON-type rod bipolar cells that, unlike cone bipolar cells, do not contact ganglion cells directly but instead contact AII amacrine cells. AII amacrine cells form gap junctions with cone ON bipolar cell terminals and inhibitory, sign-inverting glycinergic synapses with cone OFF bipolar cells. Output from AII amacrine cells, therefore, feeds rod signals into cone bipolar cells driving both ON and OFF center ganglion cells. AII amacrine cells provide the primary pathway for rod signals at very low light levels, but at higher light levels there is also a contribution from direct rod inputs into OFF bipolar cells and the transmission of rod signals through gap junctions into neighboring cones (Bloomfield and Dacheux 2001).

There is tremendous synaptic convergence in the rod pathway with as many as 75,000 rods converging onto a single ganglion cell. By contrast, cones show much less convergence, with a 1:1 connection from cones to midrange bipolar cells to midrange ganglion cells in the foveal center. Limited convergence in the cone pathway is important for the high visual acuity mediated by cone circuits. On the other hand, the large convergence of signals in the rod pathway facilitates the perception of very dim flashes of light. The ability of individual rods to respond to a single photon of light combined with convergence allows us to perceive the absorption of as few as a dozen photons within 100 ms (Field et al. 2005).

5.5 Retinal Pigment Epithelial Cells

The RPE is a monolayer epithelium of hexagonal cells whose name reflects the facts that it contains melanin pigment granules and forms the outermost layer of the retina. The apical processes of RPE cells ensheath outer segments of rods and cones and each RPE cell contacts ~20–30 rods (Strauss 2005; Marmor and Wolfensberger 1998).

Melanin granules are concentrated in the apical processes and cytoplasm of RPE cells but are nearly absent from basal cytoplasm. By absorbing stray photons of light that have passed through photoreceptor outer segments, melanin granules improve the optical isolation of individual photoreceptors.

Neighboring RPE cells are connected by tight junctions that help to create the blood/retinal barrier separating the neurosensory retina from fenestrated capillaries in the choroid. The basement membrane of RPE, together with the adjacent basement membrane of the choroid, forms a structure known as Bruch’s membrane. RPE cells possess a number of organic and ion transporters to help move polar molecules across the blood retinal barrier. These include transporters for amino acids, folate, ascorbic acid, myo-inositol, organic anions, glucose and lactate.

Photoreceptors continually synthesize new phototransduction proteins for incorporation into newly formed outer segment discs. As new discs are formed at the base of the outer segment, older discs are phagocytosed by RPE cells at the tip of the outer segment. Each outer segment disc is formed and shed in ~2 weeks. The phagocytosis of discs occurs in circadian bursts (rods at the end of night, cones at the end of day).

The bleached, all-trans form of the chromophore retinal cannot be converted back into photosensitive 11-cis-retinal within photoreceptor cells but requires participation of the RPE or, for cones, of Müller cells (Lamb and Pugh 2004; Wang and Kefalov 2011). Following the conversion of 11-cis-retinal to all-trans-retinal by light, all-trans-retinal is rapidly converted to all-trans-retinol (all-trans-vitamin A) in the photoreceptor outer segment. All-trans-retinol is then transported out of the photoreceptor cell, through the interstitial space, and into adjacent RPE or Müller cells via a process involving interstitial retinoid binding proteins (IRBP). The regeneration of cone pigment molecules by Müller cells is described in the next section. Upon entering RPE cells, retinol is bound to cellular retinol binding protein. All-trans-retinol is converted to 11-cis-retinol by retinol isomerase (RPE65) and 11-cis-retinol is converted back to 11-cis-retinal by 11-cis-retinol dehydrogenase. 11-cis-retinal is transferred to cellular retinal binding protein (CRALBP) for transport to the RPE cell surface. Finally, regenerated 11-cis-retinal is transported back to photoreceptors via IRBP. By depriving photoreceptors of chromophore, mutations of visual cycle proteins (e.g., retinol

isomerase [RPE65], 11-cis-retinol dehydrogenase, CRalBP, and IRBP) can lead to photoreceptor degeneration.

The interstitial space between RPE and photoreceptors contains a sticky interphotoreceptor matrix consisting of glycoproteins, proteoglycans, and hyaluronic acid that helps the retina adhere to the back of the eye. Retinal adhesion is also promoted by extrusion of water from the RPE to choroid. Basolateral Cl channels and apical Na/K/2Cl transporters are particularly important for water transport out of the RPE. Because photoreceptors are not physically bound to the RPE, the retina can detach from the RPE with a strong blow to the eye, fluid build-up behind the retina (rhegmatogenous detachment), or traction from overlying cells in proliferative vitreoretinopathy. Detachment of photoreceptor cells from the adjacent RPE prevents recycling of the photopigment which blocks phototransduction by depriving opsin of sufficient chromophore.

One byproduct of photoisomerization in photoreceptor outer segments is N-retinylidene-N-retinylethanolamine (A2E). A2E is ingested by RPE cells when they phagocytose outer segments. However, A2E cannot be enzymatically degraded by RPE cells and thus accumulates in these cells, where it becomes a major component of lipofuscin granules (Sparrow and Boulton 2005). Stargardt's macular degeneration involves a defect in the ABCR transporter that increases accumulation of A2E suggesting it may play a role in macular degeneration. The damage to the RPE associated with A2E accumulation may result from stimulation of apoptosis in A2E-laden RPE cells produced by exposure to blue light.

A major risk factor for age-related macular degeneration (ARMD) is the presence of drusen deposits (Velez-Montoya et al. 2014). White drusen spots visible with an ophthalmoscope are formed by deposits between the RPE and Bruch's membrane. Drusen formation involves inflammatory reactions and RPE cells overlying drusen often show signs of impending cell death. Studies on genetic factors contributing to ARMD have identified mutations in immune complement-related genes as important risk factors (Edwards et al. 2005; Haines et al. 2005; Klein et al. 2005; Gold et al. 2006). This has led to the suggestion that mutations that promote overactive inflammatory responses may contribute to drusen formation leading to RPE cell damage and ARMD.

5.6 Glia

The predominant retinal glial cell is the Müller cell. Müller cells are radial glia that span the retina from the OLM to ILM and ensheath virtually every cell in the retina. They play a number of important roles in maintaining homeostasis (Newman and Reichenbach 1996). For example, Müller cells are a primary storage depot for glycogen in the retina that

can provide metabolites (e.g., lactic acid) to neurons during times of metabolic stress. Müller cells also help to remove and redistribute metabolic waste products. They exhibit high levels of glutathione that can help protect the retina from oxidative stress. Müller cells also possess Na/HCO₃ co-transport mechanisms and carbonic anhydrase to stabilize pH levels in the retina.

Another important role of Müller cells is the spatial redistribution of K⁺ from regions of high concentration to regions of low concentration in order to maintain a stable extracellular K⁺ concentration of about 3 mM (Kofuji and Newman 2004). When neuronal depolarization causes K⁺ levels to increase in the IPL and OPL, excess K⁺ ions enter Müller cells processes. K⁺ influx in the plexiform layers is accompanied by a simultaneous efflux through K⁺ channels clustered at the vitreal surface and along blood vessels. Conversely, a reduction in K⁺ accompanying neuronal hyperpolarization is accompanied by an efflux of K⁺ out of Müller cells into the plexiform layers. The current flowing through radially oriented Müller cells as a result of this spatial buffering of K⁺ produces measurable trans-retinal potentials, such as slow PIII of the electroretinogram. It was once believed that Müller cell K⁺ currents were the predominant mechanism responsible for the ERG b-wave, but more recent studies suggest that the b-wave primarily reflects ON bipolar cell responses.

Müller cells are major sites for the uptake and removal of neurotransmitters, most notably glutamate and GABA. Glutamate transport into neurons is smaller and slower than transport into Müller cells and thus uptake into Müller cells is the principal mechanism responsible for the initial removal of extracellular glutamate following synaptic activation (Pow 2001). In addition to neurotransmitter transporters, Müller cells possess neurotransmitter receptors and can release neuroactive substances (e.g., ATP) (Newman 2004). Thus, activity of retinal neurons can influence Müller cells and Müller cell activity can in turn influence adjacent neurons.

As described in the previous section, RPE cells are required for regenerating 11-cis-retinal from all-trans-retinal derived from rods. However, regeneration of the bleached photopigment from cones is largely performed by Müller cells (Wang and Kefalov 2011). All-trans-retinol is transported into Müller cells where it is converted into the 11-cis isomer and then transported back into cones where it is oxidized to 11-cis-retinal. Regeneration of cone pigment in Müller cells is generally similar to regeneration in RPE but uses a different isomerase (isomerase II in Müller cells vs. RPE65 in RPE cells) and Müller cells export the alcohol, 11-cis-retinol, rather than the aldehyde, 11-cis-retinal.

In addition to Müller cells, the retina contains three other types of glial cells: astrocytes, oligodendrocytes and microglia. Retinal astrocytes are located primarily in the

nerve fiber layer and oligodendrocytes form the myelin sheath of axons in the optic nerve. Hematopoetically-derived microglia are small stellate cells that, when quiescent, associate with inner retinal blood vessels.

Infection or damage to the retina stimulates Müller cell gliosis (Garcia and Vecino 2003) and migration of microglia to the injured area to assist in phagocytosing debris from dying cells. Microglia and Müller cells both release cytokines in response to injury and the release of pro-inflammatory cytokines can sometimes exacerbate cell damage during retinal disease. Cytokines released by Müller cells include vascular endothelial growth factor and transforming growth factor beta, which promote neovascularization, as well as basic fibroblastic growth factor. At least in some species, Müller cells respond to injury and cytokines by dedifferentiating into progenitor cells that can give rise to neurons (Fischer and Bongini 2010).

5.7 Blood Supply

Blood is supplied to the retina by the central retinal artery and choroidal blood vessels (Oyster 1999). The central retinal artery arises from the ophthalmic artery, which in turn branches off the internal carotid artery. Upon entering the retina, the central retinal artery branches into deep capillary beds in the INL and superficial capillary beds in the ganglion cell layer. Endothelial cells of retinal capillaries are joined by tight junctions, contributing to the blood/retinal barrier. There is little or no autonomic regulation of the retinal circulation; blood flow through these capillaries is instead controlled primarily by autoregulation (Wangsa-Wirawan and Linsenmeier 2003). Retinal capillaries drain into the central retinal vein.

Choroidal vessels derive from posterior and short posterior ciliary arteries that, like the central retinal artery, branch off from the ophthalmic artery. The choroidal circulation forms a dense bed of fenestrated capillaries, known as the choriocapillaris, just beneath the basolateral surface of the RPE. The flow rate through the choriocapillaris is among the highest in the body and the arterio-venous drop in PO_2 is minimal. This high flow rate supplies the energetically demanding photoreceptors with large amounts of oxygen and maintains the retina at a constant temperature despite changing levels of radiant energy focused onto the back of the eye. Oxygen for the photoreceptors comes primarily from the choroid. The high level of oxygen consumption by photoreceptor cells in darkness produces a PO_2 of zero at the level of the inner segments in mammalian retina (Linsenmeier 1986). Under these conditions, there is no oxygen available for the remainder of the retina from the choroid. Other retinal neurons instead receive their oxygen from the retinal circulation. (By contrast with mammals, many cold-blood vertebrates

lack retinal capillaries and rely on the choroid to supply the entire retina with oxygen and other nutrition.) While capable of autoregulation (Kiel and Shepherd 1992), blood flow in the choriocapillaris is also regulated by autonomic inputs. Choroidal capillaries drain into four vortex veins, one from each quadrant of the eye.

5.8 Review Questions

1. Briefly summarize the major steps in phototransduction by rods.
2. What are the calcium-dependent steps in light adaptation?
3. What are the major physiological features of magnocellular and parvocellular retinal ganglion cells in the primate retina?
4. In mammalian retina, which capillary beds supply oxygen to the photoreceptors and which to the remaining parts of the retina?
5. For an ON-type ganglion cell, describe how the center-surround organization of visual receptive fields improves edge detection.
6. Summarize the key roles of the RPE.
7. Describe the rod pathway used in scotopic vision.
8. Describe the key enzymatic steps in the visual cycle converting bleached all-trans-retinal back into light-sensitive 11-cis-retinal in RPE cells.
9. Describe the spatial redistribution of K^+ by Müller cells.
10. Summarize the enzymatic mechanisms by which phototransduction is terminated after photo-stimulation.
11. Which of the following is the predominant glial cell type in the retina?
 - a. Astrocyte
 - b. Müller cell
 - c. Microglia
 - d. Schwann cell
 - e. RPE cell
12. In which layer of the retina do bipolar cell terminals contact ganglion cell dendrites?
 - a. Outer nuclear layer
 - b. Outer plexiform layer
 - c. Inner nuclear layer
 - d. Inner plexiform layer
 - e. Ganglion cell layer
13. Which of the following statements is true about the fovea?
 - a. The fovea contains both rods and cones
 - b. The fovea is the region of the retina where ganglion cell axons exit the eye.
 - c. The fovea is the region of the retina responsible for the highest acuity vision in humans and primates.
 - d. The location of the fovea on the retina is not a fixed anatomical feature but varies with focus.

- e. At the center of the fovea, light must first pass through ganglion, amacrine, horizontal and bipolar cells before reaching photoreceptor outer segments.
14. Upon which chromosome are genes for M cone pigments located?
 - a. *X chromosome*
 - b. Y chromosome
 - c. Chromosome 3
 - d. Chromosome 7
 - e. Chromosome 10
15. Which of the following statements is true about ON and OFF type retinal bipolar cells?
 - a. ON bipolar cells possess KA/AMPA receptors and OFF bipolar cells possess NMDA receptors.
 - b. ON bipolar cells possess NMDA receptors and OFF bipolar cells possess mGluR6.
 - c. ON bipolar cells possess mGluR6 and OFF bipolar cells possess NMDA receptors
 - d. *ON bipolar cells possess mGluR6 and OFF bipolar cells possess KA/AMPA receptors*
 - e. ON bipolar cells possess KA/AMPA receptors and OFF bipolar cells possess mGluR6
16. Which of the following is NOT considered to be a major role of Müller cells?
 - a. Spatial redistribution of potassium
 - b. Neurotransmitter uptake and removal
 - c. Homeostatic maintenance of retinal pH levels
 - d. Glycogen storage
 - e. *Promoting retinal adhesion to the back of the eye*
17. Which of the following is NOT considered to be a major role of RPE cells?
 - a. *Phagocytosis of injured cells*
 - b. Formation of blood-retinal barrier
 - c. Absorption of stray light
 - d. Photopigment recycling
 - e. Phagocytosis of outer segment discs
18. Which of the following proteins is a major constituent of synaptic ribbons?
 - a. Retinol dehydrogenase
 - b. Melanin
 - c. *Ribeye*
 - d. RGS/G β 5
 - e. Bestrophin
19. Which cell types are responsible for converting all-trans vitamin A into the 11-cis form needed for phototransduction?
 - a. Rods and cones
 - b. *Müller cells and RPE cells*
 - c. Choroid
 - d. Horizontal cells and bipolar cells
 - e. Astrocytes and microglia
20. What is the light-sensitive molecule found in intrinsically photo-sensitive retinal ganglion cells of mammalian retina?

- a. *Melanopsin*
- b. Transducin
- c. Rhodopsin
- d. Cryptochrome
- e. Peropsin

5.9 Answers

1. Absorption of a photon stimulates a conformational change in the chromophore, 11-cis-retinal (vitamin A aldehyde), so that it assumes an all-trans configuration (all-trans-retinal). This conformational change in the chromophore causes a conformational change in the G-protein-coupled receptor, rhodopsin, so that it achieves its active conformation, meta-rhodopsin. Activated meta-rhodopsin activates the G protein alpha subunit, transducin, which in turn stimulates cGMP-specific phosphodiesterase to cleave cGMP into GMP. This reduction in [cGMP] causes cGMP-gated non-selective cation channels to close. Closure of these channels reduces the influx of Na⁺ (and Ca²⁺) and thus hyperpolarizes the rod.
2. In response to light, the influx of Ca²⁺ into outer segments through cGMP-gated channels diminishes but its efflux by the Na⁺/Ca²⁺ exchanger continues. This causes the concentration of Ca²⁺ in the outer segment to diminish in light. The reduction in Ca²⁺ levels has two major effects on phototransduction: (1) Decreased [Ca²⁺] enhances the activity of guanylyl cyclase in rods and cones stimulating the production of cGMP. The resulting increase in cGMP levels opens cGMP-gated channels causing photoreceptor cells to depolarize. (2) Decreased intracellular [Ca²⁺] increases the affinity of cGMP for cGMP-gated cation channels in cones and thus enhances the opening of these channels. The membrane depolarization that results from re-opening of cGMP-gated cation channels restores the operating range of the photoreceptor cell by allowing it to hyperpolarize in response to another flash of light.
3. Magnocellular ganglion cells have large cell bodies and large dendritic arborizations resulting in large receptive fields. Because of their large receptive fields, M cells do not contribute to fine feature analysis. Instead, their output is primarily related to motion and other changes in illumination.
 Parvocellular ganglion cells have small cell bodies with small dendritic arborizations resulting in small receptive fields. P cells are also wavelength-selective. P cell output thus contributes to fine feature analysis and color vision.
4. Choroidal capillaries provide oxygen to photoreceptors. Retinal capillaries in the INL and ganglion cell layer provide oxygen to the remainder of the retina.

5. The center-surround arrangement of the receptive field is due to the presence of an annular inhibitory region surrounding a central excitatory region. A small spot of light illuminating only the excitatory center strongly excites the cell whereas an annulus of light illuminating the inhibitory surround strongly inhibits it. By contrast, stimulation of both the excitatory center and inhibitory surround by full field illumination produces relatively small changes in ganglion cell output. A bar or edge of light illuminating the entire excitatory center along with small portions of the inhibitory surround will evoke a stronger response than full field illumination, but not as strong as a spot of light illuminating just the excitatory center. The net result of this center-surround receptive field arrangement is that cells respond more strongly to spots, bars and edges than to full field illumination
6. Directional selective ganglion cells are excited by stimuli moving along one axis of the receptive field but show little response to stimuli moving in the opposite direction. The directional selectivity in ganglion cells results from the fact that cholinergic excitation from starburst amacrine cells occurs earlier than GABAergic inhibition with visual stimuli moving in the preferred direction, but GABAergic inhibition precedes excitation with stimuli moving in the opposite, non-preferred direction. Because the preceding GABAergic inhibition dampens the cell's responses to movement in the non-preferred, directional selective ganglion cells respond more strongly to movement in the preferred direction.
7. Rods contact ON-type rod bipolar cells. These rod ON bipolar cells do not contact ganglion cells directly but instead contact AII amacrine cells. AII amacrine cells form gap junctions with cone ON bipolar cell terminals as well as inhibitory, sign-inverting glycinergic synapses with cone OFF bipolar cells. Thus, AII amacrine cells feed rod signals into ON and OFF cone bipolar cells driving ON and OFF center ganglion cells, respectively.
8. After the bleaching of 11-cis-retinal to all-trans-retinal by light, all-trans-retinal converts rapidly to all-trans-retinol (all-trans-vitamin A) in the photoreceptor outer segment. All-trans-retinol is transported out of photoreceptor cells, through the interstitial space, and into the RPE through a process involving interstitial retinoid binding proteins (IRBP). In the RPE, all-trans-retinol is converted to 11-cis-retinol by retinol isomerase (RPE65) and 11-cis-retinol is converted back to 11-cis-retinal (11-cis-vitamin A aldehyde) by 11-cis-retinol dehydrogenase. Regenerated 11-cis-retinal is transported back to photoreceptors via IRBP.
9. When K^+ levels increase in the IPL and OPL due to neuronal depolarization, excess K^+ ions enter K^+ channels localized to Müller cells processes. This K^+ influx in the

plexiform layers is accompanied by a simultaneous efflux through K^+ channels clustered at the vitreal surface and along blood vessels. Conversely, a reduction in K^+ accompanying neuronal hyperpolarization is accompanied by an efflux of K^+ out of Müller cells into the plexiform layers.

10. Inactivation of the light-activated form of rhodopsin, meta-rhodopsin, begins with its phosphorylation by rhodopsin kinase. Phosphorylation of meta-rhodopsin by rhodopsin kinase allows arrestin to bind and arrest further enzymatic activity. Light-activated transducin is shut down by the intrinsic GTPase activity of transducin that converts GTP into GDP. The G protein, transducin, is de-activated by converting GTP into GDP. The intrinsic GTPase activity of transducin is accelerated by binding to an accessory protein, RGS/G β 5.

Abstract

The hippocampus is a symmetrical structure located inside the medial temporal lobe on both sides of the human brain. In cross-sections, the hippocampus consists of two interlocking sheets of cortex with three distinct sub-regions: the dentate gyrus, the hippocampus proper (CA1–CA3) and the subiculum. The hippocampus has a much defined laminar structure with layers visible where rows of pyramidal cells are arranged. A striking feature of hippocampus is its connection circuitry. The connections within the hippocampus generally follow this laminar format and are largely unidirectional. They form well-characterized closed loops that originate mainly in the adjacent entorhinal cortex. Thus information flow through the hippocampus proceeds from dentate gyrus to CA3 to CA1 to the subiculum, forming the principal trisynaptic circuit. Together with the adjacent amygdala and entorhinal cortex, the hippocampus forms the central axis of the limbic system and plays an important role in spatial learning and awareness, navigation, and episodic/event memory. In addition, the hippocampus plays a role in neuroimmunomodulation.

Keywords

CA1 • CA3 • Dentate gyrus • Hippocampus • Long-term potentiation • Mossy fibers • Neuroimmunomodulation • Neurotransmitter • Perforant path • Schaffer collaterals • Spatial memory • Synapse • Synaptic transmission

6.1 Introduction

The hippocampus is a brain structure located inside the temporal lobe. It forms a part of the limbic system and plays an important role in the formation, consolidation and retrieval of episodic memories. It has been shown that repetitive activation of excitatory synapses in the hippocampus causes an increase in synaptic strength that last for hours or days designated as long-term potentiation (LTP). It is widely believed

that LTP provides an important key to understand the cellular and molecular mechanisms by which memories are formed and stored. Sensory information enters the hippocampus mainly through the perforant pathway consisting of the axons of neurons in layers II and III of the entorhinal cortex. The perforant path axons terminate on the dendrites of the dentate gyrus granular cells. Then information flows through the hippocampus from the dentate gyrus to the CA3, the CA1 and the subiculum, forming hippocampal intrinsic trisynaptic circuit. In addition to its “traditional” role in learning and memory, the hippocampus is also involved in neuroimmunomodulation. Lesion of hippocampus alters neuroimmunomodulation and neuronal functions in the hippocampus are modulated by a variety of immune active molecules.

6.2 Anatomy of the Hippocampus

The hippocampus, so named because its shape vaguely resembles that of a seahorse, is a curved sheet of cortex folded into the medial surface of the temporal lobe. In transverse sections from rodent brain, the hippocampus has the appearance of two interlocking Cs with three distinct sub-fields: the dentate gyrus, the hippocampus proper (cornu ammonis, CA) and the subiculum (Fig. 6.1), these together is termed hippocampal formation. While hippocampus proper generally includes only CA1–CA3; the CA4 is frequently called the hilus and considered part of the dentate gyrus (Fig. 6.1). The hippocampus of primates and humans occupies less of the telencephalon in proportion to cerebral cortex than lower hierarchy animals does, reflecting it is among the phylogenetically oldest parts of the brain.

The anatomy of the hippocampus has been studied intensively in rodents since Cajal (1911) published his famous drawing illustrating the main cells, connections and flow of impulse traffic in the hippocampal formation (Fig. 6.1), followed by a consecutive of physiological, biochemical and axonal tracing studies, making it one of the most studied and best known structures in the brain (Raisman et al. 1966; Swanson and Cowan 1975; Swanson et al. 1981; Frotscher 1985). Its cytoarchitecture, neural circuit, main afferents and efferents are summarized in Fig. 6.2. Its predominant intrinsic circuit is characterized as three-order projections from dentate granular cells to CA3 pyramidal cells and then from the later to the CA1 (also including CA2) and subiculum neurons (Fig. 6.2).

6.2.1 The Dentate Gyrus

6.2.1.1 Cytoarchitecture

The dentate gyrus is a sharply folded trilayered cortex (molecular, granule cell and polymorphic layers from outer gyrus to hilus) that forms a cap over the free edge of Ammon's horn (C or V shape in rodents). The granule cells are principal neurons in the dentate gyrus which are small (about 10 μm in diameter) and densely packed in cell layer (Fig. 6.1). Their dendrites extend perpendicularly to the cell layer and into the molecular layer where they receive synaptic inputs mainly from perforant afferents (Figs. 6.1 and 6.2). The axons of granule cells are called mossy fibers and extend into the polymorphic layer in the hilus that is a transition area between the dentate gyrus and hippocampus proper. The mossy fibers synapse onto mossy cells and basket interneurons in the hilar area, the former give rise to excitatory recurrent projections to the granule cells and the later may have more than five types mostly with inhibitory feedback to the granule cells (Fig. 6.2).

Interestingly, the dentate gyrus is one of the few brain regions where neurogenesis takes place. Neurogenesis is thought to play a role in the formation of new memories. It has been shown an increased neurogenesis in response to both antidepressants and physical exercise, implying that neurogenesis may improve symptoms of depression (Yamashima et al. 2007).

6.2.1.2 Fiberarchitecture

Afferents to the dentate gyrus—The perforant path: The major afferents to the dentate gyrus are from the entorhinal cortex (but also perirhinal cortex, among others) by way of a

Fig. 6.1 Schematic drawing by Cajal (1911) of the main cells, connections and flow of impulse traffic in the hippocampus

Fig. 6.2 Schematic drawing illustrating cytoarchitecture and fiberarchitecture of the hippocampus formation

fiber system called the perforant path and terminate in outer two thirds of the dentate molecular layer (equivalent to stratum lacunosum and molecular) (Lorente de No 1934). The dentate neurons also relay the massive projections from entorhinal cortex to the CA3 pyramidal cells. Recurrent projections onto dentate neurons are conducted through hilar mossy cells and local basket interneurons (Figs. 6.1 and 6.2).

It was through the perforant pathway that LTP was first discovered (Bliss and Gardner-Medwin 1973). Approximately 60–70% of the total dendritic fields of individual granule cells are taken up with the perforant input (Desmond and Levy 1982). Other afferents to the dentate gyrus originate from brain stem raphe nuclei (Moore and Halaris 1975), the locus coeruleus (Room et al. 1981) and hypothalamic supra-mammillary nucleus (Wyss et al. 1979).

Efferents from the dentate gyrus—The mossy fibers: The dentate granule cells project predominantly to the CA3 region and less heavily to the hilus through mossy fibers. The mossy fiber terminals are large (3–6 μm) and make asymmetric synaptic contact on the dendritic shaft and dendritic spines (thorny excrescence) of the CA3 pyramidal cells. A single CA3 pyramidal cell can be innervated by more than one granule cells. This pathway has been studied extensively as a model for the functional roles of kainate receptors in synaptic plasticity. For instance, LTP is *N*-methyl-D-aspartate (NMDA) receptor-independent in this pathway, but it appears to involve pre-synaptic kainate receptors. The mossy fibers are glutamatergic, however they have also been shown to be

immunoreactive for γ -aminobutyric acid (GABA) and opiate peptides (dynorphin and enkephalin) (Commons and Milner 1996; Gutierrez and Heinemann 2006; Walker et al. 2002).

Neural tract tracing electron microscopy studies on mossy fibers has disclosed that fibers terminating onto the hilar mossy cells are branched from long projecting mossy fibers to the CA3 region (Blackstad and Kjaerheim 1961).

6.2.2 The Hippocampus Proper (CA1–CA3 Fields)

6.2.2.1 Cytoarchitecture

Hippocampus proper is a U-shaped fold of cortex composed of CA1–CA3 fields (Fig. 6.1) extending from subiculum to the hilus of the dentate gyrus. Adjacent to the subiculum is a field of tightly packed medium-sized cells, which Lorente de No (1934) named the CA1. Next to CA1 are the fields CA2 and CA3 containing large, less densely packed cells. CA2 pyramidal cells can be distinguished from CA3 pyramidal cells in Golgi preparations by the absence of characteristic thorny spines on the proximal apical dendrites.

Hippocampal pyramidal cells generally have dendrite trees with apical and basal dendrites; the former heavily branches in the molecular layer (equivalent to stratum lacunosum and molecular) and the latter gives off branches between polymorphic and pyramidal cell layers (equivalent to stratum oriens and pyramidal from outer border to center;

Fig. 6.2). The axons generally originate from or near the basal dendrite and travel into the alveus where it may bifurcate. In the CA1 field, one branched axon travels from CA1 to the subicular area and the other toward the fimbria through alveus bundle (Fig. 6.2). In the CA3 region, the pyramidal axons give rise to three branches in polymorphic layer and all of them are termed as Schaffer collaterals.

6.2.2.2 Fiberarchitecture

Afferents to cornu ammonis areas: The CA3 pyramidal cells receive robust projections from the dentate gyrus through mossy fibers, and accept less heavily afferent innervations from layer II (slightly from layer IV) of the entorhinal cortex. The CA3 neurons are also innervated by recurrent projections from themselves through Schaffer collaterals (Figs. 6.1 and 6.2).

The CA2 and CA1 pyramidal cells are predominantly innervated by bilateral CA3 neurons through Schaffer collaterals from both ipsi- and contralateral sides (Fig. 6.2). In the CA1 field, the pyramidal cells also receive projections from the layer III (slightly from layer V) of the entorhinal cortex (Fig. 6.2). The dendrite trees of CA1 neurons in both molecular and polymorphic layers are heavily innervated by CA3 neuronal axons. This Schaffer collateral to CA1 pathway is widely studied for NMDA receptor-dependent LTP and long-term depression (LTD).

Recurrent feedback innervations onto the CA1 pyramidal neurons are carried out through local interneurons and some small pyramidal cells (Fig. 6.2). The CA1 also receives a fairly substantial input from the amygdaloid complex, and a few of noradrenergic and serotonergic projections.

Efferents of hippocampus proper: The well-known efferents of the CA3 pyramidal cells are Schaffer collaterals projecting to both ipsi- and contralateral hippocampus. These efferent collaterals also give rise to recurrent innervations to the CA3 neurons (Fig. 6.2). The efferent fibers from CA1 neurons travel through polymorphic layer (equivalent to stratum oriens) and bifurcate into three bundles of branches, one group join alveus toward fimbria, the other branches project onto the subiculum cells and another group branches merge into the efferent bundle toward entorhinal cortex (Fig. 6.2). In addition, CA1 neuronal axons in the alveus again give rise to collaterals to local interneurons that feedback project to the CA1 pyramidal cells (Fig. 6.2).

The septal nucleus is the major extrahippocampal target of the pyramidal projections from all CA fields. Axons from both CA1 and CA3 terminate in the septal nucleus. The fibers from dorsal hippocampal project to dorsomedial areas of the lateral septal nucleus, while progressively more ventral parts of the hippocampus terminate in correspondingly more lateroventral bands in the lateral septal nucleus (Meibach and Siegel 1977a). Some branches of the CA1 axons terminate sparsely in olfactory bulb (de Olmos et al. 1978) and prefrontal cortex (Swanson 1981).

6.2.3 The Subicular complex

The subiculum curves anteriorly and laterally to wrap around the posterior extension of the dentate gyrus. It borders the medial entorhinal cortex and field of CA1 (Figs. 6.1 and 6.2). The subiculum can be divided into three distinct cytoarchitectural areas. The parasubiculum borders the medial entorhinal cortex and contains moderately packed medium-sized cells. The presubiculum is between parasubiculum and subiculum, which is characterized by densely packed small cells. The subiculum proper borders to the field of CA1 and has a loosely packed pyramidal cell layer and a wide molecular layer (Figs. 6.1 and 6.2).

Hippocampal intrinsic afferents to the subiculum originate from the CA1 neurons and from bilateral CA3 pyramidal cells through the Schaffer collaterals (Swanson et al. 1978). The extra-hippocampal projections to the subiculum mostly originate from layer II (slightly from layer IV) of the entorhinal cortex, and less often from the raphe nuclei (Conrad et al. 1974), locus coeruleus (Jones and Moore 1977; Haring and Davis 1985), amygdaloid nuclei (Krettek and Price 1977), septal nucleus (Meibach and Siegel 1977b) and perirhinal cortex (Kosel et al. 1983).

The targeted regions for subicular projections include, but are not limited to, thalamic nuclei (Aggleton et al. 2005), reunions nucleus (Herkenham 1978), mammillary body of the hypothalamus (Aggleton et al. 2005) and amygdaloid nucleus (Kishi et al. 2006). The parasubiculum and presubiculum project heavily to the anterior thalamic nuclei (Sikes et al. 1977; Cohen and Eichenbaum 1993).

6.3 Role of the Hippocampus in Learning and Memory

6.3.1 Memory Functions of the Hippocampus

The role of the hippocampus in learning and memory has been the focus of neuroscience studies since Scoville and Milner reported the case of Henry Molaison (HM) who had severe anterograde amnesia following bilateral medial temporal lobe resection (Scoville and Milner 1957). The pattern of impaired and spared memory functions displayed by HM prompted a now commonly acknowledged characterization of the temporal lobe amnesic syndrome. It is widely believed that damage to the hippocampus disrupts declarative memory processes and more specifically episodic memory functions (Tulving 2001; Tulving and Markowitsch 1998). Declarative memories have been further divided into episodic and semantic memories. Episodic memory is concerned with conscious recall of specific episodes, and semantic memory with the storage of factual information. The memory functions that are spared in temporal lobe

lesions have been classified as nondeclarative or procedural memories (Squire 1992; Cohen and Eichenbaum 1993). Nondeclarative or procedural memory processes are thought to operate automatically and do not include information about where or when learning experience took place. The pattern of memory deficits in humans with temporal lobe damage prompted the question, what role did the hippocampus play in memory?

The precise role of the hippocampus in learning memory remains to be determined. Accumulating evidence suggest that hippocampus has an essential role in the formation of new memories about experienced events. Damage to the hippocampus usually results in profound difficulties in forming new memories (anterograde amnesia), and normally also affects access to memories prior to the damage (retrograde amnesia). Although the retrograde effect normally extends some years prior to the brain damage, in some cases older memories remain. This sparing of older memories leads to the idea that consolidation over time involves the transfer of memories out of the hippocampus to other parts of the brain. However, it is difficult to test the sparing of older memories experimentally. Also, in some cases of retrograde amnesia, the sparing appears to affect memories formed decades before the damage to the hippocampus occurred, so its role in maintaining these older memories remains controversial.

Animal studies indicate that the hippocampus plays a role in storing and processing spatial information. In rodents, the firing rate of hippocampal neurons was found to correlate to the location of the animal in a test environment and these cells are referred to as place cells (O'Keefe and Conway 1978; O'Keefe and Dostrovsky 1971). There are many thousands of different place cells, which can be activated in response to a location in a particular environment. Different place cells have different place fields, which are not fixed in absolute space and are relative to spatial cues. The discovery of place cells led to the idea that the hippocampus might act as a cognitive map—a neural representation of the layout of the environment (O'Keefe and Nadel 1978). There has been considerable support for the cognitive mapping theory from lesion and unit recording studies. It has been reported that rats with hippocampal lesions exhibit impairment in learning as detected in radial arm (Jarrard 1983), T-maze (Bannerman et al. 2001) and Morris water maze, where lesioned rats had poor performance in finding the hidden platform (Morris et al. 1986; Morris et al. 1982). Indeed, neuroimaging studies in humans revealed that the hippocampus becomes active during spatial navigation, suggesting that the hippocampus in humans contributes to the encoding and retrieval of spatial information. This finding corresponds well with the results in animal studies, which show a significant deficit in spatial navigation resulting from hippocampal damage.

6.3.2 Synaptic Mechanisms of Memory

The nature of the physiological basis of learning and memory remains an enigma in neurobiology. The assumption that information is stored in the brain as changes in synaptic efficacy was initially proposed by Ramon y Cajal and later refined by Hebb (1949). This assumption was not tested until the early 1970s when Timothy Bliss and Terje LØmo made an important discovery that brief high frequency electrical stimulation of an excitatory pathway to the hippocampus produced a long-lasting enhancement in the strength of the stimulated synapses. This effect is now known as LTP.

LTP is expressed as a persistent increase in the size of the evoked synaptic response recorded from single cells or group of cells. It can be induced by high frequency stimulation (HFS, typically 100 Hz) or other types of stimulation, such theta-burst stimulation. These stimulus paradigms resemble the synchronized firing patterns at similar frequencies that occur in the hippocampus during learning (Otto et al. 1991), making them useful experimental means to generate “learning activities” in the hippocampus. Over the past 30 years, LTP has been intensively studied because it is the leading experimental model for the synaptic changes that may underlie learning and memory.

6.3.2.1 Basic Properties of LTP

Although LTP was first demonstrated at the perforant path synapses on the granule cells in the dentate gyrus (Bliss and Gardner-Medwin 1973), the majority of experiments on understanding the mechanisms of LTP have been performed on the Schaffer collateral/commissural synapses on the CA1 pyramidal cells in the hippocampus.

LTP in the hippocampus has three basic properties: cooperativity, associativity and input-specificity (Bliss and Collingridge 1993). Cooperativity refers to the fact that long-lasting synaptic enhancement following HFS increases with the number of stimulated afferents (McNaughton et al. 1978). Threshold stimulus intensity during HFS is required for synaptic enhancement. ‘Weak’ HFS, which activates relatively few fibers, did not produce LTP, whereas strong stimulation at the same frequency and for the same duration produced LTP. Associativity means that a weak input (small number of stimulated afferents) can be potentiated if it is active at the same time as a strong tetanus (large number of stimulated afferents) to a separate but convergent input (Bliss and Collingridge 1993). This associativity has often been viewed as a cellular analog of associative or classic conditioning (Malenka and Nicoll 1999). Another basic property of LTP is its input-specificity. When LTP is induced by repetitive stimulation the increase in synaptic strength usually does not occur in other synapses (on the same cell) that are not active at the time of repetitive stimulation (Bliss and Collingridge 1993). This property increases the storage capacity of individual neurons (Malenka and Nicoll 1999).

One remarkable feature of LTP is that it can be induced by a brief HFS, lasting less than or equal to a second and consisting of stimulation frequency well within the range of normal axon discharging. Longevity is an additional feature of LTP. Once induced, LTP can persist for many hours in brain slices *in vitro* or in the anaesthetized animal, and for days or weeks (possible even a lifetime) in the freely moving animal.

6.3.2.2 Mechanisms of Hippocampal LTP

It is well accepted that activation of postsynaptic NMDA receptors, a subtype of glutamate receptors, is required for the induction of LTP in the hippocampus. The key role that the NMDA receptors play in LTP induction relies on the voltage-dependent block of its channel by Mg^{2+} (Ascher and Nowak 1988). In this way the NMDA receptor channel complex behaves as a molecular detector for LTP induction. To trigger the induction of LTP, two events must occur simultaneously: the cell membrane must be sufficiently depolarized to expel Mg^{2+} from NMDA channels at the same time L-glutamate binds to NMDA receptors and promotes the opening of these receptor-ligand-gated ion channels. The membrane depolarization can be achieved by repetitive tetanic stimulation of synapses or by directly depolarizing the cell while continuing low frequency stimulation of synapses (Gustafsson et al. 1987). At Schaffer collateral—CA1 pyramidal cell synapses, Na^+ ions passing through the α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors are responsible for this membrane depolarization. When the membrane depolarization is sufficient and reaches a certain level, it expels Mg^{2+} from the NMDA receptor channel, allowing Ca^{2+} as well as Na^+ to enter the cell. The influx of Ca^{2+} through NMDA receptor channel raises intracellular Ca^{2+} and triggers the induction of LTP.

Considerable evidence now links this rise in postsynaptic Ca^{2+} concentration to the induction of LTP. The most compelling evidence in support of this model comes from experimental results wherein LTP induction can be blocked by pharmacological inhibition of NMDA receptors (Collingridge et al. 1983), or prevented by the injection of a Ca^{2+} chelator into the postsynaptic neuron (Yang et al. 1999; Lynch et al. 1983). Ca^{2+} imaging studies have demonstrated that tetanic stimulation directly increases Ca^{2+} within dendrites and spines as a result of NMDA receptor activation (Regehr and Tank 1990; Perkel et al. 1993; Yuste and Denk 1995). Although NMDA receptors are the primary source of Ca^{2+} entry into the dendrites and spines, activation of dendritic voltage-gated Ca^{2+} channels and Ca^{2+} release from intracellular stores also elevate Ca^{2+} levels and contribute to the induction of LTP. However, the mechanisms underlying the Ca^{2+} channel-dependent LTP may differ from NMDA receptor-dependent LTP (Malenka and Nicoll 1999).

6.3.2.3 Expression of LTP

It has long been a challenge for neurobiologists to identify whether the increase in synaptic strength is mediated primarily through a pre- or postsynaptic mechanism. Available experimental results indicate that the increase in the synaptic strength could be either presynaptic or postsynaptic or both, or through an extrasynaptic mechanism, such as reduction in uptake of glutamate by glial cells resulting in an elevated concentration of glutamate at synaptic cleft. Evidence for pre-synaptic mechanisms comes from experiments measuring the overflow of radiolabeled or endogenous L-glutamate in hippocampus before and after the induction of LTP (Bliss et al. 1986). In addition, quantal analysis of synaptic transmission reveals the proportion of synaptic failures decreases after the induction of LTP (Kullmann and Siegelbaum 1995; Malenka and Nicoll 1999). As synaptic failures represent the failure of neurotransmitter release or silent synapses, it was concluded that the induction of LTP is the consequence of an increase in the probability of neurotransmitter release. Evidence supporting this conclusion came from the finding that the variation around the mean of excitatory postsynaptic currents (EPSCs) decreased during LTP (Kullmann and Siegelbaum 1995; Malenka and Nicoll 1999). If the probability of neurotransmitter release increases during LTP, then the quantal content will, on average, increase and the coefficient of variation will decrease, because the coefficient of variation (SD/mean) is inversely proportional to the quantal content (Malenka and Nicoll 1999).

Experimental results from other studies have shown a post-synaptic mechanism for LTP induction. First, paired-pulse facilitation (PPF) is not altered after the induction of LTP and this has been interpreted as evidence for a post-synaptic facilitation of LTP. PPF occurs when two pre-synaptic stimuli are delivered with a short interval (50–200 ms) and is thought to result from residual Ca^{2+} in the pre-synaptic terminal following the first stimulus, enhancing release during the second stimulus (Malenka and Nicoll 1999). Various manipulations known to increase transmitter release do cause a decrease in the facilitation ratio, because release is already enhanced to near saturation during the first stimulus (Manabe et al. 1993). The failure in the alteration of PPF ratio suggests a post-synaptic locus of LTP expression.

A number of studies have shown that during LTP the AMPA receptor component of the EPSC is selectively enhanced, with little or no change in the component of NMDA receptors (Larkman and Jack 1995), though both receptors are frequently co-localized at individual synapses. Pharmacological modulation of transmitter release affects AMPA and NMDA components equally, arguing for a selective postsynaptic alteration in either the density or properties of AMPA receptors (Kullmann and Siegelbaum 1995).

6.4 Neuroimmunomodulation via Hippocampus

One of the important recent advances in understanding the biological basis of neurodegenerative disorders is the recognition that there is extensive communication between the central nervous system (CNS) and the immune system. Initial evidence that the immune system may communicate with the CNS was provided by Besedovsky and colleagues (1977), who observed that activation of the immune system was accompanied by changes in hypothalamic, autonomic and endocrine processes. The existence of neural-immune interactions is now supported by abundant evidence showing that the immune system communicates with the CNS through immunotransmitters (primarily cytokines) leading to direct CNS activation (Berkenbosch et al. 1987; Sapolsky et al. 1987) or by release of CNS-derived cytokines, and that the CNS regulates the immune system via neurotransmitters, hormones and neuropeptides. It has been shown that cells of immune system can synthesize and release several immunomodulatory hormones, neuropeptides and catecholamines (Blalock 1989, 1994). For example, lymphocytes and macrophages produce the endogenous opioid peptides, norepinephrine, and epinephrine (Lolait et al. 1984; Harbour et al. 1987; Engler et al. 2005). A recent study (Rivest 2003) shows that the CNS responds to systemic bacterial infection with innate immune reaction without pathogen's direct access to the brain. Whether caused by a microbe, trauma, toxic metabolite, autoimmunity, or part of a wide degenerative process, activation of the immune system results in changes in the activity of discrete populations of brain neurons, including hippocampal neurons. Accumulating evidence indicates that these mechanisms are relevant for the course of infectious, inflammatory, autoimmune and neoplastic diseases.

As resident innate immune cells in the brain, microglia behaves like a dual-edged sword. On one hand, they release neurotrophic factors to promote neuronal development and growth and, on the other hand, they produce neurotoxic substances resulting in neuronal dysfunction and injury (Block et al. 2007; Perry et al. 2010). Microglia also functions as a CNS sensor and detects neural injury, inflammation and/or infection (Perry et al. 2010; Block et al. 2007; Perry and Holmes 2014). Elevated levels of circulating pro-inflammatory cytokines and over-activation of microglia can result in the CNS neuronal injury. It has been shown that microglia density in the hippocampus is relatively higher than telencephalon cortex, diencephalon, brainstem and cerebellum (Lawson et al. 1990), suggesting a potential occurrence of neuroimmunomodulatory activities in the hippocampus.

6.4.1 Immunomodulation of Neuronal Functions in Hippocampus

Hippocampal neuronal activities have been examined thoroughly in studies on neuroendocrine, autonomic and cognitive function, as well as psychomotor behavior. Circumstantial evidence indicates that hippocampal physiology can be modulated by the immune system (Jankowsky and Patterson 1999; Jankowsky et al. 2000). This modulation could be achieved through proinflammatory cytokines including, but not limited to, interleukin-1 beta (IL-1 β), IL-2, IL-6, tumor necrosis factor alpha (TNF- α) and interferon gamma (INF- γ) (Wrona 2006). Indeed, a number of cytokines, including the aforementioned ones, are expressed in the hippocampus and alteration of their expression levels can affect hippocampal functions. Studies have shown that inflammatory cytokines, released in response to the detection of foreign substances (antigens), influence ion channel activities, intracellular Ca²⁺ homeostasis, membrane potentials, and suppress or enhance the induction of LTP in the hippocampus (Koller et al. 1997). Extensive experimental results have implicated IL-1 among the other cytokines as a likely candidate for a key immunotransmitter, communicating immunological activation to the brain including the hippocampus (Besedovsky et al. 1975; Besedovsky et al. 1986). It is worth to point out that cytokines rarely work in isolation. For instance, the release of IL-1 β is usually associated with the release of the other pro-inflammatory cytokines, such as TNF- α and IL-6, which are indeed expressed in the hippocampus.

IL-1 β and its receptors are expressed in the hippocampus (Farrar et al. 1987; Ban et al. 1991; Cunningham and De Souza 1993). High density of binding sites for IL-1 β has been detected in the hippocampus, with highest density in the dentate gyrus (Takao et al. 1990). It has been shown that peripheral immune activation by lipopolysaccharide (LPS) up-regulates IL-1 β mRNA expression and increases IL-1 β protein in the hippocampus (Laye et al. 1994; Nguyen et al. 1998). This suggests that immune activation may modulate hippocampal function via releasing immune active molecules, such as IL-1 β . As hippocampus is a brain region involved in learning and memory, the immune associated upregulation of IL-1 β mRNA and protein expression may interrupt hippocampal functions such as learning and memory. Indeed, IL-1 β suppresses the induction of LTP in the CA1 and CA3 areas of the hippocampus as well as in the dentate gyrus (Bellinger et al. 1993; Katsuki et al. 1990; O'Connor and Coogan 1999; Cunningham et al. 1996; Xiong et al. 2000), while having no significant effects on excitatory postsynaptic potential (EPSP) evoked by low frequency stimulation. The IL-1 β -mediated suppression of LTP is antagonized by an IL-1 β receptor antagonist, suggesting that

IL-1 β inhibits LTP through IL-1 β receptors. In addition to IL-1, IL-2 had similar effects on LTP in hippocampus. Application of recombinant IL-2 inhibited the induction of both short-term potentiation (STP) and LTP. It also inhibited post-tetanic potentiation (PTP) and LTP maintenance without affecting basal synaptic transmission (Tancredi et al. 1990). Moreover, IL-2 deficiency results in altered hippocampal cytoarchitecture (Beck et al. 2005). LTP was also suppressed by TNF- α in both the CA1 region (Tancredi et al. 1992) and the dentate gyrus (Cunningham et al. 1996). In the CA1, the induction of LTP was inhibited by TNF- α if the tetanic stimulation was given at least 50 min after TNF- α application. In contrast to IL-1 and IL-2, TNF- α increased basal synaptic transmission in the CA1 region of the slices acutely exposed to TNF- α (Cunningham et al. 1996) but not in the dentate gyrus. The underlying mechanisms, by which TNF- α increased basal synaptic transmission, have not been determined. Brief treatment of hippocampal slices with TNF- α did not influence LTP, while long-lasting application (>50 min) of TNF- α inhibited LTP.

Cytokines and chemokines are the messengers and regulators between neurons and glial cells communications (Harrison et al. 1998; Ransohoff 2009). It has been shown that fractalkine (CX3CL1) is the cytokine expressed predominantly by neurons and its receptor—CX3CR1 is expressed in microglia (Ransohoff and Stevens 2011). This CX3CL1 and CX3CR1 axis becomes a typical example of neural-immune communications and plays a pivotal role in neuronal modulation of microglia activity (Bachstetter et al. 2011). Studies by immunofluorescent staining have shown that CX3CL1 is highly expressed in pyramidal neurons in CA1~CA3 regions of hippocampus (Bachstetter et al. 2011; Sheridan et al. 2014), a brain structure associated with learning and memory. It has been demonstrated that high frequency stimulation induces robust LTP in the hippocampus and LTP has been considered as a cellular/synaptic mechanism for learning and memory (Tulving and Markowitsch 1998; Tulving 2001; Otto et al. 1991). Thus, alteration of CX3CL1 and CX3CR1 axis may impact the induction of LTP and LTP-associated learning and memory (Maggi et al. 2009; Rogers et al. 2011; Sheridan et al. 2014).

6.4.2 Lesion of Hippocampus Affects Neuroimmunomodulation

It has been shown that during immune challenge the hippocampus exhibits time-dependent changes in neurotransmitter levels and that an intact hippocampus is essential for the normal humoral immunity for the primary immune response in rats (Devi et al. 2004). Lesions of the dorsal hippocampus were found to produce a transient increase in splenocytes and thymocytes, as well as increased T-cell mitogen responses

(Brooks et al. 1982). Lesions of the hippocampus were also found to cause differential effects on humoral immunity depending on the lesions of different subfields of the hippocampus (Pan and Long 1993). Axotomy of afferent fibers within the molecular layer of the dentate gyrus caused activation of neural-immune elements in the slice cultures (Coltman and Ide 1996). In addition, electrical stimulation of hippocampus increased the number of neutrophils and phagocytic index while also decreasing the number of lymphocytes and plasma corticosterone level in rats (Devi et al. 1993). Lesions in hippocampus induced by kainic acid resulted in elevated antibody production including IgM and IgG (Nance et al. 1987). Taken together, these studies have clearly shown that lesions (or stimulation) in hippocampus affect immune functions.

6.5 Review Questions

1. Where is the hippocampus located in the human brain?
2. What are the three major subfields in the hippocampus?
3. What are the principal cells in the dentate gyrus and the CA1 field?
4. The main input to the dentate gyrus originates from which part of brain and via which fiber path?
5. Mossy fibers originate from which part of the hippocampus and synapse predominantly onto the neurons of which field(s)?
6. Describe sources of afferent fibers to the CA1 region.
7. Briefly describe synaptic information flow through the hippocampus
8. Damage to the hippocampus disrupts what type(s) of memory processes?
9. Describe how long-term potentiation (LTP) is expressed and why LTP is considered as synaptic base for learning and memory?
10. Lesion of hippocampus affects neuroimmunomodulation?

6.6 Answers

1. It is located in the medial temporal lobe of the brain.
2. The three major subfields in the hippocampus are dentate gyrus, CA3 and CA1.
3. The principal cells in the dentate gyrus and CA1 are granule cells and pyramidal cells, respectively.
4. The main input to the dentate gyrus originates from entorhinal cortex via perforant pathway.
5. The Mossy fibers stem from granule cells in the dentate gyrus and their axonal fibers (the mossy fiber pathway) project predominantly to the CA3 neurons.
6. The major afferent fibers to the CA1 pyramidal cells come predominantly from bilateral CA3 neurons through Schaffer collaterals from both ipsi- and contralateral sides.

The CA1 pyramidal cells also receive projections from the layer III (slightly from layer V) of the entorhinal cortex.

7. Information enters the hippocampus mainly through the perforant pathway consisting of the axons of neurons in layers II and III of the entorhinal cortex. The perforant path axons terminate on the dendrites of the dentate gyrus granular cells. Then information flows through the hippocampus from the dentate gyrus to the CA3, the CA1, forming an intrinsic tri-synaptic circuit in the hippocampus.
8. Damage to the hippocampus disrupts declarative memory processes and more specifically episodic memory functions.
9. LTP is expressed as a persistent increase in the size of the evoked synaptic response recorded from single cells or group of cells. It can be induced by high frequency stimulation (HFS, typically 100 Hz) or other types of stimulation, such theta-burst stimulation. These stimulus paradigms resemble the synchronized firing patterns at similar frequencies that occur in the hippocampus during learning, making them useful experimental means to generate "learning activities" in the hippocampus.
10. Increasing evidence indicate that hippocampus is involved in neuroimmunomodulation. Lesions of the hippocampus cause differential effects on neuroimmunomodulation depending on the site of lesion. Lesions of the dorsal hippocampus produce a transient increase in splenocytes and thymocytes, as well as increased T-cell mitogen responses. Lesions in hippocampus induced by kainic acid result in elevated antibody production including IgM and IgG. In addition, electrical stimulation of hippocampus increases the number of neutrophils and phagocytic index while also decreasing the number of lymphocytes and plasma corticosterone level in rats. The aforementioned clearly show that lesions (or stimulation) in hippocampus affect immune functions.

Eliezer Masliah

Abstract

The complex organization of the brain into neural networks allows for rapid adaption and plasticity necessary for learning and memory. Recent evidence supports the notion that in neurodegenerative disorders behavioral alterations are associated with network dysfunction. The objective of this chapter is to provide an overview of the structure and organization of the nervous system into networks relevant to the understanding of the pathogenesis of Alzheimer's disease, Parkinson's disease, HIV neurocognitive impairment and other neurodegenerative and neuroinflammatory disorders. The chapter also provides a summary of the nervous system unique circulatory organization and interactions between neural and vascular activity that accounts for the mechanisms regulating the trafficking of immune cells from peripheral tissues. This chapter provides the structural framework for the better understanding of these interactions under physiological conditions and in neurological diseases.

Keywords

Brainstem • Cerebrum • Cerebellum • Connectivity • Microcirculation • Neuroanatomy • Synapses • Trafficking

7.1 Introduction

The understanding of the gross and fine structure of the brain is of fundamental importance to elucidate how the nervous system works, how it interacts with other peripheral organs and tissues and how it responds to external stimuli. The functions and activity of the nervous system are not only regulated by its intrinsic wiring but also by interactions with cellular components of peripheral tissues. Of significant importance are the interactions between the nervous system with the immune and endocrine systems. While for the former, interactions involve trafficking of immune and hematopoietic cells into the brain; the latter interactions are primarily of a chemical nature, mediated by hormones and growth factors that reach the nervous system via the circulation.

In this context, the main objective of this chapter will be to provide an overview to the structure and organization of the nervous system that is relevant to the understanding of the unique interactions between the nervous and the immune system and to elucidate the pathogenesis of Alzheimer's disease (AD), Parkinson's disease (PD), HIV encephalitis (HIVE), and other neurodegenerative and neuroinflammatory disorders (Ringheim and Conant 2004; Gendelman 2002; Ho et al. 2005).

The central nervous system (CNS) has been traditionally considered an immunologically privileged site; however, it should be viewed as an immunological specialized region. In fact, cells from the immune system such as lymphocytes and macrophages constantly circulate through the nervous system under physiological conditions. Interactions between these trafficking immune cells and neuronal and glial components of the nervous system are critical in maintaining the stability and functional activity of selected neuronal circuitries involved in memory formation, sleep, and regulation of hormonal production (Avital et al. 2003; Opp and Toh 2003). For example, a recent study showed that trafficking of T-cells into

e-mail: emasliah@ucsd.edu

the adult hippocampus contributes to maintenance of neurogenesis and learning (Ziv et al. 2006). Remarkably, recent evidence shows that not only does the immune system regulate neuronal function but also conversely neuronal activity regulates the immune response. For example, recent studies have shown that cholinergic neurotransmission is capable of inhibiting pro-inflammatory cytokine release and protects against systemic inflammation (Pavlov and Tracey 2005).

Therefore, immunological reactions in the nervous system are not exclusively related to pathological conditions such as viral infections, autoimmune diseases, and inflammatory disorders (Owens et al. 2005; Eskandari et al. 2003) but also may be involved in regulation of neural homeostasis under physiological conditions and stress (Buller 2003). In fact immune reactions that occur in the nervous system take a unique character which is probably determined by the very specialized local anatomy. Important anatomical characteristics of the nervous system that determine the unique nature of the neuro-immune reactions include the relative lack of lymphatic drainage, the lack of endogenous antigen presenting cells, and the selective permeability of the blood brain barrier (BBB).

The distribution and patterns of migration of neuroimmune cells are regulated by genetically encoded programs, patterns of connectivity in anatomical regions and blood flow. Moreover, and as it will be described later, there are endogenously derived neuroimmune cells such as the astrocytes and microglia as well as cells derived from the peripheral circulation such as lymphocytes and macrophages. There are three routes for leukocyte entry into the nervous system: circulation through the subarachnoid space which is mediated by P-selectin, migration across the choroid plexus which is mediated by PECAM, and extravasation from post-capillary venules mediated by P-selectin, lymphocyte adhesion molecule (LFA-1) and intercellular adhesion molecule (ICAM) (Engelhardt and Ransohoff 2005).

In summary, the nervous system has a unique circulatory organization based on the flow of the cerebrospinal fluid (CSF), the microvasculature, the BBB and the regulation of the blood flow by the neural activity that provides a series of mechanisms to selectively regulate interactions between the nervous system and trafficking cells from peripheral tissues. This chapter provides the structural framework for the better understanding of these interactions under physiological conditions and in neurological diseases.

7.2 Gross Anatomical Structure of the Brain

7.2.1 General Organization of the Central Nervous System

7.2.1.1 Introduction

The nervous system is divided into the CNS and the peripheral nervous system (PNS). The CNS is composed of the

brain and spinal cord and a triple membranous covering denominated meninges. The outer membrane is the dura, the intermediate arachnoid, and the innermost pial membrane. The complexity of the CNS, with its millions of neurons and connections can be summarized to six major divisions: (1) cerebral hemispheres, (2) diencephalon, (3) midbrain, (4) pons and cerebellum, (5) medulla and (6) spinal cord (Martin 1989) (Fig. 7.1). The PNS consists of nerves connected to the brain and spinal cord (cranial and spinal nerves) and their branches within the body (Crossman and Neary 2005). Spinal nerves serving the upper or lower limbs join to form the brachial or lumbar plexus, respectively, within which fibers are distributed into named peripheral nerves. The PNS also includes some groups of peripherally located nerve cell bodies that are located within ganglia (e.g. dorsal root ganglia). Neurons that detect changes in, and control the activity of, the internal organs are denominated autonomic nervous system (ANS). Its components are present in both the central and peripheral nervous systems. The ANS is divided into two anatomically and functionally distinct components called the sympathetic and parasympathetic divisions, which generally have antagonistic effects on the structure that they innervate. The ANS innervates smooth muscle, myocardium and secretory glands and it is an important player of the homeostatic mechanisms that regulate the internal environment of the body.

7.2.1.2 Cerebral Hemispheres

The cerebral hemispheres are divided into two parts by the interhemispheric (sagittal) fissure. Interconnecting the two hemispheres is the corpus callosum (Martin 1989) (Fig. 7.1). The cerebral hemispheres have four major parts, which are the cerebral cortex, basal ganglia (or striatum), hippocampal formation, and amygdala (Fig. 7.2). The human cerebral cortex is a highly convoluted structure. The elevated convolutions are known as gyri and the folds that separate the gyri are called sulci. The cerebral cortex includes the frontal, parietal, temporal, and occipital regions (Fig. 7.1). In these regions the cerebral cortex usually has six layers. The frontal and parietal lobes are separated by the central sulcus (Rolandic sulcus) which separates two functional regions of the cortex namely the primary motor cortex which is located in the precentral gyrus and the primary somatosensory cortex which is distributed in the postcentral gyrus (Fig. 7.1). The central sulcus extends from the longitudinal fissure along the midline ventrally almost into the lateral cerebral sulcus (Sylvian sulcus) (Fig. 7.1). The frontal lobe, the largest of the cerebral lobes, extends from the central sulcus to the frontal pole. The function of the precentral gyrus is to integrate motor functions from different brain regions. The neurons are organized in a somatotopic manner, which means that different parts of the precentral gyrus are associated with distinct parts of the body both anatomically and functionally. Immediately anterior to the premotor cortex there are three parallel gyri, the superior

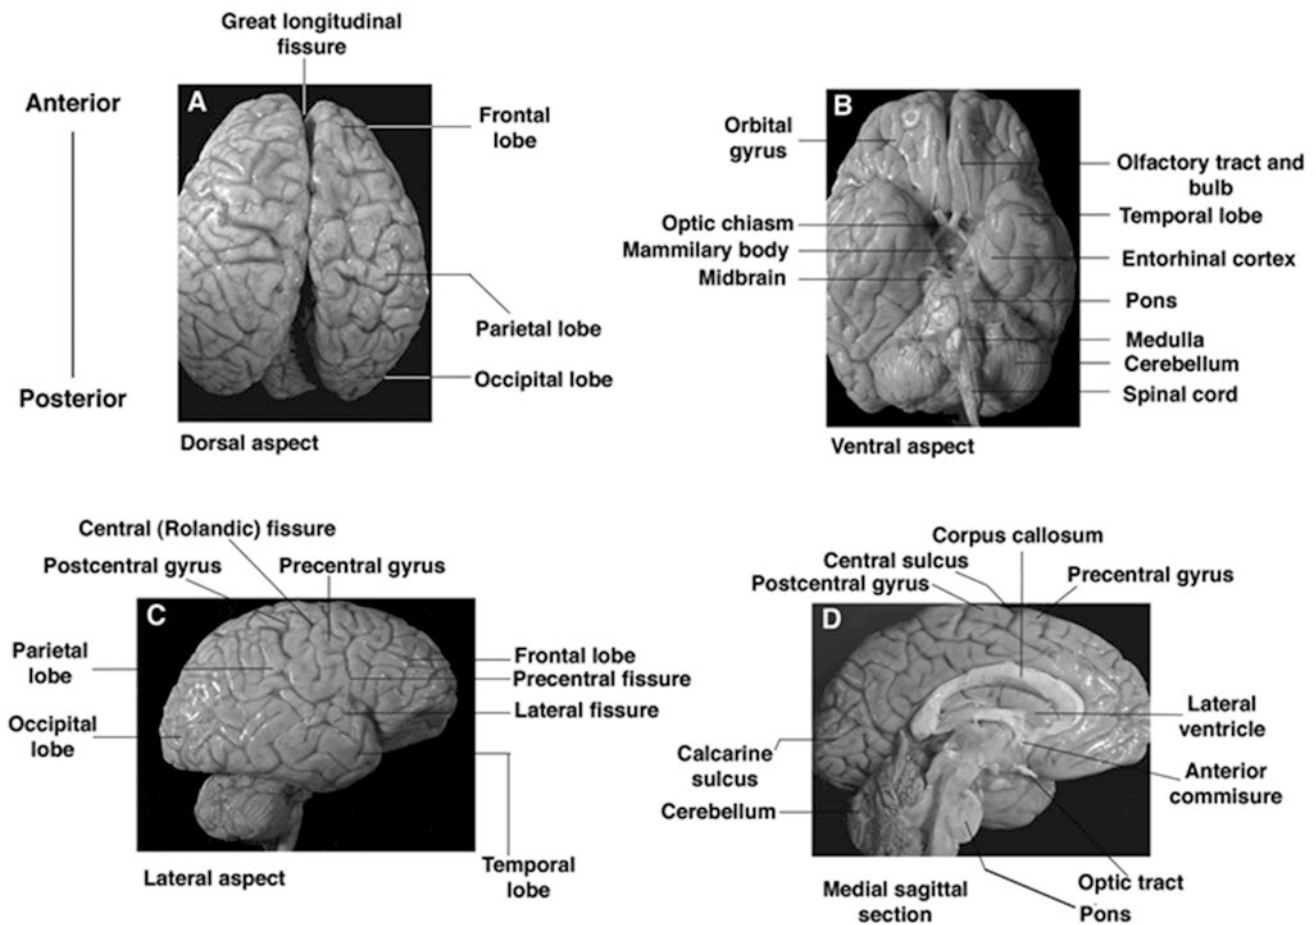

Fig. 7.1 Gross external structures of the brain

middle and inferior frontal gyri. These areas involve processing of executive functions such as abstraction, thinking, cognition, language and emotion. In patients with AD and frontotemporal dementia (FTD), these areas are heavily damaged resulting in the characteristic profile of cognitive impairment typical of these patients. Part of the inferior frontal cortex (left side) includes Broca's motor speech area, an area important in the formulation of motor components of speech. The parietal lobes include the somatosensory cortex within the postcentral gyri (Fig. 7.1). The remainder of the parietal lobe is divided into a superior and inferior lobes separated by the interparietal sulcus. The supramarginal gyrus and the angular gyrus divide the inferior parietal lobe, these regions receive input from the auditory and visual cortex and are involved in integration and discrimination of perception. Ventral to these gyri and extending into the temporal cortex is Wernicke's area; this structure is involved in language comprehension. While injury to Broca's area results in broken language, damage to Wernicke region results in difficulty understanding language.

The temporal cortex is situated inferior to the lateral sulcus and is divided into superior middle and inferior temporal gyri (Fig. 7.2). On the inner aspect of the superior temporal cortex are the gyri of Heschl, which is the primary auditory region. The inferior portion of the temporal lobe is involved in vision function and parts of the medial temporal lobe are involved in olfactory functions. The temporal lobe also includes the hippocampus and parahippocampal cortex. The hippocampus and amygdala are the second and third components of the cerebral hemispheres and are located under the cortical surface (Fig. 7.2). The hippocampus is involved in memory formation while the amygdala modulates the action of the autonomic nervous system, hormone release and emotions. These two structures are part of the limbic system which includes the cingulate cortex as well as part of the diencephalon and midbrain. Together the limbic system plays a central role in the regulation of cognitive functions and mood. The occipital cortex or striate cortex is involved in integration of visual information.

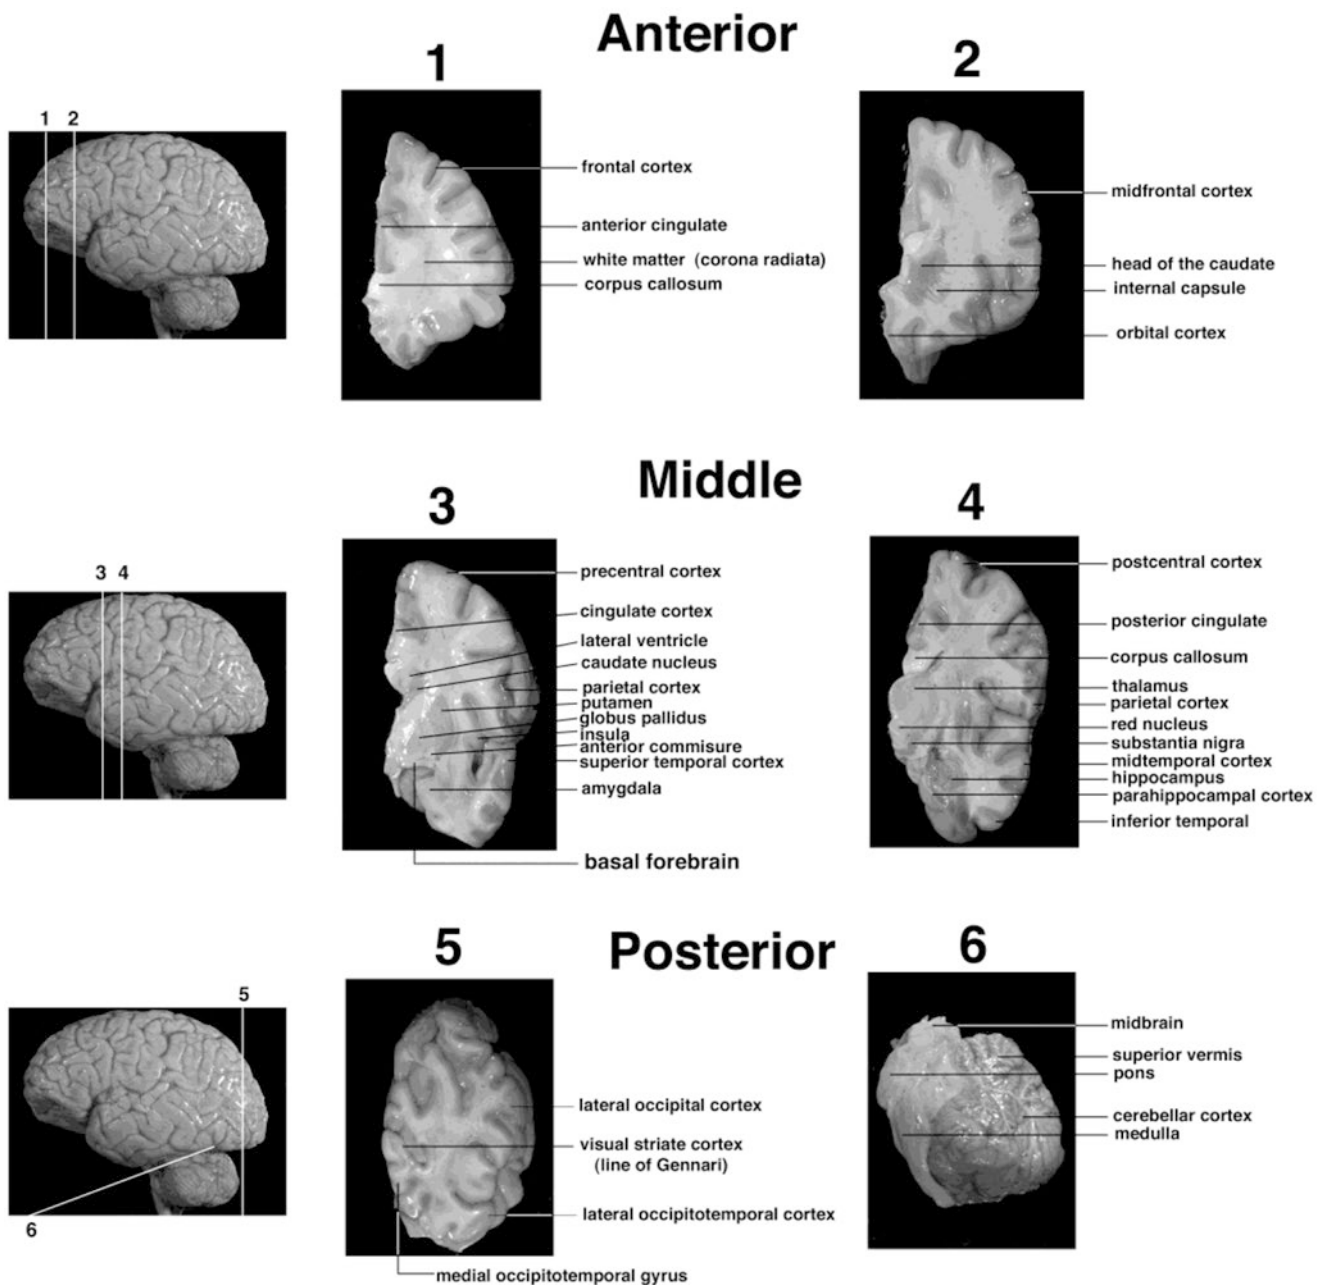

Fig. 7.2 Gross internal structures of the central nervous system

The second major component of the cerebral hemisphere is the basal ganglia, which includes the caudate, putamen and globus pallidus (Fig. 7.2). A white matter tract, denominated anterior commissure, divides the inferior aspect of the putamen and globus pallidus and separates the major cholinergic center in the brain also known as nucleus Basalis of Meynert or substantia innominata (Fig. 7.2). The loss of cholinergic input in patients with AD is related to degeneration of this region, which is dependent on NGF for survival. The caudate and putamen are divided by the anterior capsule. The basal ganglia participate in control of movement but also have a

role in behavior. In patients with Huntington's disease, this brain structure is severely affected.

7.2.1.3 The Diencephalon

Rostral to the brainstem lies the forebrain, consisting of the diencephalon and cerebral hemispheres (Crossman and Neary 2005). The two sides of the diencephalon are separated by the lumen of the third ventricle, whose lateral walls they constitute (Fig. 7.2). The diencephalon consists of four main subdivisions in a dorsoventral direction: the epithalamus, thalamus, subthalamus, and hypothalamus (Fig. 7.2).

The epithalamus is small and its most recognizable component is the pineal gland, which lies in the midline immediately rostral to the superior colliculi of the midbrain. The thalamus is by far the largest component of the diencephalon and it forms much of the lateral wall of the third ventricle. The thalamus plays an important role in sensory, motor and cognitive functions and has extensive connections with layers IV and V of the cerebral cortex. The thalamus is a central structure for relaying information to the cerebral hemispheres (Fig. 7.2). The thalamus includes a large complex of nuclei that includes three principal nuclear masses (anterior, medial, lateral) divided by the internal medullary lamina. Within the internal medullary lamina lies the intralaminar nuclei. On the lateral aspect of the thalamus, the reticular nucleus can be found. The hypothalamus forms the lower part of the walls and floor of the third ventricle (Fig. 7.2). It is a highly complex and important region because of its involvement in many systems, most notably the neuroendocrine system, the limbic system, and the ANS. From the ventral aspect of the hypothalamus in the midline emerges the infundibulum or pituitary stalk, to which is attached the pituitary gland. The hypothalamus integrates the functions of the ANS and endocrine hormone release from the pituitary gland. The subthalamus is located under the thalamus and dorsal lateral to the hypothalamus it contains the subthalamic nucleus and the zona incerta. The subthalamic nucleus is connected to the globus pallidus and substantia nigra and is important in the control of movement. This circuitry is often affected in patients with PD and is amenable to surgical manipulation.

7.2.1.4 The Brainstem

The midbrain, pons, cerebellum, and medulla constitute the brainstem (Fig. 7.2). The brainstem has three general functions. The first is to receive sensory information from cranial structures and to control muscles of the head. This function of the brainstem is similar to that of the spinal cord. The cranial nerves are constituents of the PNS that provide the sensory and motor innervation of the head and therefore are analogous to the spinal nerves. The second is related to the fact that the brainstem contains neural circuits that transmit information from the spinal cord to higher brain regions and back. Finally, the integrated actions of the medulla, pons, and midbrain regulate the levels of awareness and arousal. This function is mediated by a diffuse collection of structures in the brainstem, denominated the reticular formation. In addition to these general functions, the various divisions of the brainstem provide specific sensory and motor functions. The medulla and the pons play a role in the vital regulation of the blood pressure and respiratory functions. The midbrain, also known as the mesencephalon, is divided into dorsal and ventral parts at the level of the aqueduct (Fig. 7.2). The dorsal part is known as the tectum and includes the colliculi. The most ven-

tral part of the midbrain tegmentum contains the substantia nigra, which consists of pars compacta and pars reticularis. The substantia nigra contains melanin pigmented neurons that produce dopamine. Degeneration of the substantia nigra is characteristic of patients with PD and results in disconnection between the midbrain and the caudo-putamen region. Other important structures contained in the midbrain are the oculomotor nucleus, the red nucleus, the periaqueductal grey and the medial lemniscus. Furthermore, the branches of the third cranial nerve emerge from the midbrain.

The pons (Fig. 7.2) is further divided into ventral and dorsal sections. The ventral section contains the pontocerebellar fibers and the pontine nucleus. Corticospinal fibers run longitudinally. Other important structures in the pons include the locus ceruleus, which is main source of adrenergic fibers in the CNS. The neurons in the locus ceruleus are pigmented and produce epinephrine and norepinephrine. This brainstem structure is often affected in patients with AD, PD and depression. The medulla is divided into a caudal, mid and rostral portion. The caudal portion includes the nucleus of the spinal tract of the trigeminal nerve. The mid portion of the medulla includes the nucleus gracilis and cuneatus as well as the decussation of the pyramids. The rostral medullary portion includes the inferior olivary nucleus which connects with the cerebellum. Damage to the pons and medulla is almost always life threatening.

The cerebellum regulates body movements, and may do so by controlling the timing of skeletal muscle contractions. The cerebellum and pons are considered together because they develop from the same portion of the embryonic brain. The cerebellum is attached to the brainstem by a large mass of nerve fibers that lie lateral to the fourth ventricle on either side (Fig. 7.2). The cerebellum is divided into three sections by the inferior, middle, and superior cerebellar peduncles. These contain nerve fibers between the medulla, pons, and midbrain, respectively, and the cerebellum. The largest and most prominent is the middle cerebellar peduncle. The cerebellum consists of an outer layer of grey matter, the cerebellar cortex, surrounding a core of white matter. The cortical surface is highly convoluted to form a regular pattern of narrow, parallel folds or folia. The cerebellar cortex contains three layers the outer or molecular, the Purkinje cells, and the inner granular layer. The cerebellar white matter consists of nerve fibers running to and from the cerebellar cortex. The white matter has a characteristic branching, tree-like arrangement in section, as its ramifications reach towards the surface. The cerebellum is involved with the coordination of movement.

7.2.1.5 The Spinal Cord

The spinal cord has the simplest organization of all six major divisions. It participates in the control of limb and trunk musculature, in visceral functions, and in the processing of

sensory information from these structures. Also, it is a conduit for the flow of information to and from the brain. The spinal cord is the only portion of the central nervous system that has a clear external segmental organization, reminiscent of its embryonic and phylogenetic origins. The spinal cord is divided into the central thoracic lumbar and sacral segments. While in the cerebrum the gray matter is in the cortex and the white in the core, in the spinal cord the gray matter is central and the white is peripheral.

At cross section, the gray matter is the cord from the anterior and posterior columns, which contains the motoneurons and sensory neurons, respectively. An important feature of each spinal cord segment is the presence of a pair of roots (or associated branches or rootlets) called the dorsal and ventral roots. The dorsal roots contain sensory axons whereas the ventral roots contain motor axons. These sensory and motor axons, which are part of the peripheral nervous system, become mixed in the spinal nerves en route to their peripheral targets. The spinal nerves, which are also components of the peripheral nervous system, transmit sensory information to the spinal cord and motor commands to the muscles and viscera.

7.2.2 Internal Organization of the Central Nervous System

7.2.2.1 Projection and Connections in the Brain

The cerebral hemisphere and diencephalon have a more complex organization than that of the brainstem and spinal cord (Martin 1989). The thalamus relays information from subcortical structures to the cerebral cortex via two different functional classes of nuclei; namely, those that are for relay and those that are for diffuse projection. Three of the four anatomical divisions of the thalamus serve relay functions (anterior, medial, and lateral nuclei) and one is a diffuse projection nuclei (intralaminar). Thalamic neurons send the axons to the cerebral cortex via the internal capsule, as do cortical neurons that project to subcortical sites. There are two major somatosensory pathways: the dorsal column of the medial lemniscal system, which mediates tactile, and vibration, and the anterolateral system, which mediates pain and temperature sense.

There are three other major somatosensory cortical areas, which include the primary, secondary, and tertiary somatosensory cortical areas and are somatotopically organized. The secondary somatosensory cortex and the posterior parietal cortex receive their projections from the primary somatosensory cortex and the posterior insular cortex receives input from the secondary somatosensory cortex. Corticocortical projections as well as callasol connections are made by neurons of layers two and three. Descending projections to the striatum, brainstem, and spinal cord originate from neurons in

layer five, while projections to the thalamus originate from neurons in layer six.

Another important source of connectivity is that of the limbic system which includes the cingulate, hippocampus, and amygdala. The hippocampal formation is integrated by an infolding of the inferomedial part of the temporal lobe into the lateral ventricle along the choroid fissure. The dentate gyrus is distributed in between the parahippocampal gyrus and the hippocampus and contains a layer of granular neurons and the molecular layer, which receives connection from the entorhinal cortex and the parahippocampal gyrus. The hippocampal formation receives projections from the inferior temporal cortex via the entorhinal cortex and from contralateral fibers via the fornix. Efferent fibers merge on the ventricular surface of the hippocampus as the fimbria. The limbic system includes intrinsic as well as extrinsic connectivity. Connections between the entorhinal cortex and the molecular layer of the dentate gyrus (perforant pathway), Mossy fibers, CA1–CA4, and subiculum integrate the intrinsic connections. These structures are often affected in AD and are responsible for the short-term memory loss in this condition. The extrinsic limbic connections are between the cingulate gyrus, the hippocampal formation, the amygdala, and the septum, which in turn connect with the hypothalamus. Overall the limbic system network should be considered as functional units that include the prefrontal cortex, cingulate cortex, amygdaloid nucleus, limbic thalamus, nucleus accumbens, anterior hypothalamus, and raphe nucleus (Morgane et al. 2005).

7.2.2.2 Laminar Organization of the Cerebral Cortex

The cerebral cortex is the structure to which the dorsal column-medial lemniscal system projects and the origin of the corticospinal tract. It has a characteristic structure with neurons that are organized into layers. Different cortical regions contain characteristically different numbers of cell layers (Fig. 7.3). Most of the cerebral cortex contains at least six cell layers, and this cortex is termed the isocortex (Fig. 7.3). Because the isocortex dominates the cerebral cortex of phylogenetically higher vertebrates, it is also termed neocortex. In contrast to the isocortex, the allocortex contains fewer than six layers. Although present in higher vertebrates, the allocortex dominates the cortex of phylogenetically more primitive vertebrates. The phylogenetically oldest type of allocortex, the archicortex, constitutes the hippocampal formation and contains three cell layers, which are the molecular, granular, and pyramidal. The paleocortex, thought to be a more advanced allocortex, is associated with areas that mediate olfactory function. The neocortex comprises the major sensory, motor, and association areas. Regions of neocortex that serve different functions have a different microscopic anatomy. Areas that regulate sensation

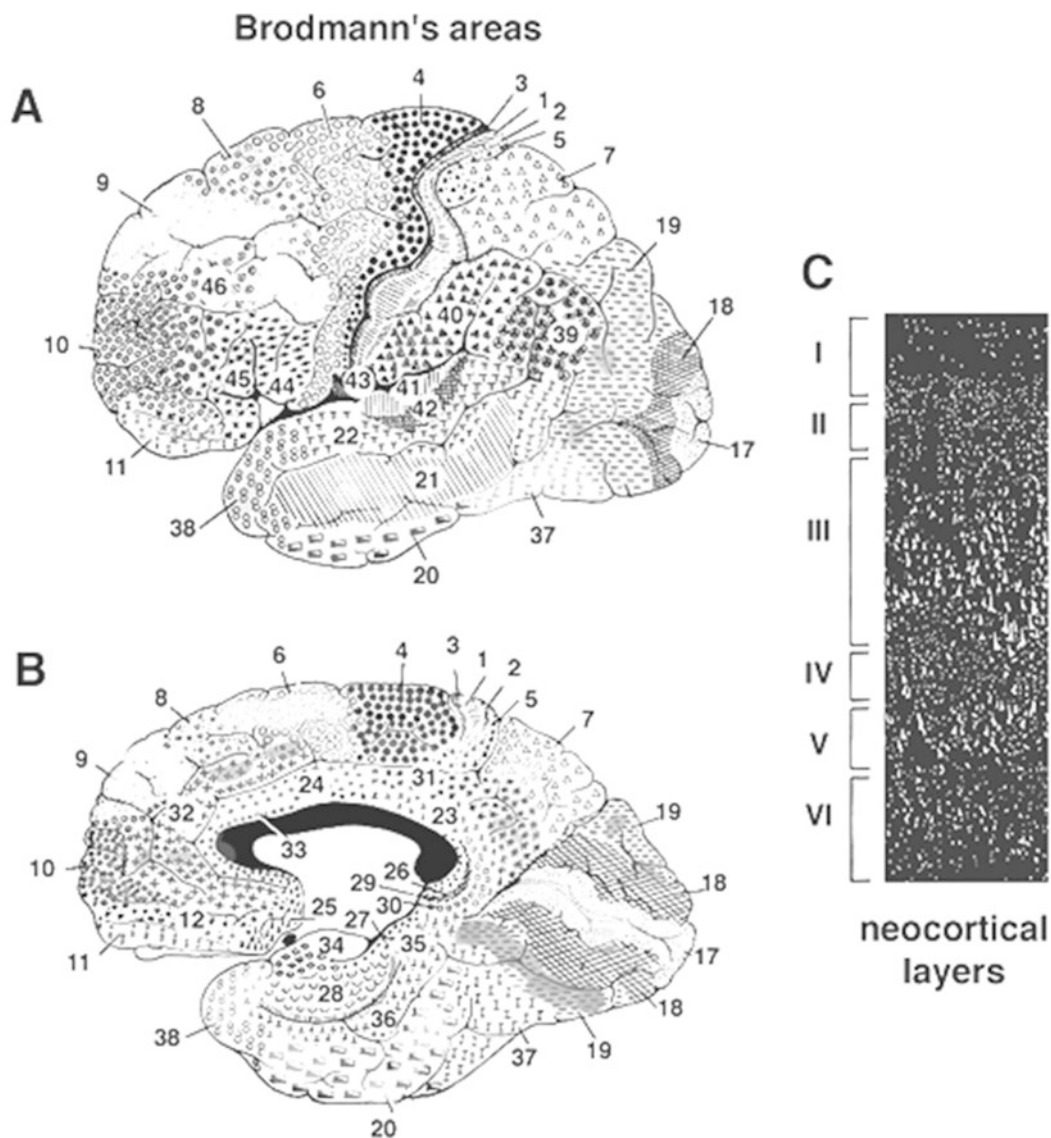

Fig. 7.3 Diagrammatic representation of the neocortical layers and Brodmann areas

have a well-developed layer IV. This is the layer to which most thalamic neurons from the sensory relay nuclei project. The primary visual cortex has this morphology. In contrast, the primary motor cortex has a thin layer IV and a thick layer V. Layer V contains the pyramidal neurons that project to the spinal cord, via the corticospinal tract. Association areas of the cerebral cortex, such as prefrontal and parietal association cortex have a morphology that is intermediate between those of sensory cortex and motor cortex. In summary, based primarily on differences in the thickness of cortical layers and on the sizes and shapes of neurons there are two types of cortex. The neocortex (or isocortex) has six layers; the allocortex has fewer than six layers and includes the archicortex of the hippocampus and the paleocortex of the olfactory regions.

7.2.2.3 Neuronal Subtypes and Patterns of Interconnectivity

The activity of the CNS depends on the complex patterns of connectivity among neurons and associated glial cells (Fig. 7.4). The neurons are composed of a neuronal cell body, axons and dendrites (Fig. 7.4a). The axons have a terminal end that constitutes the presynaptic site of the synapse. The dendrites have an apical site and multiple branches and spines. The connections among neurons are denominated synapses. Synapses occur between axons and dendrites, axons and cell bodies, and axons and axons. Neurons are excitatory and inhibitory. Excitatory neurons produce glutamate while inhibitory neurons produce GABA. Other neurotransmitters include acetylcholine as well as neuropeptides. Excitatory neurons are usually pyramidal (Fig. 7.4a) and mul-

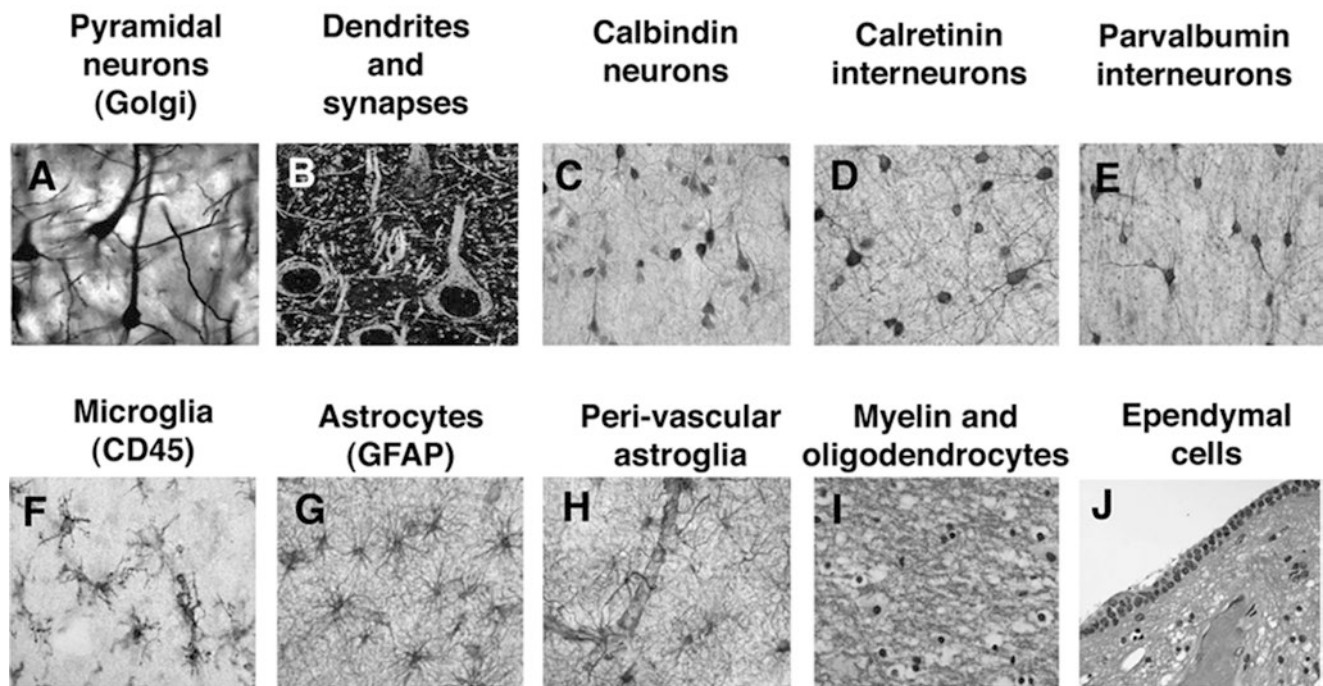

Fig. 7.4 Cellular components of the central nervous system. (a) Neurons impregnated with Golgi silver satin, (c) calbindin immunoreactive interneurons in the neocortex, (g) astrocytes immunoreactive

with an antibody against GFAP, (h) peri-vascular astrocytes components of the BBB, (i) oligodendrocytes and white matter tracts stained with luxol fast blue, (f) ependymal cells around the periventricular zone

tipolar. Inhibitory neurons, also known as interneurons, are bipolar or pseudo unipolar and contain calcium binding proteins such as calbindin (Fig. 7.4b), parvalbumin and calretinin. Types of interneurons include the Martinotti cells, chandelier cells, double bouquet cells, giant basket cells, Cajal Retzius cells and bipolar cells. These sensory neurons receive information through dendrites and transmit that information to the ICNS via axon terminals (Siegel and Sapru 2006). Retinal bipolar cells, sensory cells of the cochlear, and vestibular ganglia are included in this category.

Pseudo-unipolar neurons have a single process that arises from the cell body and divides into two branches. One of these branches projects to the periphery, while the other projects to the CNS. Each branch has the structural and functional characteristics of an axon. Information collected from the terminals of the peripheral branch is transmitted to the CNS via the terminals of the other branch. Unipolar neurons are relatively rare in vertebrates. In these neurons, dendrites arise from the apical part of the cell body and axons form the base where the dendrites are located. Neurons can also be divided into principal or projecting neurons also known as type I or Golgi type I neurons. Principal neurons (e.g., motor neurons in the ventral horn of the spinal cord) have very long axons and form long fiber tracts in the brain and the spinal cord. Intrinsic neurons, also known as type II or Golgi type II neurons, have very short axons. These neurons are interneurons and are considered to have inhibitory function. They are abundant in the cerebral and cerebellar cortex.

7.3 Cerebrovascular Circulation

7.3.1 Blood Supply to the Central Nervous System

The cerebral hemispheres and diencephalon receive blood from the anterior and posterior circulations (Fig. 7.5). The cerebral cortex receives its blood supply from the three cerebral arteries: the anterior and middle cerebral arteries, which are part of the anterior circulation, and the posterior cerebral artery, which is part of the posterior circulation. The diencephalon, basal ganglia, and internal capsule are supplied from branches of the internal carotid artery, the three cerebral arteries, and the posterior communicating artery (Crossman and Neary 2005). The anterior and posterior systems are interconnected by two networks of arteries: (1) the circle of Willis, which is formed by the three cerebral arteries, the posterior communicating artery, and the anterior communicating artery, and (2) terminal branches of the cerebral arteries, which anastomose on the superior convexity of the cerebral cortex (Fig. 7.5). The arterial supply of the cerebral cortex is provided by the distal branches of the anterior, middle, and posterior cerebral arteries. These branches are often termed “cortical” branches (Lee 1995). The anterior cerebral artery originates at the division of the internal carotid artery, and courses within the interhemispheric fissure and around the rostral and dorsal surfaces of the corpus callosum.

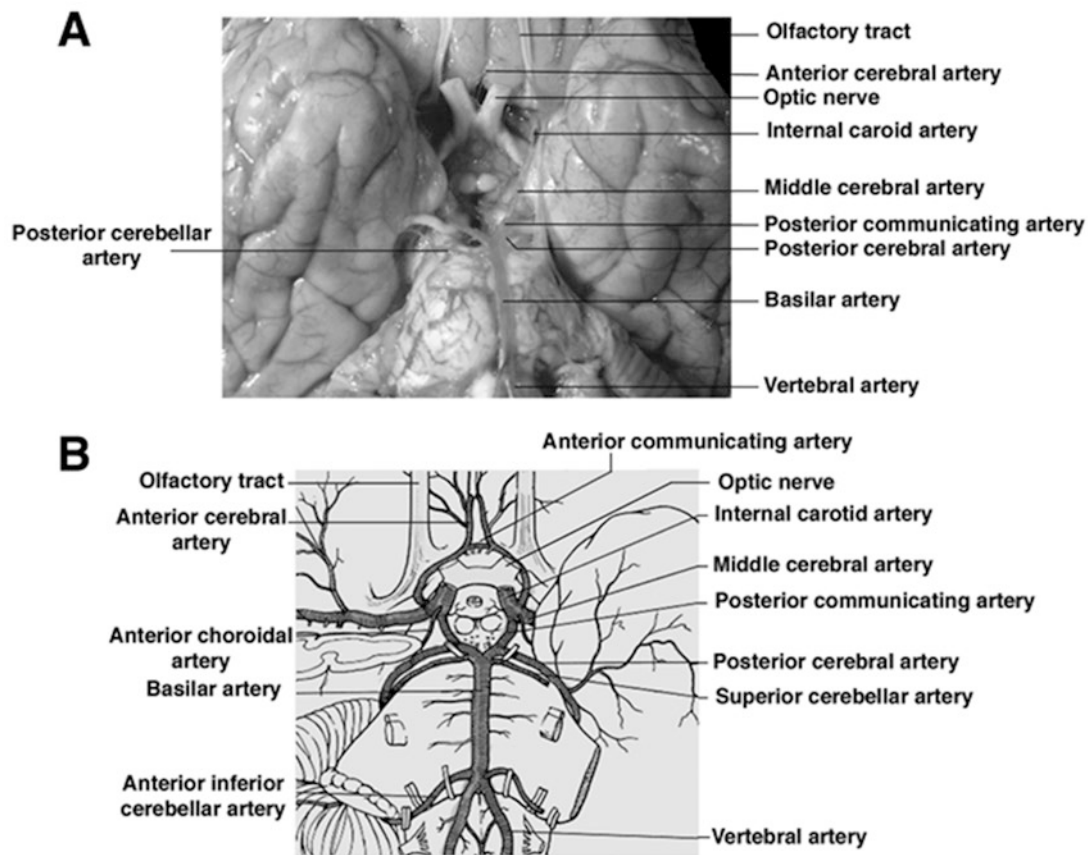

Fig. 7.5 Gross external appearance of the circle of Willis and subarachnoid vessels

The middle cerebral artery, which originates at the division of the internal carotid artery passes through the lateral sulcus (Sylvian fissure) en route to the lateral convexity of the cerebral hemisphere, to which it supplies blood. The middle cerebral artery travels along the surface of the insular cortex, over the inner surface of the frontal, temporal, and parietal lobes, and appears on the lateral convexity. The posterior cerebral arteries originate at the bifurcation of the basilar artery, and each one passes around the lateral margin of the midbrain. The posterior cerebral artery supplies the occipital lobe and portions of the medial and inferior temporal lobe. The arterial supply of the spinal cord is derived from the vertebral arteries and the radicular arteries. The brain is supplied by the internal carotid arteries (the anterior circulation) and the vertebral arteries, which join at the pontomedullary junction to form the basilar artery (collectively termed the posterior circulation). The brainstem is supplied by the posterior system. The medulla receives blood from branches of the vertebral arteries as well as from the spinal arteries and the posterior inferior cerebellar artery (PICA). The pons is supplied by paramedian and short circumferential branches of the basilar artery. Two major long circumferential branches are the anterior inferior cerebellar artery (AICA) and the superior cerebellar artery. The midbrain receives its arterial supply pri-

marily from the posterior cerebral artery as well as from the basilar artery. The venous drainage of the spinal cord drains directly to the systemic circulation. By contrast, veins draining the cerebral hemispheres and brain stem drain into the dural sinuses. Cerebrospinal fluid also drains into the dural sinuses through unidirectional valves termed arachnoid villi.

7.3.2 Immune Cell Trafficking Through the Cerebral Vascular Network

The subarachnoid vessels penetrate the cortical structures and branch to produce the microvascular network which is in turn surrounded by the cellular components of the BBB through which immune cells may need to traffic (Fig. 7.5b). The capillary endothelium of the BBB contains tight junctions that control the movement of leukocytes. In addition these cells are surrounded by a basement membrane and the processes of astroglial cells. The routes for trafficking of leukocytes into the nervous system are through the choroid plexus, subarachnoid space, and perivascular space (Ransohoff et al. 2003). In the first route, leukocytes migrate from the blood to CSF across the choroid plexus. In this pathway of migration, leukocytes travel across the fenestrated endothelium of the

choroid-plexus, migrate through the stromal core villi, interact with epithelial cells of the choroid plexus and enter the CSF at its site of formation. This pathway is likely to be one route by which immune cells enter the CSF under physiological conditions using P-selectin and PECAM.

For the second route, leukocytes reach the CNS from blood to subarachnoid space. In this pathway, leukocytes travel from the internal carotid artery, across postcapillary venules at the pial surface of the brain into the subarachnoid space and the Virchow-Robin perivascular spaces. There, they might encounter cells of the monocyte/myeloid lineage that are competent for antigen presentation. The perivascular regions, where there is direct communication with the CSF compartment, are considered probable sites of lymphocyte-APC interaction and therefore, of immune surveillance of CNS. This pathway is also dependent on P-selectin.

The third pathway involves leukocyte immigration from blood to parenchymal perivascular space. In this third pathway, immune cells can enter the parenchyma directly, passing from internal carotids through the branching vascular tree of arterioles and capillaries and finally extravasating through postcapillary venules. In this case, leukocytes are required to cross the BBB and the endothelial basal lamina. Trafficking of activated lymphocytes across a resting cerebrovascular endothelium is a low-efficient event. This process is dependent on P-selectin, LFA-1 and ICAM (Greenwood et al. 2002).

7.4 Glial Cell Types

The supporting cells located in the CNS are called neuroglia or glial cells. They are relatively nonexcitable and more abundant. Neuroglia has been classified into the following groups: astrocytes, oligodendrocytes, microglia, and ependymal cells (Siegel and Sapru 2006) (Fig. 7.4). Astrocytes are the largest and have a stellate (star-shaped) appearance because their processes extend in all directions (Fig. 7.4g). Their nuclei are ovoid and centrally located. The astrocytes provide support for the neurons, a barrier against the spread of transmitters from synapses, and insulation to prevent the electrical activity of one neuron from affecting the activity of neighboring neurons. Some transmitters (for example, glutamate and γ -aminobutyric acid [GABA]), when released from nerve terminals in the CNS, are taken up by astrocytes, thus terminating their action. The neurotransmitters taken up by astrocytes are processed for recycling. When extracellular K^+ increases in the brain due to local neural activity, astrocytes take up K^+ via membrane channels and help to dissipate K^+ over a large area because they have an extensive network of processes. Astrocytes are further divided into the following subgroups: protoplasmic astrocytes, fibrous astrocytes, and Muller cells. Protoplasmic astrocytes are cells present in the gray matter in close association with neurons. Because of their close association with the neurons, they are

considered satellite cells and serve as metabolic intermediaries for neurons. They give out thicker and shorter processes, which branch profusely. Several of their processes terminate in expansion called end-feet. The neuronal cell bodies, dendrites, and some axons are covered with end-feet joined together to form a limiting membrane on the inner surface of the pia mater (glial limiting membrane) and outer surface of blood vessels (called perivascular lining membrane). The perivascular end-feet may serve as passage for the transfer of nutrients from the blood vessels to the neurons across the BBB (Fig. 7.4h). Abutting of processes of protoplasmic astrocytes on the capillaries as perivascular end-feet is one of the anatomical features of the blood-brain barrier. Fibrous astrocytes are found primarily in the white matter between nerve fibers. Several thin, long, and smooth processes arise from the cell body; these processes show little branching. Fibrous astrocytes function to repair damaged tissue, which may result in scar formation. Muller Cells are modified astrocytes present in the retina.

The oligodendrocytes are involved in the myelination process (Fig. 7.4i). The oligodendrocytes present in the gray matter are called perineurial oligodendrocytes. Oligodendrocytes are smaller than astrocytes and have fewer and shorter branches. Their cytoplasm contains the usual organelles (e.g., ribosomes, mitochondria, and microtubules), but they do not contain neurofilaments. In the white matter, oligodendrocytes are located in rows along myelinated fibers and are known as interfascicular oligodendrocytes.

The microglia are the smallest of the glial cells and are involved in phagocytosis and neuroinflammatory response in the CNS (Fig. 7.4f). These cells are probably derived from monocytes from the bone marrow. They usually have a few short branching processes with thorn-like endings. These processes arising from the cell body give off numerous spine-like projections. They are scattered throughout the nervous system. When the CNS is injured, the microglia become enlarged, mobile, and phagocytic. Ependymal cells consist of three types of cells: ependymocytes, tanycytes, and choroidal epithelial cells. Ependymocytes are cuboidal or columnar cells (Fig. 7.4g) that form a single layer of lining in the brain ventricles and the central canal of the spinal cord. They possess microvilli and cilia. The presence of microvilli indicates that these cells may have some absorptive function. The movement of their cilia facilitates the flow of the CSF. Tanycytes are specialized ependymal cells that are found in the floor of the third ventricle, and their processes extend into the brain tissue where they are juxtaposed to blood vessels and neurons. Tanycytes have been implicated in the transport of hormones from the CSF to capillaries of the portal system and from hypothalamic neurons to the CSF. Choroidal epithelial cells are modified ependymal cells. They are present in the choroid plexus and are involved in the production and secretion CSF. They have tight junctions that prevent the CSF from spreading to the adjacent tissue.

7.5 Brain Regions Linked to Neurodegeneration and Other Neurological Diseases

As the life expectancy of the human population continues to increase, the possibility of developing neuroinflammatory and neurodegenerative diseases has increased considerably during the past 50 years. Of the neurodegenerative disorders, Alzheimer's disease continues to be the leading cause of dementia in the aging population. Traditionally, neurodegenerative disorders have been defined as conditions in which there is selective loss of neurons within specific regions of the brain accompanied by astrogliosis. However, in the past 20 years, we have learned that the pathological process leading to the disfunction of selected circuitries in the brain initiates with damage to the synapses rather than with the loss of neurons. In fact, neuronal loss is a late event that is probably preceded by damage to axons and dendrites followed by shrinkage of the neuronal cell body and abnormal accumulation of filamentous proteins.

Therefore, the revised concept of neurodegeneration suggests that neuronal injury initiates at the synaptic junction and propagates throughout selected circuitries leading to neuronal dysfunction, which resolves in the classical clinical symptoms characteristic to each of the neurodegenerative disorders (Hashimoto and Masliah 2003). For example, in Alzheimer's disease, early damage to the synapses between the entorhinal cortex and the molecular layer of the dentate gyrus (perforant pathway) results in the short term memory deficits characteristic of this dementing disorder. Later on disconnection of the cortico-cortico fibers in the frontal, parietal, and temporal cortex results in more severe memory deficits, alterations in executive functions, and abstraction. Degeneration of connections between the nucleus basalis of Meynert and the neocortex results in attention and memory deficits usually associated with loss of cholinergic neurons. Other circuitries and neuronal populations are also affected in Alzheimer's disease, illustrating the complexity of these disorders and the fact that the concept of single population is affected needs to be expanded to multiple populations. This is the case with several other disorders including Parkinson's disease, where degeneration is not limited to the dopaminergic system but also involves the limbic system, the raphe nucleus, the insula, and other systems.

In response to injury, neurons produce adhesion molecules and trophic factors that recruit astroglial and microglial cells to participate in the process of repair. In addition, the microvasculature and other glial systems might also participate in the process. Thus, neurodegeneration is accompanied by astrogliosis, microgliosis, and microvascular remodeling. While astroglial cells initially produce trophic factors and cytokines that aid in tissue repair, eventually these factors could amplify the inflammatory response by increasing vascular permeability resulting in microglial

activation, which in turn might lead to the production of more proinflammatory cytokines and chemokines. A critical balance between the repair and proinflammatory factors often determines the future rate and progression of the degenerative process.

The understanding of the mechanisms of neurodegeneration and inflammatory response in these neurological conditions has undergone a tremendous progress in the past 10 years. It is now generally accepted that small soluble misfolded protein aggregates denominated oligomers are responsible for the injury. So for example, in Alzheimer's disease, A-beta protein oligomers might damage the synapses in the limbic system while in Parkinson's disease; α -synuclein oligomers damage the axons in the striatum and cortical regions. While significant progress has been made in understanding the fundamental mechanisms for the neuronal injury, less is known about the reasons for the selective neuronal vulnerability characteristic to these neurological conditions.

7.6 Summary

The understanding of the gross and fine structure of the brain is of fundamental importance to elucidate how the nervous system works, how it interacts with other peripheral organs and tissues and how it responds to external stimuli. The main objective of this chapter will be to provide an overview to the structure and organization of the nervous system that is relevant to the understanding of the unique interactions between the nervous and the immune system and to elucidate the pathogenesis of Alzheimer's disease (AD), Parkinson's disease (PD), HIV encephalitis (HIVE), and other neurodegenerative and neuroinflammatory disorders. The nervous system has a unique circulatory organization based on the flow of the cerebrospinal fluid (CSF), the microvasculature, the BBB and the regulation of the blood flow by the neural activity that provides a series of mechanisms to selectively regulate interactions between the nervous system and trafficking cells from peripheral tissues. This chapter provides the structural framework for the better understanding of these interactions under physiological conditions and in neurological diseases and includes sections of gross anatomical structure of the brain, projections, cellular variety, and cerebrovascular circulation.

7.7 Review Questions

1. Interconnecting the two hemispheres is the
 - (a) *Corpus callosum*
 - (b) Anterior commissure
 - (c) Rolandic fissure
 - (d) Sylvian fissure
 - (e) Precentral gyrus

2. The Central fissure divides the

- (a) Visual cortex
- (b) *Sensory and motor cortex*
- (c) Limbic system

Manmeet K. Mamik and Christopher Power

Abstract

Since the discovery of inflammasomes more than a decade ago, there has been tremendous development in the understanding of inflammasomes as central nervous system (CNS) disease determinants. The cytokines, IL-1 β and IL-18, are implicated in both acute and chronic neuro-inflammatory disorders. The cells of macrophage lineage represent the powerhouse of inflammasome activation in the CNS, although other cells including astrocytes and neurons exhibit inflammasome activation in stimulus and species restricted manner. The outcomes of inflammasome activation in the CNS are wide ranging encompassing both protective and pathogenic consequences depending on the individual PAMP/DAMP, inflammasome, cell type and species. The activation of inflammasomes is a complex sequence of events that lends itself to opportunities for modulation at multiple steps and demands further exploration. However, with the current understanding of molecular mechanisms underlying the effects of inflammasome inhibitors, it is feasible to target inflammasome activation at an early stage to delay neurological disease onset and progression. A major concern remains as to whether targeting at the level of inflammasome or blocking the cytokines will be beneficial for control of neuropathogenesis. Given an early prediction of disease, targeting upstream at the level of inflammasome induction would optimize outcomes by not only limiting levels of cytokine release into the brain micro-environment, but also by reducing cell death due to pyroptosis. As new therapies are developed targeting the sensor, adaptor and effector components of inflammasomes, the prospect of regulating inflammasome activation at multiple stages may become a clinical reality, permitting improved outcomes for inflammasome-driven neurological diseases.

Keywords

Cytokines • Inflammasome • Interleukin-1 • Neuroinflammation • Pyroptosis

8.1 Introduction

8.1.1 Discovery of Inflammasomes

Inflammation in the central nervous system (CNS), termed neuroinflammation, is an integral aspect of many neurological diseases. The CNS has its own immune cells that

directly mediate innate immune actions and also contribute to adaptive immunity in the CNS. Innate immune responses are initiated by host recognition of pathogen-associated molecular patterns (PAMPs) expressed on microbial pathogens (e.g., bacteria, viruses, parasites) or by danger-associated molecular patterns (DAMPs) produced by host cells (e.g., ATP, DNA, uric acid). These molecules serve as ligands for pattern-recognition receptors (PRRs) expressed on cells of innate immune system (Bryant and Fitzgerald 2009). Inflammasomes are cytosolic protein scaffolds and represent pivotal components of innate immune system. In response to PAMPs' or DAMPs' ligation by PRRs, inflammasomes

assemble into multiprotein complexes providing platforms for proteolytic cleavage and subsequent release of two pro-inflammatory cytokines, interleukin (IL)-1 beta (IL-1 β) and IL-18 as immune defenses. It has been established that several protein-protein interactions are required for inflammasome assembly. Although IL-1 α binds to IL-1 receptors like IL-1 β , it does not undergo proteolytic cleavage to enable activation and release. IL-1 β is present in cells as an inactive precursor (pro-IL-1 β) and requires cleavage (at Asp116) for conversion into mature active form, which subsequently drives host responses to injury and infection. This cleavage is mediated by inflammasome regulation of caspase-1, also known as IL-1 β -converting enzyme (ICE) (Dagenais et al. 2012; Martinon et al. 2002). Pro-caspase-1 undergoes autocatalysis during inflammasome activation to yield active caspase-1, which can cleave IL-1 β and IL-18. An important and unique consequence of inflammasome activation is cell death by pyroptosis (fiery death), usually following microbial infection. Pyroptosis is a type of programmed cell death accompanied by swelling and rupture of the cell with extrusion of cellular contents including cytokines into the extracellular space (Bergsbaken et al. 2009).

Inflammasomes were first described in 2002 by Jurg Tschopp's group, as caspase-activating complexes, and since have been identified to be present in macrophages, monocytes, dendritic cells, neutrophils, epithelial cells etc. Nucleotide-binding domain (NB) and leucine-rich repeat (LRR) containing receptors (NLR), also called Nod like receptors, are cytosolic PRRs found in myeloid cells. Before the term 'inflammasome' was coined, mutations in NLR genes were linked to several inflammatory diseases, including systemic acute inflammation due to cold temperature exposure. The intracellular protein implicated in the phenomenon was named 'cryopyrin' since patients developed fever when exposed to cold. Later, inflammasomes were identified as intracellular molecular platforms and key elements in innate immunity. NLR family, pyrin domain containing 3 (NLRP3), also termed NACHT, LRR and PYD domains-containing protein 3 (NALP3), inflammasome was one of the first intracellular PRRs to be identified in humans (Tschopp and Schroder 2010). Since the initial discovery more than a decade ago, inflammasome research has witnessed substantial advancements in understanding and associated applications.

8.1.2 Periodic Fever Syndromes

Periodic Fever Syndromes (PFS) denote a spectrum of hereditary disorders caused by mutations in innate immune-associated proteins leading to disruption of IL-1 related pathways. The PFS are a spectrum of autoinflammatory

diseases resulting from immune activation in an antigen-independent manner. Most of these syndromes (e.g., Familial Mediterranean Fever, Tumor Necrosis Factor (TNF) receptor associated periodic syndrome) present in children with recurrent fevers lasting from few days to few weeks, with symptom free-period in between episodes (Drenth and van der Meer 2001). The term 'autoinflammation', which is primarily linked with innate immunity, was introduced in 1999 and is different from 'autoimmune' diseases which are linked to adaptive immunity (McDermott et al. 1999).

There are several recognized 'gain-of-function' mutations in the *NLRP3* gene that result in over activation of the inflammasome and increased secretion of IL-1 β and IL-18. These disorders are better known as cryopyrin-associated periodic syndromes (CAPS). Symptoms include urticarial rash, fever, musculoskeletal and ocular disorders, progressive deafness, etc. The specific mutation determines the ensuing severity of disease. Genetic testing is required for precise diagnosis of CAPS. Treatment strategies include IL-1 β blockade to control inflammation (Giat and Lidar 2014).

Another disorder, Deficiency of IL-1 Receptor Antagonist (DIRA), is caused by 'loss-of-function' mutation in the IL-1 receptor antagonist gene, *IL1RN*. This gene encodes for an endogenously expressed antagonist of IL-1 signaling, therefore, the mutation leads to blocking of IL-1 signaling. Systemic inflammation often occurs within first few weeks of birth. Failure to diagnose and treat can lead to severe inflammatory response and multiorgan failure (Jesus and Goldbach-Mansky 2014). However, there are other monogenic 'hereditary fever syndromes', which are not caused by mutations in IL-1 pathways, but are indirectly mediated by IL-1 activation.

8.2 Molecular Structure of Inflammasomes

Inflammasome assembly occurs in the cytosol and is comprised primarily of three components: a sensor component, an adaptor component and an effector component. The sensor components are the most upstream and first molecules to detect danger signals and subsequently recruit the adaptors. Inflammasomes are named after the sensor components forming that particular inflammasome (van de Veerdonk et al. 2011). Two known classes of sensor molecules have been defined: NOD-like receptors (NLRs) and AIM2-like receptors (ALRs). In early 2000s, the NLR gene family was discovered in humans and it is now well established that NLR family comprises innate immune genes in species ranging from sea urchins to humans (Ting et al. 2008). In the human genome, 22 NLRs are encoded but to date only NLRP1, NLRP2, NLRP3, NLRP6, NLRP7 and NLRP12 have been reported to participate in inflammasome assembly. The sensor components of inflamma-

somes have effector domains such as pyrin domain (PYD), caspase recruitment domain (CARD) or nucleotide-binding and oligomerization domain NACHT and a leucine-rich repeats (LRR) domain (Lu et al. 2014a).

The most common adaptor component is formed by apoptosis-associated speck-like protein containing a caspase recruitment domain (ASC). The inflammasomes can be 'ASC-dependent' or ASC-independent. In 'ASC-dependent' inflammasomes, two-step polymerization process results in inflammasome assembly through N-terminal PYD and C-terminal CARD of ASC. First, the sensor protein oligomerizes to form a cluster of PYD, which serves to recruit monomeric ASC, which in turn serves as a platform for the CARD to cluster and to recruit the caspase-1 filament by a homotypic CARD/CARD interaction (Lu et al. 2014a). Thus, ASC acts as a core protein that is essential for translating stimulation of inflammasome to its activation. However, in 'ASC-independent' inflammasomes this function is mediated by CARD/CARD interactions. The classic example is NAIP/NLRC4/caspase 1 inflammasome where CARD of NLRC4 (NLR family CARD domain-containing protein 4) nucleates caspase-1 for activation. Another ASC-independent inflammasome is formed by mouse NLRP1b, which lacks the N-terminal PYD required for ASC recruitment.

The effector component is formed by caspases including caspase-1 (caspase-11 in mouse) as well as caspases-4 and -5 in humans. These caspases are characterized by the presence of CARD domain at the N-terminus which is essential for interaction with the adaptor component. (The 'c' in 'caspase' refers to cysteine protease and 'aspase' refers to the ability to cleave after aspartic acid.) All caspases are produced in cells as catalytically inactive zymogens and require proteolytic cleavage before activation (Martinon and Tschopp 2007). Caspase-1, first described in 1989, was identified as enzyme able to cleave pro-IL-1 β and pro-IL-18. IL-33 is also reported to be cleaved by caspase-1 although the location and consequences of IL-33 proteolysis remain unclear (Zhao and Hu 2010).

Some of the better characterized inflammasomes include NLRP1, NLRP3, NLRP6, NLRC4 and AIM2. NLRP1 is formed by ASC, NACHT and LRR as the adaptors and pyrin domain containing protein 1 (NLRP1) as sensor component. It acts like a cytosolic toll like receptor (TLR) and activates caspase-1 to induce inflammation through IL-1 β . NLRP3 (also called NALP3 or cryopyrin) is the best known inflammasome and is activated by multiple PAMPs and DAMPs. Bacterial pathogens, prokaryotic mRNA, ER stress, extracellular ATP are some of NLRP3 inducers (Sollberger et al. 2014). NLRC4 is required exclusively for bacterial-induced caspase-1 activation and subsequent inflammation. ASC is required for caspase-1-mediated and NLRC4-dependent activation of pro-IL-1 β and proIL-18, but not for caspase-1-

dependent cell death. AIM2 is another inflammasome which binds to double stranded DNA and plays an important role against viral infections.

8.3 Inflammasomes in the Healthy Central Nervous System

Inflammasome-mediated processes are vital for immune responses against microbial infections. Inflammasome assembly is highly regulated at multiple steps to prevent its aberrant activation in immunologically unchallenged conditions. The inflammasome components are auto-inhibited by various domains, which form first check-point to restrict activation. Secondly, the compartmentalization of individual inflammasome components in different cellular organelles limits the interaction and provides efficient mechanism of regulation of inflammasome activation. For example, ASC is found in mitochondria and nucleus whereas NLRP3 is located in endoplasmic reticulum (Misawa et al. 2013). Upon stimulation with ligands, the components assemble in cytosol and lead to downstream production of inflammatory cytokines.

Microglia, neurons, oligodendrocytes and astrocytes comprise the principal cell types of central nervous system (CNS); all of these cells can exert immune effects depending on the circumstances although neurons and oligodendrocytes are not usually regarded as immune effector cells. Inflammasome-mediated inflammatory pathways have been implicated in different CNS disorders with overexpression of pro-inflammatory cytokines (e.g., IL-1 β and IL-18) linked to neuroinflammation. However, basal level of cytokine expression is essential for normal physiological function of the brain and cytokine deficiencies can be detrimental just as their overexpression is widely seen to be pathogenic. Cytokines are recognized to participate in fundamental molecular and cellular mechanisms linked to learning, memory and cognition under physiological conditions (McAfoose and Baune 2009). Therefore, it is of utmost importance to understand the inflammasome in the healthy CNS. Neurocognitive function in humans is influenced by IL-1 β through its actions on long term potentiation (LTP). LTP is an indication of the strengthening of synapses to produce a long lasting increase in signal transmission between two neurons and is associated with learning and memory. To some extent, there is cell-specific inflammasome expression in the CNS, with NLRP3 found predominantly in microglia and macrophages, NLRP2 in astrocytes and AIM2 and NLRP1 in neurons; although cell type expression is likely dependent on the individual species. In healthy physiological conditions, IL-1 β is required to maintain an optimum LTP balance, thereby positively correlating with learning and memory (Ross et al. 2003). This effect is primarily observed in hippocampus, the area of brain associated with declarative memory function.

The brain has been classified as first-tier tissue (based on a three tier classification), which constitutively expresses inflammasomes, primarily NLRP1 and NLRP3. According to this model, first tier tissues (including brain, blood and thymus) initiate inflammation more rapidly than second and third tier tissues (Yin et al. 2009).

Inflammasomes in different CNS cell types: In the CNS, inflammasomes are expressed ubiquitously in microglia, trafficking macrophages, astrocytes and perhaps in a species-specific manner in neurons. Microglia are the resident tissue macrophages of the brain originating from distinct progenitor cells rather than hematopoietic macrophages, which traffic into the brain post-natally. The NLRP3 inflammasome is activated in microglia and macrophages by various priming PAMP or DAMP signals e.g., lipopolysaccharide (LPS), muramyl dipeptide (MDP), adenosine-triphosphate (ATP). Microglial NLRP3 activation was shown by priming signals derived from macrophages infected with mycobacteria (Lee et al. 2013). Primary microglia respond to the same innate stimuli as hematopoietic macrophages but often with a different magnitude of response than macrophages. Conversely, microglial responses are more persistent due to lack of negative regulation on pro-IL-1 β expression (Burm et al. 2015). Microglia are the primary producers of IL-1 β , following NLRP3 upregulation, in a rat depression model. Microglial NLRP3 inflammasome activation is increasingly seen as a mediator of IL-1 β -related neuroinflammation during chronic stress (Pan et al. 2014). In addition to NLRP3, AIM2 plays a critical role in regulating IL-1 β release and cell survival during acute CNS bacterial infection by *Staphylococcus aureus* (Hanamsagar et al. 2014). Flagellated bacteria, *Legionella pneumophila*, infect and replicate in macrophages and invade brain. During bacterial infection by *L. pneumophila*, primary microglial cells responded via activation of NLRC4 inflammasome (Jamilloux et al. 2013).

Astrocytes are resident brain cells functioning in synaptic formation and provide support and protection to neurons. Astrocytes can also respond to diverse stimuli and are major contributors of chemokines and cytokines, including IL-1 β . Elevated levels of IL-1 β have been detected in astrocytes in neurodegenerative disorders like Alzheimer's disease (AD) and HIV infection. Palmitate, the most abundant saturated fatty acid in the diet, can activate astrocytes eventually causing neuronal damage. The involvement of NLRC4 and ASC has been shown in the inflammatory response to palmitate by astrocytes, associated with AD. Expression of both NLRC4 and ASC is elevated in AD patients (Liu and Chan 2014). In a Parkinson's disease model, intracellular oxidative stress in astrocytes exacerbated neuroinflammation to dopaminergic neurons via the activation of NLRP3 inflammasome in astrocytes (Lu et al. 2014b). It was recently demonstrated that human astrocytes express a novel NLRP2 inflammasome complex, activated by ATP. The adaptor protein in NLRP2

complex is ASC with caspase-1 as the effector protein. NLRP2 interacts with P2X7 receptor and the pannexin 1 channel for the downstream activation of caspase-1 and IL-1 β production. Astrocytic NLRP2, thus, is an important component during CNS inflammatory responses (Minkiewicz et al. 2013).

Neurons can also sense danger stimuli associated with mechanical, thermal or chemical nature. They express TLRs and are known to express inflammasomes like NLRP3 and AIM2. However, the study of activation of inflammasomes in neurons is at its beginning stage and needs further exploration (Santoni et al. 2015).

Thus, multiple inflammasomes exist in the CNS and are functional in different neural cell types which are activated depending upon nature of stimuli. The overall mechanism is complicated by the simultaneous activation of multiple inflammasomes, in either similar or different cell types.

8.4 Inflammasomes in Acute Neurological Disease

Stroke, bacterial meningitis and traumatic brain injury (TBI) represent prototypic acute neurological disorders with inflammatory activation implicated in the disease process. Inflammasome activation in acute and chronic neurological disorders is summarized in Table 8.1.

Stroke: Stroke is a common cause of death, implicated in 10% of deaths worldwide and often leads to long-term disability in rest of the cases. Stroke is characterized by reduced blood flow in focal areas of the CNS leading to neurological disability. It may be caused either by thrombotic or embolic occlusion of a cerebral artery (ischemic stroke) or by rupture of a cerebral blood vessel (intracerebral or subarachnoid hemorrhage). Amongst the two types, ischemic stroke is most common and occurs in 80% of patients with stroke (Fann et al. 2013). Inflammation during stroke begins with secretion of pro-inflammatory cytokines (e.g. TNF- α , IL-1 β and IL-18) by activated glial cells in response to ischemia and perhaps hypoxia. This primary response is followed by secondary infiltration of neutrophils and monocytes from the vascular circulation, which also secrete additional cytokines and cytotoxic agents e.g., reactive oxygen species (ROS), inducible nitric oxide synthase (iNOS) and matrix metalloproteinases (MMPs). Activated MMPs can disrupt the blood-brain barrier (BBB) leading to hemorrhage, brain edema and eventually neuronal cell death. This secondary damage is referred to as ischemic reperfusion injury. During ischemic stroke, NLRP1 and NLRP3 inflammasomes are major sensors for cellular damage detection. However the precise stimuli for activation of these inflammasomes are unknown. One of the major drivers of inflammasome activation during ischemic stroke is lower cytosolic ATP. Lower ATP/AMP (adenosine monophosphate) ratio

activates AMPK (AMP-activated protein kinase), which eventually activates NLRP1 receptor. Interestingly, AMPK activation alone is not enough to drive NLRP1 inflammasome activation, but lower ATP is a co-requirement, suggesting that ATP in normal cellular conditions inhibits NLRP1 receptor (Liao and Mogridge 2013).

Extracellular or intracellular acidosis leads to activation of the NLRP3 inflammasome in glial cells. Extracellular acidosis may result from the release of H⁺ ions by necrotic cells, whereas intracellular acidosis could result from reduced oxygen availability and accumulation of lactic acid resulting from anaerobic glycolysis. Another important factor for NLRP3 activation during stroke is cytosolic high Ca²⁺ and reduced K⁺ concentration. Lower ATP results in abnormal functioning of Na⁺/K⁺-ATPase pump, resulting in imbalance in ionic concentrations and eventually NLRP1 and NLRP3 inflammasome activation (Ding et al. 2000; Rajamaki et al. 2013; Munoz-Planillo et al. 2013).

Mitochondria are a significant source of ROS during stroke. Disturbed electron transport chain produces ROS in cytoplasm which activates NLRP3 inflammasome. Following NLRP3 activation, ASC on mitochondria translocates into perinuclear space, which brings ASC closer to NLRP3 and thus NLRP3 can receive mitochondria-derived signals such as ROS (Misawa et al. 2013). Mice models of cerebral ischemia have shown the evidence of inflammasome activity. The activation of NLRP1 and NLRP3, during stroke, mediates caspase-1 induced apoptosis and pyroptosis in neuronal and glial cells. Binding of IL-1 β to IL-1 receptor 1 (IL-1R1) in cells of injured cerebral tissue results in neurotoxicity; however, initial response is meant to be neuroprotective (Zhang et al. 2014; Denes et al. 2010).

Current treatments in stroke consist of administration of recombinant tissue plasminogen activator for removal of the blood clot. However, a major obstacle is the 3–4.5 h treatment window after which the treatment is less efficacious and possibly dangerous. Therefore, targeting inflammasome signaling is emerging as new therapeutic strategy for controlling neuronal damage during stroke. The potential targets include inflammasome components (NLRPs, ASC and caspase-1), signaling pathways (NF- κ B and MAPK), plasma membrane receptors/channels (P2X7 receptors, pannexin 1 and K⁺ channels), cytokines (IL-1 β and IL-18) and cytokine receptors (i.e. IL-1R1 and IL-18R) involved in inflammasome signaling (Fann et al. 2013).

Meningitis: Meningitis refers to acute inflammation of meninges or membranes of the brain and spinal cord. The meninges are comprised of three membranes including the outermost dura mater, middle arachnoid mater and the innermost and most delicate, pia mater. The dura mater is thick and durable membrane attached to the skull whereas the pia mater forms contact with the brain and spinal cord. Meningitis may be caused by various infectious pathogens including bacterial or viral infections. Bacterial meningitis is often caused by *Streptococcus pneumoniae* and carries a mortality rate of 16–37%, with approximately half of the survivors suffering from neurological disabilities (Hoogman et al. 2007). It occurs as a result of poor host defenses resulting in pathogens reaching the subarachnoid space in meninges.

Inflammasomes have been extensively implicated in bacterial meningitis. This is because inflammasomes are known to be activated by microbial PAMPs and endogenous DAMPs such as ATP, oxygen radicals and imbalance in cellular ion concentrations. Cerebrospinal fluid (CSF) of patients with

pneumococcal meningitis shows evidence of upregulation of caspase-1 activity and cytokines IL-1 β and IL-18 (Hoegen et al. 2011). A murine model of meningitis was developed by intranasal inoculation of pneumococci with hyaluronidase. Correlation of elevated IL-1 β and IL-18 levels with disease severity and complications has been reported (Zwijnenburg et al. 2001). Interestingly, ASC and NLRP3 knockout mice exhibited decreased bacterial loads; however, NLRP3 expression was protective against brain damage. NLRP3 knockout mice showed increased leukocyte infiltration and cerebral hemorrhage following bacterial infection with worse outcomes (Geldhoff et al. 2013). Inflammasome activation may be detrimental in some chronic conditions but it is likely intended to be protective in acute inflammation. Indeed, it was shown that IL-1 receptor knockout mice were more susceptible to developing meningitis after intranasal infection with *S. pneumoniae*. Higher mortality and enhanced growth of pneumococci in IL-1R $^{-/-}$ mice compared with wild-type mice has been reported (Zwijnenburg et al. 2003). These studies emphasized on the beneficial effects of IL-1 β induction and expression in bacterial clearance during host immune responses.

In bacterial meningitis, protease activity works upstream of NLRP3 inflammasome activation. It is proposed that lysosomal damage releases lysosomal proteases such as cathepsin B into the cytoplasm. These proteases activate NLRP3 either by catalyzing degradation of an NLRP3 inhibitor or cleavage of a substrate releasing NLRP3 ligand into the cytoplasm. Nigericin, one of the important activators of NLRP3, also acts through lysosomal release of cathepsin B and subsequent caspase-1 activation (Hoegen et al. 2011). Meningitis has high mortality rate and alternative treatment regimens are necessary because of spread of penicillin-resistant *S. pneumoniae* (Fiore et al. 2000). Enhanced inflammasome signaling during meningitis might be a promising therapeutic strategy in the future.

Traumatic brain injury: Traumatic brain injury (TBI) is a complex injury leading to long-term disabilities. It occurs when a sudden trauma causes mild, moderate or severe damage to the brain. Some of the moderate symptoms include headache, dizziness and blurred vision but can also result in epileptic seizures, loss of motor control and co-ordination as well as memory impairment. A robust inflammatory response is generated in the injured tissue immediately after TBI. The complexity of this post-traumatic response includes the activation of resident glial cells; microglia, and astrocytes along with infiltration of blood leukocytes. Acute CNS injury models show recruitment of inflammatory cells, elevated pro-inflammatory cytokines at both gene expression and protein levels along with inflammasome-related signaling cascades (Woodcock and Morganti-Kossmann 2013).

Caspase-1 is activated after both spinal cord injury (SCI) and TBI. The expression levels of NLRP1 inflammasome

were unchanged but ASC and caspase-1 protein levels were elevated in CSF of patients with TBI. Expression of NLRP3 inflammasome in cerebral cortex was found post injury in a rat TBI model (Liu et al. 2013). An interesting experimental observation in TBI is inflammasome activation in neurons. It was shown that NLRP1 was activated in rat neurons and constituted important inflammatory response following SCI (de Rivero Vaccari et al. 2008). A recent report shows that neurons respond to injury by activation of AIM2 inflammasome and oligomerization of ASC. Neurons then undergo pyroptosis following caspase-1 activation, formation of discrete pores in plasma membrane and release of IL-1 β (Adamczak et al. 2014). Thus, inflammatory innate immune responses, especially in the post-injury period, are important therapeutic targets for controlling neuronal damage during TBI.

8.5 Inflammasomes in Chronic Neurological Disease

Prolonged activation of inflammasomes in the brain leads to neuroinflammation which is pathogenic in many chronic neurological disorders. HIV/AIDS associated brain disease (NeuroAIDS), Alzheimer Disease (AD) and Multiple Sclerosis (MS) are chronic neurological diseases in which inflammasome-driven pathways are key aspects of the disease process. Specifically, the NLRP3 inflammasome has been reported to be activated in a number of neuroinflammatory disease scenarios including NeuroAIDS, MS and AD (Walsh et al. 2014).

NeuroAIDS: Human Immunodeficiency Virus (HIV) enters into the brain very early during the infection. The persistence of HIV infection in the brain represents a challenge to the researchers attempting to fully eradicate HIV infection. TNF- α and IL-1 β are the cytokines that have been most consistently implicated as participants during CNS HIV infection (Tyor et al. 1993; Wesselingh et al. 1997; Xing et al. 2009a, b). These are central regulatory molecules that are directly activated by HIV-1 infection and are responsible for driving the inflammatory response through their effects on immune cell activation and recruitment. In addition to the further recruitment of immune cells into the brain, several of these molecules have been reported to exert effects on local cell types, such as astrocytes and neurons, to promote neuropathology (Bezzi et al. 2001; Zhang et al. 2003). Despite the characterization of an inflammatory response to HIV in the brain, there is still relatively little known about the innate immune sensing of the virus or virus-infected cells at the molecular level. Current studies on HIV's interaction with the innate immune system have focused on the sensing of viral genomic products and activation of antiviral interferon (IFN) responses. In the periphery, HIV-1 elicits a strong Type 1 interferon response from specialist plasmacytoid dendritic

cells (pDC) (Lepelley et al. 2011). In these cells, virus is endocytosed and sensed by TLR7 and TLR9 which bind to viral RNA (Beignon et al. 2005). Type 1 interferon responses have been reported in the context of CNS HIV infection (Polyak et al. 2013). The release of both TNF- α and IL-1 β in response to whole virus has been replicated using individual viral proteins such as viral envelope protein gp120/gp160 and HIV trans-activating protein Tat (Cheung et al. 2008; Ben Haij et al. 2013; Jin et al. 2012) and the viral protein R (Jones et al. 2007). Recent data from our laboratory show that IL-1 β , IL-18 and caspase-1 are induced in brains of HIV-1 infected individuals, specifically in microglia. Induction of pro-IL-1 β occurred within 4 h of microglial infection with HIV, by NLRP3 dependent mechanism. Adapter protein ASC translocated from nucleus to cytoplasm, pointing towards assembly of inflammasomes, within few hours following HIV infection. The study highlighted that targeting the inflammasome activation in brain might represent a therapeutic intervention in HIV-associated neurocognitive disorder (HAND) (Walsh et al. 2014).

Alzheimer Disease: Alzheimer disease (AD) is clinically characterized by extracellular accumulation of amyloid- β (A β) in senile plaques together with phosphorylated neurofilaments comprised of the tau protein. It is a chronic neurodegenerative disease that accounts for more than 50% of dementia cases. The early symptoms include short-term memory loss which then progresses into speech impairment, disorientation and memory loss with progressive neurocognitive decline (Burns and Iliffe 2009).

The causes of sporadic age-related AD (the most common type) are not well defined but both genetic and environmental determinants have been associated with AD. The accumulation of A β activates NLRP3 inflammasome in resident microglia with associated neuroinflammation. Multiple inflammatory cytokines and chemokines are reported to be activated in brain and CSF from AD patients and IL-1 β is one of the prominent cytokines amongst those (Tan et al. 2013). The mechanism of NLRP3 activation during AD involves the following steps: a) increased A β phagocytosis by microglia b) lysosomal breakdown in microglia c) release of cathepsin B d) NLRP3 activation followed by caspase-1 activation and IL-1 β release. NLRP3 activation is positively correlated with neuropathology in transgenic mice expressing A β . These findings were corroborated with findings of decreased A β deposition and better spatial memory in NLRP3 knockout mice (Heneka et al. 2013). One of the important observations was the restriction of NLRP3 activation in plaque-associated microglia, which emphasized the direct relation between A β and NLRP3 activation. It also suggested that NLRP3 activation was linked to disease progression in AD. Neurons undergo excitotoxic death that is modulated by IL-1 β signaling. IL-1 β -mediated neuronal cell death in AD is mediated by mitogen-activated protein kinase (MAPK) pathway and

by iNOS production in hippocampal neurons (Barone et al. 2001). Further investigations are required to understand the inflammatory signaling pathways involved in AD. The NLRP3 inflammasome might be a future molecular target for therapeutic intervention for AD.

Multiple sclerosis: Multiple Sclerosis (MS) is defined by progressive neurological disability caused by inflammation in the CNS, although the cause of MS remains unknown. Neuroinflammation is accompanied by demyelination and eventual axonal loss (Legroux and Arbour 2015). Immune system pathways (innate and adaptive) are implicated in activating the brain's inflammatory molecular machinery with both adverse and protective outcomes, but what drives these inflammation-mediated neurological outcomes remains uncertain.

Given the established associations between IL-1 β and -18 and neuroinflammation, it is not surprising that substantial evidence implicates inflammasomes in the pathogenesis of MS and associated MS models. Several inflammasome components are known to be upregulated at the mRNA and protein levels in both acute and chronic demyelinating MS lesions, including ASC, caspase-1 (Furlan et al. 1999; Laule et al. 2011), NLRP3 (Hauser et al. 1990), IL-18 and IL-1 β (Broz and Monack 2011). Elevated expression of IL-18, IL-1 β and caspase-1 can also be found in peripheral blood mononuclear cells, serum and CSF from MS patients.

Different groups have investigated the contributions of inflammasome components in models of MS, including experimental autoimmune encephalomyelitis (EAE) and the cuprizone model of demyelination. In EAE, multiple reports indicate that knock-out of key inflammasome components (NLRP3^{-/-}, ASC^{-/-}, and caspase-1^{-/-}) causes an attenuated form of EAE. Knock-out of the key inflammasome cytokine, IL-18, causes a similar phenotype, as does knock-out of the IL-1 β receptor, IL-1R. Both IL-1 β and IL-18 promote Th1, Th17 and humoral immunity; IL-18 is important for IL-17 production by Th17 cells. Pharmacological inhibition of both caspase-1 and the ATP receptor, P2X7 (known to induce inflammasome activation) causes attenuation of disease severity in the EAE model. The inflammasome's key role in demyelination was also reported in the cuprizone model; knock-out of NLRP3, ASC and IL-18 all cause reduced neuroinflammation and demyelination (Guarda et al. 2011). However, other studies found that demyelination can occur in the absence of the inflammasome. For example, NLRP3 knockout exerts variable effects on the pathogenesis of EAE and IL-1 β knock-out does not affect demyelination or neuroinflammation in the cuprizone model. These latter results may reflect heterogeneity in genetic backgrounds of mice such as Nlrp1 allelic variants. This dichotomy also implies that multiple inflammasomes and inflammasome-independent processes may contribute to inflammatory demyelination. Of interest, Type 1 interferons, one of several

MS-associated disease modifying therapies regulate IL-1 β production and inflammasome activation. Thus, inflammasomes are essential to investigate in MS because they provide insight into the cause(s) of MS by deciphering their agonists/signals. They participate in the fundamental mechanisms underlying MS yielding a greater understanding of the disease and they offer immediate 'drug-able' targets for interventions in MS.

8.6 Pharmacological Inhibition of the Inflammasome

Inflammasomes are multi-protein complexes and each component is controlled by various regulatory mechanisms. Thus, inflammasomes are unique candidates for the development of effective anti-inflammatory therapeutics. Targeted therapies with inhibition of inflammasome complexes can be achieved to improve neurological outcomes in particular diseases.

Conventional anti-inflammatory therapies are predicated on inhibiting the effects of IL-1 β using anti-IL-1 β antibodies or recombinant IL-1 receptor antagonists. However, effective anti-IL-18 therapies are currently unavailable (Netea et al. 2015). Blockade of IL-1 signaling to control inflammation was an early approach, which dates back to 1993 with the introduction of anakinra. Anakinra is a recombinant IL-1 receptor antagonist that blocks the activity of both IL-1 α and IL-1 β and was approved for use as a drug by the U.S. Food and Drug Administration (FDA) in 2001. The advantages of anakinra as a drug include safety, short half-life and multiple routes of administration. As a result, it has been extensively used in treatment of broad range of diseases including rheumatoid arthritis, CAPS and Type 2 diabetes (Dinarello et al. 2012). Neutralizing IL-1 β with specific antibodies is another therapeutic strategy for control of IL-1 β -induced inflammation. Canakinumab, a human monoclonal antibody, was approved by the FDA in 2009 because of its specificity against IL-1 β . It is currently in clinical trials for several inflammatory disorders including arthritis, other inflammatory joint diseases, Type 1 diabetes and pulmonary diseases (Chakraborty et al. 2013; Howard et al. 2014). Some of the endogenous inhibitors of inflammasomes are IL-37 and Type 1 interferons. IL-37 is a 30 kDa member of the IL-1 family of ligands and has amino acid residues common with those of IL-18. It can, therefore, bind to IL-18 receptor in a non-competitive manner. IL-37 exerts its anti-inflammatory effects by nuclear translocation followed by inhibition of cytokines such as IL-1 and TNF- α . The inhibitory effects of IL-37 have been confirmed in cells of myeloid lineage such as bone marrow derived macrophages and neutrophils (Moretti et al. 2014). IFN- β is a widely used drug to treat MS and is shown to inhibit NLRP3-mediated brain inflammation

in mouse EAE model. Innate immune cells, such as macrophages and dendritic cells (DCs), exert inhibitory effects through IFN- β , which in turn is exerted by inhibition of T helper 17 (TH17) responses. IFN- β reduces the production of mitochondrial ROS with subsequent inhibition of NLRP3 inflammasome activity. In addition, IFN- β had no effect on progression of NLRP3-independent EAE and could reduce disease progression only in case of NLRP3-dependent EAE. This clearly demonstrated a direct relationship between IFN- β and NLRP3 suppression (Inoue et al. 2012).

Pro-inflammatory cytokines represent key factors mediating macrophage-driven inflammation in ischemic heart disease. Interestingly, moderate consumption of alcohol is associated with reduced risk of coronary disease-associated mortality. Recently, it was established that ethanol inhibits both NLRP3 and AIM2 inflammasome in macrophages, providing a potential molecular mechanism underlying ethanol-induced protection in ischemic heart disease. Ethanol reduced the secretion of IL-1 β by reducing caspase-1 activity but pro-IL-1 β production was unaffected, hence, acting at the level of NLRP3 inflammasome assembly. Ethanol inhibited inflammasome by maintaining lysosomal integrity and preventing the release of cathepsin B. It also reduced oligomerization of ASC, thereby, inhibiting upstream of caspase-1 activation. Ethanol also inhibited AIM2 inflammasome, which was evident as reduced IL-1 β production even in the presence of synthetic double stranded DNA. Ethanol-mediated reduced IL-1 β secretion might explain atheroprotective effects of alcohol and also susceptibility to infections associated with excessive alcohol consumption (Nurmi et al. 2013).

Many small molecule compounds have been identified as inhibitors of inflammasome assembly and activation. Some of these are already in use whereas others are in clinical trials for efficacy and safety.

Glyburide: Glyburide is a commonly used drug for treatment of Type 2 diabetes and belongs to sulfonylurea class of drugs. In pancreatic β cells, glyburide inhibits ATP-sensitive K⁺ channels (K_{ATP}), which regulate glucose-dependent insulin secretion (Ashcroft 2005). With the inhibition of K_{ATP} channels, membrane potential changes resulting in calcium influx. This triggers release of insulin stored in small vesicles inside the pancreatic β cells. In addition, it was the first compound reported to act upstream of NLRP3, thus inhibiting, PAMP- and DAMP-induced caspase-1 activation, IL-1 β secretion and subsequent cell death. However, the inhibitory effect of glyburide on NLRP3 is independent of its action on K_{ATP} channels; for example, glyburide can block NLRP3 even in the absence of K_{ATP} channels (Lamkanfi et al. 2009). It inhibits NLRP3 downstream of the P2X7 receptor. Of note, P2X7 receptor signaling leads to ROS-dependent inflammasome activation (Bartlett et al. 2013).

Although glyburide is an oral medication used in the treatment of Type 2 diabetes, there is also formulation for intravenous

injection, RP-1127, which is in clinical trials for preventing malignant edema in patients with ischemic stroke. It is also being tested against mild, moderate or severe traumatic brain injury for safety and efficacy in preventing hemorrhage and edema (<https://clinicaltrials.gov> ID#NCT01794182, NCT01454154). These studies, if successful, will clearly emphasize the role of inflammasome activity in disease progression and an important therapeutic target.

One of the major limitations of glyburide as an anti-inflammatory compound is that it is effective only when delivered in high-doses, leading to side-effects of hypoglycemia. To address this problem, an intermediate substrate free of the cyclohexylurea moiety in the glyburide synthesis, was developed. Since cyclohexylurea is indispensable for insulin release, absence of this moiety results in a compound possessing the inhibitory activity against NLRP3 but without effects on insulin release. The compound (5-Chloro-2-methoxy-*N*-[2-(4-sulfamoylphenyl) ethyl] benzamide) successfully inhibits NLRP3 in cardiomyocytes and limits infarct size in experimental model of myocardial infarction, without affecting glucose metabolism (Marchetti et al. 2014). It is intriguing that insulin also suppresses IL-1 β expression as well as other cytokines together with inducing expression of PPAR γ , which exerts anti-inflammatory effects (Hyun et al. 2010).

VX-765: The prodrug VX-765 (Vertex Pharmaceuticals, Cambridge, MA) is an orally absorbed compound that is converted to an active metabolite, VRT-043198, by plasma and liver esterases. VRT-043198 is a small molecule and a selective caspase-1 inhibitor. Distinct structural features of caspase-1 have been utilized for designing potent reversible and irreversible inhibitors. The mode of action is based on incorporation of an aspartic acid residue into the active site of caspase-1, which mimics the substrate pro-IL-1 β (MacKenzie et al. 2010). As release of active IL-1 β is dependent on caspase-1 activation by the inflammasome complex, a caspase-1 inhibitor would be expected to lower IL-1 β levels. Indeed, VX-765 reduces the production of IL-1 β and IL-18 both in vitro and in vivo. It has no effect on either cell apoptosis or cell proliferation, when tested in human neuroblastoma cells. This property imparts beneficial effects of usage as an anti-inflammatory drug. In addition, it also reduces the severity of disease in models of rheumatoid arthritis and skin inflammation by controlling inflammatory cytokine production (Wannamaker et al. 2007).

Oral administration of VX-765 results in blockade of active IL-1 β . Chronic stress-induced depression is associated with over production of IL-1 β in murine models. VX-765 reduced serum and hippocampal levels of IL-1 β along with significantly improving depression-like behaviors induced by chronic mild stress (Zhang et al. 2015). VX-765 is currently in clinical trials to assess the reduction in seizure frequency in patients with epilepsy (<https://clinicaltrials.gov> ID#NCT01501383), based on studies showing reduction of

seizures in animals following IL-1 β inhibition by VX-765 (Maroso et al. 2011).

Parthenolide: Parthenolide is a plant lactone extract and has been extensively used as an herbal remedy for treatment of various inflammatory diseases including fever, arthritis and psoriasis. It inhibits the NF- κ B pathway, but in addition, parthenolide is also an inflammasome inhibitor. It acts by directly inhibiting both the protease activity of caspase-1 and ATPase activity of NLRP3. Compared to the NF- κ B inhibitor, BAY 11-7082, which specifically inhibits NLRP3, parthenolide can inhibit multiple inflammasomes including NLRC4-induced caspase-1 activity (Juliana et al. 2010). In a rat model of stroke, parthenolide treatment reduced blood-brain barrier permeability and infarct size along with suppression of caspase-1 expression (Dong et al. 2013).

Cytokine Release Inhibitory Drugs (CRIDs): These are class of sulfonylurea containing compounds that inhibit post-translational processing of IL-1 β . CRID3, a small molecule inhibitor of both NLRP3 and AIM2, was developed which inhibits caspase-1 activation and IL-1 β secretion in response to stimulation of NLRP3 and AIM2 but not NLRC4. CRID3 also prevents AIM2-dependent pyroptosis, as compared to the NLRP3 inhibitors glyburide and parthenolide, which do not inhibit AIM2 activation. CRID3 exerts its effect by inhibiting the formation of ASC complexes, in response to NLRP3 and AIM2 activation (Coll et al. 2011).

Other Inhibitors: Small molecule inhibitors are being developed to improve safety, efficacy and mode of delivery for an effective potential therapy in humans. For example, MCC950 is a potent and selective inhibitor of NLRP3, but not AIM2, NLRC4 or NLRP1 inflammasomes. It suppresses IL-1 β production in vivo, in conjunction with reduction in severity of EAE (Coll et al. 2015). It might be effective in MS, arthritis and other inflammatory disorders because it is readily absorbed from the gut and can potentially cross the blood-brain barrier.

In addition several inflammasomes (e.g. NLRP1, NLRP3 and NLRC4) can be inhibited by arsenical compounds including sodium arsenite and arsenic trioxide. These compounds have been shown to inhibit inflammasome-dependent pyroptosis by modulating cellular environment, which indirectly inactivates caspase-1. Arsenic trioxide is used to treat hematological cancers, and therefore, has a clinical range of efficacy (Maier et al. 2014).

8.7 Review Questions

1. What are inflammasomes? How were they discovered?
2. Describe the role of ASC in inflammasome activation. How does the inflammasome assembly work in the absence of ASC?

3. How is anakinra used as an anti-inflammatory drug? How is it different from small molecule inflammasome inhibitors such as glyburide and VX-765?
4. The activation and assembly of NLRP3 inflammasome in the cytoplasm results in which of the following:
 - (a) pro-IL-1 β is degraded.
 - (b) pro-IL-1 β is synthesized.
 - (c) *pro-caspase-1 is cleaved into active caspase-1, which further cleaves pro-IL-1 β into active IL-1 β .*
 - (d) Blockade of IL-1 receptor and thus reducing the effects of IL-1 β secretion.
5. One of the major drivers of inflammasome activation during ischemic stroke is:
 - (a) IL-1 β and IL-18
 - (b) Lower cytosolic ATP
 - (c) Cytosolic high Ca²⁺ and reduced K⁺ concentration
 - (d) All of the above
 - (e) *b and c*
6. Pyroptosis is characterized by:
 - (a) Programmed cell death mediated by caspase-1
 - (b) Programmed cell death mediated by caspase-4
 - (c) Rupture of plasma membrane with release of intracellular contents
 - (d) *a and b*
 - (e) *b and c*

8.8 Answers

1. Inflammasomes are oligomeric multiprotein complexes that assemble in the cytoplasm in response to danger- or pathogen-associated molecular patterns (DAMPs or PAMPs). Inflammasome assembly and activation leads to caspase-dependent activation of interleukin-1 β (IL-1 β) and IL-18, and pyroptotic cell death. Inflammasomes were discovered during identification of underlying mechanisms of periodic fever syndromes. Inflammasomes were first described in 2002, as caspase-activating complexes. Researchers discovered mutations in NLR family genes, while studying patients who were exquisitely sensitive to cold. The intracellular protein implicated in the phenomenon was named 'cryopyrin' since patients developed fever when exposed to cold. Later, inflammasomes were identified as intracellular molecular platforms and key elements in innate immunity.
2. The inflammasome assembly comprises of a sensor component, an adaptor component and an effector component. The apoptosis-associated speck-like protein containing a caspase recruitment domain (ASC) is the most common adaptor protein for most of the inflammasomes (e.g. NLRP1, NLRP3 etc). Following stimulation, sensor component oligomerizes resulting in formation of clusters of N-terminal

pyrin domain (PYD). This is followed by recruitment of monomeric ASC, which in turn serves as a platform for the caspase recruitment domain (CARD) to cluster and recruit the caspase-1 filament by a homotypic CARD/CARD interaction. Thus, ASC acts as a core protein that acts as a bridge between stimulation of inflammasome and its activation. However, few other inflammasomes (e.g. NLRC4) do not require ASC. This function is mediated by CARD/CARD interactions. The CARD domain of sensor component directly nucleates caspase-1 for activation.

3. Pro-inflammatory cytokine IL-1 β , one of the major products of inflammasome activation, is up-regulated and implicated in many acute and chronic neurological diseases. Anakinra is a recombinant IL-1 receptor antagonist that blocks the activity of both IL-1 α and IL-1 β and was approved for use as a drug by the U.S. Food and Drug Administration (FDA) in 2001. Because of advantages like safety and efficacy, it has been used in treatment of broad range of diseases including rheumatoid arthritis and Type 2 diabetes. Glyburide acts upstream of NLRP3 and inhibits inflammasome assembly. VX-765 inhibits caspase-1 activation which results in reduced IL-1 β production. Therefore, the important difference between anakinra and small molecule inflammasome inhibitors is the mechanism and the site of action.

Abstract

Leucine rich repeat kinase 2 (LRRK2) is a large protein with a GTPase and kinase domain and several protein-interacting domains. Mutations in the LRRK2 gene, specifically the enzymatic domains, are one of the most common causes of autosomal dominant Parkinson's disease (PD). LRRK2 has been reported as a regulator of many cellular pathways including inflammatory signaling, cytoskeletal maintenance, and autophagy. LRRK2 expression is enriched in cells of the immune system (CD4+ and CD8+ T cells, CD14+ monocytes, and CD19+ B cells), but its function in the immune system and its effects on age-related immunosenescence are as yet unknown. Mutations or polymorphisms in the LRRK2 gene are also associated with several other immunological diseases, including Crohn's disease and increased risk for leprosy infection, indicating that LRRK2 plays an important role in proper immune function. Inhibition of the LRRK2 kinase activity has been proposed as a potential new therapeutic for PD, but specificity and blood brain barrier permeability of the compounds still remain a problem. With widespread expression in both the immune and nervous systems, LRRK2 remains an interesting, yet challenging, pharmacological target. Through the development of more specific LRRK2 kinase inhibitors, the possibility of a disease-modifying therapy for a progressive condition that hasn't seen a new treatment in over 60 years remains a bright spot on the horizon.

Keywords

Immune cell • Immunity • Inflammation • Kinase inhibition • Leucine-rich repeat kinase 2

9.1 Introduction

Parkinson's disease (PD) is a progressive age-related movement disorder characterized pathologically by degeneration in dopaminergic neurons of the substantia nigra and formation of neuronal inclusions of aggregated α -synuclein called Lewy bodies. Although the disease has been extensively studied for decades, the etiology of the disease remains unclear and the development of new treatments and therapeutics has been slow-paced. Mutations in the leucine-rich

repeat kinase 2 (LRRK2) protein were identified in 2004 as a potential marker for PD (Paisan-Ruiz et al. 2004; Zimprich et al. 2004). The identification of the link between LRRK2 mutations and PD led to an exciting new pathway for researchers to pursue. Because clinical presentation of LRRK2-associated PD and idiopathic PD is very similar (Aasly et al. 2005; Thaler et al. 2009; Haugarvoll et al. 2008; Kumari and Tan 2009), the study of LRRK2 function is likely to give insight into sporadic PD etiology. Up to this point, studies involving LRRK2 and its associated mutations have focused on their effects on neuronal function. Within the past few years, it has become clear that increased inflammation, both in the brain and the periphery, is associated with the pathology of the disease (Russo et al. 2014; Pradhan and Andreasson 2013; Neumann et al. 2009; McGeer et al.

1988; Whitton 2007). The enriched expression of LRRK2 in both innate and adaptive immune cells and its designation as a member of the immune-regulating receptor-interacting protein kinase (RIPK) family (Meylan and Tschopp 2005; Zhang et al. 2010) places LRRK2 in a unique position as a potential regulator of inflammatory and immune responses that influences risk for age-related degeneration.

9.2 LRRK2 Structure and Function

In 2002, the *PARK8* locus on chromosome 12 was identified in a study involving a large Japanese family with many generations affected with PD (Funayama et al. 2002). Two years later, two labs independently cloned and identified mutations in the *PARK8* gene encoding LRRK2, as causes for dominantly inherited PD (Paisan-Ruiz et al. 2004; Zimprich et al. 2004). LRRK2, also known as dardarin (from the Basque word ‘dardara’, for tremor), is a large protein, containing 51 exons and 2527 amino acids (~286 kDa), with several different functional and protein-interacting domains (Mata et al. 2006; Funayama et al. 2002). Enzymatic domains include a ROC (Ras of complex) GTPase domain (Guo et al. 2007) and a serine/threonine kinase domain (Gilsbach et al. 2012). Several protein-interacting domains including a leucine-rich repeat (LRR) domain, a C-terminal WD40 repeat domain, and armadillo and ankyrin repeat domains also comprise the LRRK2 protein.

The kinase domain is a serine/threonine kinase whose physiological substrate has not been definitively established; however, potential substrates include autophosphorylation sites, ERM (ezrin/radixin/moesin) proteins, mitogen activated protein kinase (MAPK), eukaryotic initiation factor 4E (eIF4E)-binding protein (4E-BP), and 14-3-3 proteins (Drolet et al. 2011). There have been over 20 autophosphorylation sites found on LRRK2 including both serine and threonine residues (Kamikawaji et al. 2009; Li et al. 2010; Greggio et al. 2009; Gloeckner et al. 2006; Webber et al. 2011). There is currently much debate over which sites are “bona fide” autophosphorylation sites; however, the primary candidate sites cluster to the GTPase domain-binding pocket as opposed to the kinase domain (Webber et al. 2011; Greggio et al. 2009; Gloeckner et al. 2006). Most kinases have a conserved DFG (aspartic acid, phenylalanine, and glycine) motif at the hinge region of the kinase activation loop, but LRRK2 has a DYG (aspartic acid, tyrosine, and glycine) motif. Although the significance of this alteration has not been determined, it could contribute to unique structural differences in the kinase domain. The most common LRRK2 mutation G2019S occurs in the glycine of this loop, giving mutant LRRK2 a DFS (aspartic acid, phenylalanine, and serine) loop potentially altering protein dynamics and flexibility (Drolet et al. 2011).

LRRK2 is part of the Roco family of GTPases with a ROC-COR domain: a ROC domain with a C-terminal of Roc (COR) domain directly following it (Bosgraaf and Van Haastert 2003). LRRK2 GTPase function has been confirmed and GTP binding is essential for the regulation of LRRK2 kinase activity (Biosa et al. 2013). There are currently two theories about the GTPase function and its regulatory role. The first involves the GTP-dependent formation of LRRK2 dimers composing the active state. Consistent with this idea, the G2019S mutation appears to increase the amount of LRRK2 in dimer form (Sen et al. 2009). The second theory proposes that LRRK2 acts as Ras-GTPase with an “on-off” switch where GTP binding activates the protein and hydrolysis to GDP inactivates terminating signaling. This model requires tight regulation via GEFs (guanine nucleotide exchange factor) to promote GDP release and new GTP binding thereby activating the protein and GAPs (GTPase activating protein) to promote GTP hydrolysis to GDP turning the protein off. In support of this model, a putative GEF (Haebig et al. 2010) and GAP (Xiong et al. 2012; Stafa et al. 2012) have been proposed although they may not be specific to LRRK2 (Gómez-Suaga et al. 2014). Further studies are needed to parse out the activating mechanism of the GTPase.

LRRK2, but not LRRK1 (a LRRK2 paralogue similar to, but distinctly different from LRRK2) can interact with 14-3-3 proteins (Reyniers et al. 2014). This interaction is mediated by phosphorylation at the Ser⁹¹⁰ and Ser⁹³⁵ sites (Nichols et al. 2010). Pathogenic LRRK2 mutations display reduced phosphorylation at these sites, disrupting 14-3-3 protein binding and leading to accumulation of LRRK2 in the cytoplasm in pools that resemble inclusion bodies (Nichols et al. 2010). It is worth noting that phosphorylation at these two serine sites does not control kinase activity. Inhibiting LRRK2 kinase activity via H-1152 and sunitinib in HEK-293 cells recapitulates the mutant phenotype by decreasing phosphorylation at Ser⁹¹⁰ and Ser⁹³⁵ and disrupting 14-3-3 binding resulting in LRRK2 inclusion bodies (Dzamko et al. 2010). Results from these studies indicate that LRRK2 does not directly autophosphorylate at these sites, but somehow indirectly regulates phosphorylation of these serine residues either by activating a nearby kinase or inhibiting phosphatase activity (Dzamko et al. 2010).

LRRK2 has been linked to regulation of autophagy, neurite outgrowth, vesicular trafficking and cytoskeletal components (Plowey et al. 2008; Gómez-Suaga et al. 2012; Tong et al. 2012; Ramonet et al. 2011). An interesting new model proposes that LRRK2 regulates clearance of vesicles derived from the trans-Golgi network in an autophagy-dependent manner (Beilina et al. 2014). This function is regulated by the phosphorylation of LRRK2 by casein kinase 1 α which promotes recruitment of LRRK2 to the trans-Golgi membrane (Chia et al. 2014). Interaction with the GEF,

ARHGEF7, mediates these effects which is consistent with the ideas stated above, where GEFs mediate GTPase activity which in turn regulate kinase activity.

Given the multiple and highly diverse protein interacting domains, it is not surprising that LRRK2 has also been identified to be involved in the Wnt signaling pathway (Berwick and Harvey 2012, 2014). The Wnt signaling pathway has many cell regulatory functions, both in immune cells discussed further below and in neuronal cells (Staal et al. 2008). LRRK2 interacts with the disheveled family of proteins that are essential to Wnt signaling cascade via the ROC-Cor domain. Experiments also showed that this interaction stabilizes LRRK2 protein expression (Sancho et al. 2009). LRRK2 has also been associated with MAPK signaling (Yang et al. 2013; White et al. 2007) and the transcription factors NFkB (Gardet et al. 2010; Hongge et al. 2014) and nuclear factor of activated T cells (NFAT) (Liu et al. 2011), detailed below. With multiple enzymatic and protein interacting domains, it has been difficult to determine the specific physiologic function of LRRK2 and its relation to PD etiology.

9.3 LRRK2 Expression

LRRK2 expression is ubiquitous. It is expressed throughout brain tissue, including human cortex cerebri, hippocampus, and striatum (Westerlund et al. 2008). Cell specific expression in the brain includes astrocytes, microglia (Miklossy et al. 2006), and neurons (Taymans et al. 2006). Expression in peripheral tissues such as lung, heart, kidney, and immune organs such as thymus, spleen, and lymph nodes has also been reported (Paisan-Ruiz et al. 2004; Zimprich et al. 2004; Miklossy et al. 2006; Westerlund et al. 2008). Full length LRRK2 has been detected via western blot in monocytes, dendritic cells, microglia, B cells and T cells (Hakimi et al. 2011; Gardet et al. 2010). Reports of expression in CD4+ and CD8+ T cells have been inconsistent and contradictory depending on the assay (western blot, real time PCR, and flow cytometry) and reagents used (antibodies, primers). Although it has been reported that LRRK2 mRNA is close to undetectable in CD4+ and CD8+ T cells (Thevenet et al. 2011), the authors have reproducibly shown protein expression via the more reliable flow cytometric analysis and can say with confidence that LRRK2 is expressed in both circulating CD4+ and CD8+ T cells (Tansey et al. 2014). Protein expression is highest in CD14+ monocytes, with an intermediate level in CD19+ B cells and the lowest expression in CD4+ and CD8+ T cells. Most recently, expression has been shown in endothelial cells (Hongge et al. 2014).

In neurons, endothelial cells, and immune cells, LRRK2 localizes mostly to the cytoplasm, with some enrichment at mitochondrial membranes, and presence at cellular mem-

branes following stimulation (West et al. 2005; Schapansky et al. 2014; Berger et al. 2010). Recruitment of LRRK2 to the membrane results in the formation of LRRK2 dimers that have increased kinase activity compared to the monomeric form (Berger et al. 2010). Consistent with previous reports, this increased kinase activity is associated with increased GTP binding (Guo et al. 2007; Berger et al. 2010). Membrane-associated LRRK2 also has decreased levels of phosphorylation compared to cytosolic LRRK2 (Berger et al. 2010). More recently, Schapansky et al. provided evidence suggesting that membrane recruitment of LRRK2 in macrophages is an essential step necessary for the regulatory role of LRRK2 in autophagy (Schapansky et al. 2014).

Although the focus of this chapter is on immune cells, the reader is directed to reviews that highlight the role of LRRK2 in neuronal cells and its function in the brain. Gomez-Suaga et al. writes an in depth review of the neurobiology of LRRK2 and its role in autophagy and synaptic alterations (Gómez-Suaga et al. 2014), Blesa et al. discusses dopaminergic cell vulnerability in the context of LRRK2 animal models of PD (Blesa and Przedborski 2014), Martin et al. provides an overview of LRRK2 pathobiology and neuronal dysfunction (Martin et al. 2014), and Rudenko et al. details the direct toxic effect LRRK2 can have on neurons in addition to the shortening of neurite outgrowths associated with mutations (Rudenko and Cookson 2014).

9.4 LRRK2 Mutations, Polymorphisms, and Disease

There are multiple mutations and normal genetic variations in the LRRK2 locus that have been identified and associated with disease (Brice 2005); however, six of these are known to be the most common pathogenic mutations in PD (Rudenko and Cookson 2014). Four of these, R1441G, R1441C, R1441H, and Y1699C, are located in the ROC-COR GTPase domain, and two, G2019S and I2020T are in the kinase domain (Rideout and Stefanis 2014; Greggio and Cookson 2009). Mutations in LRRK2 account for 1–2 % of all PD cases, but are particularly prevalent in the Ashkenazi Jewish population (40 %) and North African Arab population (39 %) (Thaler et al. 2009). The mutation penetrance ranges from 28 % at 54 years of age to 74 % at 79 years of age. In terms of clinical presentation and pathology, LRRK2-associated PD most closely resembles sporadic PD, making it an important model to study the underlying cause of sporadic PD (Aasly et al. 2005; Thaler et al. 2009; Haugarvoll et al. 2008; Kumari and Tan 2009). Because LRRK2 mutations generally cause late-onset PD, LRRK2 is thought to be a susceptibility gene that increases an individual's risk with age.

The R1441G and R1441C mutations, located in the ROC GTPase domain, result in decreased GTPase activity (Guo et al. 2007; Lewis et al. 2007). These mutations also exhibit neuronal toxicity. In an R1441C knock-in mouse model, although there was no dopaminergic neuron loss, the mice had impaired dopaminergic neurotransmission and D2 dopamine receptor dysfunction (Tong et al. 2009). Another mutation, Y1699C is in the COR domain and also results in a decrease in GTPase activity (Gotthardt et al. 2008). This mutation also disrupts Wnt signaling by weakening interactions between LRRK2 and disheveled (DVL) proteins while the R1441G and R1441C mutations strengthen the interaction (Sancho et al. 2009).

The most abundant mutation, G2019S, is located in the kinase domain and results in enhanced kinase activity (West et al. 2005; Greggio et al. 2006) due to stabilization of the kinase activation loop (Gilsbach and Kortholt 2014). Neuronal cell death induced by mutations in LRRK2 has been shown to be kinase dependent (Greggio et al. 2006; Smith et al. 2006). The kinase domain has homology with mitogen activated kinase kinase kinase (MAPKKK) proteins, a series of proteins essential to the MAPK signaling pathway. MAPK signaling is a pathway that begins at the membrane and ultimately results in activation of transcription factors that affect gene expression (Yang et al. 2013). Studies addressing signal transduction of the MAPK pathway in leukocytes found decreased phosphorylation of Src, HSP27, and JNK in both patients with G2019S PD and idiopathic PD compared to healthy controls (White et al. 2007). Although not directly correlated with LRRK2 kinase activity, this indicates a potential dysregulation of MAPK signaling that could contribute to the development of disease regardless of mutation. The similar pathology seen in both the G2019S PD and idiopathic PD is consistent with the clinical features of G2019S PD closely resembling those of idiopathic PD (Aasly et al. 2005; Thaler et al. 2009; Haugarvoll et al. 2008; Kumari and Tan 2009), reinforcing the notion that elucidation of the molecular mechanism underlying the dominantly inherited LRRK2 mutations will shed light on the causes of idiopathic PD.

In a study evaluating both protein and mRNA expression patterns in idiopathic PD and G2019S patients, it was found that there are no differences in neuronal mRNA distribution (using in situ hybridization) between idiopathic PD and G2019S subjects, with widespread neuronal LRRK2 mRNA expression seen in the neocortical regions, brainstem, locus coeruleus, hippocampus, and dopaminergic neurons of the substantia nigra. Consistent expression was also seen in vascular smooth muscle cells. Using qPCR, the authors discovered that total mRNA expression was decreased in idiopathic PD cases in the parietal cortex, cerebellum, amygdala, frontal cortex, and cingulate gyrus; however, there were no alterations in protein levels (by western blot analyses) between subjects (Sharma et al. 2011).

The I2020T mutation in LRRK2 is also located in the kinase domain, but its effect on kinase activity remains controversial. There are multiple studies reporting increased kinase activity (Gloeckner et al. 2006; West et al. 2007; Imai et al. 2008), one decreased activity (Jaleel et al. 2007), and several reports of no change (Anand et al. 2009; Luzón-Toro et al. 2007; Greggio and Cookson 2009). More recently, it has been reported that I2020T does increase kinase activity via stabilization of the kinase activation loop, similar to the mechanism of the G2019S mutation (Ray et al. 2014). The development of improved and consistent kinase assays for LRRK2 is needed to fully understand how these mutations alter enzymatic activity.

In addition to mutations, single nucleotide polymorphisms (SNPs) in LRRK2 have also been associated with disease risk. In 2008, SNPs in LRRK2 were identified as a susceptibility factor for the chronic inflammatory condition Crohn's Disease by a meta-genome wide association study (GWAS) (Barrett et al. 2008). Liu et al. identified a potential mechanism for LRRK2 in Crohn's disease via negative regulation of the (NFAT). Mice deficient in LRRK2 show increased translocation of NFAT into the nucleus and NFAT activity. LRRK2 knock-out mice also had exacerbated colitis consistent with a role for LRRK2 as a negative regulator important in controlling inflammatory bowel disease (Liu et al. 2011). LRRK2 SNPs have also been associated with susceptibility to leprosy in the Han Chinese population (Zhang et al. 2009; Wang et al. 2015). There is a protective variant of LRRK2 (M2397T) that appears to increase NFAT activity in HEK293 cells following LPS stimulation, indicating that increasing the immune response is a necessary mechanism to control *M. leprae* infection. Through the study of myriad mutations and SNPs, LRRK2 has been identified as a regulator of MAPK signaling, a negative regulator of NFAT, and thus, we have gained insight into the kinase domain and its activity. With this new and exciting information, the link between LRRK2 and immune regulation becomes stronger.

9.5 LRRK2 Regulation of the Immune System

The immune system is a highly complex and tightly regulated system responsible for protecting the body against infection, cancer, and other cellular damage. When an immune cell recognizes a foreign antigen the cell enters an activated state; a series of signaling cascades (NFAT, NFkB, Wnt, etc.) begins that results in the upregulation of pro-inflammatory cytokines, adhesion molecules, and further activation and differentiation of innate and adaptive immune cells. This pro-inflammatory state results in altered cell trafficking, differentiation, and mRNA and protein expression,

all of which are part of an orchestrated response aimed at elimination or neutralization of the invading pathogen.

LRRK2 is a member of the receptor interacting protein (RIP) kinase family, which are proteins that detect and respond to cellular stress by regulating cell death and activation of the immune system (Meylan and Tschopp 2005; Zhang et al. 2010). In various cell types, LRRK2 expression has been reported to increase in response to the pro-inflammatory signals IFN- γ (Thevenet et al. 2011; Gardet et al. 2010; Kuss et al. 2014), LPS (Hakimi et al. 2011; Moehle et al. 2012), and IL-1 β (Hongge et al. 2014). Increases after IFN- γ stimulation have been observed in CD14+ macrophages, CD3+ T cells, and CD19+ B cells (Thevenet et al. 2011; Gardet et al. 2010; Kuss et al. 2014). Also, IFN- γ stimulation was shown to increase LRRK2 mRNA and protein expression specifically in the non-classical CD14+CD16+ monocyte population (Thevenet et al. 2011). Inhibition of LRRK2 with multiple inhibitors results in decreased CD14, CD16, and MHC-II expression indicating that LRRK2 is playing a significant role in the activation of monocytes via IFN- γ (Thevenet et al. 2011). Recently, it was reported that increased expression of LRRK2 in monocytes following IFN- γ stimulation is via extracellular signal-related kinase 5 (ERK5) signaling (Kuss et al. 2014).

G2019S LRRK2 has also been linked to increased phosphorylation of ERK1/2 and dysregulation of basal autophagy through this pathway (Bravo-San Pedro et al. 2013; Reinhardt et al. 2013). LRRK2 mRNA levels increased following LPS stimulation of mouse bone marrow derived macrophages (BMDMs) (Hakimi et al. 2011). In addition, LRRK2 protein levels in these BMDMs increased following transduction of lentiviral particles (Hakimi et al. 2011). Following cranial injection of LPS, microglia also display increased expression of LRRK2 and increased kinase activity (Moehle et al. 2012). Interestingly, despite strong up-regulation of LRRK2 protein with LPS stimulation, no changes in LRRK2 mRNA levels were seen (Moehle et al. 2012). LRRK2 is also increased in the gut lamina propria macrophages, B cells, and dendritic cells of patients with Crohn's disease who experience chronic inflammation in the gut (Gardet et al. 2010). Increased LRRK2 expression after inflammatory stimulus dependent on ERK signaling implicates LRRK2 as key player in regulation of inflammatory signaling pathways.

In human umbilical vein endothelial cells (HUVECs), LRRK2 expression is increased following stimulation with IL-1 β (Hongge et al. 2014). In addition, IL-1 β also leads to increased induction of VCAM-1, an adhesion molecule important for immune cell trafficking, in HUVECs overexpressing both WT and G2019S LRRK2. This increased VCAM-1 induction appears to be kinase dependent, as the kinase dead LRRK2 mutant, K1347A, does not recapitulate this phenotype (Hongge et al. 2014). Overexpression of WT

LRRK2 and expression of the G2019S mutant led to increased phosphorylation of I κ B α allowing for increased translocation of NF κ B into the nucleus (Hongge et al. 2014). NF κ B is the transcription factor that controls expression of pro-inflammatory cytokines, chemokines, and adhesion molecules. In this way, LRRK2 levels or activity may be critical in modulating NF κ B-dependent responses in immune cells.

In support of this, the LRRK2 knockout rat was reported to be protected from LPS and α -synuclein induced neurodegeneration. There are also fewer proinflammatory myeloid cells in the brains of these rats indicating that inhibition of LRRK2 could decrease the neuroinflammation and cell loss seen in PD (Daher et al. 2014). Furthermore, there are altered immune cell frequencies detected in the spleen of these LRRK2 knockout rats (Ness et al. 2013). Under normal resting conditions, the LRRK2 knockout rat spleens have higher percentages of CD4, CD3, and CD11b positive cells, but significantly lower B cells (Ness et al. 2013). When infected with a rat-adapted influenza virus, the LRRK2 knockout rats showed a decreased percentage of CD11b+ cells, but an increase in the percentage of CD3+, CD4+, and CD8+ cells compared to their wild-type counterparts (Ness et al. 2013). Although these LRRK2 knockout animals have little-to-no PD-like pathology, they do exhibit significant pathology in the kidneys with accumulation of α -synuclein and ubiquitinated proteins, severe dysfunction in the autophagic-lysosomal pathways, and increased inflammatory and oxidative stress damage (Tong and Shen 2012; Ness et al. 2013).

In addition to kidney pathology, LRRK2 knockout rats and mice also have lung pathology with enlarged lysosome-related storage organelles called lamellar bodies (LB) in type II alveolar lung epithelial cells (Herzig et al. 2011; Baptista et al. 2013; Miklavc et al. 2014). LBs are important for storage of surfactant, a compound necessary to maintain proper surface tension and equilibrium in the lung. After ATP treatment, LRRK2 knockout rats showed increased calcium-dependent exocytosis of LBs indicating that LRRK2 plays a modulatory role in calcium signaling and exocytic pathways (Miklavc et al. 2014). With the lung being a barrier site in the immune system, the apparent homeostatic role of LRRK2 in lung function is another indication that LRRK2 is necessary for proper immune function and control.

In a study using mice overexpressing LRRK2 with the R1441G mutation, microglia stimulated with LPS had increased expression and secretion of proinflammatory cytokines compared to wild type LRRK2 microglia (Gillardon et al. 2012). Expression of LRRK2 protein was also significantly increased in both wild type and R1441G microglia following stimulation with LPS or IFN- γ (Gillardon et al. 2012). Conditioned media from the LRRK2 R1441G mutant stimulated microglia was then added to primary neuronal cultures and resulted in an increase in neuronal death compared to the conditioned media from wild type LRRK2

stimulated microglia (Gillardon et al. 2012). In an *in vitro* kinase assay, R1441C mutations lead to increased kinase activity and a decreased rate of GTP hydrolysis (Guo et al. 2007). Additionally, there is evidence supporting the idea that GTP binding stimulates LRRK2 kinase activity, indicating the potential role of LRRK2 in integrating cellular signaling pathways (Guo et al. 2007).

In a human dermal fibroblast model, a LRRK2 dependent increase in COX-2 RNA, but not protein levels, was observed in subjects with G2019S PD, R1441G PD and idiopathic PD compared to age-matched controls (Lopez de Maturana et al. 2014). Knockdown of LRRK2 also led to blunted COX-2 responses after LPS stimulation (Lopez de Maturana et al. 2014). Following stimulation with LPS, fibroblasts from subjects with idiopathic PD and subjects with LRRK2 R1441G mutations showed blunted responses as evidenced by diminished IL-6 and TNF- α RNA levels (Lopez de Maturana et al. 2014). Consistent with previous reports, in these fibroblasts LRRK2 RNA levels increased following IFN- γ stimulation, but were shown to decrease with LPS stimulation (Lopez de Maturana et al. 2014). Following LPS stimulation, in R1441G and iPD fibroblasts, NF κ B transcriptional activity was attenuated, consistent with a modulatory role of LRRK2 in NF κ B activation (Lopez de Maturana et al. 2014). Taken together, these studies implicate LRRK2 as a key regulatory protein in inflammation. These types of studies remain unreplicated in immune cells, but studies of this kind would shed light on the physiological role of LRRK2 in immune cells should the regulation turn out to be similar in nature.

9.6 LRRK2 Kinase/Small Molecule Inhibitors

Because many pathogenic LRRK2 mutations result in enhanced kinase activity, a proposed logical next step in PD therapeutics has been to develop inhibitors to dampen this increased activity. Because the sequence similarities between kinases are high, it is difficult to develop an inhibitor specific to the LRRK2 kinase domain; however, there are a few significant amino acid differences in LRRK2 that can be exploited. The DFG hinge motif in the activation loop of most kinases is DYG in LRRK2 and DYS in the G2019S mutation (West 2014; Peng et al. 2013). Despite this unique sequence, highly selective LRRK2 inhibitors remain elusive. What follows is a brief summary of important experiments using inhibitors to investigate LRRK2 function. The reader is directed to a review of LRRK2 inhibitors, their efficacy and specificity by Kramer et al. (Kramer et al. 2012) and a review of patents by Kethiri et al. (Kethiri and Bakthavatchalam 2014) for additional detail.

LRRK2-IN-1 is currently the most popular and widely used small molecule inhibitor of LRRK2; however its use has significant caveats. It does not cross the blood brain bar-

rier limiting its utility as a therapy for neurodegeneration. It also potentially inhibits ERK5, another ubiquitous kinase that regulates cell signaling, limiting its use both in research and the clinic (Deng et al. 2011). In a mouse microglial culture, treatment with LRRK2 inhibitors LRRK2-IN-1 and sunitinib decreased p38 MAPK phosphorylation and iNOS induction, two molecules important for the TNF release pathway (Moehle et al. 2012). Although, this data suggests that inhibition of LRRK2 could dampen a damaging inflammatory response in the brain, LRRK2-IN-1 was also shown to inhibit TNF and CXCL10 in LPS-stimulated astrocytes equally well in both LRRK2 wild-type and knock-out cultures, indicating the glaringly significant off-target effects of the inhibitor (Luerman et al. 2014).

LRRK2-IN-1 inhibits IFN- γ -dependent induction of LRRK2 in THP-1 differentiated macrophages and human monocyte-derived macrophages (Kuss et al. 2014). This inhibition is specific, as other LRRK2 kinase inhibitors do not prevent increased LRRK2 expression after stimulation (Kuss et al. 2014). Because of the cross-reactivity of LRRK2-IN-1 with extracellular signal-regulated kinase 5 (ERK5), IFN- γ -induced expression of LRRK2 was proposed and determined to be dependent upon ERK5 levels and activity (Kuss et al. 2014).

A promising new inhibitor, PF-06447475 was recently characterized and shown to be highly specific to LRRK2. Because it has just become available for commercial research, few experiments have been done, but *in vivo* studies from the initial characterization of the drug show high blood brain barrier (BBB) permeability and safety. Future studies will provide more accurate information on the kinase activity and specific function of LRRK2. Unfortunately, these studies indicate that the PK is too high to develop as a therapeutic in the clinic (Henderson et al. 2015).

The requirement for BBB permeability further complicates the use of LRRK2 inhibitors to treat neuronal dysfunction. As research supporting the regulatory role of LRRK2 in the peripheral immune system increases, BBB permeability may no longer be necessary for therapeutic use of inhibitors, slightly improving the ease of developing clinically relevant therapies. Currently, there are no clinical trials with LRRK2 inhibitors, however large cohorts of LRRK2 mutations carriers have been identified to expedite the process of future clinical trials (West 2014). With the current information about LRRK2 mutations, specifically G2019S, and the lack of disease-modifying therapies available, the case for LRRK2 inhibitors is strong.

9.7 Conclusion

Although the physiological roles of LRRK2 and the molecular mechanism and pathways that link it to PD pathogenesis have yet to be fully defined, it is an important kinase.

Elucidating LRRK2 function will give researchers a better understanding of the relationship between chronic inflammatory conditions and age-related neurodegenerative disease. Through the study of LRRK2 mutation carriers both with and without disease, we have gained better understanding of the multiple domains and the complex activities of this large protein in neuronal and non-neuronal cells. With widespread expression in both the immune and nervous systems, LRRK2 remains an interesting, yet challenging, pharmacological target. Through the development of more specific LRRK2 kinase inhibitors, the possibility of a disease-modifying therapy for a progressive condition that hasn't seen a new treatment in over 60 years remains bright on the horizon.

9.8 Review Questions

1. What is the role of the relationship between the GTPase and the kinase domains in LRRK2 in terms of kinase function?
2. What cell types have been shown to express LRRK2 protein?
3. What diseases have been associated with common genetic variants in LRRK2 or in mutations in LRRK2?
4. What signaling pathways has LRRK2 function been implicated in that may have a role in immune cell function?
5. How might LRRK2 kinase inhibitors be potentially beneficial even if they do not cross the blood-brain barrier?

9.9 Answers

1. The LRRK2 GTPase domain has been shown to function as a GTPase and GTP binding is essential for the regulation of LRRK2 kinase activity.
2. Full length LRRK2 has been detected via western blot in neurons, microglia, astrocytes, monocytes, dendritic cells, B cells and T cells as well as endothelial cells.
3. Common genetic variants or single nucleotide polymorphisms in LRRK2 have been associated with Crohn's disease. Mutations in LRRK2 in the GTPase and kinase domains cause dominantly inherited forms of Parkinson's disease. The R1441G, R1441C, R1441H, and Y1699C mutations are located in the ROC-COR GTPase domain, and the G2019S and I2020T mutations are in the kinase domain. Mutations in LRRK2 account for 1–2 % of all PD cases, but are particularly prevalent in the Ashkenazi Jewish population (40 %) and North African Arab population (39 %).
4. LRRK2 has been implicated in regulation of autophagy, lysosomal flux, NFAT, NFkB, and MAPK and Wnt sig-

naling, all of which play important regulatory roles in immune cell effector function.

5. LRRK2 kinase inhibitors may be beneficial in the periphery to treat the inflammatory phenotype that may be associated with LRRK2 dysfunction in immune cells in patients with PD.

Malabendu Jana and Kalipada Pahan

Abstract

Astrocytes being the most abundant cell types in the mammalian brain are intimately associated with a plethora of functions that are vital to central nervous system (CNS) physiology, including the development and maintenance of the vasculature scaffold and blood brain barrier, synaptogenesis, neurotransmission, and preservation of metabolic homeostasis. Astrocytes also play important roles in supporting the development and maintenance of central nervous system myelin. Accordingly, astrocytes have been directly associated with several neurological disorders including Alzheimer's disease (AD), Parkinson's disease, inflammatory demyelinating diseases, HIV-associated dementia (HAD), acute traumatic brain injury, and prion-associated spongiform encephalopathies. Other non-neuronal cell types such as, oligodendrocytes in the CNS and Schwann cells in the peripheral nervous system (PNS) are known to play an important role in the homeostasis of the nervous system. These cells wrap their plasma membranes around axons to organize myelinated nerve, thereby allowing rapid saltatory conduction. Oligodendrocytes and Schwann cells produce different type of protein, lipid and growth factors that promote neuronal survival, axonal growth and process formation.

Astrocytes • Autoimmunity • Calcium excitability • Ceramide • CNPase • Gap junction • Glial activation • Glial fibrillary acidic protein • Glial scar • Myelination • MBP • MOG • Neurotrophins • PLP • Oligodendrocytes • Oxidative stress • Schwann cells • Vimentin

10.1 Introduction

The only difference between Albert Einstein's brain and others is the greater presence of healthy-looking and star-like astrocytes in the former. Therefore, astrocytes are not silent partners

of neurons providing only structural and metabolic support. These cells also regulate synapse formation, maturation, efficacy and plasticity. They ultimately control learning and memory and for Einstein his genius. It is now well accepted that astrocytes possess ion channels as well as G-protein coupled receptors necessary to sense and respond to neuronal activities. Similarly, myelination of neurons, oligodendrocytes, the other macroglia secrete growth factors to help neuronal growth and development and participate in cell-to-cell communication in more sophisticated way in humans than rodents, probably contributing to superior plasticity of the human brain. However, under disease conditions, astrogliosis occurs as a consequence of activation and cell proliferation. Activated astroglia also secrete proinflammatory molecules that affect neuronal loss and damage oligodendrocytes in neurodegenerative and

neuroinflammatory demyelinating disorders. The present chapter discusses the biology and functional aspects of astrocytes, oligodendrocytes and myelinating Schwann cells ranging from their genesis to their immense role in maintaining peripheral and central nervous system (PNS and CNS) homeostasis and plasticity.

10.2 Astrocyte and Oligodendrocyte Development

The vertebrate nervous system including neurons, astrocytes, oligodendrocytes (OLs), and other cells originates from a flat sheet of neuroepithelial cells, constituent of the inner lining of neural plate along the dorsal surface of embryo (Fujita 2003). These neuroepithelial cells are the earliest precursors in the developing CNS. During embryonic development, radial glia cells derived from the neuroepithelium are the primary neural stem cells (NSCs) that produce neurons, astrocytes and OL throughout the brain (Kriegstein and Alvarez-Buylla 2009).

10.2.1 Generation of Glial Precursor Cells

During neurogenesis, neuroblasts are first derived from stem cells and then migrate peripherally to the mantle and marginal layers in the developing brain. After that, DNA synthesis in neurons is completely ceased and the progenitor cells enter into the phase of gliogenesis in the neural tube. These glioblasts eventually differentiate first into functional astrocytes and then OLs. Differentiation of cortical progenitor cells is being controlled by some transcription factors having basic-helix-loop-helix (bHLH) motifs. These are NeuroD, Neurogenin, Mash, Olig, Id, and Hes families of protein. The restricted and time-dependent binding of these transcription factors with corresponding DNA sequences present in the promoter of different developmental genes determines the outcome of final cell types.

10.2.2 Signaling Events Driving the Precursors to Astrocytes

Astrogenesis occurs toward after neurogenesis. Astrocyte development is regulated, in part, by cell-intrinsic pathways such as chromatin modifications. Extrinsic signals such as growth factors/cytokines affect the molecular mechanisms involved in astrocyte fates from neural progenitor cells (NPCs) to mature glia remain poorly understood.

One signaling pathways known operative in astrocyte growth and differentiation is Wnt signaling. It is required for critical activation of the proneural genes neurogenin (ngn) 1 and 2 in neural progenitor cells (NPCs). However, Wnt

ligands continue to be expressed in the nervous system even after the neuron to glia transition, during which time they fail to induce neurogenin expression in NPCs. Hirabayashi et al. found key intrinsic changes in histone H3 acetylation and trimethylation at the neurogenin 1 and 2 promoters in NPCs (Hirabayashi et al. 2009). Treatment with histone deacetylase (HDAC) inhibitors results in an increase in neurogenin expression in older, but not younger NPCs, which indicate that HDAC activity negatively regulates the expression of neurogenin in late NPCs. Consistent with a closed chromatin conformation at ngn loci, it was also observed that RNA polymerase II associated at relatively low rates with ngn promoters in late-stage NPCs. This epigenetic change in NPCs competence is mediated by the polycomb group complex (PcG). Knockout of key components of the complex prolongs the NPC neurogenic phase and delays the production of astrocytes. Thus despite the continued presence of Wnts, NPCs are able to make the neuron-to-glia switch in part because of intrinsic epigenetic changes that lead to PcG-dependent suppression of expression of the neurogens.

Activation of bone morphogenic protein 2/4 (BMP 2/4) signaling results in phosphorylation of SMAD transcription factors and their association with STAT3 to regulate expression of astrocyte-specific genes. It is also well established that the BMP and Notch pathways cross-talk with the JAK-STAT pathway and promote astrocyte differentiation. DNA methylation at astrocytic gene loci maintained by Dnmt1 is essential for antagonizing STAT signaling during the neurogenic phase, and the Notch-NF1A pathway has been shown to overcome this effect of Dnmt1 in inducing astrocyte differentiation. Other molecules unrelated to STAT signaling have also been implicated in the regulation of astrocyte differentiation, including Sox9, SCL, REST, SRF, KLF15, HMGN, MEK-Etv5, and NFE2L1. However, how these factors regulate astrocyte differentiation is not yet fully understood (Nagao et al. 2014).

Furthermore, β 1-integrin signaling is also becoming an important regulator of astrocytic differentiation. Conditional knockout of β 1-integrin enhances astrogliogenesis both by cultured ESCs and by subventricular zone (SVZ) progenitor cells. Integrin-linked kinase (ILK) is known to interact with the cytoplasmic domain of β 1 integrin. Recent study demonstrates an important role for β 1-ILK signaling pathway in regulating astrogliosis from ESCs and suggest ILK as a potential target for limiting glial scar formation after nervous system injury (Pan et al. 2014).

10.2.3 Signaling Events Driving the Precursors to Oligodendrocytes (OLs)

During mammalian development, oligodendrocyte precursor cells (OPCs) differentiate into OL, ultimately resulting into

myelination of axons. The OPCs in caudal as well as ventral neural tube originate under the influence of Shh protein secreted from ventral midline. At this initial stage, Shh patterns the ventral neuroepithelium by controlling the expression of a set of transcription factors PAX6, NKX 2.2, high mobility group protein SOX10, and basic helix-loop-helix proteins OLIG1 and OLIG2. These Olig genes and SOX10 are co-expressed in cells before the appearance of PDGF- α on OPCs. These PDGF-positive OPCs then proliferate and migrate away from the ventricular surface to all parts of the CNS before differentiating into functional myelin forming mature cells. Other transcription factors, including SOX9, SOX17 and Ying Ying, play a critical roles in OL specification.

In the CNS, astrocytes produce ciliary neurotrophic factor (CNTF) and leukemia inhibitory factor (LIF). Both CNTF and LIF are capable of enhancing the generation of OL in cultures of dividing O-2A progenitors. CNTF and LIF also promoted OL maturation, as determined by expression of MBP, and could promote OL survival similar to insulin-like growth factor-1 or insulin (Mayer et al. 1994).

Activation of the Notch pathway is another important regulator of OL differentiation. It has been shown that the differentiation of OL is suppressed by the activation of the Notch signaling pathway (Yoon and Gaiano 2005). It is possible that aberrant expression of Notch ligand limits the amount of remyelination that occurs after injury.

10.3 Astrocytes: Biology and Function

In the middle of the nineteenth century, German anatomist and pathologist Rudolph Virchow was wondering about the group of cells in the brain that surround the neurons and fill the spaces between them. Dr. Virchow named these cells as “neuroglia” means “neural glue”. He used the term ‘glue’ to represent the gluing function of these cells to hold the neurons in place. Nowadays ‘neuroglia’ is collectively used for all glial cells in the CNS. Later on, due to “star-shaped” appearance, the major neuroglial cells were named as “Astrocytes” (Astra: star; cyte: cells).

10.3.1 Morphology and Markers

Morphologically, astrocytes are classified into two types: fibrous and protoplasmic astrocytes (Oberheim et al. 2012). Fibrous astrocytes are located predominantly in white matter and possess fewer but longer processes. These processes form cytoplasmic bundles of intermediate filaments (IFs). The major constituent of these are glial fibrillary acidic protein (GFAP). Under light microscope, the fibrous astrocytes look like a star-shaped cell body with finer processes.

Until recently, most studies used GFAP stains to characterize astrocyte morphology. This marker, however, reveals only the structure of primary branches, which represent a meager ~15 % of the total cell volume. Immunohistochemical staining with an aldehyde dehydrogenase 1 family member L1 (Aldh1L1)-specific polyclonal antibody divulges highly branched astrocytes morphology, including the astrocyte cell body and its extensive processes. In contrast, GFAP antibodies primarily label the thick main processes of some astrocytes. All cells positive for GFAP are also labeled with Aldh1L1, whereas Aldh1L1 strongly labels many more astrocytes (Cahoy et al. 2008).

The protoplasmic astrocytes, on the other hand, are found throughout all grey matter and generally express S100 β . They contain highly branched processes that form membranous sheets surrounding the neuronal processes, cell bodies and end-feet on capillaries. In contrast to fibrous astrocytes, these cells have fewer IFs and a greater density of organelles. Classical and modern neuroanatomical studies also indicate that both astrocytes subtypes make extensive contacts with blood vessels.

Apart from the ultrastructural study, astrocytes can also be identified on the basis of marker proteins (Table 10.1).

10.3.2 Heterogeneous Population of Astrocytes in the CNS

Astrocytes are amongst the most heterogeneous and versatile type of neuroglia. Astrocytes cover many types of cell such as, e.g., protoplasmic, fibrous, velate, perivascular and marginal astrocytes, radial glia of retina and cerebellum, Bergmann glia of the cerebellum, cribrosocytes at the optic nerve head, tanycytes and pituicytes of hypothalamus and neurohypophysis as well as ependymocytes and choroid plexus cells. Astrocytes are present throughout the CNS populating both gray and white matter (Verkhratsky et al. 2003). On the basis of morphology and antigenicity, astrocytes from optic nerve cultures were also designated as type 1 and type 2 (Raff et al. 1983). The type 1 astrocytes were originally defined as flat, polygonal cells that expressed GFAP but did not bind anti-ganglioside monoclonal antibodies A2B5 or R24 and LB1 except rat neural antigen 2 (Ran 2). These type 1 astrocytes proliferate well in the presence of epidermal growth factor and are found during gliogenesis in early developmental stage. On the other hand, type 2 astrocytes are found as GFAP⁺A2B5⁺ cells in rat optic nerve culture.

However, it is yet to be delineated whether these morphologically distinct heterogeneous populations of astrocytes are also different in their function or such morphological differences are merely intrinsic.

Table 10.1 Markers of astrocytes

Marker	Function	Cellular localization	Molecular weight
GFAP	Major constituent of intermediate filament found mostly in adult astrocytes	Cytoplasm	50 kDa (predicted)
EAAT1	Transport of amino acids	Cytoplasm	59.5 kDa
Glutamine synthase	In CNS, the enzyme found only in astrocytes; it catalyzes conversion of glutamate to glutamine	Cytoplasm	43 kDa
S-100 β	Ca-binding proteins	Cytoplasm/nucleus	21–24 kDa
Aldh1L1	Nucleotide biosynthesis and regeneration of methionine	Cytoplasm	99 kDa

GFAP glial fibrillary acidic protein, EAAT1, excitatory amino acid transporter, Aldh1L1 aldehyde dehydrogenase 1 family member L1

Fig. 10.1 Maintenance of CNS integrity by astrocytes. Astrocytes end-feet forms a network on blood capillary and regulate transfer of water, ions and sugars. The presynaptic position of astrocytes is critical for the uptake of excitotoxic glutamate from neuronal synapse

10.3.3 Physiological Role of Astrocytes in the CNS

10.3.3.1 Maintaining CNS Homeostasis

Providing Structural Support

Astrocytes are considered as structural support cells. The anatomy of brain microvasculature shows that astrocytic end feet constitute an envelope around blood vessels (Kacem et al. 1998). Astrocytic processes are positioned beneath the pial membrane and the ependymal surface and thereby

segregate the CNS parenchyma from external environment (Fig. 10.1). The cytoplasmic processes of astrocytes form a close network around the synaptic complex and maintain synaptic integrity (Newman 2003). Over the past 10 years, many compelling lines of evidence have shown that astrocytes powerfully control every stage of synapse formation, maturation and elimination to support the development and maintenance of neural circuits. The Barres laboratory identified the proteins involved as TSPs, a group of matricellular proteins that are expressed in astrocytes of the developing but not mature brain, and TSP1/2-deficient mice were shown to have reduced numbers of synapses in vivo (Molofsky et al. 2012)

Maintaining Water Balance

Water is essential to the CNS for formation and maintenance of cerebrospinal fluid. Water enters into the CNS either through diffusion due to difference in osmotic pressure or through some specified channels. Astrocytes, through membrane-bound transporter system, maintain water and ionic homeostasis in the brain. The co-transporter system like “sodium-glutamate co-transporter” (Na⁺-glutamate, EAAT1) and sodium-potassium-chloride ion co-transporter (Na⁺-K⁺-Cl⁻ co-transporter, NKCC) are located on astroglial membrane and regulate astrocytic water transport into the CNS (Fig. 10.1).

Apart from the co-transporters, astrocytic perivascular system in the brain involves membrane-bound water channels, called aquaporins. Among several members of the aquaporin family, aquaporin 1, 4 and 9 are expressed in astrocytes. Specifically, aquaporin 4 water channels are densely clustered along astrocyte processes that contact blood vessels and play a critical role in regulating fluid homeostasis in healthy CNS and play roles in vasogenic and cytotoxic edema (Nagelhus and Ottersen 2013). The aquaporins activities are regulated by transmembrane G-protein coupled receptor (GPCR) family of hormonal receptors and micro RNA-130a.

Maintaining Ion Homeostasis

Astrocytes are responsible in maintaining extracellular K⁺ ion concentration at a level compatible with neuronal function.

Astrocytes form a syncytium through which it efficiently redistributes K^+ from perineuronal to perivascular space. Such redistribution of K^+ is mediated by inwardly rectifying K^+ ion channels. One such K^+ ion channel Kir 4.1 is expressed in astrocytes surrounding neuronal synapses as well as blood vessels in the brain (Nagelhus et al. 2004). In addition to having K^+ channels, astrocytes bear plenty of other ion channels such as Na^+/K^+ ATPase, the K^+/Cl^- co-transporter KCC1 and $Na^+/K^+/Cl^-$ co-transporter NKCC1; function of many of these transporters is still under research. Similarly astrocytes regulate extracellular concentration of Cl^- through either Cl^- efflux via anion channels or Cl^- accumulation by NKCC1. Astrocyte cell surface bears an atypical sodium channel Nax that is assumed to be under voltage-gated sodium channel family. It has been suggested that glial cells bearing Nax channel are the first to sense a physiological increase in sodium level in body fluids (Watanabe et al. 2002).

Regulating Neurotransmitter and Amino Acid Levels

Astrocytes are active participants in the formation of tripartite synapse and modulate synaptic activity of neurons. Glutamate plays a central role in astrocytic-neuronal interactions. This excitatory amino acid released by neurons, is taken up by astrocytes from the neuronal synapses via their glutamate transporters. Astrocytes convert glutamate into glutamine and release into the synaptic cleft for being taken up by neurons (Hertz and Zielke 2004). Accumulated glutamine is converted to glutamate in glutamatergic neurons within the mitochondrial membrane, enters the mitochondrial matrix, and is returned to the cytoplasm in a pseudomaltate-aspartate shuttle". Astrocytes express several receptors linked to ion channels and second messenger pathways. Activation of receptors e.g. metabotropic glutamate receptor, in turn, elevates intracellular level of Ca^{2+} . Calcium-dependent glutamate release from astrocytes modulates the activity of both excitatory and inhibitory synapses (Fig. 10.1). Apart from glutamate, astrocytes uptake a number of neurotransmitters. This includes gamma amino butyric acid (GABA), aspartate, taurine, β -alanine, serotonin and catecholamines. The fate of such neurotransmitters is astrocyte metabolism.

Detoxifying Ammonia

The brain is especially vulnerable to ammonia as it readily crosses the blood-brain barrier in its gaseous form, NH_3 , and rapidly saturates its principal removal pathway located in astrocytes. Ammonia toxicity may result in neurological abnormalities leading to seizures, mental retardation, brain edema, convulsion, coma and death. Diverse and complex amino acid cycles have been suggested to be involved in the transport of NH_4^+ from neurons to astrocytes. NH_4^+ may be transported as such, especially since NH_4^+ is rapidly accumu-

lated in astrocytes by Na^+ , K^+ -ATPase activity. One of the most important enzymes that catalyze the formation of ammonia in the brain is glutamate dehydrogenase. The enzyme catalyzes reversible oxidative deamination of glutamate and produces ammonia particularly in astrocytes, thereby provides a mechanism for the removal of excess nitrogen from certain amino acids. Brain lacks carbamoyl phosphate synthase 1 and ornithine transcarbamylase, essential enzymes for the urea cycle, and thereby unable to remove accumulated ammonia (Cooper and Plum 1987). However, astrocytes convert excess ammonia to glutamine via glutamine synthase (Fig. 10.1). The excreted glutamine from astrocytes is taken up by neurons. In fact, either in physiological condition or even in hyperammonemic condition, rapid conversion of ammonia to glutamine is the predominant CNS detoxification event (Bak et al. 2006).

10.3.3.2 Supplying Energy

Glucose and ketone bodies are the primary source of energy in mammalian brain under normal physiological conditions. In comparison to its weight, which is only 2–3 % of total body weight, brain consumes up to one fourth of body's total glucose supply.

Glycolysis

Astrocytes are the major food depot in the CNS. The rate of glycolysis is higher in astrocytes than neurons. Astrocytes contain higher levels of a key glycolytic enzyme, 6-phosphofructo-2-kinase/fructose-2,6-biphosphatase 3 (PFKB3) than neuron. Therefore, astrocytes defend themselves against bioenergetic crises by upregulating glycolysis, a response that is absent in neurons. Several studies suggest that glycogen phosphorylase and synthase are predominantly localized in astrocytes. Glucose is utilized in astrocytes mainly via glycolysis (Wiesinger et al. 1997). Sugars enter into the metabolic pathway through phosphorylation which is considered as rate determining step. Astrocytes express hexokinase 1, the primary isoform of hexokinase in the CNS. This enzyme is mostly localized in mitochondria, only about 30 % of it is found in cytosol. Neurons need glucose and oxygen to function, and the delivery of these essential substances from the blood is regulated by astrocytes.

Oxidative Metabolism

In order to generate energy in the form of ATP, sugars are bound to enter into oxidative metabolic pathway, the tri carboxylic acid cycle (TCA cycle) (Fig. 10.1). Glycolysis generates 2 molecules of ATP and the TCA cycle generates 30 more ATP molecules from one molecule of glucose. The formation of energy in astrocytes is either through utilization of glucose under normal physiological condition or from reserve food storage glycogen via gluconeogenesis.

10.3.3.3 Organizing the Information Network in the CNS

It is increasingly becoming clear that astrocytes form an integral and active component of the information network in the CNS and have received the ‘stardom’ reflecting their morphology (Haydon 2001; Ransom et al. 2003; Nedergaard et al. 2003). Human astrocytes are quite unique when compared to other animals; they are over 20 times larger by volume and contact up to ten-times the number of synapses as individual rodent astrocytes (Oberheim et al. 2009). Furthermore, transcriptome data of human brains demonstrate significantly increased expression of astrocyte-derived synaptogenic proteins (Caceres et al. 2007; Sloan and Barres 2014).

Astrocytes are a critical participant of “the tripartite synapse” (Araque et al. 1999; Perea and Araque 2002). Any discussion on astrocyte biology remains incomplete without a consideration of their role in information transfer and intercellular communications in the brain.

Role of GAP Junctions

In the brain, astrocytes form a syncytium, or a network of integrated cells (Scemes 2000). Such a syncytium consists of astrocytes that have cytoplasmic continuity in adjacent cells

through gap junctions (Bennett et al. 2003). There are abundant Gap junctions between astrocytes themselves, fewer between OLs and astrocytes, and few or none between OLs themselves or between neurons and glia. Gap junctions serve as a conduit between two astrocytes and consist of two hemichannels, also called connexones. These hemichannels or connexones are contributed by the juxtaposed cells and together form the gap junction (Fig. 10.2). Hemichannels assembled in the endoplasmic reticulum consist of junctional proteins belonging to the family of connexins (Contreras et al. 2003; Saez et al. 2003). Although a variety of connexins are expressed by astrocytes, connexin Cx30 and Cx43 are the predominant astrocyte connexin (Theis et al. 2005). Whereas Cx43 is expressed in early development in the nervous system and colocalizes throughout the white and gray matter in adult rodents, Cx30 is expressed later and localizes primarily to gray matter. These gap junctions form channels or pore about 1–1.5 nm in diameter and allow for the intercellular exchange of metabolites (e.g. ADP, glucose and glutathione), second messengers (e.g. cAMP and IP3) and ions (Ca²⁺, K⁺ and Na⁺) (Weber et al. 1970).

The presence of gap junctions between astrocytes and the tripartite synapse consisting of the conventional synapse ensheathed by astrocyte processes together serve as models

Fig. 10.2 The astrocyte nexus: the astrocyte processes engulf the synapse forming what is now known as the tripartite synapse, consisting of pre- and post-synaptic elements as the two components along with the astrocyte ensheathment as the third. The brain astrocytes communicate with each other through intercellular connections forming a large network on interconnected cells. These cells join through gap junctions that form a channel through which small molecules can pass from one cell to the next. Calcium, one of the molecules that can pass through these gap junctions can lead to exponential transfers within the astrocyte nexus forming a calcium wave. Such connexin 43 containing functional gap junctions are primarily observed in the astrocytes in the brain

for neuroglial interactions. Indeed, evidence from astrocyte-neuron co-cultures has demonstrated that the presence of astrocytes in neuronal cultures increases the number of synapses and their efficiency. On the other hand, gap junctional communication and function can be regulated by neurons (Nakase and Naus 2004; Orthmann-Murphy et al. 2008).

Role of Calcium

While neurons are most prominently identified with their electrical excitability and astrocytes lack such electrical impulses, calcium waves that propagate through gap junctions have emerged as the parallel mechanism to that of the transfer of electrical impulse from one neuron to another. This of course by no means suggests that calcium communication is unique to astrocytes; indeed, such signals are commonly used by a variety of cells and neurons are no exception to this. In neurons, calcium signals lead to an instant integrated electrical and chemical communication in synaptic cells. In both cultured astrocytes and astrocytes in intact brain slices, excitation of one cell can form a calcium wave transferred to several neighboring astrocytes and neurons in multiple directions. This involves elevated calcium in a single cell followed by elevated intracellular calcium in other cells. Such transfer of the calcium wave has been related to the Cx43 gap junction coupling of astrocytes both in vitro and in situ (Schipke and Kettenmann 2004). Mobilization of intracellular calcium is also widely used by astrocytes as a prominent cell signaling mechanism in response to a variety of stimuli both in physiological and pathological conditions (Verkhratsky and Kettenmann 1996).

Even more exciting is that neuronal activity can stimulate such calcium communication in astrocytes and vice versa. Thus, the role of calcium in the function of the tripartite synapse has received significant recent attention (Perea and Araque 2005; Hirrlinger et al. 2004; Araque and Perea 2004). Ca^{2+} excitability of glia is observed in response to a variety of stimuli (Verkhratsky and Kettenmann 1996). Such an elevation in intracellular calcium in a single astrocyte thus leads to the elevated calcium in the neighboring cells or the calcium wave described above. The complexity of calcium regulation in astrocytes is even greater, as has been revealed by recent studies showing that the calcium oscillations in a single cell may not even encompass the entire cell volume, but remain restricted to certain microdomains or certain processes within the astrocyte. Thus, we see the beauty of the autonomous functioning of a specific part of the cell that may have encompassed a syncytium of other cells or may ensheath certain synapses, and provide at the same time the possibility of chemical coupling of the entire cell when given the appropriate stimulus (Nett and McCarthy 2002; Kettenmann and Filippov 2002; Carmignoto and Pozzan 2002). The question as to what such calcium excitability of glia does in the neuroglial interactions is evolving.

Releasing Neuropeptides and Neurotrophins

Apart from its function as “support” cells by maintaining integrity of the CNS, astrocytes release several neuropeptides and neurotrophins. So far, five families of neuropeptides have been demonstrated to be expressed in astrocytes:

Renin-angiotensin family: The major function of renin-angiotensin system (RAS) in periphery is to maintain body-fluid homeostasis and regulate blood pressure.

Endothelins: Endothelins (ETs), a group of vasoactive peptides, acts as growth factor, exerting different functions like induction of proliferation, protein synthesis or changes in morphology. The ET1 also increases the rate of glucose 6-phosphate utilization via pentose phosphate pathway.

Enkephalins: The pentapeptide enkephalins are the ligand of orphan receptors in brain and are present mostly as precursor form in astrocytes.

Neurotrophins: Astrocytes are capable of releasing several growth factors and neurotrophic factors including epidermal growth factor (EGF), transforming growth factor (TGF), insulin like growth factor-1 (IGF-1), fibroblast growth factor-2 (FGF-2), brain-derived neurotrophic factor (BDNF), glial-derived neurotrophic factor (GDNF), and neurotrophin-3 (NT-3) (Wu et al. 2004).

IL-6 family of neuropeptides: Astrocytes release ciliary neurotrophic factor (CNTF), interleukin 11 (IL-11) and leukemia inhibitory factor (LIF), which use the same transducer chain (signal transducer gp130) as IL-6. Interestingly, these molecules help in OL survival and differentiation (Kahn and De Vellis 1994).

10.3.3.4 Facilitating Neurogenesis

One of the key advances in the field of neurobiology is the discovery that astroglial cells can generate neurons not only during development, but also throughout adult life and potentially even after brain lesion. It has been shown that in neurogenic regions of adult brain (ventricular zone, hippocampus and olfactory subependyma), astrocytes secrete factors like FGF-2, IGF-1, Shh, BDNF, GDNF, and NT-3 that induce neurogenesis (Ruiz i Altaba et al. 2002) and support the growth of neurons and neural progenitor cells (Wu et al. 2004).

10.3.3.5 Do astrocytes Help in Myelination?

Astrocytes are themselves a major source of mitogens and differentiation factors for OPCs. For example, astrocytes release PDGF α and FGF2, which in combination promote self-renewal of the OPC population. In addition, astrocytes can secrete factors (promoting- γ -Secretase, TIMP-1, TNFR2/CXCL12, CNTF and LIF-1, Osteopontin, IGF, BDNF, NRG1, Laminin & fibronectin, NT3, GDNF & NGF) that are known to modulate myelination in a positive manner.

10.3.4 Role of Astrocytes in CNS Disorders

10.3.4.1 Activation of Astrocytes and Gliosis

Astrocytes react to various neurodegenerative insults rapidly, leading to vigorous astrogliosis. This reactive gliosis is associated with alteration in morphology and structure of activated astrocytes along with its functional characteristics (Eddleston and Mucke 1993). The astrocytic processes construct a bushy network surrounding the injury site, thus secluding the affected part from the rest of the CNS area. Subsequently, astrogliosis has been implicated in the pathogenesis of a variety of neurodegenerative diseases, including Alzheimer's disease (AD), Parkinson's disease, inflammatory demyelinating diseases, HIV-associated dementia (HAD), acute traumatic brain injury, and prion-associated spongiform encephalopathies (Eng and Ghirnikar 1994). Although activated astrocytes secrete different neurotrophic factors for neuronal survival, it is believed that rapid and severe activation augments/initiates inflammatory response leading to neuronal death and brain injury. This response to injury is characterized by increased expression of GFAP, vimentin, and other proteins, including CSPGs, lipocalin 2, and serpin3n (Zamanian et al. 2012). Enhanced up-regulation of GFAP is considered as a marker for astrogliosis (Eng and Ghirnikar 1994). GFAP increases at the periphery of ischemic lesion following neurodegenerative insults. Senile plaques, a pathologic hallmark of Alzheimer's disease, are associated with GFAP-positive activated astrocytes (Nagele et al. 2004). It is reported that in various neuroinflammatory diseases, the increased GFAP expression corresponds to the severity of astroglial activation (Eng and Ghirnikar 1994).

We have described that various neurotoxins increase the expression of GFAP in astrocytes via nitric oxide (NO) (Brahmachari et al. 2006), suggesting that scavenging of NO may be an important mechanism in attenuating astrogliosis. Although the activation of NF- κ B is involved in neurotoxin-induced production of NO in astrocytes, once NO is produced, it does not require the activation of NF- κ B to induce the expression of GFAP (Fig. 10.3). However, NO induces/increases the expression of GFAP in astrocytes via guanylate cyclase (GC)—cyclic GMP (cGMP)—protein kinase G (PKG) pathway (Fig. 10.3).

10.3.4.2 Release of Proinflammatory Molecules

Upon severe activation in response to various neurodegenerative and neuroinflammatory challenges, astrocytes secrete various proinflammatory molecules including proinflammatory cytokines (TNF- α , IL-1 α , IL-1 β , IL-6, and lymphotoxin), chemokines, reactive oxygen species, reactive nitrogen species, and eicosanoids (Gendelman et al. 1994;

Van Wagoner et al. 1999). These secreted proinflammatory molecules play an important role in the pathogenesis of various neurological disorders (Heales et al. 2004). In cultured murine astrocytes, bacterial lipopolysaccharides (LPS) act as a prototype inducer of various inflammatory responses. LPS is capable of inducing the expression of proinflammatory cytokines and inducible nitric oxide synthase (iNOS) in rat primary astrocytes (Pahan et al. 1997) but unable to induce the expression of iNOS in human astrocytes.

Among different proinflammatory cytokines (IL-1 β , TNF- α and IFN- γ) tested, only IL-1 β alone is capable of inducing iNOS in human primary astrocytes (Jana et al. 2005). Similarly, among different cytokine combinations, the combinations involving only IL-1 β as a partner are capable of inducing iNOS in human astrocytes (Fig. 10.4). The combination of IL-1 β and IFN- γ induces the expression of iNOS at the highest level in human astrocytes. Different proinflammatory transcription factors are involved in the transcription of iNOS in various cell types including astrocytes (Liu et al. 2002; Pahan et al. 1997). However, it has been found that the activation of CCAAT/enhancer-binding protein β (C/EBP β) plays an essential role in the expression of iNOS in human astrocytes (Jana et al. 2005). In addition to proinflammatory cytokines, viral double-stranded RNA (Auch et al. 2004) and HIV-1 Tat also induce the expression of iNOS and the production of NO in human astrocytes (Liu et al. 2002).

10.3.4.3 Do Astrocytes Present Antigen Under Autoimmune Response?

The CNS has long been known as “immunological privileged site” as it is secluded by BBB from peripheral immune system. However, this hypothesis is gradually becoming wrong. Microglia are capable of functioning as antigen-presenting cells (APC) as they express MHC I and II molecules (Dong and Benveniste 2001). In addition, microglia also expresses co-stimulatory molecules B7.1 and B7.2 molecules which play a role during antigen presentation. Another possible candidate as CNS APC is astrocyte. Expression of MHC II in astrocyte upon stimulation with IFN- γ or viruses has been demonstrated both in vivo and in vitro. However, capability of astrocytes as APC is still a controversial point. Examination of CNS tissues in MS, shows expression of B7-1 or B7-2 co-stimulatory molecules on macrophages and microglia but not on astrocytes. Human astrocytes also do not express co-stimulatory molecules B7-1 or B7-2. On the other hand, murine astrocytes express B7-1 or B7-2 either constitutively or in the presence of IFN- γ . Conflicting results are also found in case of CD40 expression. For example, CD40 expression is observed in fetal human astrocytes but not in adult human astrocytes. Therefore, functional ability of astrocytes as APC needs more research.

Fig. 10.3 Various neurotoxins induce the expression of inducible nitric oxide synthase (iNOS) via the activation of NF- κ B. Nitric oxide produced from iNOS then induces the activation of guanylate cyclase (GC) that catalyzes the production of cGMP. Inhibition of phosphodiesterase may also increase the level of cGMP. Cyclic GMP utilizes protein kinase G (PKG) to increase the expression of GFAP. *IL-1R* IL-1 receptor, *TLR4* toll-like receptor 4, *TLR2* toll-like receptor 2, *GPCR* G protein-coupled receptor, *TLR3* toll-like receptor 3

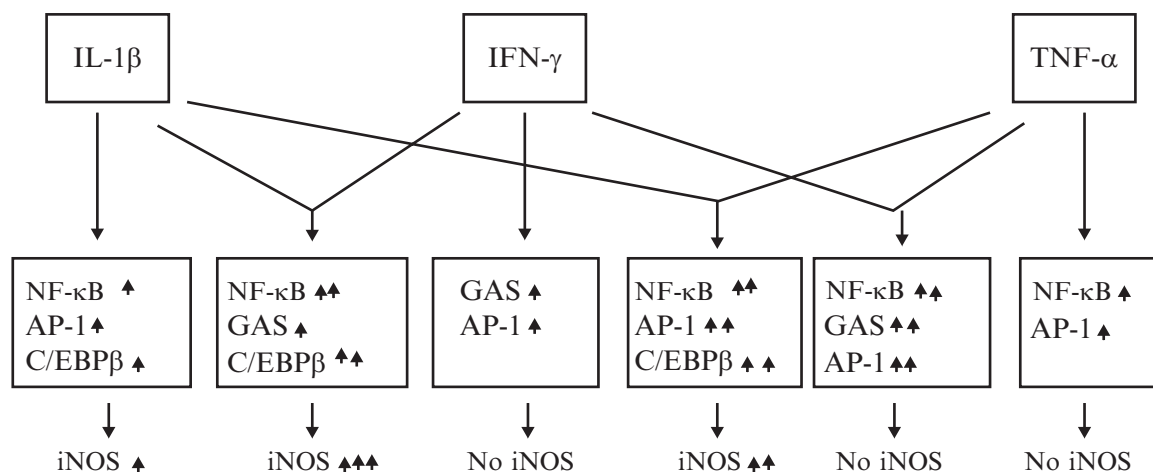

Fig. 10.4 Expression of iNOS by various proinflammatory cytokines in human primary astrocytes. TNF- α and IFN- γ alone or in combination is unable to induce the expression of iNOS. On the other hand, IL-1 β alone or in combination with other cytokines induces iNOS in human astrocytes. Activation of AP-1 and GAS together by IFN- γ is not sufficient for the expression of iNOS. Activation of AP-1 and NF- κ B together by TNF- α is also not sufficient for iNOS expression. Activation

of AP-1, NF- κ B and GAS together even at a higher level by the combination of TNF- α and IFN- γ compared to that induced by individual cytokines is also not sufficient for the expression of iNOS. However, IL-1 β capable of activating C/EBP β , AP-1 and NF- κ B induced iNOS in human astrocytes suggesting an important role of C/EBP β in the expression of iNOS in human astrocytes

10.3.4.4 Formation of Glial Scar: A Double-Edged Sword

Astrocytes play a dual role in inflammatory insults and regeneration. In one hand, activated astrocytes, characterized by cellular hypertrophy, proliferation and increased GFAP expression represent anisomorphic gliosis. This is the consequence of gross tissue damage and results in the

formation of tightly compacted limiting glial margin termed as astroglial scar or glial scar. The proinflammatory molecules released by reactive astrocytes in the scar cause tissue damage and inhibit neurite outgrowth as well as induce OL death. Chondroitin and keratin sulphate proteoglycans are among the main inhibitory extracellular matrix molecules that are produced by reactive astrocytes in the glial

scar and are believed to play a crucial part in failure to regeneration. The molecular mechanisms underlying glial scar formation have not been fully understood. STAT3, which contributes to neuroinflammation and promotes neuronal survival and regeneration after SCI, is one of the most important transducers in the process of glial scar formation. Moreover, S100A and SOX9 have also been reported to be directly involved in glial scar formation (Gris et al. 2007). More recently, it has been reported that miR-21 and miR-145 regulates astrocytic hypertrophy and glial scar progression after SCI (Yuan and He 2013). On the other hand, isomorphic gliosis, formed in response to insult, results in improved recovery and regeneration of the damaged tissue (Silver and Miller 2004). At the sites distant from injury, activated astrocytes get transformed to a more pronounced stellate shape with increased production of antioxidants and soluble growth factors that coordinate tissue remodeling in enhancing the survival of adjacent neurons and glia.

10.3.4.5 Trying to Defend Neurons Against Oxidative Stress and Excitotoxic Damage

One of the hallmarks of various neurodegenerative and neuroinflammatory disorders is oxidative stress-induced CNS damage. Such oxidative stress can damage lipids, proteins and nucleic acids of cells and power-house mitochondria causing cell death in assorted cell types including neurons and OL. However, astrocytes having high levels of antioxidant enzymes (glutathione peroxidase, catalase, glutathione reductase, and superoxide dismutase) and anti-oxidants (glutathione and ascorbic acid) try to absorb reactive oxygen species ($O_2^{\cdot-}$, O_2^- and OH^-) and reactive nitrogen species (NO , $ONOO^-$), maintain redox homeostasis and defend the insulted CNS (Dringen and Hirrlinger 2003; Chen and Swanson 2003). Accordingly, overexpression of the protective proteins, HSP72, or mitochondrial super oxide dismutase in astrocytes preserved the astrocytic glutamate transporter GLT-1 and reduced oxidative stress in the CA1 regions (Ouyang et al. 2014). In addition, astrocytes also scavenge detrimental molecules such as glutamate, produced during synaptic transmission through neurons (Hertz and Zielke 2004). Astrocytes convert glutamate to glutamine by glutamine synthetase. Moreover, activation of astrocyte specific purinergic P2Y1 receptor protects neurons from ischemic insult (Fujita et al. 2009).

10.3.4.6 Swelling of Astrocytes

Astrocytes undergo rapid swelling in certain acute pathological conditions like ischemia and traumatic brain injury. Different mechanisms are involved in such swelling process of astrocytes. Some of these are, decreasing extracellular

fluid osmolarity, intracellular acidosis, formation of ammonia, increase in Na^+ , K^+ , $2Cl^-$ co-transporter system, and due to drastically elevated levels of arachidonic acid and its metabolites. Alteration in glutamate metabolism and accumulation of glutamine and its transamination product, alanine is another possible cause of astrocytes swelling. In ischemic condition or in acute brain trauma, proton accumulation in the cytoplasm cause astroglial swelling predominantly via activation of Na^+/H^+ and Cl^-/HCO_3^- exchangers. Cytotoxic brain edema, caused due to astrocyte swelling, is a major neurological complication of the acute form of hepatic encephalopathy, a condition likely caused by elevated levels of brain ammonia. Potential mediators of ammonia-induced astrocyte swelling include oxidative/nitrosative stress (ONS), the activation of MAPKs, and the mitochondrial permeability transition (mPT) and NF- κ B. Recent studies showed that astrocyte cultures exposed to ammonia activate p53, and that such activation is mediated through ONS and MAPKs. Activation of p53 resulted in the induction of the mPT and NF- κ B activation, ultimately causing astrocyte swelling (Jayakumar et al. 2014). Blockade of p53 activation suppressed astrocyte swelling and glutamate uptake inhibition.

10.3.4.7 Apoptosis After Acute Insults

Although astrocytes usually undergo proliferation and gliosis in various neurodegenerative disorders, under acute insults, astrocytes may undergo apoptosis. Ex vivo cell culture studies demonstrate that tumor suppressor protein p53 plays a role in neuronal as well as astrocyte apoptosis (Bonini et al. 2004). HIV-1 infection of the central nervous system (CNS) frequently causes dementia and other neurological disorders in which apoptosis of astrocytes along with neuron has been found. HIV-1 infection of primary brain cultures induces the receptor tyrosine kinase c-kit and causes apoptosis of brain cells including astrocytes (He et al. 1997). The importance of c-Kit in apoptosis of astrocytes has further been confirmed by overexpressing c-Kit in an astrocyte-derived cell line in the absence of HIV-1. The mechanism of c-kit induction by HIV-1 involves transactivation of the c-kit promoter by the HIV-1 Nef protein.

10.4 Oligodendrocytes: Biology and Function

Camillo Golgi was the first to give a good description of glia. A few years later, Cajal, student of Hortega (1921) showed that there are two quite distinct cell types of neuroglia besides astrocytes using silver carbonate impregnation technique that he named oligodendrocyte (OL) and microglia. OLs are specifically the myelin-forming cells of the CNS.

10.4.1 OL Characteristics During Development

Among different brain cells, the development of OL has been well characterized. During differentiation, OL lineage cells (early OL progenitors, OL progenitors, pro-OL, immature OL, and mature OL) (Fig. 10.5) express stage-specific components that serve as markers of lineage progression (Table 10.2). Morphological characteristics of various developmental stages are shown in Fig. 10.5.

10.4.2 OL and the CNS

The major biological role of OL is myelination. However, OL may also promote neuronal survival, axonal growth and process formation. Neuronal function is also influenced by OL-derived soluble factors that induce sodium channel-clustering along axons. Trophic factors (NGF, BDNF, CNTF,

and NT3) produced from OL may provide the trophic support for both OL and local neurons.

10.4.2.1 Myelinating CNS Neurons

Myelination is a sequential multi-step process in which a myelinating cell recognizes and adheres to an axon, then ensheathes, wraps and ultimately excludes its cytoplasm from the spiraling process to form compact myelin. In humans, the period of myelination begins before birth and continues in some brain regions until 25–30 years of age. An OL is able to myelinate up to 50 axons depending on its localization. Although myelinating OLs are post mitotic, a slowly dividing population of OPCs persists in the adult brains. In addition, new OPCs are generated from subventricular zone progenitors following injury (Fancy et al. 2011).

Myelin is composed of lipids and proteins, most of which are specific for the myelin sheath. The major proteins are

Fig. 10.5 Differential stages of oligodendroglial development

Table 10.2 Stage-specific markers of OL

Developmental stages	Markers	Detection	Characterization
Precursor	PSA-NCAM, Nestin, PDGFR- α , DM-20, PAX6, SOX10, Musashi	Anti-PDGFR- α antibody	PSA-NCAM ⁺ /Nestin ⁺ /A2B5 ⁻
Oligodendrocyte Progenitor cells (OPCs)	NG2/AN2+ proteoglycan, PDGFR- α protein or mRNA, GD3-related gangliosides, DM-20, CNPase, Nkx2.2, OLIG1 (nucleus)	Anti-NG2 antibody, Anti-PDGFR- α antibody, A2B5 antibody	A2B5 ⁺ /O4 ⁻
Pro/pre-oligodendrocyte	PDGFR α , O4, GD3, NG2/AN2+, PLP/DM20, CNPase	Anti-NG2 antibody, Anti-PDGFR- α antibody, O4 antibody	A2B5 ⁺ /O4 ⁺
Immature oligodendrocytes	GalC, O4, CNPase, PLP/DM20	O4, O1/GalC, CNPase, RIP	A2B5 ⁻ /MBP ⁻ /R-mAb ⁺
Mature oligodendrocytes	GalC, O4, CNPase, MBP, PLP, MAG, MOG, OLIG1 (cytoplasm)	MBP, MOG, PLP, MAG	A2B5 ⁻ /MBP ⁺

PSA-NCAM polysialylated form of neural cell adhesion molecule, PDGFR- α platelet-derived growth factor receptor α , MBP myelin basic proteins, PLP proteolipid protein, DM20 isoform of PLP, MOG myelin oligodendrocyte glycoprotein, MAG myelin-associated glycoprotein, CNPase 2',3'-cyclic nucleotide 3'-phosphodiesterase, OLIG1 oligodendrocyte transcription factor 1 (Baumann and Pham-Dinh 2001; Deng and Poretz 2003)

MBP, PLP, CNPase, and MAG. In the CNS, axonal factors play a critical role in the myelination process and thickness of the myelin, and that myelination in the CNS depends on a balance between positive and negative axonal signal (Sherman and Brophy 2005).

Role of Proteins

Role of CNPase: CNPase was first identified in CNS myelin and it represents about 4% of the total myelin protein in the CNS. It is localized in the inner and outer margins of myelin, paranodal loops, and OLs cytoplasm but is absent from compact myelin. It possesses enzymatic activity that catalyses the hydrolysis of 2', 3'-cyclic nucleotides into their corresponding 2'-nucleotides. However, to date any substrates of this enzyme has not been detected in the brain. Therefore, precise role of this enzyme in brain is unknown. However, it is one of the earliest myelination-specific polypeptides, synthesized by OL prior to the appearance of the myelin structural proteins (MBP and PLP) and its synthesis persists into the adulthood, suggesting a role in the synthesis and maintains of the myelin sheath. Over-expression of CNPase in transgenic mice perturbs myelin formation and creates aberrant OL membrane expansion. CNPase knockout mouse study shows that this protein is required for maintaining the integrity of para-nodes (Rasband et al. 2005). Recent studies have correlated the behavior of CNPase deficient mice with psychiatric disorders. Interestingly, CNPase null mice display progressively decreasing emotionality and lower fear expression than wild type controls. Reduced expression of CNPase in heterozygous mice increases age-induced axonal degeneration, brain inflammation, and astrogliosis (Hagemeyer et al. 2012).

Role of MBP: In the CNS, the adhesion of the cytoplasmic surfaces of the multilamellar compact myelin is maintained by MBP, one of the predominant proteins in CNS myelin. It constitute about 25–30% of the total protein. The 18.5 kDa isoform of myelin basic protein (MBP) is the exemplar of the family, being most abundant in adult myelin, and thus the most-studied. Shiverer mutation of MBP gene results in the absence of MBP proteins and morphological analysis of the CNS reveals an almost total lack of myelin in the brain, and also the existing myelin is abnormal, presenting no major dense line. Therefore, MBP is necessary for the formation of the major dense line in the CNS myelin. One of the best characterized protein ligands for MBP is calmodulin, a highly acidic calcium sensor. MBP also interacts with several other proteins, including actin, tubulin, and SH3 domain-containing proteins, and thus may be a signaling hub during myelin development and remodeling (Harauz and Libich 2009).

Role of MOG: MOG is a member of the immunoglobulin super family, preferentially localized on the outside surface of myelin sheath and on the surface of OL process.

Immunocytochemical studies demonstrate that the expression of MOG is late in OL differentiation compared with other major myelin proteins. It is used as a surface marker of OL maturation. This specific CNS protein is a minor component of myelin, constituting 0.01–0.05% of total myelin proteins. It is a 26–28 kDa integral glycoprotein and like other myelin proteins it may exist in multiple forms. Since the location of this protein in outermost surface of the myelin, it is easily accessible to a humoral immune response. MOG not only binds C1q but also may be the protein in myelin responsible for complement activation (Han et al. 2013).

Role of PLP/DM20: PLP/DM20 is the most abundant intra-membrane protein and constitutes about 17–45% of the total protein of CNS compact myelin. DM-20 and PLP arise from alternative splicing of a genomic transcript and differ by a hydrophilic peptide segment of 35 amino acids long, the presence of which generates the PLP product. PLP/DM20 is crucial for the proper assembly and physical stability of CNS myelin and thus for the transmission of nerve impulses in the CNS. PLP/DM20 participates in OL membrane adhesion, compaction of myelin, formation of the myelin intraperiod line, and wrapping the axons. In human, mutation of PLP and DM20 gene causes Pelizaeus-Merzbacher disease (PMD), an X-linked dysmyelinating neuropathy, and spastic paraplegia type II (SPG-II) (Duncan 2005). PLP has an important role in supporting normal axonal function. PLP is necessary for the transport of certain proteins, such as the NAD⁺-dependent deacetylase, sirtuin 2 and cholesterol into CNS myelin (Han et al. 2013).

Role of other myelin proteins: Besides these four proteins, myelin also contains other proteins that play a critical role in myelin compaction and neuronal function.

Myelin-associated glycoprotein (MAG): MAG is a minor constituent of both the CNS and PNS myelin, and it localizes to the noncompact regions of the myelin membrane. MAG found on the myelin membrane adjacent to the axon. MAG is a critical component of axon-glia interactions with multiple functions in the biology of both neurons and glial cells. MAG is believed to participate in axonal recognition and adhesion, inter-membrane spacing, signal transduction during glial cell differentiation, regulation of neurite out growth, and in the maintenance of myelin integrity (Jones et al. 2013).

Myelin associated/oligodendrocyte basic protein (MOBP): MOBP is abundantly expressed in the CNS myelin and shares several characteristics with MBP. MOBP is synthesized by mature OL and localized at the major dense line, suggesting a role in the myelin compaction process.

P2: P2 is a fatty acid binding protein with a molecular weight about 13.5 kDa, is located on the cytoplasmic side of the compact myelin membranes. It presents at high abundance in PNS myelin. It may serve as lipid carrier and thus could be involved in the assembly, remodeling and maintenance of myelin (Majava et al. 2010).

Oligodendrocyte-specific protein (OSP/claudin-11):

OSP/claudin-11 and PLP are both tetraspan proteins concentrated in CNS myelin. OSP represents about 7% of total myelin proteins. They possibly play an important role in myelin formation and maintenance due to their localization and concentration in membrane sheaths. Individual OSP/claudin-11- and PLP-null mice have relatively normal-appearing myelin and mild neurological deficits due to their compensatory role. However, when both OSP/claudin-11 and PLP genes are knocked out, mice show severe neurological deficits, markedly abnormal myelin compaction, and smaller axon diameters. OSP/claudin-11 in association with K(V)1 family voltage-sensitive K(+) plays a significant role in OPC proliferation, migration and myelination of axons (Tiwari-Woodruff et al. 2006).

Cx32: Cx32, an integral membrane protein, is structurally related to PMP22 with four hydrophobic transmembrane domains. Recent studies show that it is also expressed on some areas of the CNS myelin and corresponding myelinating OL. Cx32 is preferentially expressed in OL in the CNS and in Schwann cells in the PNS. In addition to forming gap junctional channels, Cx32 also forms functional hemichannels. Mutation in Cx32 causes a common peripheral demyelinating neuropathy, X-linked Charcot-Marie-Tooth disease (Schiza et al. 2014). However, mice lacking Cx32 or Cx 47 develop minimal CNS pathology and no obvious phenotype but loss of both OL connections in Cx32/Cx47 double knockout mice leads to severe and early CNS demyelination.

Oligodendrocyte-myelin glycoprotein (OMgp): It is a glycosylated protein with molecular mass 120 kDa. It is located in the para-nodal areas of myelin. During injury, it inhibits the axonal growth by interacting with Nogo-66 receptor (NgR) complex and paired Ig-like receptor-B (PiRB). Mechanistic studies reveal that Nogo-66 and OMgp suppress long term potentiation (LTP) in an NgR1-dependent manner. OMgp inhibits LTP in part through PiRB but independently of p75.

Myelin/oligodendrocyte specific protein (MOSP): MOSP is a novel surface protein which is exclusively expressed in CNS myelin. It also plays an important role in membrane/cytoskeleton interactions during the formation and maintenance of CNS myelin.

Lipids

In the CNS, lipids play an important role in myelin formation along with various protein molecules. One of the major biochemical characteristics that distinguish myelin from other biological membranes is its' high lipid-to-protein ratio. About 70–80% of the dry weight of myelin is comprised of lipid components and 20–30% protein. In every mammalian species, myelin contains cholesterol, phospholipids and glycolipids in molar ratios ranging from 4:3:2 to 4:4:2. In mature brain, cholesterol is the major lipid in myelin (about 20–25%)

but generally normal myelin does not contain any cholesterol ester. Cholesterol helps to increase membrane thickness and fluidity as well as ion leakage through membranes which may be relevant to its property of electrical insulation.

Other abundant lipids in myelin are galactosylcerebro-sides (Gal-C) and their sulfated derivatives (sulfatides). GalC represent 20% lipid dry weight in mature myelin. Immunological and chemical perturbation studies indicate that these lipids are involved in OL differentiation, myelin formation and myelin stability. These galactolipid-deficient animals exhibit severe tremor, hindlimb paralysis and display electrophysiological deficits in both CNS and PNS (Baumann and Pham-Dinh 2001).

Lysophosphatidic acid (LPA) is an intercellular signaling lipid that regulates multiple cellular functions, acting through specific G-protein coupled receptors (LPA₁₋₆). Specifically LPA1 regulates OLs differentiation and myelination in the CNS (Garcia-Diaz et al. 2014).

Molecules Involved in Positive and Negative Regulation of Myelination

The formation and maintenance of the myelin sheath require the coordination of a number of gene products. While some gene products facilitate myelination, some others try to suppress myelin formation. In the following lines, we describe such positive and negative regulatory mechanisms.

Regulation of myelination: OLIG1 and OLIG2 are closely related basic helix-loop-helix transcription factors that are expressed in myelinating OL and their progenitor cells in the developing CNS. Both OLIG1 and OLIG2 are positive regulators of myelination. Specifically OLIG1 has an essential role in OL differentiation and myelination, as it regulates the transcription of major myelin-specific genes MBP, PLP and MAG. On the other hand, OLIG2 is required for the initiation of oligodendroglialogenesis but its role in myelination is controversial (Xin et al. 2005).

Another important molecule that stimulates myelination is GPI-linked neural cell recognition molecule F3/contactin. This is a physiological ligand of Notch that signals via DTX1 to promote the development of OL (Popko 2003). Additionally, F3 also transduces signals to glial intracellular Fyn, which then interacts with Tau protein to mediate myelination. As expected, different neurotrophins also favor myelination through the maintenance of OL health and viability. For example, neurotrophin-3 (NT3) is known to induce both survival and proliferation of OL. NT3 interacts with TrkC to activate CREB that plays a critical role in proliferation and maturation of OPCs, and in the expression of myelin genes (MBP, P2, P0 MOG, PLP, and MAG) and anti-apoptotic gene Bcl-2. In addition, recent studies have identified many other molecules (e.g. PAX3, PPAR- δ , MyT1, SOX10, GTX, Sp1, YY1, Nkx2.2, Zfp488, MRF, Zfp191 and SCIP/Oct6/Tst-1) that may function as positive regulators of myelination

Fig. 10.6 Schematic diagram showing different molecular signalling pathways for the induction of myelin gene expression in differentiating oligodendrocytes. The crosstalk between extrinsic signal, transcription factors, miRNAs, and chromatin modifiers determine the balance

between repressive signals that inhibit OLs differentiation and de-repressive signals that OLs differentiation. Double headed arrows indicate physical interactions

(Barca-Mayo and Lu 2012) (Fig. 10.6). TACE/ADAM17 is essential for OL development and CNS myelination. Recently, it has been shown that antiaging protein klotho enhances OLs maturation and myelination through AKT and ERK signaling pathways (Chen et al. 2013).

OL differentiation is also regulated at the level of chromatin remodeling by histone deacetylases (HDACs) as pharmacological inhibition of HDAC activity in postnatal rat causes a delay in OLs differentiation and myelination. Conditional deletion of HDAC1 and HDAC2 in the OLs lineage causes a loss of OPCs and OLs, suggesting that this HDAC activity is required at multiple stages of the lineage. Histone deacetylase likely promote OL differentiation by inhibiting the expression of pathways and genes that otherwise act to block differentiation. These include HDAC-mediated inhibition of the Wnt/β-catenin pathway and HDACs acting in conjunction with the transcription factor YY1 to inhibit expression factors such as ID4 and Tcf4 (Emery 2010). Recent studies have demonstrated a critical role of miRNAs in OLs development, including cell proliferation, differentiation, and myelination. Micro-RNA -338 and miR-219 are highly expressed in OLs

and promote OLs differentiation by inhibiting the expression of differentiation inhibitors (e.g. Sox5/6 & Hes5) and OPCs proliferation factors (PDGFRα) (Fig. 10.6).

Molecules involved in negative regulation of myelination: Bone morphogenic proteins (BMP4s) should have a role in regulating bone density! Yes, they do have and in addition, these important molecules also regulate OL development. At early stage, BMPs regulate cell lineage decision and at later stage, they inhibit cell specialization in OL. For example, BMP4 signaling inhibits the generation of OL and enhances the generation of astrocytes from neural progenitor cells both in vitro and in vivo. BMP4 induces the expression of all four members of the inhibitor of differentiation (ID) family of helix-loop-helix transcriptional inhibitors and blocks OL lineage commitment through the interaction with OLIG1 and OLIG2 (Samanta and Kessler 2004). The other inhibitory signaling pathways mediate through specific downstream effectors such as Wnt/β-catenin, Notch/Hes factors, Sox5/6, and NF1a/b at different developmental stages to inhibit OL differentiation and myelination (Barca-Mayo and Lu 2012).

LINGO-1, a transmembrane protein containing a leucine-rich repeat (LRR) and immunoglobulin domain, functions as a component of the NgR1/p75 and NgR1/Taj (Troy) signaling complexes. Recent studies show that LINGO1 is also expressed in OL where it negatively regulates OL differentiation and axonal myelination by down-regulating the function of Fyn kinase and up-regulating the activity of RhoA-GTPase. Lack of LINGO-1 expression promotes more axonal myelination due to increased expression of myelin gene such as MBP, CNPase and MOG in OL. LINGO-1 knockout mice also show earlier onset of CNS myelination (Mi et al. 2005). SIRT1, a protein deacetylase inhibits the production of new OPCs in the adult mouse brain, in part by acting in NSCs and inhibits myelinating OL formation (Fig. 10.6).

10.4.3 OL and CNS Pathology

Death of OL and subsequent myelin loss has been reported in a variety of myelin disorders including, multiple sclerosis (MS), X-adrenoleukodystrophy (X-ALD), adrenomyeloneuropathy (AMN), vascular dementia, periventricular leukomalacia (PVL), hypoxia, and ischemia. Rates of OLs loss as high as 30–40% are observed following axon injury in the mature CNS after months to years. Several factors that might be associated with OL death in these pathophysiological conditions are discussed briefly in below.

10.4.3.1 Autoimmune Triggers

MS and experimental allergic encephalomyelitis (EAE), an animal model of MS, are autoimmune diseases of the CNS mediated by T cells recognizing self-myelin proteins including MBP, MOG and PLP. T cells are activated in the periphery by unknown antigens of both myelin and nonmyelin origins. After activation, T cells cross the blood-brain barrier and invade into the brain where they accumulate and proliferate in response to antigen re-stimulation. These activated T cells secrete different pro-inflammatory molecules which stimulate not only the resident glial cells (microglia and astroglia) but also other infiltrating cells. CD4⁺ and $\gamma\delta$ T cells express Fas-L which is found to be associated with OL death. Furthermore, infiltrating CD8⁺ T cells interact with MHC class 1 surface receptor of OL and in turn cause OL lysis. T cell-derived perforin may also be responsible for OL death (Scolding et al. 1990).

10.4.3.2 Cytokines

Cytokines are important mediators in the inflammatory demyelination observed in MS, EAE, X-adrenoleukodystrophy (X-ALD), and Theiler's virus infection. In these pathologies, pro-inflammatory cytokines and others factors released by endogenous glial cells and/or infiltrated macrophages and CD4⁺ Th1 cells, accumulate and exert pleiotropic effects on

OL. At lower concentrations, these cytokine may be involved in normal development of the nervous system while following brain trauma or inflammatory insults, the overproduction of these cytokines may result in a homeostatic imbalance and may contribute to the outcome of the pathological event. Various cytokines can directly kill OL or it may also affect other signaling pathways that could be involved in the susceptibility of OL. For example, IFN- γ produced by T cells may induce OL apoptosis and cell death via JAK-STAT pathway. It has been shown that CXCL10 contributes to neuropathology by promoting OPC apoptosis (Tirota et al. 2012).

Another proinflammatory cytokine TNF- α induces OL death via death signaling pathways (e.g. death initiating signaling complex (DISC), ceramide signaling pathway and stress-activated protein kinase pathways (SAPK) (Buntinx et al. 2004). IL-1 β is a strong stimulus for TNF- α release from astrocytes and microglia. Both IL-1 β and TNF- α are capable of inhibiting the expression of myelin genes via redox-sensitive mechanism (Jana and Pahan 2005). Increased level of IL-1 β is also known to induce OL excitotoxicity via P2X₇ receptor.

10.4.3.3 Nitric Acid

Nitric oxide (NO), a short-lived and highly reactive free radical, is an important physiological messenger in the CNS. However, high level of NO in the CNS has been associated with different neuroinflammatory and neurodegenerative diseases. During CNS inflammation, activated microglia, astrocytes and infiltrating cells express inducible nitric oxide synthase (iNOS) producing excessive amount of NO. OL at different stages of differentiation are differentially sensitive to NO. For example, OPCs and immature OL are more susceptible than mature OL to NO. However underlying mechanisms are poorly understood. It has been shown that NO reacts with superoxide generated by NADPH oxidase from activated glial cells and infiltrating cells to form peroxynitrite, the most reactive NO derivative. This peroxynitrite plays a critical role in the death of OL (Jana and Pahan 2013; Li et al. 2005). Combination of IFN- γ and bacterial lipopolysaccharide (LPS) or double stranded RNA in the form of polyIC induced the production of NO and decreased the expression of myelin gene in human fetal mixed glial cultures. This study illustrates a novel biological role of NO in down-regulating the expression of myelin genes preceding the death of OLs (Jana and Pahan 2013).

10.4.3.4 Oxidative Stress

Reactive oxygen species (ROS) and reactive nitrogen species (RNS) leading to oxidative stress have been implicated as mediators of demyelination and axonal damage in both MS and EAE. Oxidative stress can damage lipids, proteins and nucleic acids of cells and mitochondria potentially causing OL cell death. During oxidative stress-induced OL apoptosis,

cytochrome c is released from damaged mitochondria, which in turn leads to the activation of the death-related caspases 3 and 10. Another study by Vollgraf et al. shows that mature OL exposed to oxidative stress undergo chromatin segmentation, condensation via mechanisms involving transcriptional activation of the immediate early stress genes (c-fos and c-jun) (Vollgraf et al. 1999). An induction of Bax protein has also been reported under oxidative stress condition in OL.

10.4.3.5 Ceramide

Ceramide, the lipid second messenger and a hydrolyzed product of sphingomyelin, is involved in apoptosis of OL. In pathological conditions, proinflammatory cytokines (TNF- α and IL-1 α) released specifically from activated microglia and astroglia leads to the activation of sphingomyelinases and production of ceramide in OL via the redox-sensitive mechanism (Singh et al. 1998). According to Jana and Pahan (2013), oxidative stress induces apoptosis in human OL via neutral sphingomyelinase (Jana and Pahan 2007). During Alzheimer's disease, amyloid- β is aggregated in the plaque region that also causes OL death by activating the NSMase-ceramide cascade via redox-sensitive pathways. In addition, ceramide can inhibit inwardly rectifying K⁺ currents and cause depolarization in OL.

10.4.4 Regeneration

Recent evidences indicate that OPCs remain intact both in normal white matter and in demyelinating CNS of patients with MS. OPCs can give rise to new OL in experimental conditions and have the ability to repopulate areas from where they are missing.

10.4.4.1 OL Regeneration

Recent identification of several genes associated with regeneration of OL has become helpful to understand the mechanism of remyelination and formulate a strategy for possible therapeutic intervention in demyelinating disorders. It has been shown that the levels of Nkx2.2, Olig1, Olig2, Ascl1 (Mash1), MYT1, and Sox9/10 at different stages of OL are similar during remyelination and myelination. Therefore, the upregulation of these factors during active remyelination likely results from the rejuvenation of a developmental genetic program enabling OPCs to actively proliferate, migrate and differentiate into new remyelinating OLs (Nakatani et al. 2013). EGFR signaling is also known to regulate oligodendrogenesis and remyelination by NG2+ MASH1+ OLIG2+ progenitors. According to Nakatani et al., GOLLI MBP is capable of stimulating OPC proliferation and differentiation in remyelinating adult mouse brain (Nakatani et al. 2013). Endothelin-1 (ET-1), which is highly expressed in reactive astrocytes of demyelinated lesions,

drastically reduces the rate of remyelination via activation of Notch signaling (Hammond et al. 2014).

10.4.4.2 Schwann Cells

During demyelination, after macrophages/microglia remove myelin debris and glial scar, SCs enter into the CNS from PNS sources such as spinal and cranial roots, meningeal fibers, or autonomic nerves where they remyelinate axons in the absence of reactive astrocytes. During this period, survival of SCs requires the axon-derived trophic factors. Schwann cell can also produce some growth factors like IGF1, FGF2 and PDGF, which promote the migration of OPCs and maturation into myelinating OL.

10.4.4.3 Thyroid Hormones

Thyroid hormone (TH) plays an important role by regulating several stages of OL development and maturation. The increasing TH levels in vivo accelerate both myelin gene expression and myelination during development, and also myelin regeneration after demyelination. OLs express TH receptors and during demyelination, TH increases the expression of NGF that protects OLs from cell death. TH induces the activation of kruppel-like factor 9 (KLF9), basic helix-loop-helix family member e22 (bHLHe22), hairless (Hr), and Albumin D box-binding protein (DBP), and thereby regulates OL differentiation and myelin regeneration (Dugas et al. 2012). TH hormone also up-regulates the expression of PDGFR- α , MBP and CNPase in CNS tissues of animals with MS (Calza et al. 2005).

10.5 Schwann Cells: Peripheral Glia

One of the major differences between the CNS and the PNS is the proportion of myelinated versus unmyelinated fibers. In the CNS, nearly all white matter tracts are myelinated, whereas in the PNS, there are approximately four times as many unmyelinated axons as myelinated ones (Griffin and Thompson 2008). The peripheral nervous system contains a number of distinct glial cells, each of which is intimately associated with different parts of the neurons or with specific neuronal cell types. Earlier, these cells were known as the supporting cells of the PNS but recent studies delineate their multifunctional role. These cells are of two types: satellite cells and Schwann cells (SCs). Satellite cells surround the neuronal cell bodies in dorsal root sensory ganglia and in sympathetic and parasympathetic ganglia. These cells help to maintain a controlled microenvironment around the nerve cell body, providing electrical insulation and a pathway for metabolic exchange. The other cells named after German physiologist Schwann are flattened cells with an elongated nucleus oriented longitudinally along the nerve fiber. Surface of all axons in peripheral nerves are ensheathed by non-myelinating or myelinating SCs.

10.5.1 Schwann Cells (SCs): Overview

In the mature nervous system, SCs can be divided into three classes based on their morphology, biochemistry and function: myelinating Schwann cells (MSCs), nonmyelinating Schwann cells (NMSCs) and perisynaptic Schwann cells (PSCs) (Fig. 10.7).

MSCs are well characterized and they wrap around axons with a diameter of 1 μm or greater, including all motor neurons and some sensory neurons. This is a mystery why they wrap a specific diameter of the axons. Smaller diameter axons including many sensory and all postganglionic sympathetic neurons are myelinated by NMSCs. The NMSCs provide the metabolic and mechanical support to the axon. The NMSCs appear later than MSCs. They express higher levels of GFAP, p75NTR and cell adhesion molecule L1 compare to MSC. The PSCs located at the neuromuscular junction incompletely wrap around the presynaptic terminal of motor axons. They help to maintain a stability of the neuromuscular junction and regulate synaptic transmission (Corfas et al. 2004).

10.5.2 Schwann Cell Development

SCs originate from the neural crest cells, a transient population of cells migrating away from the dorsal part of the neural tube. Neural Crest cells are multipotent cells that differentiate

to form neurons and glia of the PNS, and also additional cell and tissue types such as melanocytes and connective tissue of the head. Several molecules (e.g. ErbB3, transcription factor SOX10, AP2 α and Ets1, the N-Cadherin 6, the low affinity receptor for nerve growth factor p75NTR) have been shown to play important roles during the detachment of neural crest from neural tube (Jessen and Mirsky 2005).

Markers of lineage progression: Characterization of a number of specific biochemical markers has increased our knowledge on the stages of SC maturation, both in vivo and in vitro. Some of the biochemical markers have been shown to overlap partially (Table 10.3).

10.5.3 Survival, Migration and Death

10.5.3.1 Survival

The survival of immature SCs in late embryonic and prenatal nerves is probably controlled by a balance between factors that support survival and factors that cause death. Axon-derived neuregulin family (NRG-1, NRG-2 and NRG-3) have been implicated in the biological processes of SCs including fate specification, proliferation, survival, migration, regulating the extent of myelination, and triggering demyelination. It is believed that the interaction between several NRG ligands with different ERB receptors (ErbB2,

Fig. 10.7 Different stages of Schwann cell development

Table 10.3 Stage-specific markers of Schwann cells

Stages	Markers
Neural crest cells	SOX10, AP2 α
Schwann cell precursor (SCPs)	Cadherin19, AP2 α , low level P0, GAP43, F-spondin, SOX10, BFABP, DHH
Immature Schwann cells	S100 β , GFAP, low level of P0, SOX10, O4 antigen, BFABP, DHH
Myelinating Schwann cells	P0, PMP-22, MBP
Non myelinating Schwann cells	NCAM, GFAP

SOX10 SRY (sex determining region Y) box 10, *AP2 α* activator protein 2 α , *DHH* desert hedgehog, *GAP43* growth associated protein 43, *P0* protein zero, *O4* lipid antigen, *BFABP* brain fatty acid-binding protein, *S100* calcium-binding protein, *PMP22* peripheral 22 kDa myelin protein, *MBP* myelin basic protein, *GFAP* glial fibrillary acidic protein, *NCAM* neuronal cell-adhesion molecule

ErbB3 and ErbB4) on SCs plays a critical role in regulating these steps (Michailov et al. 2004). SCs can support their own survival by producing a number of growth factors such as IGF2, NT3, PDGF- β , LIF, and lysophosphatidic acid (LPA) in an autocrine fashion. This mechanism ensures very little SC death after axon injury, allowing SCs to play an active supportive role in PNS axon regeneration. However, following periods of chronic denervation lasting several months or more, increased SCs death is ultimately observed. The autocrine survival circuits are probably important in maintaining the survival of SCs in injured nerves.

10.5.3.2 Migration

During development of the PNS, neural crest cells migrate along the outgrowing axons and proliferate in order to produce sufficient number of cells for myelination of axons. Various factors or signaling molecules present on the neighboring cells effect Schwann cell migration in cell culture and it is possible that these signals lead to SC movements during radial sorting in vivo. Integrins, a subgroup of adhesion receptors mediate interaction between cytoplasm and the extracellular environment. This interaction influences the migration of neural crest cells, axonal out growth and SC differentiation. Integrins can interact with different growth factors, cell adhesion molecules (NCAM and F3) and intracellular cytoskeleton or adaptors proteins. This interaction is crucial for conformational changes and movement of SCs. Several growth factors that regulate the migration of SCs include NRG1, BDNF, GDNF, NT3, and IGF-1. The majority of these molecules are also expressed by SC itself. Recent

studies show that miR-221 and miR-222 promote Schwann cell proliferation and migration by targeting LASS2 after sciatic injury. The miR-182 inhibits SC proliferation and migration by targeting FGF9 and NTM, respectively at an early stage following sciatic nerve injury. On the other hand, the miR-9 inhibits SC migration by targeting Cthrc1 following sciatic nerve injury (Zhou et al. 2014).

10.5.3.3 Death

NGF acting via the p75 neurotrophin receptor promotes cell death during the SC injury or infection via activation of c-jun-N-terminal kinase (JNK). It has been found that neonatal p75 neurotrophin receptor mutant mice are less prone to cell death after nerve transection. Here it is to be noted that the same neurotrophin signaling pathway may also promote survival of SCs via activation of NF- κ B. Yeiser et al (2004) have shown that NGF signaling through the p75 receptor is deficient in TRAF-6 ($-/-$) mice and that NGF is unable to kill TRAF-6 ($-/-$) SCs (Yeiser et al. 2004). In addition, TGF β is also known to cause apoptosis of SCs via JNK in culture (Jessen and Mirsky 2005). Other inducers that also contribute to the death of SCs are P2X7 purinoreceptors and proinflammatory cytokine TNF- α .

10.5.4 OL and SC

Although both OL and SC share the common task of synthesizing myelin, there are some differences between the two cell types (see Table 10.4).

Table 10.4 Differences between oligodendrocytes (OL) and Schwann cells (SC)

OL	SC
1. OLs are present only in the CNS	1. SCs are the major glial cells in the PNS
2. The sub ventricular zone (SVZ), which is present in late gestational and early postnatal mammalian brain, is a major source of OL	2. SCs are originated from the neural crest
3. OL developmental steps are irreversible	3. Fully differentiated SCs retain an unusual plasticity throughout the life and can readily de-differentiate to form cells similar to immature SCs
4. One OL extends several processes and can myelinate up to 1–50 axons with distinct internodes	4. One SC has an intimate association with axon and each SC forms myelin around a single axon, and lines up along the axon to define a single internode
5. GM4, one of the most abundant lipids of the CNS, is present in OL	5. Some glycolipids such as sulfated glucuronyl paragloboside and its derivatives are specific to SC
6. CNS myelin contains more choline and plasmalogens than PNS myelin (Garbay et al. 2000)	6. PNS myelin contains more ethanol phosphoglycerides than CNS myelin
7. Basic proteins (MBP and PLP) are major constituents of CNS myelin (about 80 % of the total protein) (Baumann and Pham-Dinh 2001)	7. Glycoproteins (P0 and PMP22) are major constituents of PNS myelin
8. OLs have phagocytic activity	8. SCs do not have phagocytic activity
9. OLs migrate slower and divide and remyelinate at a slower rate than SCs	9. SCs migrate faster and divide and remyelinate at a faster rate than OLs
10. OLs are less resistant than SCs to injury	10. SCs are more resistant than OLs to injury
11. CNS myelin is a potent inhibitor of axon regeneration	11. PNS myelin is a less-potent inhibitor of axon regeneration
12. MiR-219, a critical miRNA implicated in OL differentiation	12. This is not present in SC

10.5.5 Biological Roles

10.5.5.1 Myelinating Peripheral Neurons

SCs cover most part of the PNS neurons by myelin sheath. Although the PNS myelin is mainly formed by the differentiation of the plasma membrane of SCs, myelination of mammalian PNS is a very complex developmental process. It requires intricate timing of several gene expression and cellular interactions between the axon and differentiated SCs (Michailov et al. 2004). In the PNS, mature SCs express *Dhh*, a family member of the Hh signaling proteins that is involved in the formation of peripheral nerve sheath and is also responsible for the formation of nerve-tissue barrier. Therefore, it has been found that *Dhh* mutant mice are defective in nerve barrier formation and unable to protect themselves against inflammatory responses. The activity of *Dhh* is regulated by several molecules such as *Notch1*, *Hes5*, *MASH-1* and others (Parmantier et al. 1999).

In addition, some well-known transcription factors and molecules such as, *KROX20*, *SOX10*, *OCT-6*, brain class III POU-domain protein (*BRN2*), *GPR126*, *SREBPs*, *NF-kB*, and *Lpin1*, also play an important role in PNS myelination. *KROX-20*, a master regulator for myelinating SCs, appears to be fundamental in controlling SC differentiation, regulating the expression of a number of genes including *periaxin*, *P0*, *MBP*, and *PMP22* by interacting with *NAB* (*NGF1-A* binding) proteins. Mutation of this transcription factor *Krox-20* is associated with lethal human neuropathy such as congenital hypomyelinating neuropathy (*CHN*), *Dejerine Sottas* syndrome (*DSS*) and the *Charcot-Marie-Tooth* (*CMT*) disease. *Oct6* and *Brn2* have been implicated in the expression of *Krox-20* and may therefore positively regulate myelination (Reiprich et al. 2010).

Histone deacetylases *HDAC1/2* are major epigenetic regulators of SC development in the PNS. It has been reported that *HDAC1/2* are required for *Pax3* expression in neural crest cells and that *Pax3* is necessary for *HDAC2*-dependent control of *Sox10* levels and expression of early determinants of SCs and satellite glia. In addition, *HDAC1/2* controls the expression of *P0* directly. By regulating the interplay between *Sox10* and *Pax3*, *HDAC1/2* is thus essential for specification of neural crest cells into peripheral glia.

After nerve injury, SCs have an important role for repair by contributing growth permissive environment that allows peripheral axons to regenerate. At the same time, Wallerian degeneration completely disrupts axon-SC contacts, which is persisted throughout normal development. After Wallerian degeneration, SC redifferentiation begins in the absence of axonal *NRG1-III* and denervated SCs require autocrine *NRG1* type 1 signaling for timely redifferentiation, whereas neuronal *NRG1* (specifically the axon-bound isoform) stimulates remyelination by itself.

10.5.5.2 Tissue Repair/Regeneration

The SCs play a pivotal role during the event of mechanical damage such as spinal or peripheral nerve injury due to their regenerative properties. Following peripheral nerve injury, distal axons degenerate while differentiated SCs and macrophages remove cell debris and inhibitory molecules via phagocytosis. SCs in the distal stumps of adult animals can survive for several months in the absence of axons due to injury/insult and these SCs provide both trophic factors and adhesive substrates that promote axonal regeneration and restore the original function. After nerve injury, SCs can transform their phenotype from differentiated myelinating state to the de-differentiating state. During this process, there is also upregulation of regeneration-associated genes such as the neurotrophin receptor *p75 NTR*, *neuregulin* and their receptors (*erbB2*, *erbB3*, *erbB4*), and *GAP-43*. They also produce different trophic factors (*BDNF*, *NGF*, *CNTF*, *FGF*, *GDNF*, *TGF-β*, *IGF-2*, *NT3*, *PDGF-β*, and *LIF*), adhesion molecules (*L1*, *NCAM*), extra-cellular matrix molecules (*laminin*, *fibronectin*, and *tenascin*), and hormones such as *progesterone* and *erythropoietin*, *NFATc4*, *proteoglycans*, and *collagen type IV* in an autocrine/paracrine manner and thereby providing a favorable environment for axonal re-growth and their own survival (Taveggia et al. 2010). Transcription factor *c-Jun* is a global regulator of a SC repair program. This program involves the regulation of molecules (surface proteins *N-cadherin*, *p75NTR* and *NCAM*, and the signaling molecules *GDNF*, *artemin*, *sonic hedgehog*, and *BDNF*) that have been directly implicated in repair.

10.6 Summary

Astrocytes, OL and SC are not silent partners of others anymore as thought a couple of decades earlier. Recent works have put these cell types in the forefront of neuroscience research. Although astrocytes being the major cell type in the CNS get more attention than the other two cell types, both OL and SC play an equally important role in human health and disease through myelination of neurons in the CNS and PNS, respectively. As a result, thousands of cutting-edge research articles are coming out each year describing biological and functional aspects of astrocytes, OL and SC. Therefore, now it is an uphill task to compile everything about these three important cell types in a single chapter. However, here we have made an honest attempt to briefly delineate major biological and functional aspects of these cell types. Although there are vast body of evidence that implicate dysfunction and dysregulation of astrocytes, OL and SC in a number of human neurological diseases, we are still more or less in the dark to draw an unifying picture from these data. An improved understanding of their genesis and

function in both healthy and diseased conditions is necessary for better preservation of brain in physiological conditions and for better repairing of this organ under pathophysiological situations.

10.7 Review Questions

- During developmental stage which cell types come last:
 - microglia
 - neuron
 - astrocyte
 - oligodendrocyte*
- If there is formation of abnormal Shh protein during embryogenesis:
 - genesis of astrocyte will be affected
 - genesis of oligodendrocytes will be affected
 - genesis of neurons will be affected
 - brain development will be impaired
 - all are true*
 - none are true
- Enzyme glutamine synthetase is not found in
 - astrocytes
 - oligodendrocytes
 - none of the above is true
 - all are true*
- Tripartite synapse is formed by
 - neurons
 - microglia
 - astrocytes
 - microglia and astrocytes
 - neuron and astrocyte*
- In the central nervous system, major role of astrocyte is to
 - scavange glutamine
 - scavange cell debris
 - produce ATP
 - all the above*
 - none the above
- In the CNS, glycogen is found only in
 - oligodendrocyte
 - microglia
 - astrocyte*
 - neuron
 - all the above
- In astrogliosis, astrocytes form
 - cluster all around the CNS
 - bushy network surrounding the injury site*
 - all are true
- Schwann cells but not oligodendrocytes have phagocytic activity.
 - True*
 - False
- Unmyelinated axons generally have a smaller diameter than myelinated axons.
 - True*
 - False
- A single Schwann cell forms myelin around one and only one axon while a single
 - oligodendrocyte forms myelin around several separate axons.
- Oligodendrocyte forms myelin around several separate axons.
 - True*
 - False
- Oligodendrocytes progenitors are identified by A2B5 antibody whereas
 - Pre-oligodendrocytes are identified by O4 antibody.
- Pre-oligodendrocytes are identified by O4 antibody.
 - True*
 - False
- Which of the sequential stage is correct for oligodendroglial development?
 - Neural stem cells, progenitors, pre-oligodendrocytes, precursors and mature oligodendrocytes.
 - Progenitors, precursors, pre-oligodendrocytes, mature oligodendrocytes and neural stem cells.
 - Neural stem cells, precursors, progenitors, pre-oligodendrocytes and mature oligodendrocytes.*
 - Pre-oligodendrocytes, precursors, mature oligodendrocytes, progenitors and neural stem cells.
 - None of the above.
- Action potentials are conducted rapidly through (choose one)
 - myelinated axons*
 - unmyelinated axons
 - large diameter axons
 - small diameter axon
 - both a and c
- Which of the following molecule is not a part of the peripheral nervous system?
 - LINGO-1*
 - BDNF
 - CNTF
 - PDGF
 - EGF
- Which of the following functions in the nervous system is not provided by the
 - oligodendrocytes?
- Oligodendrocytes?
 - Ensheath axons
 - Supply neurotrophic factors
 - Form the node of Ranvier
 - Phagocytic properties to remove debris.*
- Non-myelinating Schwann cell is characterized by the following properties EXCEPT
 - Wraps axons greater than 1 μ m.*
 - Appear later than myelinating Schwann cells.
 - Myelinate all postganglionic sympathetic neurons.
 - Produce more p75NTR and GFAP.

- (e) Provide mechanical and metabolic support to the neuron.
- 20. Gliogenesis and Neurogenesis during development
 - (a) occur simultaneously during development
 - (b) *follow this sequence i.e. gliogenesis followed by neurogenesis*
 - (c) occur one after the other after the first is completed
 - (d) occur sequentially with overlapping periods

Mary G. Banoub and Howard E. Gendelman

Abstract

The mononuclear phagocyte (MP; monocyte, macrophages, dendritic cells and microglia) is part of innate immunity that functions by nonspecific surveillance and clearing response through phagocytic and intracellular killing activities. MPs included are present within the reticular connective tissues and accumulate in lymph nodes, spleen, liver and as histiocytes, tissue macrophages, Kupffer cells and microglia. It is estimated that there are at any time six billion MP/L of blood. MPs are divided into non-professional and professional categories based on function. Phagocytosis is a key function that phagocytes possess to survey their environment, ingest and process material. This chapter expands on the mechanisms, benefits, and uses of the mononuclear phagocyte.

11.1 Introduction

The mononuclear phagocyte (MP) or reticuloendothelial system is part of innate immunity that functions by nonspecific surveillance and clearing response through phagocytic and intracellular killing activities. MPs included are present within the reticular connective tissues and accumulate in lymph nodes, spleen, liver and as histiocytes, tissue macrophages, Kupffer cells and microglia. These are present in connective tissue, spleen, liver and brain, respectively (Van Furth and Cohn 1968; Hickey et al. 1992). MP (monocytes, macrophages and dendritic cells) play critical first line functions in human defense after pathogens, cancerous cells and injured tissues breach the skin and mucosal surfaces. MP's abilities to ingest then destroy microorganisms such as

mycobacteria, fungi, bacteria, protozoa, and viruses define them for immune surveillance. The removal of injured tissues, senescent or dying cells that reached the end of life provide a homeostatic function for aged erythrocytes, leukocytes and megakaryocytes amongst other cell types. The mechanism operative is also their coined name that is professional phagocytes. These cells have an essential role in clearance of organs through inflammation, as well as having an engaged role in the immune tumor surveillance (Diebold 1986). Removal of damaged or destroyed biological material is through phagocytosis, digestion and intracellular degradation (Klebanoff 1999).

It is estimated that there are at any time six billion MP/L of blood. MPs are divided into non-professional and professional categories based on function. The former includes epithelial and endothelial cells, fibroblasts, mesenchymal cells, lymphocytes and natural killer cells. This category has more limited phagocytic function and unlike the macrophage and dendritic cells phagocytosis is not their principal function. While they do serve to rid the body of apoptotic cells and foreign organisms and remold scars they do not produce reactive oxygen species. In the current chapter the main focus is

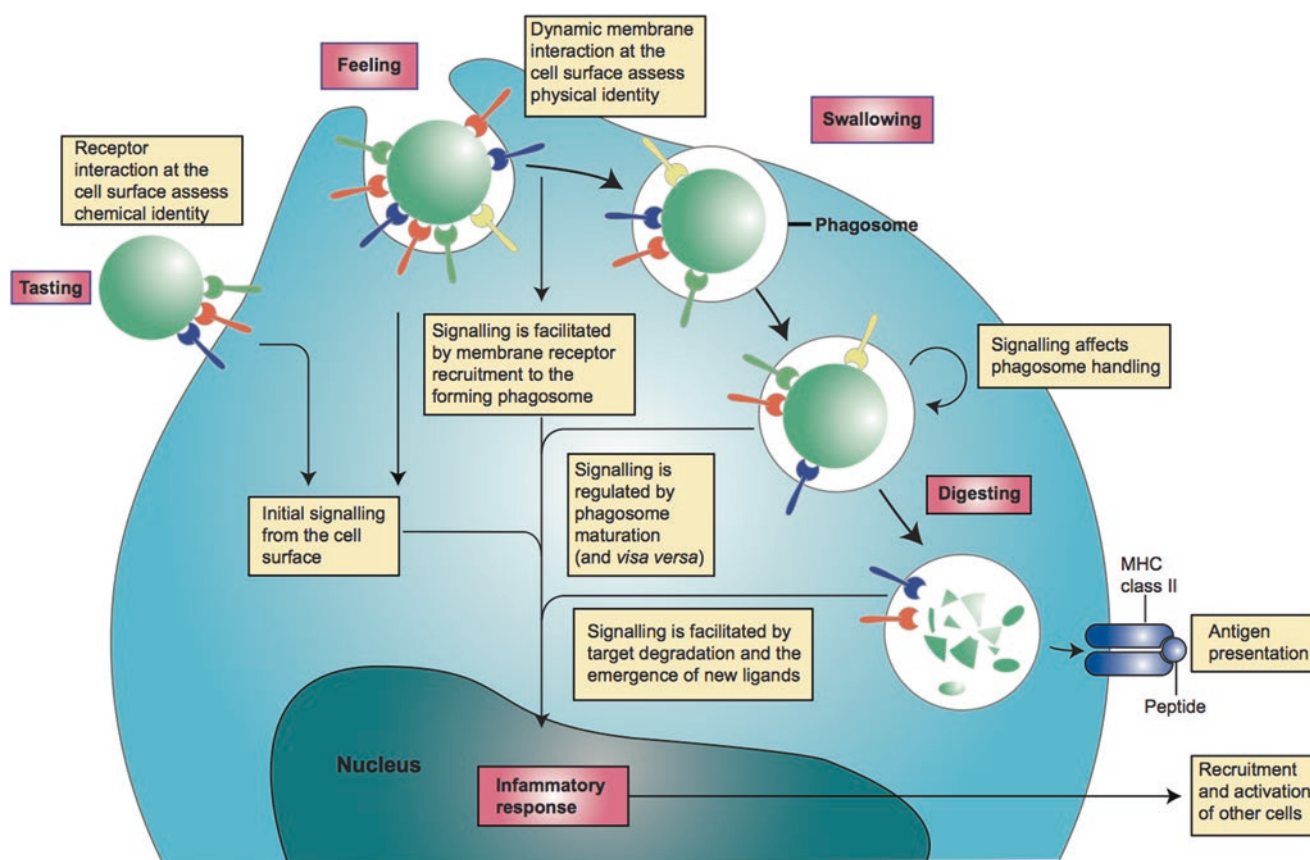

Fig. 11.1 Pathogen engulfment by phagocytosis is initiated by the pathogen-associated molecular patterns (PAMPS) on the microbe's surface. Pattern recognition receptors (PRRs) on the phagocyte sense these PAMPS and bind to them through different receptors (mannose receptors, Fc receptors, TLRs, etc.). This interaction between the receptor and ligand leads to activation of downstream pathways responsible for activation of actin filaments leading to changes in the membrane of the phagocyte to wrap around the microbe and surround it in a vesicle known as the phagosome. The phagocyte proceeds to degradation of the microbe using different intracellular killing mechanism to digest the microbe and fragment it inside the phagosome. The intracellular killings

of the phagocyte initiates appropriate inflammatory response depending on the activated downstream pathway leading to activation of other defense cells (such as T-cells and B-cells) to initiate further immune responses against the invading pathogen. Meanwhile, the phagocyte presents fragments of the digest microbe (antigens) on its MHC class II receptor. This presented antigen on the MHC II receptor would later bind to other cells to activate a full immune response against that invader. Permission was obtained to reproduce figure. Underhill DM, Goodridge HS (2012) Information processing during phagocytosis. *Nat Rev Immunol* 12(7):492–502

on professional phagocytes defined as cells expressing the major histocompatibility complex class II with specific roles in T cell immunity. The three professional phagocytes are the macrophage, the dendritic cell and B cells.

MPs evolve from blood monocytes. When they reach tissue and fully differentiate they are called by a variety of names dependent on their locale. In the liver they are called Kupffer cells, the spleen splenic macrophages, connective tissue histiocytes, brain microglia, bone osteoclasts, placenta Hofbauer cells, lymph node sinus histiocytes and perivascular macrophages through body cavities. They all together digest cellular debris and process and present antigens. In most mammalian species, monocytes make up approximately 5 % of all white blood cells. By chromosome marker and other techniques it is now well known that they are developed from pro-monocyte precursors in the bone marrow (Virolainen 1968). Following about a 3-day long devel-

opmental phase (Van Furth and Cohn 1968; Whitelaw et al. 1968) the monocytes circulate for a short period of time in the blood (less than 1 day) before they migrate to their final destinations to become fully mature macrophages where they serve as scavengers, secretory and antigen presenting cells (Volkman and Gowans 1965; Van Furth and Cohn 1968; Virolainen 1968) (Fig. 11.1).

11.2 Function

11.2.1 Phagocytosis

Phagocytosis is a key function that phagocytes possess to survey their environment, ingest and process material. The word phagocytosis is of Ancient Greek origin where phagein means “to eat/devour”, kytos means “cell”, and osis means “process”.

Hence phagocytosis means the process of cell eating or devouring. The process proceeds through endocytosis by which unicellular organisms such as protists feed while in multicellular organisms phagocytosis is a more complex process. For the latter is actin-dependent and essential for the organism's immune surveillance function and enabling the organism to face and overcome myriad of proteins, tissue metabolic products and microbial pathogens. For the immune system, phagocytosis plays an arch role in host survival. Indeed, without phagocytosis and subsequent antigen processing and presentation the ability of surveying and scanning the environment and maintaining homeostatic function would be lost rendering the organism defenseless (Volkman and Gowans 1965; Van Furth and Cohn 1968; Virolainen 1968). This is vital as a result of constant exposures to infectious agents and also to cancerous cells. MP has unique abilities to use a myriad of functions that not only include phagocytosis, by intracellular killing, secretion, migration and antigen presentation to defend itself in its environment. The vitality of the immune system rests, in large measure on the integrity of the MP system (MPS); in a study, depletion of phagocytes in the progression of a nonlethal plasmodium yoelii infection lead to severe malaria in mice accompanied with multiple organ failure and increased death. The affected mice showed critical pathological damages including coagulative necrosis in liver, fibrin deposition, and tubulonecrosis in kidney (Terkawi et al. 2016). We also posit that the broad functional capabilities of the MP can be harnessed for therapeutic gain and taking advantage of phagocytosis and antigen presentation functions to rid the body of toxic agents and microbes. Recent studies explored utilizing macrophages as depots for nanoformulated antiretroviral therapies targeting HIV reservoirs to facilitate the viral clearance (Guo et al. 2014; Martinez-Skinner et al. 2015).

During phagocytosis, the MP must recognize ligands on the microbe through specific receptors on its membrane (Kerrigan and Brown 2009). Once receptor-ligand interactions are formed, attachment takes place leading to the engulfment of that foreign body and the internalization inside the phagocyte cell; hence why phagocytosis proceeds from endocytosis (Heinrich 2015). When phagocytes come into contact with dead cells or microbes its cell surface receptors bind then engulf the microbe or cells. Destruction of these materials occurs with oxidants, nitric oxide and a range of proteases (Klebanoff 1999). Upon engulfment the foreign body persists within the phagocyte's defensive core the MP uses oxygen dependent or independent mechanisms to kill and degrade the foreign body. In most cases the process involves reactive oxygen species to degrade the engulfed substance. Innate pathogen recognition of the phagocytic cell is mediated by various germ-line PRRs found either soluble or membrane-bound on the cell such as the mannose receptor (CD206), dendritic cell-specific inter-

cellular adhesion molecule-3-grabbing non-integrin (DC-SIGN), liver/lymph node-specific intercellular adhesion molecule-3-grabbing integrin (L-SIGN), and macrophage galactose type C-type lectin (MGL) (Londrigan et al. 2012). PRRs are able to recognize conserved microbial structures known as PAMPs (Janeway and Medzhitov 2002). The soluble PRRs include many proteins such as ficolins, collectins, and complement that opsonize the microbe body and mark it for ingestion using specific opsonic receptors (Kerrigan and Brown 2009) In the sections following we explore the different membrane receptors that mediate the phagocytic processes.

The process of phagocytosis utilizes a variety of receptors such as mannose receptors, complements, Fc receptors, scavenger receptor, and β -glucan. Different phagocytic pathways and their signal transduction affect engulfment of pathogens (Greenberg et al. 1993; Sung et al. 1983a). Fc receptors are considered among the best-studied mediating phagocytosis. Binding of ligands and cross linking of the phagocyte's Fc receptor initiates various signaling cascades ultimately leading to formation of the activated phagosome. These receptors signal by the activation of the ITAM (immunoreceptor tyrosine-based activation motif). In 1993, experiments done on mouse macrophages revealed that the phosphorylation of tyrosines on proteins involving the Fc receptor followed signal/ligand interaction with the Fc receptor (Greenberg et al. 1993). These phosphorylated tyrosine proteins were found to be located in higher densities where filamentous actin appeared beneath phagocytic cups appearance (Greenberg et al. 1993). When they used tyrosine kinase inhibitor, genistein, they found that the appearance of tyrosine phosphoproteins were blocked along with the accumulated filamentous actin that usually formed beneath IgG opsonized particles along with their engulfment. Fc γ R-mediated phagocytosis starts by the clustering of the receptors of IgG particles. Phosphorylation of specific tyrosines with the ITAMs follows (Isakov 1997). Those ITAMs are on the cytoplasmic portion of Fc γ RIIA and also are found on γ and ζ chains joined to the Fc γ RI and Fc γ RIIIA. Src tyrosine-kinase family is the acting enzyme phosphorylating the ITAM during the initial phosphorylation (Korade-Mirnic and Corey 2000). These src kinases are inactive when a tyrosine residue that is associated with their carboxy end, SH (Src homology)-2 domain, is phosphorylated. The phosphorylated tyrosine causes a conformational change within the enzymes that leads to blocking the access to the catalytic sites of the Src enzymes rendering them inactive (Erpel and Courtneidge 1995). Upon dephosphorylation of this tyrosine residue via phosphatases, the Src kinases are active again and ready to phosphorylate the ITAMs, in leukocytes phosphatase CD45 is responsible for this dephosphorylation process (Adamczewski et al. 1995). In other instances, it was found that protein-protein interaction leading to receptor

cross-linking could also activate Src kinases. This process is thought to involve autophosphorylation and protein-protein interaction (Korade-Mirmics and Corey 2000). Few active Src kinases are thought to be joined to the cytoplasmic tails of those ITAM-containing Fc γ R chains, as a result of these receptors being close, cross-linking induce the local kinases activation (Isakov 1997; Strzelecka et al. 1997). Hence, Fc receptors can be activated by binding to IgG-coated particles where phagocytosis is initiated. In 1980, it was demonstrated that the phagocytosis of IgG-tagged lipid vesicles was dependent on the Fc surface receptors on RAW264 macrophages (Petty et al. 1980). This was measured using rosette assays for receptors measuring and monitoring the loss Fc receptors on the surface of cells when incubated with these antibody-coated lipid vesicles, in comparison with C3b receptor activity (Petty et al. 1980). The experimental results suggested that Fc receptors were depleted through IgG-mediated phagocytosis independent of the IgG density, highlighting the specific receptor-mediated phagocytic activity of macrophages. IgG-coated and uncoated erythrocytes were used to treat mouse peritoneal macrophages to determine the fate of the internalized Fc receptors. Receptor-mediated phagocytosis resulted in more than 50 % removal of the surface-expressed Fc receptors from the macrophages, compared to other surface receptors such as complements (Mellman et al. 1983). These phagocytized-internalized receptors were rapidly degraded; this was measured by immunoprecipitation experiments from lysates of 125 I-labeled macrophages. A mathematical model was developed to measure the effects of antibodies concentration on the phagocytic index of the Fc and complement receptors. The model consisted of macrophages and *Cryptococcus neoformans* fungus as the foreign pathogen. In this model, phagocytosis studies of the fungus occurred in the presence of opsonins which are the antibodies in this experiment. The system also showed antibody-mediated phagocytosis involving both the Fc and unusually complement receptors in the absence of complement (Macura et al. 2007). Experimental yields revealed reduction in phagocytic index when treating the cells with excess Fc-antibodies that blocked the Fc-mediated phagocytosis while phagocytosis via the complement receptors made up for this negative effect, pointing out the complement receptors' phagocytic function. When further increasing the antibody concentrations, the phagocytic index was also further reduced due to blockage and interference with the complement receptors (Macura et al. 2007). The engulfing mechanisms of particles through the Fc receptor differs from the complement receptor; particles coated with IgG are engulfed by lamellipodia projecting from the surface of the phagocyte while particles opsonized with complement sink in the cell (Allen and Aderem 1996). Immunofluorescence and confocal microscopy were applied to examine the different association of cytoskeletal proteins that form with phagosomes

containing IgG beads and complement-coated particles in peritoneal macrophages. During the Fc-mediated phagocytosis, proteins involved in the formation of phagosomes like F-actin, vinculin, alpha-actinin, paxillin, and phosphotyrosine-containing proteins were found to be uniformly spreading near the phagosome forming surface. While with the phagocytosis of particles coated with complement, these proteins were distributed over the phagosomal area forming a foci underneath the bound particle in less than a minute of cellular incubation in the presence of active protein kinase C (PKC) (Allen and Aderem 1996).

Complement receptors on phagocytes naturally are involved in phagocytic function and as a result are implicated in autoimmune diseases resulting from the demyelination of axons in the central nervous system such as multiple sclerosis where invading macrophages phagocytose myelin. This was demonstrated by experiments on the multiple sclerosis animal model; experimental allergic encephalomyelitis (EAE) in rats. Huitinga et al. demonstrated the critical role macrophages play in the progress of EAE. When the macrophages were eliminated, in vivo, by injecting mannosylated dichloromethylene diphosphate-containing liposomes that are capable of crossing the blood brain barrier, the liposomes were able to deplete almost all macrophages in spleen and liver due to the toxic effect manifested once these liposomes are phagocytosed. Treatment of the animals with these liposomes, after the onset of EAE, significantly slowed down the expression of the diseases (Huitinga et al. 1990). In 1991, Brück and Friede demonstrated myelin phagocytosis mediation by the complement receptor type 3 on macrophages. Macrophages attack degenerating nerves, however incubating macrophages with degenerating nerves in a C3-deficient media showed no invasion of the macrophages on the nerves. C3-deficient media meant that it lacked the complement opsonins that would have coated the myelin that shed from the degenerated nerves and hence the receptors could not detect them. Furthermore, exchanging the normal media with C3-deficient media after macrophage invasion on these nerves resulted in loss of the phagocytic activity of these cells for the myelin produced from the degenerating nerves. This highlights the crucial role of macrophages' CR3 in myelin phagocytosis. To confirm their results, an in vivo experiment was done using monoclonal antibody to the CR3 showing reduced myelin phagocytosis due to blockage of these receptors (Brück and Friede 1990). In a similar experiment, Lewis EAE model rats were treated with cobra venom factor (CVF) to abolish the serum's complement resulting in noticeably reduced clinical expression of the disease, further establishing the involvement of complements and complement receptors in the progression of EAE and similar demyelination-associated diseases (Linnington et al. 1989).

Phagocytosis of apoptotic cells is an essential physiological cell death process. Apoptotic cells are phagocytosed in an

early stage of the apoptotic onset; with intact plasma membrane before any toxic leakage occurs from the cells, avoiding activation of inflammation pathways. Unlike lipopolysaccharide (LPS), apoptotic cells do not induce pro-inflammatory cytokines' production from macrophages. These dying cells are marked by phagocytes for phagocytosis by the cluster of differentiation receptor CD14 (Devitt et al. 1998). CD14 recognizes LPS on bacterial cells as well as markers on the apoptotic cells and the same receptor mediates different macrophage-induced responses. Reacting with LPS activates pro-inflammatory function of the macrophages while interaction with apoptotic cellular markers engages the macrophages in apoptotic clearance. This highlights the effects of self and nonself stimulants on the phagocyte's role and function. Apoptotic cells interact with CD14 inducing the phagocytic function of the phagocytes to engulf the apoptotic cells (Devitt et al. 1998).

The C-type lectin superfamily are characterized by the presence of C-type lectin-like domains. The C-type lectin superfamily consists of 17 groups and categorized based on their phylogeny and domain organization (Drickamer and Fadden 2002; Zelensky and Gready 2005). Mannose receptor is an endocytic carbohydrate-binding receptor found on populations of macrophages, dendritic cells, and nonvascular endothelium. The receptor is characterized as a type-I transmembrane protein belonging to the Group VI C-type lectin and is involved in many functions among them are clearance of endogenous molecules, promotion of antigen presentation, and mediation of cellular activation and trafficking. Mannose receptor Cluster of Differentiation 206 (CD206) is considered the prototype member of the mannose receptor family of proteins. Members of this family are known to be endocytic receptors sharing common structures like the N-terminal, Cysteine rich domains, fibronectin type II domains, and many CTLDs (C-type lectin-like domains). CD206 stands out in that it is the only member of the family with a functional cysteine rich domain. It consists of a cysteine rich amino terminal in the extracellular region, fibronectin type II repeat domain, eight CTLDs, a transmembrane hydrophobic region and a short cytoplasmic tail with a single tyrosine residue occurring within a diaromatic amino acid sequence (Kruskal et al. 1992). Mutation of that single cytoplasmic tyrosine can lead to reduction of phagocytosis but would not compromise it completely (Kruskal et al. 1992). Boskovic and his colleagues had proposed a structural model of the receptor where two conformations of the receptor exist; extended form and bent compacted form (Boskovic et al. 2006). CD206 expression is up-regulated by cytokines; IL-4, IL-13, and IL-10, while interleukin IFN γ shows a down-regulatory effect on the receptor's expression (Harris et al. 1992; Stein et al. 1992; Doyle et al. 1994; Martinez-Pomares 2012). The mannose receptor binds to numerous harmful microorganisms, including *Leishmania*

donovani and *Mycobacterium tuberculosis* (Schlesinger 1993; Chakraborty et al. 2001). The receptor recognizes sugar moieties on the microbe; mannose, fucose or N-acetylglucosamine sugar residues (Largent et al. 1984). Recognition of the carbohydrates resides in the C-type lectin-like domains (CTLDs) 4-8 (Taylor et al. 1992). Taylor, Bezouska, and Drickamer found that at least three carbohydrate-recognition domains (CRDs) are needed for high affinity binding to the receptor. Several CRDs with weak affinity for single sugars are grouped and cluster to achieve that high affinity binding needed for endocytosis induction. In the case of mannose receptor, these clustered weak interactions are obtained via many active CRDs from a single polypeptide chain (Taylor et al. 1992). While there are only few examples showing the important role mannose receptor plays in the MR-dependent phagocytosis, there are enough experiments done to remove the doubt that mannose receptors are not implicated in phagocytosis. The first experiment done in 1983 showed the mannose receptor as a phagocytic receptor by demonstrating inhibition of zymosan uptake by mice peritoneal macrophages (Sung et al. 1983b), using yeast mannan which is also recognized by other receptors rendering the experiment unreliable since uptake inhibition could have been induced by those other receptors inhibited by mannan as well. However, other studies followed that proved the role of mannose receptor in phagocytosis; experiments done in 1990 showed that transfecting non-phagocytic COS-1 cell line with the receptor's cDNA resulted in the receptor-mediated phagocytosis of mannose-rich glycoconjugate and yeasts (Ezekowitz et al. 1990). Ezekowitz and colleagues also showed the importance of the cytoplasmic tail of the mannose receptor for phagocytosis to take place, they transfected the same non-phagocytic COS-1 cells with mutant mannose receptor cDNA that expressed the mannose receptor minus the cytoplasmic tail. This mutation compromised phagocytosis and showed a great reduction in the uptake of radiolabeled mannose-BSA (Ezekowitz et al. 1990). In another study using cells of the murine macrophage cell line J774A.1 to measure the phagocytosis of *Francisella tularensis*; a gram-negative bacteria and tularemia's causative agent. Expressing the mannose receptors in the cell line J774A (MR-positive J774 cells) was found to be sufficient to enhance *Francisella tularensis* phagocytosis; the cells ingested nearly threefold more bacteria than the negative control (MR-negative J774) cells (Schulert and Allen 2006). There remain contradictions regarding the importance of mannose receptors in mediating phagocytosis and the research is ongoing to clear those doubts. Various players are recruited to the phagosome; F-actin, talin, PKC α , MARCKS and myosin I. However, in contrast to phagocytosis mediated by Fc γ Rs and complement, vinculin and paxillin are not recruited during phagocytosis via the mannose receptors (Allen and Aderem 1996; Kerrigan and Brown 2009).

Toll-Like receptors are members of the pattern recognition receptors family that also recognize the PAMPs on foreign microbes. TLRs were recently found to be involved in phagocytosis. Stimulation of microglial TLR1/2, TLR3, TLR4 and TLR9 with their corresponding agonists leads to an increased phagocytic function of the cells and increased the phagocytosis of *Cryptococcus neoformans* (Redlich et al. 2013). These investigators showed that stimulating these receptors lead to increased production and release of TNF- α , CXCL1 (KC), IL-6, IL-10 and MIP-2 and reflecting microglial activation. Compared to TLR-stimulated cells, they found that unstimulated cells had a noticeable reduced phagocytosis of the *Cryptococcus neoformans* as well as decreased intracellular killing ability. That experiment was successful to show that stimulation of TLR receptors of brain macrophages (microglia) increased the immunity function of these cells against CNS pathogen/microbes. In another experiment, phagocytosis of the gram-negative bacterium *E-coli* was increased in the RAW264.7 cell line, which normally has a low basal phagocytic activity, upon stimulation of the TLR9 (Doyle et al. 2004). Doyle et al. also found that phagocytosis stimulation by TLR9 induction relied on the myeloid differentiation factor 88-dependent signaling mediated by the interleukin 1 receptor-associated kinase-4 and p38 which eventually lead to up-regulation of scavenger receptors that are heavily involved in phagocytosis (Doyle et al. 2004), hence there is a positive feedback. Moreover, stimulation of TLR3 on mouse peritoneal macrophages was found to improve bacterial uptake by inducing the activation of interferon-regulating factor 3, which plays an essential role in the innate immune system response against viral pathogens (Deng et al. 2013).

11.2.2 Intracellular Killing

After the formation of a phagolysosome, the phagocyte begins to kill/degrade the engulfed foreign body it phagocytosed. The phagolysosomal pH could be as low as 4.0 as a result of lactic acid accumulating inside; the acidity is sufficient to halt majority of pathogens growth and as a result, survival. Upon engulfment of bacteria, there is almost an immediate loss of viability so as to stop it from reproducing. The phagocyte then proceeds to lyse and digest the pathogenic body by lysosomal enzymes. This microbicidal lysis/degradation activity can be divided in two categories depending on the type of the phagocytic cell; oxygen-dependent killing and oxygen-independent killing. In the oxygen-independent intracellular killing utilizes the lysosomal granules to render the germ inactive. The lysosomal granules contain different cationic basic proteins that are able to damage the germ cell's permeability barriers, for example the lysosomal granules in the neutrophils contain

lactoferrin, which is known to be a strong iron-chelating agent that stops bacterial growth by sequestering the iron needed for the bacterial growth and survival. This is in addition to the already acidic phagolysosomal environment which optimizes the degradative lysosomal enzymes that could include nucleases, phospholipases, lysozymes, and glycosylases (Cooper 2000).

As noted crosslinking of Fc receptors on neutrophils, monocytes, or macrophages, and mannose receptors on macrophages and dendritic cells eventually leads to the formation of the activated phagosome (Greenberg et al. 1993). The signaling of the Fc and mannose receptors leads to increases of cell oxygen uptake causing a case known as respiratory burst (Root et al. 1975). The burst is initiated by the phagocytic cell receptors; Fc and mannose receptors, that are capable of activating a membrane-bound NADPH oxidase that acts to produce reactive oxygen species by reducing the oxygen to a superoxide that can be further reduced to hydroxyl radical or dismutated to hydrogen peroxides via the action of the enzyme superoxide dismutase. NADPH oxidase gets assembled into activity upon the translocation of its cytosolic proteins components; gp40^{phox}, gp47^{phox}, gp67^{phox} and Rho-family GTPase Rac2. In addition to being activated by the phagocytic receptors, NADPH oxidase can be induced by microbial products, i.e. endotoxins, also by IFN- γ , and IL-8. Those reactive oxygen species are powerful oxidizing agents capable of inflicting irreversible damage to cellular structures; membranes and nucleic acids. In addition to the reactive oxygen species; myeloperoxidase (MPO) plays an important role in intracellular killing. MPO is a heme protein that is found in the granules of monocytes and neutrophils. Once the neutrophil is activated, it released the myeloperoxidase into the phagolysosome formed with the engulfed microbe. Myeloperoxidase can also be released in the extracellular space following the binding of specific agonists. During oxygen-dependent activity, the NADPH-dependent oxidase is activated leading to the generation of hydrogen peroxides. In an activated neutrophile, both MPO and hydrogen peroxides form MPO-hydrogen-peroxide-halide system, toxic hypohalites (Klebanoff 1999); this has a powerful and potent microbicidal activity. Mice lacking MPO production in their phagocytes showed increased susceptibility to *Candida albicans* (Aratani et al. 1999). In addition to the presence of ROS, reactive nitrogen species (RNS) that are synthesized via the iNOS, macNOS, or NOS2 enzyme (inducible isoforms of nitric oxide synthase), play important and potent microbicidal role. NOS is activated by cytokines and various immunological triggers as well as being regulated on transcriptional and post-transcriptional levels including various signal transduction pathways and molecules (Bogdan et al. 2000) Both ROS and RNS exist in most phagocytic cells however each species can be more/less present depending on the phagocytic cell in topic; greater

amounts of ROS is produced in neutrophils than in macrophages, in the meantime more ROS is generally produced in macrophages (Nathan and Shiloh 2000; Fang 2004). Reactive nitrogen species can also be referred to as reactive oxygen intermediates and they range from nitric oxides to nitrates, including S-nitrosothiols, peroxynitrite, and dinitrosyl-iron complexes. While reactive oxygen and nitrogen species might seem to be redundant functionally they both play essential roles in the host immunity against harmful attacks and often work synergistically (Rutkowski et al. 2007). “A phenotype indicating that a given gene product is important for resistance to a pathogen does not imply that other gene products are unimportant in defense against the same pathogen.” (Nathan and Shiloh 2000). The oxygen and nitrogen species intermediates can and do in fact damage the host DNA and kill the cells eventually in many cases but in the immediate immunity, the phagocytic cells are quick to sacrifice themselves to prevent microbial spread (Nathan and Shiloh 2000). Mice that showed deficiency in the phagocyte oxidase (phox), the major source of microbe-induced reactive oxygen intermediate production, were found to be at higher risk of various inoculated microbes such as chronic granulomatous disease (Sharon et al. 1995; Pollock et al. 1995), CGM is characterized by repeated life-compromising bacteria and fungal infections and granuloma formation in the patient’s tissue. Intracellular digestion results from the phagocytic killing of the microbes that are now dead and degraded in the phagolysosomes. Microbes are broken down to lower molecular weight fragments using hydrolytic enzymes that include proteases, lipases, lysozymes, nucleases, and glycosylases. Neutrophils lyse following a prolonged phagocytosis and macrophages digest the microbe as well but also undergo antigen presentation into the plasma membrane for presentation to the lymphocytes for a full immune response.

11.2.3 Secretory Activities

In addition to their phagocytic activity of foreign invading microbes, phagocytes have a critical secretory role by which mediate and are involved in inflammation especially in the case of the tissue macrophages that exist throughout the human body. The table shown below lists some of the different secretory products of the MPs such as lysosomal enzymes, complement proteins, prostaglandins and interferon. In this section, we’ll focus on the importance of some of these secretory activity products secreted by the monocytes-macrophages and how they contribute to the immunity homeostasis and inflammation; the different secretions work in concert with each other and at times against each other. Activated macrophages secrete various neutral proteinases; collagenases, elastases, plasminogen, and a

cytolytic type proteinase (Adams et al. 1980; Mainardi et al. 1980; Werb and Gordon 1975a, b; Unkeless et al. 1974).

MP secrete soluble products that enhance the immune system by activating more T-cells rendering an active immune attack against invading pathogens. Endogenous leukocytic pyrogen monokine produced by phagocytic cells was shown to augment the antigen-induced proliferation of murine T cells in a similar manner as macrophage cultures containing LAF (lymphocyte activating factor—IL-1) activity (Rosenwasser and Dinarello 1981). Moreover, Takemura and Werb were able to show that the macrophage secretions of proteinases’ concentrations (elastase and plasminogen activator) can be different depending on what receptor on the macrophage gets activated by the foreign pathogen (Takemura and Werb 1984). They were able to observe different rates of proteinases secretions when IgG erythrocytes and complement-coated erythrocytes interacted with the Fc receptors and complement receptors on the macrophages, respectively. They noticed that activation of the Fc receptors resulted in accelerated synthesis of the enzyme while activation of the complement receptors resulted in a transient secretion that dropped back to control levels sooner. Different macrophage secretion products have different and multiple activities. Human recombinant IL-1 is responsible for T-lymphocytes potentiation and activation (Gery et al. 1972). In addition, IL-1 produced by the human synovial cells was found to have a great role in collagenase and prostaglandin E2 production (Dayer et al. 1986).

Some macrophage secretions can enhance each others’ release and effects in a positive or negative manner. Production of TNF (tumor necrosis factor) enhances the macrophage ability to produce its intracellular reactive oxygen intermediates which enhances TNF performance since both have antitumor activity (Badwey and Karnovsky 1980; Hori et al. 1987). Macrophage-derived interferon- α , on the other hand, can have a negative effect on the production of interferon- γ or the macrophages’ superoxides (Yoshida et al. 1988).

11.2.4 Migration

Monocytes have essential roles in both innate and adaptive immune responses. Derived from bone marrow progenitor cells (CD34⁺), monocytes circulate the blood and differentiate into myeloid dendritic cells or tissue macrophages in response to the cytokine gradient or by chemokines released in response to a microbe or toxic proteins (Volkman and Gowans 1965; Van Furth and Cohn 1968; Virolainen 1968; Wang et al. 1988; Sozzani et al. 1991; Randolph and Furie 1995). Within hours of infection, neutrophils are mobilized to the site of attack; which is now characterized with inflammatory cytokines gradient production. Those mature

neutrophils are considered the chief population of circulating granulocytes (Imhof and Aurrand-Lions 2004). On the other hand, the monocytes are not mature (undifferentiated) when released from the bone marrow. These monocytes circulate in the blood for a time span of 1–3 days (Van Furth and Cohn 1968).

Monocytes are recruited to non-inflamed tissues as well as inflamed tissues; different cytokines recruit the monocytes to different conditions of tissues. In the absence of inflammatory stimuli, cytokines as well as specific adhesion molecules are the main players in the differentiation of monocytes and their accumulation into macrophages and dendritic cells in the peripheral tissues. Those cytokines and adhesion molecules are constitutively active to allow the accumulation of macrophages and dendritic cells at all time to set up a ready immune system soldiers at all time. One of the chemoattractant proposed to play a role in the constitutive trafficking of monocytes is BRAK (breast and kidney-expressed chemokine); also known as CXCL14 (Kurth et al. 2001). There have been numerous studies done to investigate monocytes' migration and recruitment to inflamed tissue. With the use of flow cytometry, classification of the monocytes was revealed based on the expression of surface markers that included chemokine receptors like CCR2, CCR5, or CXCR3 (Grage-Griebenow et al. 2001). The inflammatory monocytes known as CD14⁺ express increased levels of CCR2 which is the receptor for CCL2; monocyte chemoattractant protein 1, MCP1 (Boring et al. 1997). Boring and his colleagues showed that CCR2 minus mice's recruitment of peritoneal macrophages was critically decreased; leukocytes failed to migrate in response to the receptor's ligand MCP1. They, hence, concluded that CCR2 played a critical role in the immune response; being involved in the recruitment of monocytes/macrophages to the inflammatory sites (Boring et al. 1997). Additional experiments on mice deficient for the expression of the CCR2 yielded the same results, reduction of the monocyte recruitments (Kuziel et al. 1997; Kurihara et al. 1997). Mice deficient in the CCR2 ligand, MCP-1, also yielded the same result of abnormally decreased monocyte recruitment (Lu et al. 1998). These experiments confirmed the critical role CCR2 and its ligand play in modulating the immune system and recruitment of the inflammatory monocytes to sites of attacks.

Many others proteins play important roles in the migration of phagocytes; of these proteins MRP8 and MRP14. The two proteins were found to be involved in the transendothelial migration of phagocytes on the level of microtubule reorganization (Vogl et al. 2004). Major calcium-binding proteins of monocytes and neutrophils, gene disruption of MRP14 (S100A9) revealed its role in transendothelial migration. MRP14 binds to MRP8 (S100A8) in a complex to induce polymerization of microtubules. The phosphorylation of MRP14 by p38 mitogen-activated protein kinase (MAPK)

results in the disruption of the microtubules polymerization induced by the MRP14/MRP8 complex. When phosphorylated, higher levels of MRP8 are needed to overcome the antagonistic effect of phosphorylated MRP14 on the microtubule polymerization (Vogl et al. 2004). The microtubule polymerization takes place in a calcium-dependent manner. Polymerization decreases with increased activity of the MAPK phosphorylation activity on the MRP14 and increases with higher levels of calcium to overcome the conformational change resulting from the phosphorylation. Another factor that induces monocyte migration is the recombinant macrophage colony-stimulating factor (M-CSF) (Wang et al. 1988). Macrophage colony stimulating factor was found to be a potent chemoattractant with a preferential effect on the monocyte-macrophage cell lineage.

11.2.5 Antigen Presentation

Most phagocytes are antigen presenting cells (APC); to mention the main phagocytic cells macrophages, dendritic cells, and B cells. There are two main classes of MHC, also known as the human leukocyte antigen (HLA); MHC I and MHC II. MHC I is recognized by CD8 T cytotoxic cells while MHC II is strictly recognized by CD4⁺ T helper cells. MHCs were first discovered during mice studies involving tissue transplantation for its critical role in histocompatibility. Antigen presenting cells express MHC II (Class II histocompatibility molecules) in order to present fragments of the antigen that the APC had encountered, to the T helper cells. Intracellular killing and processing of the antigen is a necessary step before proceeding to present the antigen to the T helper cells. The degraded processed antigen fragments are known as determinant peptides or antigen epitopes. Processing the antigen into smaller peptides/molecules is followed by the presentation of these fragments on the MHC II molecules where they can be seen by CD4⁺ (T helper cells), which then establishes and maximizes the adaptive immune response against that antigen. Upon binding of the T lymphocytes to the MHC molecule, the antigen epitope held in the binding groove of the MHC molecule then interacts with the variable Ig-like domain of the T-cell receptor (TCR) to trigger its activation.

MHC I has three main regions; telomere class I, centromeric class II, and the central class III each with different functional roles (Dukkipati et al. 2006). General structure of MHC is conserved throughout the different mammalian species. MHC genes are polymorphic; there are various alleles in a population where MHC genes are codominantly expressed markers (Amills et al. 1998). MHC I molecules are glycoproteins molecules that are, as previously mentioned, expressed on every nucleated somatic cell. MHC I is a heterodimer. Its subunits consist of a heavy chain,

composed of three extracellular subunits $\alpha 1$, $\alpha 2$, $\alpha 3$, that is bound non-covalently to a light chain ($\beta 2$ -microglobulin chain) (Bjorkman et al. 1987). Only the heavy chain of the MHC-I glycoprotein is a transmembrane segment that transverse the APC's membrane.

MHC II molecule is also a heterodimer consisting of two transmembrane chains; α II and β II chains; α II chain consists of $\alpha 1$ and $\alpha 2$ domains and β II chain consists of $\beta 1$ and $\beta 2$ domains. The chains have N-linked glycosylation sites, connecting peptides, transmembrane regions to transverse the cell's membrane, and the cytoplasmic domains (Ottaviani et al. 2008). The α and β domains form the peptide-binding groove where they present the antigenic peptide to the T cell. And as with MHC I, α and β domains are also polymorphic showing high variability, which indicates the limitless diversity of the antigens to be presented (Brown et al. 1993).

11.2.6 Drug Carriage and Depots

Targeted drug nanoparticles are the recent drug evolution that is now taking over drug research and industry. Targeted-nanoparticles delivery enables the specific and localized targeting of the drug to the cells that the drug need to be in. In some cases those receptors being targeted could be redundant between cells however the targeted system still is much more efficient and focused on fewer cells in that case rather than the whole population of innocent cells in the drug's path/vicinity. This can improve the drug pharmacodynamics and pharmacokinetics as well as bioavailability; since only specific cells are being targeted drugs could be synthesized so that they would not biodegrade/unravel from their formula unless they are in the specified cell's environment and that would not take place until they are endocytosed/phagocytosed in their targeted cells. This is one important feature about using the nanoparticles for drug delivery because it can provide controlled release hence enabling a longer half life of the drug which is an issue with almost any drug that would indicate the potency of the drug and hence the dosage and frequency of drug administration. Complex biological barriers can block treatments to prevent and treat different diseases such as the blood brain barrier. Nanocarriers can be used to reach and penetrate these biological barriers that while are vital to maintain the system viability, could prevent drug delivery from reaching the infected and diseased cells (Table 11.1).

These targeting systems for nanocarriers can utilize lipids, biodegradable polymers, or even nonbiodegradable materials. The main prototypic example of lipid-based nanocarriers are the liposomes that were first described by Bangham in 1965. Following Bangham's discovery, 30 years passed before the first nontargeted liposomal formulated drug, Doxil, was made and approved by the FDA. Using

liposomes for drug delivery proved to be efficient for many ways; since liposomes are basically consisted of lipids; hence they are poor immunogenic and as a result tolerated by the body. The other advantage of liposomes is the possibility to synthesize them in different size which gives the option of packing the liposomes with a specified amount of drug and control the payload hence minimizing the side effects. The size of the nanoparticle is essential because it would determine whether it is eliminated easily from the body or accumulated in certain organs representing a danger to the whole system. In a study with quantum dots, it was found that particles smaller than 5.5 nm resulted in a rapid and efficient urinary excretion, otherwise excretion was slow or halted with bigger particles causing particles to be accumulated in certain organs such as the liver causing detrimental pharmacotoxicity (Choi et al. 2007). These liposomes could be modified with ligands that would target certain receptors on certain cells. The more specific and localized that receptor is the more of a localized, focused targeting these liposomes would have when launched in the system/body. Another important advantage of using liposomes is their ability to be loaded with hydrophobic or hydrophilic agents to deliver into the cells, which could prove to be challenging using any other techniques. In a study targeting monocyte-derived myeloid dendritic cells, mainly targeting the DC-SIGN (CD-209), a MyDC-associated C-type lectin involved in the transmission of HIV-1 to the T helper cell, liposomes encapsulated with fluorochrome targeted the receptor on the MyDCs showing a high liposomal binding and uptake visualized by the fluorochrome (Gieseler et al. 2004).

11.3 History and Cell Discovery

The discovery of phagocytosis by the Ukrainian Zoologist, Elie Metchnikoff, in 1882 marked the official beginning of the modern immunology field as we know it. Prior to Metchnikoff's discovery for phagocytosis by 30 years, there were evidences of endocytosis (phagocytosis is a type of endocytosis) by leukocytes, the main players of the immune system, however it was Metchnikoff who officially brought phagocytosis to the light by explaining its function and crucial role in immunity. To achieve recognition of the phagocytosis theory, Metchnikoff diligently worked on it for 25 years and as a result the theory was viewed to be "the first experimentally based theory in immunology" (Heifets 1982).

In Messina, while continuing a work on comparative embryology that he had started, Mechnikov stumbled on the phenomenon of phagocytosis. This finding was a result of observations he made with starfish larvae where he saw mobile cells which he hypothesized to have connection with the organism's defense/immune system. To prove his hypothesis, Mechnikov introduced thorns from a tangerine

Table 11.1 Secretory products of mononuclear phagocytes^a

Polypeptide hormones	Inhibitors of enzymes and cytokines
Interleukin 1- α and 1- β (collectively, IL-1)	Protease inhibitors: α -2-macroglobulin, α -1-antiprotease, plasminogen activator inhibitors, plasmin inhibitors, collagenase inhibitor
Tumor necrosis factor- α (cachectin) (TNF)	Phospholipase inhibitor: lipomodulin (macroscortin)
Interferons- α	IL-1 inhibitors
Interferon- γ (confirmation needed)	
Platelet-derived growth factor(s)	Proteins of extracellular matrix or cell adhesion
Fibroblast growth factors	Fibronectin
Fibroblast activating factors	Gelatin-binding protein of 95 kD
Transforming growth factor- β	Thrombospondin
Insulinlike activity	Chondroitin sulfate proteoglycans
Thymosin B4	
Erythropoietin	Other binding proteins
Colony-stimulating factor for granulocytes and macrophages (CSF-G/M)	For metals: transferrin, acidic isoferitins, transcobalamin II
Colony-stimulating factor for granulocytes (CSF-G)	For lipids apolipoprotein E, lipid transfer protein
Erythroid colony-potentiating factor	For biotin: avidin
Factor-inducing monocytopenia	
β -Endorphin	Bioactive oligopeptides
Adrenocorticotrophic hormone	Glutathione
Plasmacytoma growth factor	
Neutrophil-activating factor	Bioactive lipids
Complement (C) components	Cyclooxygenase products: prostaglandin E ₂ (PGE ₂), prostaglandin F _{2a} , prostacyclin, thromboxane
Classical path: C1, C4, C2, C3, C5	Lipoxygenase products: monohydroxyeicosatetraenoic acids, dihydroxyeicosatetraenoic acids, leukotrienes B ₄ , C, D, E
Alternative path: factor B, factor D, properdin	Platelet-activating factors (1-O-alkyl-2-acetyl-sn-glyceryl-3-phosphorylcholine)
Inhibitors: C3b inactivator, β -1H	
Active fragments generated by macrophage proteases: C3a, C3b, C5a, Bb	Sterol hormones
Coagulation factors	1 α , 25-Dihydroxyvitamin D ₃
Intrinsic path: IX, X, V, prothrombin	
Extrinsic path: VII	Purine and pyrimidine products
Surface activities: tissue factor, prothrombinase	Thymidine, uracil, uric acid, deoxycytidine
Prothrombolytic activity: plasminogen activator	Neopterin (2-amino-4-oxo-6-trihydroxypropylpteridine)
Antithrombolytic activities: plasminogen activator inhibitors, plasmin inhibitors	
Other enzymes	Reactive oxygen intermediates
Neutral proteases: plasminogen activator, elastase, collagenases, angiotensin convertase, others	Superoxide, hydrogen peroxide, hydroxyl radical, hypohalous acids
Lipases: lipoprotein lipase, phospholipase A ₂	
Glucosaminidase: lysozyme	Reactive nitrogen intermediates
Lysosomal acid hydrolases: proteases, lipases (deoxy) ribonucleases, phosphatases, glycosidases, sulfatases	Nitrites, nitrates
Deaminase: arginase	

Table was reproduced with permission from the journal and author. Nathan, CF (1987) Secretory products of macrophages. J Clin Invest 79(2):319–326

tree that he had prepared as a Christmas tree for his family. Next morning, Mechnikov noticed that the thorns he had introduced were surrounded by those mobile cells he had observed in the starfish larvae. Making the connection between those mobile cells and the leukocytes that migrate

in the blood stream of organisms with a blood vascular system, play similar role in the host's defenses where they could be engulfing and eating up foreign and harmful bacteria the same way the mobile cells of the starfish larvae had eaten up the tangerine thorns. In Vienna, Mechnikov shared

his ideas with Claus, professor of Zoology, who suggested the name *Phagocytes* for those mobile cells that engulfed the tangerine thorns. In 1883, in Odessa, he gave his first paper on phagocytosis marking a fundamental breakthrough in immunology. In Paris, at the Pasteur Institute, he kept busy on establishing his theory of cellular immunity. During that time, he wrote several papers and two volumes on the comparative pathology of inflammation and in 1901 he published his famous treatise known entitled *Immunity in Infectious Disease*. In 1908 he was honored, along with Paul Ehrlich, with the Nobel Prize for Physiology or Medicine (Nobel Lectures 1967). Metchnikoff's discovery of the phagocytic function of leukocytes to rid the body of harmful bacteria lead to a huge advancement and progress in immunology and earned him the title "Father of natural immunity". The first person known to have observed phagocytosis in action under the microscope is a German clergyman and an amateur naturalist, Johann August Ephraim Goeze. In 1777 Goeze published his observations of protists ingesting other protists. In his publication, Goeze writes his observations of predators and preys as some protists ingest other "weaker" or smaller protists.

11.4 Review Questions

1. Tissue macrophages evolve from:
 - (a) Neutrophils
 - (b) Basophils
 - (c) *Monocytes*
 - (d) Dendritic cells
2. Two types of phagocytes are the _____ and _____ phagocytes.
3. Some of the critical phagocytes' receptors that play a significant role in recognizing PAMPS on foreign antigens are _____, _____, and _____.
4. This receptor was found to be implicated in demyelination-associated diseases:
 - (a) Mannose receptor
 - (b) TLR4
 - (c) CD209
 - (d) *Complement receptor 3*
5. Intracellular killing of the engulfed pathogens takes place through _____ or _____.
6. Unlike all the other cells, antigen presenting cells also express this receptor on their surface
 - (a) MHC I
 - (b) *MHC II*
 - (c) CD206
 - (d) FcR
7. Macrophage secretions can enhance each others' release and effect in a _____ or _____ manner.

8. Monocytes circulate the blood and differentiate into myeloid dendritic cells or tissue macrophages due to the _____ released in response to a microbe or toxic proteins.
9. All of these steps are involved in phagocytosis except:
 - (a) Intracellular killing
 - (b) Phagolysosome formation
 - (c) Receptor recognition
 - (d) Secretory activity
 - (e) *None of the above*
10. This protein is found to be involved in the phagosome formation mediated by Fc-mediated phagocytosis
 - (a) F-actin
 - (b) Vinculin
 - (c) Alpha-actinin
 - (d) Paxillin
 - (e) *All of the above*

11.5 Answers

2. Professional; nonprofessional
3. Fc receptors; C-type lectin receptors; Toll-like receptors
5. Oxygen-dependent killing; oxygen-independent killing.
7. Positive; negative
8. Cytokine gradient

Abstract

Mononuclear phagocytes (MP; monocytes, macrophages, microglia and dendritic cells) are joined together based on common function and phenotypic properties. In regards to phagocytic, interacellular killing, secretory, antigen presentation and mobility properties differentiating the cell types can be difficult. Ontogeny, locale and modest phenotype differences underlie differences. Similarities abound in innate immunity and protection of a steady-state homeostatic environment and engaging inflammatory responses that direct surveillance and clearance responses. A clear benefit of spanning tissue origins and species differences underlies the importance of these cells that serve as the first line of immune defense.

Keywords

Dendritic cells • Macrophages • Major histocompatibility • Microglia • Mononuclear phagocytes • Multiple sclerosis • Neurodegeneration • Neuroprotection • Pathogen-associated patterns • Progenitor cells • Reactive oxygen species • Toll-like receptors

12.1 Mononuclear Phagocytes (MP)

Mononuclear phagocytes (MP) encompass a diverse collection of immune cells including monocytes, tissue-resident macrophages, microglia, and dendritic cells (DC) (Chow et al. 2011). Seemingly distinct, MP all possess the ability to facilitate phagocytosis, secrete cytokines, and initiate lymphocyte interactions (Wiktor-Jedrzejczak and Gordon 1996). Early description of MP ontogeny reported bone marrow (BM) derived promonocytes giving rise to circulating monocytes, which subsequently can populate peripheral tissue, ultimately generating tissue-resident macrophages (van Furth and Cohn 1968). Further investigation yielded the discovery of a novel cell type of discrete lineage and morphologically distinct from macrophages, termed dendritic cells (DC) (Steinman and Cohn 1973). Current research has expanded and redefined the

origins of all MP. Specifically, common myeloid progenitors (CMP) have the potential to give rise to all cells of myeloid lineage, and in more immediate terms, granulocyte/macrophage (GMP) and monocyte-macrophage-DC precursors (MDP) (Akashi et al. 2000; Geissmann et al. 2010). Further downstream, monocytes, macrophages, and dendritic cells each arise from a defined set of precursors specific to each cell type and will be expanded upon in this chapter. Each MP has a defined role in the immune system, protecting the body from and/or responding to potential pathogens. Interestingly, during infection or an inflammatory response, increased expression of macrophage colony-stimulating factor (MCSF), can directly effect the differentiation of hematopoietic stem cells (HSC) by interacting with myeloid master regulator PU.1 to transiently increase myeloid progeny (Mossadegh-Keller et al. 2013). MCSF modulation of HSC differentiation is a deviation from previous theories suggesting the influence of MCSF was on lineage-committed progenitors such as GMP, not the HSC themselves (Rieger et al. 2009; Mossadegh-Keller et al. 2013). This chapter will focus on each subtype of MP, with a specific emphasis on their interactions with the central nervous system (CNS).

12.1.1 Monocytes

12.1.1.1 Origin and Development

Monocytes represent a diverse leukocyte subset that rapidly responds to injury or infection, aiding in the scavenging of toxic compounds or apoptotic cells (Geissmann et al. 2008; Auffray et al. 2009; Ginhoux and Jung 2014). Originating from HSCs in the bone marrow, the two main mouse monocyte subsets (LY6C^{Hi} and LY6C^{Low}) emerge from differentiation of the monocyte-macrophage DC progenitor (MDP) and subsequently the common monocyte progenitor (cMoP) (Fogg et al. 2006; Hettinger et al. 2013; Ginhoux and Jung 2014). Upon entry into the bloodstream, LY6C^{Hi} monocytes have the potential to differentiate into the LY6C^{Low} subset (Sunderkotter et al. 2004). In addition, LY6C^{Hi} monocytes actively migrate to sites of inflammation where they can differentiate into monocyte-derived macrophages (Geissmann et al. 2003). Interestingly, in the absence of inflammation, LY6C^{Hi} monocytes retain the potential to circulate back to the BM and undergo further differentiation (Varol et al. 2007). In contrast, LY6C^{Low} monocytes constitutively provide immune surveillance by patrolling endothelial cells, thereby allowing prompt responses to infection leads to inflammation (Auffray et al. 2007). Although monocytes foster the ability to differentiate into macrophages, they are not the primary source of tissue-resident macrophages (Ginhoux and Jung 2014). Certainly, this provides a stark shift from the traditional ideology of monocyte function and behavior. Tissue macrophage populations, such as those of the brain, liver, spleen, and lung are embryonically derived, thus undergo self-renewal in adult tissue (Ginhoux et al. 2010; Hashimoto et al. 2013; Jakubzick et al. 2013; Yona et al. 2013). Exceptions, such as intestinal macrophages persist, where circulating monocytes are principally responsible for the tissue macrophage population (Zigmond and Jung 2013). Monocytes are a fundamental component of the innate immune system and their biological function in the presence of neuropathology is discussed below.

12.1.1.2 Monocyte Neuroimmunology

Monocytes have a substantial role in HIV-1 pathogenesis. Infected monocytes cross the blood brain barrier (BBB) via surface adhesion molecules expressed on brain microvascular endothelial cells (BMVEC) such as E-selectin and VCAM-1 (Nottet and Gendelman 1995). Upon CNS entry, monocytes differentiate into macrophages, and develop a viral reservoir in the brain (Koenig et al. 1986). Specifically, HIV-1 infected CD14⁺/CD16⁺ monocytes cross the BBB in a CCL2-mediated mechanism and do so at a rate higher than uninfected counterparts (Eugenin et al. 2006; Williams et al. 2013). Populations of circulating CD14⁺/CD16⁺ monocytes increase during late stages of HIV-1 infection and not only accumulate in perivascular regions of the CNS, but also pre-

ferentially harbor HIV-1 compared with CD16⁻ subsets (Thieblemont et al. 1995; Fischer-Smith et al. 2001; Ellery et al. 2007). Furthermore, HIV-1 infected monocytes are resistant to apoptosis, thereby maintaining a cell population that is susceptible to infection (Giri et al. 2009). HIV-1 seeding within the CNS by monocytes significantly impacts the development of HIV-1 associated cognitive disorders (HAND). Continued research into the effect of monocytes on the progression of HIV-1 neuropathogenesis is imperative for the advancement of new therapeutic designs.

In mouse models, LY6C^{Hi} monocytes migrate to sites of infection and further differentiate within inflamed tissue. For example, in experimental autoimmune encephalomyelitis (EAE), a model of multiple sclerosis (MS), significant portions of LY6C^{Hi} monocytes infiltrate the CNS, where they differentiate into monocyte-derived macrophages (King et al. 2009). CNS infiltrating monocytes during EAE may have a detrimental effect as evidence suggests monocytes recruited to the CNS via a CCL2/CCR2 mediated mechanism actually increase disease progression (Ajami et al. 2011). In terms of relapsing EAE, the balance between pro-inflammatory M1 and immunoregulatory M2 phenotypes is important. Specifically, it was observed that when the monocyte population in the blood is shifted toward M1, relapse is favored, thus subsequent administration of ex vivo M2 monocytes can suppress EAE, thereby balancing the M1/M2 equilibrium (Mikita et al. 2011).

12.1.2 Dendritic Cells

12.1.2.1 Background

Dendritic cells (DC) were discovered in the 1970s when Steinman and Cohn observed a novel cell type with a stellate and elongated morphology, constantly using its cellular processes to probe its environment (Steinman and Cohn 1973; Steinman 2007). Observed in both lymphatic and non-lymphatic tissue, dendritic cells have the capacity to ingest antigens and provide surface presentation in conjunction with major histocompatibility complex (MHC) molecules (Steinman 2007; Ransohoff and Cardona 2010). Therefore, immature DCs probe their environment for potential antigens; possess a vast array of pathogen associated molecular pattern receptors (e.g. TLRs), and react to numerous cytokines (Iwasaki and Medzhitov 2004; Villadangos and Schnorrer 2007). Receptor engagement triggers migration to lymphoid organs, where DCs can specifically engage and activate T-cells (Banchereau and Steinman 1998). Therefore DCs are essential for presenting antigen to T-cells in lymph nodes, thereby facilitating an appropriate immune response (Villadangos and Schnorrer 2007). Further detail into the ontology and biological role of DCs during neuropathology will be presented in the proceeding section.

12.1.2.2 Ontology

Dendritic cells (DC), generally categorized as either classical (cDC) or plasmacytoid (pDC), arise from progenitors within the bone marrow (Merad et al. 2013). Specifically, MDPs possess the capacity to differentiate into a common DC progenitor (CDP) (Onai et al. 2007; Liu et al. 2009). Flt3 ligand (Flt3L) is imperative for further downstream development to either cDC or pDC, as Flt3L-deficient mice have severe deficiencies in these cell types (McKenna et al. 2000). In terms of differentiation, CDPs can produce pDCs or Pre-cDCs, with only Pre-cDCs having the capacity to further differentiate into cDCs (Naik et al. 2006). The specific functions and characteristics of each cell type (cDC or pDC) will be expanded upon below.

12.1.2.3 Classical Dendritic Cells (cDC)

Pre-cDCs, generated in the bone marrow, enter the bloodstream and distribute to lymphatic tissue ultimately generating both subsets (CD11b⁺/CD8⁺) of mature cDCs (Liu et al. 2009; Merad et al. 2013). Specifically, pre-DCs gain entrance into lymph nodes through high endothelial venules (HEV), where they mature and distribute (Liu et al. 2009). Additionally, populations of CD103⁺ cDCs (resemble CD8⁺ cDCs) found in nonlymphoid tissue are also derived from pre-cDCs (Ginhoux et al. 2009). In terms of the CNS, DCs have been observed in meninges and/or choroid plexus, suggesting their potential importance in autoimmune diseases of the brain (Matyszak and Perry 1996; McMenamin 1999; Zozulya et al. 2010). Specifically, DCs populate this area in an Flt3L specific manner, in which replenishment from the bone marrow occurs every 5–7 days (Anandasabapathy et al. 2011). In mouse models of multiple sclerosis (MS), such as experimental autoimmune encephalomyelitis (EAE), disease progression can be introduced through adoptive transfer of encephalitogenic CD4⁺ T helper (T_H) cells (Greter et al. 2005). Interestingly, Greter et al. observed CD11c⁺ DCs associated with the meninges and CNS blood vessels can prime encephalitogenic CD4⁺ T_H cells, resulting in CNS inflammation and disease progression. In fact during the onset of EAE, infiltrating cDCs are found in perivascular regions, ultimately migrating to the spinal cord during disease progression (Clarkson et al. 2014). Further investigation into the biological role of DCs during EAE is necessary and may yield substantial insights in regards to MS therapeutic development.

12.1.2.4 Plasmacytoid Dendritic Cells (pDC)

pDCs, which are characterized morphologically by a rounded shape, circulate in the bloodstream and enter the lymph nodes in a CCR7 dependent manner upon activation (Sozzani et al. 1998; Cella et al. 1999; Reizis et al. 2011). Additionally, the defining characteristic of pDCs remains its

capacity to secrete large quantities of Type 1 Interferon (IFN- α/β) upon detection of foreign nucleic acids by intracellular Toll-like receptors (TLRs) (Liu 2005; Reizis et al. 2011). Specialized for viral nucleic acid detection, pDCs are able to ingest foreign antigens and engage in cross presentation to T-cells, when activated by a TLR-7/9 dependent mechanism (Kadowaki et al. 2001; Mouries et al. 2008). pDCs are active participants during neuroinflammation, exemplified by their significant infiltration into the CNS during MS and its subsequent animal model, experimental autoimmune encephalomyelitis (EAE). In EAE, pDCs accumulate around white matter lesions, but have also been observed in the cerebrospinal fluid (CSF) of MS patients (Pashenkov et al. 2001; Bailey-Bucktrout et al. 2008; Lande et al. 2008). Characterization of pDCs isolated from MS patients' revealed drastic reductions in co-stimulatory molecules CD86 and 4-1BBL expression leading to inefficient maturation, and a potential source of the immune dysregulation observed in MS (Stasiolek et al. 2006). Furthermore, Derkow et al. investigated the mechanism behind interferon- β treatment in relapse-remitting MS (RRMS) patients. Interestingly, it was observed interferon- β upregulates TLR7 in pDCs, thereby increasing its immunoregulatory activity, a possible source of protection from virus-triggered relapse in MS patients (Derkow et al. 2013). Certainly, the role of pDCs in CNS autoimmune diseases such as MS is complex and research is beginning to elucidate their pathological influence.

A hallmark of progressive immune system suppression in HIV-1 infection is reduction of CD4⁺ T-cells. In addition, infected individuals exhibit decreased levels of circulating pDCs facilitating further suppression of the immune system and development of opportunistic infections (Soumelis et al. 2001). Although numerically reduced, pDCs of HIV-1 infected individuals exhibit a hyperactivated state whereby TLR mediated chemokine/cytokine production is significantly higher than uninfected controls (Sabado et al. 2010). HIV-1 activates pDCs by interacting with CD4 on the cell surface, as well as intracellularly via TLR7 viral RNA recognition (Beignon et al. 2005). This activation produces IFN- α/β thereby facilitating activation of neighboring cDCs (Beignon et al. 2005). In addition, HIV-1 infected patients termed long-term non-progressors (LTNP) do not show deficiencies in pDC levels suggesting an important role in disease progression (Almeida et al. 2005). On the contrary, continual activation of pDCs may be detrimental as persistent IFN- α expression leads to IDO production, as well as specialized DCs with the ability to kill uninfected CD4⁺ T-cells (Fitzgerald-Bocarsly and Jacobs 2010). Certainly, pDCs play a complex role in HIV-1 infection and continued research is necessary to elucidate its role in disease progression and potential therapeutic target.

12.1.2.5 DC Vaccines

Dendritic cells constitute an integral arm of the immune system by facilitating antigen ingestion, presentation, and subsequent T-cell activation. Therefore, the design of immune therapies harnessing the specificity and potency of DCs has tremendous potential. One such therapeutic option involves the injection of ex vivo generated DCs loaded with tumor antigens in an effort to activate a tumor-specific T-cell response in patients (Steinman and Banchereau 2007). To this end, investigators have explored DC vaccines as an alternative strategy for the treatment of primary malignant gliomas, where current treatment focuses on radiation therapy and surgery (Liau et al. 1999). In early research conducted in animal models, Liau et al. pulsed dendritic cells with glioma antigens, thereby generating a DC population, which could facilitate a cytotoxic T-lymphocyte (CTL) response against the tumor and significantly increased the survival of treated mice compared to controls. Development of DC vaccines has progressed from animals into Phase I/II clinical trials in glioma patients and is thoroughly reviewed by Kim and Liau (2010) and Sampson and Mitchell (2015). Currently, DC vaccines have been predominantly clinically ineffective, although clinical trials have deemed the approach feasible and well tolerated (Sampson and Mitchell 2015). Lack of clinical efficacy may lie in the inability of a significant portion of injected DCs to migrate from injection site to the lymph nodes (Steinman and Banchereau 2007; Sabado and Bhardwaj 2015). To this end, Mitchell et al., primed DC injection sites with tetanus/diphtheria (Td) toxin and significantly increased DCs in draining lymph nodes compared to controls (Mitchell et al. 2015). Focus of current research centers around the development of adjuvants to improve the efficacy of DC vaccines and its progress bear monitoring (Sampson and Mitchell 2015).

12.2 Mononuclear Phagocytes in the CNS

The CNS contains a heterogeneous population of myeloid derived mononuclear phagocytes. Specific anatomical regions such as the choroid plexus, meninges, and perivascular space are occupied by hematopoietically-derived macrophages under pathological conditions (Prinz et al. 2011; Prinz and Priller 2014). In fact, CNS inflammation is a consistent hallmark of neurodegenerative diseases such as Parkinson's disease (PD), Alzheimer's disease (AD), MS, Amyotrophic Lateral Sclerosis (ALS), despite their discordant etiologies (Schwartz and Baruch 2014). Alternatively, microglia reside within the CNS parenchyma as a self-renewing resident macrophage population during both physiological and pathological states. Microglia have a distinct ontology compared to the BM-derived macrophages, which transiently infiltrate areas of the CNS during brain pathology. This section will describe in

detail the mononuclear phagocytes in the CNS and their role in the contexts of neuroimmunology.

12.2.1 Choroid Plexus (CP)

The blood-CSF barrier (BCSFB) surrounding the choroid plexus is structurally and functionally distinct from the blood-brain barrier (BBB) (Schwartz and Baruch 2014). In fact it is more permissive, exemplified by observations of CD4⁺ T-memory cells in the CSF of healthy individuals performing immune surveillance (Kivisakk et al. 2003). During incidence of neuropathological conditions such as spinal cord injury (SCI), an IFN- γ /IFN- γ R pathway is used to recruit leukocytes to the choroid plexus (Kunis et al. 2013). In models of SCI, Ly6c^{Low} monocytes infiltrate the CNS via the choroid plexus and subsequently differentiate into M2 monocyte-derived macrophages (Shechter et al. 2013). Monocyte exit from the bloodstream and subsequent passage across the BCSFB, involves adhesion molecules (VCAM-1/VLA-4, ICAM-1) expressed on the BCSFB surface, as well as CD73, an epithelial enzyme that can assist movement across epithelial cell barriers (Steffen et al. 1996; Szmydynger-Chodobska et al. 2012; Shechter et al. 2013; Schwartz and Baruch 2014).

12.2.2 Perivascular Space

Perivascular macrophages (PVM) reside within spaces surrounding cerebral vasculature and present a convergence between the immune system and the CNS (Williams et al. 2001; Kim et al. 2006). Continuously replaced by bone marrow derived monocytes, perivascular macrophages maintain functional phagocytic and antigen presentation capabilities (Hickey and Kimura 1988; Williams et al. 2001). Identification of PVM from invading monocytes and resident microglia is often difficult. Originally, CD163 was used to specify PVM, but further evidence revealed their expression in microglia as well as subsets of monocytes (Kim et al. 2006; Holder et al. 2014). Therefore, CD206 or the macrophage mannose receptor is used to differentiate PVM from CNS resident microglia and other infiltrating monocytes (Galea et al. 2005; Holder et al. 2014). In terms of neuropathological conditions such as HIV/SIV, PVM are the major CNS cell type infected in SIV and significantly increase in numbers post infection (Lane et al. 1996; Williams et al. 2001). PVM provide a means of HIV entry (other than cell free mechanisms) and facilitate the progression of disease within the CNS. Furthermore, patients exhibiting HIV-1 related neurocognitive disorders (HAND) present with increased levels of infiltrating perivascular macrophages in the brain parenchyma and represent the main population of infected cells in the CNS (Fischer-Smith et al. 2001).

12.2.3 Microglia

12.2.3.1 Background

Microglia are highly dynamic resident immune cells of the brain. Originally considered “resting” during normal physiological conditions, recently it was determined microglia constantly probe their microenvironment in an effort to thwart potential pathogens or localized cellular injury (Nimmerjahn et al. 2005). Subtle changes in the CNS microenvironment in terms of foreign DNA, antibodies, cytokines, chemokines, or abnormal endogenous protein levels, are sensed by receptors (TLRs, Scavenger receptors, MAC1, etc.), which facilitate a transition to an “activated” microglial state more apt to provide an appropriate cellular response (Block et al. 2007; Hanisch and Kettenmann 2007). Microglial activation causes polarization a kin to what occurs in macrophages, thus developing an M1 or M2-like phenotype, each presenting a markedly different cellular response (Prinz and Priller 2014). The rest of this section will focus on the mechanisms by which microglia survey its microenvironment, its reaction to environmental changes, and its role during neurological pathology.

12.2.3.2 Origin and Development

Microglia, the tissue-resident macrophage of the brain, regulates tissue homeostasis during normal physiology, as well as in CNS pathogenesis (Prinz and Priller 2014). Originally conceived as BM-derived, current evidence suggests microglia arise from a yolk-sac lineage during the early stages of embryogenesis (Ginhoux et al. 2010). Ginhoux et al., determined yolk sac macrophages arising before E8.0 significantly contribute to the homeostatic pool of microglia in the healthy adult brain. Therefore, under the current model, macrophages of the yolk sac enter the brain via the circulatory system, subsequently enter the neuroepithelium around E9.5 resembling macrophages in terms of morphology and F4/80 and CD11b surface expression (Ginhoux et al. 2010; Perry and Teeling 2013; Nayak et al. 2014). Once in the CNS, the development and differentiation of microglia is not completely defined. New molecules are continually being identified as effectors/mediators of microglia development. One such molecule, Colony stimulating factor 1 receptor (Csf1-r), is indispensable in microglial development, in that Csf1-r knockout mice exhibit extensive reductions (~99%) in microglia postnatally (Erblich et al. 2011). In addition, microgliogenesis, the process by which microglia emerge from yolk sac-derived erthromyeloid precursors is dependent on an interferon regulatory factor 8 (Irf8)/PU.1 specific pathway (Kierdorf et al. 2013). Runt related transcription factor 1 (Runx1), a regulator of proliferation and differentiation in myeloid progenitors promotes the transition of phagocytic prenatal amoeboid microglia into the ramified cells found in the healthy developed brain (Kurokawa 2006; Zusso

et al. 2012; Prinz and Priller 2014). Certainly continued research is necessary to elucidate the complex molecular and transcriptional regulation required for successful microglial development and differentiation.

12.2.3.3 Microglia Function in the Healthy Brain

Research in microglial biology often focuses on cellular behaviors during disease or tissue injury/inflammation. Interestingly, microglia exhibit dynamic behavior in the CNS under normal physiological conditions. Morphologically, “resting” microglia exhibit a ramified architecture and express low levels of CD45, MHC II, and Fc receptors on their cell surface (Perry and Teeling 2013). In terms of gene expression, neighboring neurons provide substantial input, exemplified by nerve growth factors (NGF) inhibitory effect on MHC II expression in “resting” microglia (Neumann et al. 1998). In fact, evidence continues to emerge for the prominent role of microglia during brain development and synaptic maintenance (Graeber 2010). Therefore, firm understanding of microglia cell biology under steady state conditions may provide insight into neurocognitive or degenerative conditions associated with synaptic loss or aberration.

During development, microglia actively participate in synaptic pruning (Paolicelli et al. 2011). In fact, studies utilizing two-photon microscopy confirm “resting” microglia frequently contact neuronal synapses, thereby efficiently monitoring synaptic health (Wake et al. 2009). Furthermore, interactions were prolonged in response to transient ischemia, ultimately resulting in presynaptic terminal removal (Wake et al. 2009). Moreover, microglia phagocytize retinal ganglion cell (RGC) presynaptic inputs in an activity dependent manner during development (Schafer et al. 2012). This interaction was facilitated by complement component 3 (C3) and its receptor (CR3), in what is deemed to be a microglia-specific phagocytic pathway (Schafer et al. 2012). This evidence corroborates previous work in which mice deficient of C3 exhibit developmental deficiencies in terms of synaptic elimination (Stevens et al. 2007). Furthermore, Cx3cr1 KO mice, which lack Cxcr1 expression on the microglial surface, exhibit decreased levels of microglia, as well as deficient synaptic pruning, therefore leading to increased persistence of immature synapses (Harrison et al. 1998; Jung et al. 2000; Paolicelli et al. 2011). Moreover, the neurodevelopmental deficiencies observed in Cx3cr1-KO mice manifested in decreased social interaction, coupled with increased repetitive behaviors; phenotypes often associated with models of autism spectrum disorders (Zhan et al. 2014). Research into the role of microglia during development, as well as, normal physiological conditions continues reshape our conceptions. Continued research investigating the role of microglia in maintenance and/or remodeling of synaptic networks is currently being investigated.

12.2.3.4 Microglia and CNS Homeostasis

Microglia constantly probe their microenvironment garnering information necessary to maintain CNS tissue homeostasis. Detection of environmental aberrations, such as foreign molecules or those familiar but at atypical concentrations, cause microglia to shift toward one of two activated states (Hanisch and Kettenmann 2007). This shift in phenotype, which is coupled with a transition to a more amoeboid morphology and altered surface receptor expression (CD14, MHC), facilitates an effective response to the perceived environmental changes (Block et al. 2007; Kettenmann et al. 2011). Traditional macrophages become polarized to either M1 or M2 macrophages. Phenotypically, M1 macrophages exhibit a rounded morphology and produce pro-inflammatory cytokines (IL-1, IL-6, IL-23), while conversely M2 macrophages possess a bipolar nature, and have the potential to induce T_H2 cells responses and secrete pro-inflammatory cytokines (e.g. IL-10) (Mosser and Edwards 2008; Durafour et al. 2012; Prinz and Priller 2014). Microglia in the CNS adopt similar but not identical phenotypes, thus their polarization is termed M1 and M2-like (Durafour et al. 2012). Certainly the balance between these two phenotypes is imperative. Prolonged release of pro-inflammatory cytokines by M1-like activated microglia activates NADPH oxidase and production of reactive oxygen species (ROS), potentially a source of cytotoxicity (Block et al. 2007). In the next few sections, the role of microglia (M1/M2) will be explained in terms of different disease states, yielding a better understanding into the functional role of each distinct phenotype in various disease models.

12.2.3.5 Alzheimer's Disease (AD)

Post-mortem studies of AD patients reveal accumulation of β -amyloid (A β) protein in conjunction with activated microglia, rendering a prominent pathological hallmark (Dickson et al. 1988; Hickman et al. 2008). Microglia become activated in the presence of aggregated β -amyloid and subsequently release proinflammatory cytokines, such as TNF- α (Meda et al. 1995). Additionally, microglia have been observed to secrete proteolytic enzymes in attempts to degrade these protein accumulations (Qiu et al. 1998). Receptor complexes on the microglia surface mainly comprised of CD36, $\alpha_6\beta_1$ -integrin, and CD47, bind fibrillar A β , thereby activating intracellular signaling cascades resulting in proinflammatory cytokine release (Bamberger et al. 2003). Additionally, further evidence revealed the TLR4, TLR2, and CD14, function on the surface of microglia to aid in fibrillar A β phagocytosis and microglial activation (Reed-Geaghan et al. 2009). Early phase microglial β -amyloid scavenging has been hypothesized to slow the onset of disease progression (Solito and Sastre 2012). Studies in PS1-APP mice models of AD, reveal that over time microglia lose

their ability to effectively clear A β , as evidenced by reduced expression of surface receptors responsible for A β clearance (Hickman et al. 2008). Additionally, not only do they become inefficient in A β clearance, but they continue to secrete pro-inflammatory cytokines, potentially causing cytotoxicity (Hickman et al. 2008). Continued research into the behavior of microglia during AD is critically important. Understanding the molecular biology of microglia during its different activation states, will allow the design of new targeted therapeutics slow the progression of AD.

12.2.3.6 Parkinson's Disease (PD)

PD is notoriously hallmarked by the presence of aggregated α -synuclein (Lewy bodies) and massive neuronal loss within dopaminergic neurons of the substantia nigra pars compacta (SNpc) (Braak et al. 2003). Furthermore, it has been observed that activated microglia accumulate in the SNpc of PD patients (McGeer et al. 1988). In fact, PD patients exhibit enhanced reactive microgliosis, a process of recruitment, proliferation, and activation of microglia in sites of neuronal injury (Hu et al. 2008). Upon aggregation, microglia phagocytize α -synuclein and become subsequently activated, thereby facilitating neuronal toxicity (Zhang et al. 2005). Activated microglia, which present with an upregulation of MHC-II and release TNF- α and IL-6, are observed to not only interact with lewy bodies, but also damaged neurons themselves (Imamura et al. 2003). Furthermore, activated microglia in early PD present an M1-like phenotype, which is coupled with an upregulation of NADPH-oxidase and subsequent ROS production are observed in the substantia nigra of PD patients and MPTP mouse models (Wu et al. 2003). Prolonged microglial activation may have a negative impact on disease progression. In fact, microglia is hypothesized to be the prominent facilitator of neuroinflammation during states of neurodegeneration such as PD, exemplified by blockade of microglial activation has a neuroprotective effect (Wu et al. 2002; Gao and Hong 2008). Efforts to control the inflammatory response provoked by activated microglia has been studied with the use of non-steroidal anti-inflammatory drugs (NSAIDs), anti-inflammatory cytokines, as well as treatment strategies centered on regulatory T-cells (T_{Reg}) (Qian et al. 2010). Specifically, adoptive transfer of Tregs in MPTP mice was able to produce a neuroprotective effects by modulating the response of microglia to neural injury (Reynolds et al. 2007). Subsequent studies using GM-CSF to induce a Treg cell response in MPTP mice provided reductions in microgliosis, as well as neuroprotection (Kosloski et al. 2013). Restoring the balance between T_H1/T_{Reg} cells in response to neuroinflammation in diseases such as PD may have significant therapeutic importance and are currently under development (Mosley et al. 2012).

12.2.3.7 HIV-1 Associated Neurocognitive Disorders (HAND)

Early studies with HIV-1 infected patients observed evidence of progressive cognitive impairments, often coupled with motor and behavioral aberrations, and was originally termed AIDS dementia complex (Navia et al. 1986). Research involving HIV-1 infection of the CNS and its clinical effects has significantly progressed and currently are described as HIV-associated neurocognitive disorders (HAND), which can be further broken down into asymptomatic neurocognitive impairment (ANI), mild neurocognitive disorder (MND), or HIV-1 associated dementia (HAD) (Antinori et al. 2007). The advent of combination antiretroviral therapy (cART) greatly improved patient's quality of life, whereby patients exhibit viral suppression and immune function restoration (Katlama et al. 2013). The effect of cART on HAND is still being investigated but reports suggest pre-cART patients have a prevalence for motor skill aberration, while cART treated patients effected by HAND tend to be deficient in learning/memory tasks. Interestingly, cART adherent patients that are cognitively asymptomatic still harbor activated microglia (Garvey et al. 2014). In fact, HIV-1 DNA has been isolated from parenchymal microglial in presymptomatic HIV-1 infected individuals (Thompson et al. 2011). HIV-1 infection of microglia is mediated not only by CD4, but co-receptors CCR5 and CCR3 (He et al. 1997). Microglia have low surface expression of CD4 and evidence suggests that viral variants, which can infect cells with very low CD4 expression, are present in the CSF of HAD patients (Schnell et al. 2011). In fact, this Microglia/macrophage tropic viral variant is differentially distributed as its found in very low levels in the blood compared with the CSF (Schnell et al. 2011). HIV-1 infection of microglia and macrophages promote the secretion of neurotoxins that facilitate the progression of HAND (Nottet and Gendelman 1995). Specifically, recent research suggests HIV-1 infected microglia can induce neurotoxicity by increased release of glutamate by means of upregulation of glutaminase C (Huang et al. 2011). Further research on microglial HIV-1 infection and its subsequent effects on HAND progression is currently being delineated and imperative towards the design of future therapeutics.

12.3 Future Perspectives

Mononuclear phagocytes (MP), consisting of monocytes, macrophages, microglia, and dendritic cells are prominent cells types of the innate immune system (Chow et al. 2011). A dynamic interplay between MP and the CNS is critical during several neuropathologies. In fact, neuroinflammation is conspicuous in neuropathological conditions of diverse etiologies ranging from PD, AD, and HAND, thus illuminating the importance of MP and the immune system during

CNS disorders. Harnessing and altering the response of MP and the rest of the innate and adaptive immune system during CNS diseases has vast therapeutic potential. For example, immunomodulation of PD, in which agents promoting Treg production can attenuate the neurotoxic effects of activated microglia by stimulating an anti-inflammatory and neuroprotective environment have been proposed and are being investigated (Olson and Gendelman 2016). Moreover, dendritic cells continue to be harnessed as potential treatments for cancers affecting the CNS, such as gliomas. (Sampson and Mitchell 2015) Furthermore, in numerous neurological conditions, infiltrating monocytes tend to have a negative effect on disease progression, often exacerbating pathological conditions. Therefore, harnessing the phagocytic and migratory capabilities of monocyte and monocyte-derived macrophages (MDM) to design new therapeutic treatments has immense potential. Specifically, nanoparticles surface functionalized with ligands (e.g. Folic Acid) which specifically bind and enter MDM create a cell-based delivery system to the brain to treat CNS disorders (Gendelman et al. 2015). Thus, advancements in MP biology will not only improve our understanding of the innate immune system, but also elucidate the intricate mechanisms of neurodegeneration. Understanding the dynamic interplay between CNS resident cells and infiltrating immune cells may be essential in halting the progression of numerous neuropathologies, thus moving neuroimmunological research to the forefront of disease modification efforts.

12.4 Review Questions

- The functions of mononuclear phagocytes include all except:
 - Phagocytic
 - Interacellular killing
 - Secretory
 - Antigen presentation
 - Transformation to lymphoblasts*
- Mononuclear phagocytes include each of the following except:
 - Monocytes
 - Macrophages
 - Dendritic Cells
 - B Cells*
 - Kupffer Cells
- Neuroinflammation is conspicuous in neuropathological conditions of diverse disorders ranging from PD, AD, and HAND. The following are produced by activated microglia and macrophages known to negatively affect neuronal integrity except:
 - Tumor necrosis factor alpha
 - Interleukin-1 beta

- (c) Interleukin-6
 - (d) *Brain derived neurotrophic factor*
 - (e) Quinolinic acid.
4. Harnessing MP function can be used in the following ways for treatment of CNS disease.
- (a) Anti-inflammatory
 - (b) De-activation
 - (c) Phenotypic transformation from an M1 to an M2
 - (d) Secretion of trophic factors
 - (e) *All of the above*
5. Which of the following cells do not arise from progenitor cells in the bone marrow.
- (a) Dendritic Cells
 - (b) *Microglia*
 - (c) Perivascular Macrophages
 - (d) Monocytes
 - (e) b and c

True/False

- 6. Microglia express both CD4 and CCR5, two receptors essential for R5-tropic HIV cellular entry.
- 7. LY6C^{Hi} and LY6C^{Low} monocytes both emerge from cMoP in the bone marrow.
- 8. The number of circulating pDCs increases during the course of HIV-1 infection.
- 9. During normal brain physiology, microglia express high levels of MHC II on the cell surface.
- 10. VCAM-1 and I-CAM-1 are essential for the passage of circulating monocytes across the BCSFB and entering the choroid plexus.

Abstract

Microglia are resident cells of the brain involved in regulatory processes critical for development, maintenance of the neural environment, injury and repair. They originate from erythromyeloid progenitors (EMPs) in the yolk sac and develop in the forming CNS. Microglia serve as brain immune cells to orchestrate innate immune responses, however, they are distinct from other tissue macrophages due to their unique homeostatic phenotype and tight regulation by the CNS microenvironment. They exhibit multiple morphological phenotypes and functional profiles depending on their environment. Microglia actively survey the surrounding parenchyma and respond rapidly to changes such that any disruption to neural architecture or function can contribute to the loss in regulation of the microglia phenotype. Alterations in microglia functionality are involved in brain aging, as well as in neurodegenerative diseases. In many models of neurodegeneration and neurotoxicity, early events of synaptic degeneration and neuronal loss are accompanied by an inflammatory response including activation of microglia, perivascular monocytes, and recruitment of leukocytes. As the primary source for pro-inflammatory cytokines, microglia are implicated as pivotal mediators of neuroinflammation and can induce or modulate a broad spectrum of cellular responses. One key question in determining the consequence of neuroinflammation is whether the response is an initiating event or the consequence of tissue damage. Microglia execute varied tasks, not typical of those carried out by peripheral macrophages, which support optimal function of neurons and neuronal networks. Recent observations about microglia ontogeny combined with extensive gene expression profiling and emerged novel tools to study microglia biology allow us to characterize the variety of microglial phenotypes during development, homeostasis and disease.

13.1 Introduction: History of Microglia

Microglia—from micro (small) and glia (glue)—are the resident innate immune myeloid cells in the central nervous system (CNS) parenchyma. These cells constitute about 5–12 % of the total glial population (Ling and Leblond 1973). They are present throughout the CNS, including the spinal cord, although some regions are more populated than others. The white matter generally contains fewer microglia than the

grey matter. Robertson and Nissl were the first to describe these cells at the end of the nineteenth-century. Nissl first recognized microglia in the brain (1899). However, microglia were first identified as a defined cellular component or “mesoglia” by Pio del Rio Hortega in 1919 (Rio-Hortega and Sociedad española de historia natural Madrid. [from old catalog] 1932). He first characterized a small cell in the neuroectodermal tissue, which apparently was of mesodermal origin and seemed to be related to other tissue macrophages in the body (Rio-Hortega and Sociedad española de historia natural Madrid. [from old catalog] 1932). Rio Hortega postulated that microglia enter the brain during early development and take on a distinct amoeboid morphology. Moreover, he described functional features, such as the ramified phenotype in a mature brain (Fig. 131), or amoeboid phenotype in case of lesion. Based on these features he hypothesized that microglia have a defined territory to survey but they are able to migrate, proliferate, and phagocytize debris in the brain. These conclusions remain valid but they can be refined with the increased amount of research generated on microglia over the last few decades. In particular, new exciting results showing that microglia are highly dynamic and frequently interact with neuronal elements, raised the possibility that microglia play a fundamental role in monitoring of neuronal activity, the surveillance of the neuronal milieu, structural remodeling of neurons and modulation of neuronal and synaptic plasticity

brain, microglial cells demonstrate a typical ramified phenotype as shown in *Panel C*. In neuroinflammatory diseases, such as HAD, cells from the periphery infiltrate the brain as shown in *Panel D*. A blood vessel in brain parenchyma is surrounded by perivascular macrophages

(Blais and Rivest 2003; Hanisch 2013; Kettenmann et al. 2011, 2013; Prinz et al. 2014).

Microglia are one of the first cells to respond to an environmental change in the brain. Perivascular cells such as CD163⁺ macrophages, at the blood brain barrier (BBB) located in the circumventricular organs, will sense any stimulus coming from the periphery and relay this information to microglia. When a tissue is damaged or a bacterial or viral infection is detected in the CNS, microglia is playing a critical role to clean and restore brain homeostasis. Microglia are not only essential under pathological conditions but they also maintain homeostasis in non-inflammatory conditions. They constantly sense their environment by extending and retracting their processes to probe the brain parenchyma for any tissue/cell damages or intruders. Microglia contribute also actively to shape the brain during neurodevelopment. They act on neuronal proliferation, neurogenesis and formation/suppression of synaptic connections by phagocytizing.

13.2 Origin of Microglia

Defining the origin of microglia has been an intensive question and a longstanding issue of debate. Traditionally, microglia were considered as the brain macrophages defending the CNS following acute lesions and neurodegenerative

diseases. An increasing number of studies pointed to a very early colonization of the CNS by mesodermal progenitors (Kaur et al. 2001) and indicated that microglial progenitors arise from the yolk sac (Alliot et al. 1999). Since the work of Ginhoux et al. (2010), microglia are now known to originate from the yolk sac during embryogenesis (Alliot et al. 1999; Ginhoux et al. 2010; Herbolme et al. 2001). Although there is a consensus about the myeloid origin of microglia, much controversy remained concerning the origin of microglia progenitors.

Microglia were shown to derive from primitive myeloid progenitors of the yolk sac that invade the CNS during early embryonic development around E8.5 (Ginhoux et al. 2013) after the establishment of the blood circulation. Once in the parenchyma, they start to proliferate and differentiate in mature microglia during postnatal brain development. Microglia were first thought to be similar to macrophages but it is now apparent that they differ in ontogeny and functional capacity (Nayak et al. 2014). Microglia are derived from an uncommitted F4/80-negative erythromyeloid precursor in the yolk sac that develops via immature F4/80-CX3CR1⁻ myeloid progenitor subsets into F4/80⁺CX3CR1⁺ mature macrophages, which finally colonize the CNS to give rise to microglia (Kierdorf et al. 2013). Fate-mapping studies have established that transcription factor Myb, required for hematopoiesis is not necessary for the generation of microglia (Schulz et al. 2012) and that they specifically originate from CD45-c-kit⁺ erythromyeloid progenitor cells (Kierdorf et al. 2013).

Circulating monocytes and tissue macrophages thought to participate to microglia population are no longer considered as microglia progenitors in a healthy brain (Gomez Perdiguer et al. 2013; Kierdorf et al. 2013; Neumann and Wekerle 2013). Indeed, knocking-down of Pu.1 gene leads to the absence of yolk sac-derived microglia in the postnatal brain (Beers et al. 2006), and infiltration of bone marrow-derived myeloid cells in the brain. Peripheral monocytes and macrophages derive from hematopoietic stem cells initially located in the fetal liver and later in the bone marrow (Gomez Perdiguer et al. 2013). Monocytes can infiltrate the CNS and play the role of microglia under specific conditions (Fig. 131) (Ajami et al. 2007; Ginhoux et al. 2013; Varvel et al. 2012).

In the adult brain, microglia population is exclusively maintained by self-renewal in physiological conditions (Ginhoux et al. 2013). It was originally hypothesized that continual replenishment of the microglia population occurred into adulthood via peripheral recruitment of circulating monocytes, followed by subsequent differentiation steps. However, although murine monocytes have been shown to invade the CNS amidst insult (Andersson et al. 1992) and microglia demonstrate the potential to differentiate into either CNS-macrophage or dendritic cell profiles in vitro

(Santambrogio et al. 2001), evidence for monocyte to microglial differentiation in the CNS is lacking (Ginhoux et al. 2010; Ajami et al. 2007). Microglia are then the only immune cells, and permanently reside in the CNS parenchyma, alongside neurons, astrocytes, and oligodendrocytes. Specifically, colony-stimulating factor 1 receptor (CSF1-R) but not colony-stimulating factor 1, is necessary for regulating the microglia lineage, because inhibition of CSF1-R in mice leads to depletion of 99 % of the microglial population (Elmore et al. 2014a). Microglia, upon successful CNS-seeding of their progenitors in early development, act as an independent, self-renewing population into adulthood (Ginhoux et al. 2010; Bruttger et al. 2015).

13.3 Phenotypic Diversity in Development and Aging

Microglia cells are often sub-divided in either resting or activated states depending on the inflammatory milieu (Ransohoff and Cardona 2010; Kettenmann et al. 2011; Hanisch and Kettenmann 2007; Hanisch 2013). Contrary to this simplistic view, microglia can also be considered “active” in normal conditions. Microglia show high level of phenotypic and functional plasticity in healthy and inflamed brains. Indeed, multiples microglial phenotypes exist and they will adapt and switch phenotype based on alterations in response to cues from the microenvironment (Hanisch 2013, 2014). The spectrum of activated microglia phenotypes is based on macrophages plasticity at the periphery. Peripheral macrophages are known to show phenotype plasticity represented by varied expression of cell surface receptors (Mantovani et al. 2005). Microglia phenotypes following polarization have been adapted from macrophage polarization studies which include M1-like (proinflammatory signaling and neurotoxicity) vs. M2-like phenotype (resolution of inflammation) (Martinez and Gordon 2014). M1/M2 phenotypes represent different states of macrophage activation, based on Th1/Th2 phenotypes for lymphocytes. This last decade, scientists have been focusing on microglia plasticity trying to demonstrate that microglia can adopt different phenotypes such as M1/M2 phenotypes in disease. Microglia were then thought to present different states of activation including classical activation state M1 (in response to interferon gamma and LPS) and alternative activation state M2 (after exposure to IL-4 and IL-13) (Liao et al. 2012; Gordon and Martinez 2010; Colton 2009). Classical activated microglia were considered neurotoxic whereas alternatively-activated microglia would be neuroprotective (Liao et al. 2012; Kigerl et al. 2009). However, this is a simplistic view of microglia activation. Indeed, microglia can adopt a pro-inflammatory M1 phenotype and become neurotoxic in advanced stages of neurodegenerative diseases, such as

Alzheimer's disease, multiple sclerosis and amyotrophic lateral sclerosis (Liao et al. 2012; Muzio et al. 2007; Butovsky et al. 2012), but microglia phenotype and function can be difficult to classify based on these characteristics. During disease, different microglia phenotypes are apparent, however, these phenotypes differ with the brain structure and pathology. Moreover, in the past, disease-associated microglial phenotypes have been studied using approaches that could not distinguish between resident microglia and recruited myeloid cells. However, these phenotypes do not represent microglia states in health or disease and increasing evidence, including data from this report, suggest that the M1/M2 paradigm does not apply to microglia in disease (Butovsky et al. 2014; Holtman et al. 2015a, b; Hickman et al. 2013; Chiu et al. 2013). Thus, characterization of microglia diversity in pathology and physiology is complex and may be left to interpretation but with the help of new developed technologies, research on microglia phenotypic diversity will be more efficient in next few years.

13.3.1 Development

During prenatal development, fetal microglia is characterized by an amoeboid morphology which is not conserved after maturation of the CNS when they become ramified. However, this morphology can be found in the adult under certain pathological conditions during a lesion or an infection of the CNS. Fetal microglia are characterized by a large cell body, a large amount of cytoplasm and the expression of specific markers. Microglia during development express low-density protein receptors (LDL) (Giulian and Baker 1986) and scavenger-type receptors (Husemann et al. 2002). Fetal microglia have been shown to express Iba1, CX3CR1 and CD45 molecules around E12–E15 days of development (Harry 2013). Recently, fetal microglia have been shown to present a specific molecular signature during development and before maturation during postnatal period (Butovsky et al. 2014). Indeed, they express molecules that are usually present after an immune activation and during phagocytosis.

13.3.2 Adulthood

The idea of microglia phenotypic plasticity is not new. Microglia plasticity corresponds to the diversity of phenotype and functions the cells can adopt and do to face a challenge. This is already known in the context of neuroinflammation and during microglia activation. Indeed, it is known that during neuroinflammation, microglia will become amoeboid and secrete inflammatory factors. However, microglia plasticity is a more complex phenomenon that some have observed in inflammatory conditions based on the concept of macrophage morphoplasticity already detailed at the periphery (Mantovani

et al. 2005). In physiology, this is more complex to describe and is biased by the techniques employed to observe microglia. Recently, several groups identified a unique homeostatic signature for microglia at different ages and in different conditions. Microglia homeostatic signature has been shown to be dependent on TGF β signaling (Butovsky et al. 2014) with the expression of specific genes such as *P2ry12*, *Tgfb1*, *Tmem119*, *Fcrls*, *Hexb*, *Cx3cr1* (Butovsky et al. 2014). Microglia present a unique signature at the cell surface but also a specific sensome which is dysregulated during aging (Hickman et al. 2013).

13.3.3 Aging

Aging is a complex process of cumulative changes. A key feature is the progressive decline in physiological functions and behavioral capacity, which is observed at various levels of the organism and in particular in the CNS. Some responses of the immune system also decline with age increasing the vulnerability to infections and cancer. On the opposite, other immune responses are exacerbated such as generation of chronic neuroinflammation mediated by the dysregulation of the innate immune system. Microglia is undergoing several age-related changes that contribute to a chronic inflammatory environment including production of inflammatory cytokines and reactive oxygen species. Microglia are activated in nearly all CNS diseases (Kreutzberg 1996a; Hanisch and Kettenmann 2007; Neumann et al. 2009). Genes that encode microglia surface receptors for neuron-microglia crosstalk are affected. Microglia with aging are controlled by transcription factors such as Runx1, Irf8, Pu.1 and Tal1 (Kierdorf and Prinz 2013). Aged microglia display morphological changes with fewer and shorter processes, an increased cell body and formation of spheroid swellings, which refers to a dystrophic microglia (Streit et al. 2004; Streit 2006; Flanary et al. 2007). Microglia colocalize with neurodegenerating neurons and present an accumulation of phagocytic inclusions (Hefendehl et al. 2014; Tremblay et al. 2012). The unique signature present during adulthood is dysregulated during aging with the downregulation of most of their homeostatic genes and upregulation of genes associated to inflammation (Holtman et al. 2015b).

13.4 Morphological Characterization

13.4.1 Homeostasis

Microglial cells have been classified into three types: ramified, amoeboid and reactive. In the prenatal brain, the amoeboid phagocytic microglia are the predominant form, with a large spherical cell body and short processes (Hess et al. 2004). During postnatal maturation, amoeboid microglia

transform into ramified resting microglia, and these cells remain a semi-permanent population with relatively slow turnover rates when compared to peripheral macrophages (Dick et al. 1995; Becher and Antel 1996). Ramified microglia act as surveying cells by actively sensing the surrounding environment via dynamic processes (Schlegelmilch et al. 2011; Stence et al. 2001; Hanisch and Kettenmann 2007; Nimmerjahn et al. 2005). As homeostatic (“resting” previous term) ramified microglia, they monitor their microenvironment and adapt their morphology and express cell surface markers accordingly (Table 131) (Lawson et al. 1990, 1992). The resident microglial cells in the healthy brain can be seen in all regions of the CNS including optic nerve and retina (Kaur et al. 2001). They remain homeostatic (“quiescent”-previous term) until stimuli from injury, infection or neurodegenerative process activate their transformation into amoeboid phagocytic cells (Schroeter et al. 1997; Zhang et al. 2001). Microglia exhibit multiple morphological phenotypes and, presumably, multiple functional profiles depending on their environment (Streit 2006; Streit et al. 2004). Structurally, microglia display a dynamic and active phenotype with ongoing retraction and extension of processes into the brain parenchyma (Raivich 2005). The morphology of a “resting” microglial cell is characterized by a very small cell soma with elongated ramified processes (Cuadros and Navascues 1998). Under healthy conditions, microglial cell processes do not overlap with processes of neighboring cells and each cell seems to have a scavenger function for its own immediate area. The position of the cell soma remains stable, whereas the processes of the resting microglia are continuously elongating and retracting to explore the tissue environment. In vivo imaging of microglia in intact brain tissue demonstrated highly dynamic processes which continuously scan the surrounding microenvironment (Nimmerjahn et al. 2005).

13.4.2 Disease

Amoeboid microglia are highly motile and participate in phagocytosis (Suzumura et al. 1991; Szabo and Gulya 2013). In addition, bipolar/rod-shaped microglia transiently form trains of cells aligned end-to-end at the damaged site after brain injury (Taylor et al. 2014). Bipolar/rod-shaped microglia are also found in the cerebral cortex of Alzheimer’s subjects (Wierzb-Bobrowicz et al. 2002). Upon recognition of a pathogen or other inflammatory stimuli, microglia can rapidly retract their processes and become efficient mobile effector cells (Davalos et al. 2005). These observations highlighted the important immune surveillance function of microglia in the healthy CNS parenchyma. In general, microglia activation is triggered by a plethora of well-described subsets of immune receptors such as Toll-like receptors (TLRs), scavenger receptors, and numerous cytokine and chemokine receptors. This supports the idea of a surveillance function for microglia in the healthy brain and indicates that these cells are poised to rapidly respond to environmental changes. This concept has been supported by the observation that microglial activation is likely an early event in all forms of pathology. In the human brain, microglial activation and neuroinflammation have been associated with viral or bacterial infection, autoimmune disease such as multiple sclerosis, head trauma, vascular system damage, neuropsychiatric disorders, and neurodegenerative diseases. The presence of activated microglia was initially considered as a sensitive marker to identify sites predestined for imminent tissue destruction. Based upon this, a role for microglial activation and neuroinflammation has more recently been considered as an underlying and, possibly, unifying factor of neurotoxicity from environmental exposures.

13.5 Neuroinflammation

Upon infection or insults within the adult CNS parenchyma, microglia are rapidly activated and efficiently phagocytose pathogens and dying cells (Hanisch and Kettenmann 2007; Ransohoff and Perry 2009) and release effector molecules for the recruitment of other immune cells from the blood to limit infections in the CNS (Saijo and Glass 2011). In addition, they help in the regeneration of damaged tissue by secretion of growth factors and anti-inflammatory molecules (Saijo and Glass 2011). Therefore, microglia are indispensable in the adult CNS as stabilizers and modulators of tissue homeostasis under physiological conditions.

Inflammation is a host defense response to injury, tissue ischemia, autoimmune responses or infectious agents. Classical signs of swelling, redness, heat and pain are witnessed in all tissues except that of brain as manifestations of inflammation. These symptoms are caused as a result of increased amount of blood flow to the site of injury to get more nutrients and immune cells to an area in need (Benacerraf and McCluskey 1963). Invasion of circulating immune cells (lymphocytes and macrophages), induction or activation of inflammatory mediators such as cytokines, kinins, reducing and oxidizing species aid the repair and removal of injured or infected cells (Eming et al. 2007).

The central nervous system differs from the other systems and its response to pathogenic challenges is significantly different. In contrast to the historic view that the CNS is an immune-privileged organ, lacking a lymphatic system and shielded from the circulatory system by the blood-brain barrier recent studies and evidences have revised the idea significantly. The CNS has been found to have its own system of combat through inflammatory response and an adapted system of immunosurveillance with coordination with the systemic immune system is also evident (Badie and Schartner 2000). Nevertheless the inflammatory response of the other tissues and the brain are varied. This is most evident in leukocyte recruitment, which is rapid in many systemic organs, but modest and delayed in the brain. While leukocyte invasion may be delayed in response to acute insults, activation of brain's own immune cells and release of inflammatory mediators are rapid, occurring within minutes or hours (Lucas et al. 2006).

Inflammation in the brain is characterized by activation of glial cells (mainly microglia and astrocytes) and expression of key inflammatory mediators as well as neurotoxic free radicals. In the central nervous system, microglia is the resident phagocytes of the innate immune system and astrocytes provide nutrients to the nervous tissue and help maintain the extracellular ion balance (Stoll and Jander 1999).

A role for immune responses, involving antigen presentation and immune-response-generating cytokines, in neurodegenerative diseases such as Alzheimer's disease was recognized for a decade before the term neuroinflammation

came into widespread use. While some chronic/remitting neurological diseases, such as multiple sclerosis, have long been recognized as inflammatory, the term neuroinflammation has come to denote chronic, CNS-specific, inflammation-like glial responses that do not reproduce the classic characteristics of inflammation in the periphery but that may engender neurodegenerative events; including plaque formation, dystrophic neurite growth, and excessive tau phosphorylation. In this way, neuroinflammation has been implicated in chronic unremitting neurodegenerative diseases such as Alzheimer's disease – diseases that historically have not been thought of as inflammatory diseases.

This new understanding has come from rapid advances in the field of microglial and astrocytic neurobiology over the past 15–20 years. These advances have led to the recognition that glia, particularly microglia, respond to tissue insult with a complex array of inflammatory cytokines and actions, and that these actions transcend the historical vision of phagocytosis and structural support that has long been enshrined in the term “reactive gliosis.” Microglia are now recognized as the prime components of an intrinsic brain immune system, and as such they have become a main focus in cellular neuroimmunology and therefore in neuroinflammation. This is not the inflammation of the adaptive mammalian immune response, with its array of specialized T-cells and the made-to-order antibodies produced through complex gene rearrangements. This is, instead, the innate immune system, upon which adaptive immunity is built.

Many researchers now consider this innate immune response in the brain to be a potentially pathogenic factor in a number of CNS diseases that lack the prominent leukocytic infiltrates of adaptive immune responses, but that do have activated microglia and astrocytes, i.e., neuroinflammation.

The idea that neuroinflammation is detrimental implies that glial cell activation precedes and causes neuronal degeneration, a sequence of events that appears to be at odds with experimental models of neurodegeneration in which glial cell activation occurs secondary to neuronal damage. What is missing from this simple linear model is the understanding that chronic neurological diseases are just that—chronic, and that this chronicity introduces complex interactions and feedback loops between neurons and glia that render attempts to construct simple, linear cascades of cause and effect inelegant. Neuroinflammation can be further explained as two distinct responses- acute and chronic neuroinflammation.

13.5.1 Neuroinflammation as Physiological Response

Neuroinflammation is a process in which the brain responds to infections, diseases and injuries through release of proinflammatory molecules (Nencini et al. 2003; Schmidt 2005).

These responses are mediated by two types of immune cells: lymphocytes, monocytes and macrophages of the hematopoietic system and glial cells of the CNS (astrocytes and microglia—the supporting cells of the CNS) (Stoll and Jander 1999; Streit and Stern 1999).

In response to a brain insult, glial cells are the first to be activated. The astrocytes upon activation, increases expression of glial fibrillary acidic protein, and produces cytokines; also contributing to the formation of the glial scar, which isolates the damaged area. These reactive astrocytes produce neurotrophic factors such as nerve growth factor and brain-derived growth factor which help in blood brain barrier repair and remyelination (Faulkner et al. 2004). On the other hand, within any scenario of immune-mediated brain injury, microglia qualifies as the main intrinsic immune effector cells of the brain. They are potentially phagocytic cells, have a pronounced cytotoxic potential (reviewed by (Banati et al. 1993)) may express several immunomolecules on their surface, may effectively present antigen to T-lymphocytes (Matsumoto 1992) and are capable of releasing a plethora of mediator substances such as inflammatory cytokines.

Most inflammatory mediators have relatively few actions in healthy CNS tissue and are expressed at very low or undetectable levels. Nevertheless some cytokines also modulate neuronal activities in the mature CNS and participate in neuro-immune–endocrine communication. However, they are induced rapidly in response to tissue injury or infection; certain cytokines appear in the affected brain region and the cerebrospinal fluid (CSF) when the CNS homeostasis is disturbed as a result of trauma, stroke, ischemia, infection, or degenerative processes. This increased cytokine levels in the CNS may result from blood–brain barrier (BBB) disruption or synthesis by invading immune cells, both of which originate from extraneuronal sources. These disruption of the blood-brain barrier (BBB), allows cells from the hematopoietic immune cells to leave the blood stream and come in contact to the injury site (Lossinsky and Shivers 2004). The immune cells respond to injuries by eliminating debris and, synthesizing and releasing a host of powerful regulatory substances, like complements, cytokines, chemokines, glutamate, interleukins, nitric oxide, reactive oxygen species and transforming growth factors (Bonifati 2002) which in turn start the cycle all over.

13.5.1.1 Acute Neuroinflammation

Acute neuroinflammation is more of a physiological response either to injury or insult to the CNS. Before “neuroinflammation” became a commonly used term, endogenous CNS tissue responses to injury were referred to as ‘reactive gliosis’. Reactive gliosis entails accumulation of enlarged glial cells, notably microglia and astrocytes, appearing immediately after CNS injury has occurred (Wolfgang 1999). Glial reactivity is majorly a passive response to injury whereas glial

activation implies a more aggressive role in responding to activating stimuli. Activated glial cells release factors that act on and engender responses in target cells equivalent to the responses of activated immune cells in the periphery; however, peripheral immune cells activation leads to leukocyte infiltration of tissues, which is notably absent in the brain unless there has been destruction or compromise of the blood brain barrier (Stoll and Jander 1999). In the presence of such destruction or compromise, peripheral leukocytes do enter the brain producing a scenario similar to that seen in inflammatory responses in the periphery.

In limited, acute reactions to injury, in the absence of blood-brain barrier breakdown, there is the subtler response of the brain’s own immune system, composed largely of rapid activation of glial cells. These responses represent the other end of the spectrum of CNS injury, where limited neuronal insults trigger glial cell activation without breakdown of the blood brain barrier and without concomitant leukocytic infiltration. This form of “pure” glial response occurs in neuronal injury caused by either loss of afferents (Kreutzberg 1996a) or loss of efferents (Ito et al. 1997).

The term “neuroinflammation” as generally used and understood applies to more chronic, sustained cycles of injury and response, in which the cumulative ill effects of immunological microglial and astrocytic activation contribute to and expand the initial neurodestructive effects, thus maintaining and worsening the disease process through their actions.

Before “neuroinflammation” became a commonly used term, neuroscientists spoke of “reactive gliosis” in describing endogenous CNS tissue responses to injury. Reactive gliosis specifically referred to the accumulation of enlarged glial cells, notably microglia and astrocytes, appearing immediately after CNS injury has occurred. In contrast to glial reactivity, which suggests a largely passive response to injury; glial activation implies a more aggressive role in responding to activating stimuli: activated glial cells release factors that act on and engender responses in target cells analogous to the responses of activated immune cells in the periphery. Activation of immune cells in the periphery leads to leukocyte infiltration of tissues, but this is notably absent in the brain unless there has been destruction or compromise of the blood brain barrier (Streit et al. 1998; Sroga et al. 2003). In the presence of such destruction or compromise, peripheral leukocytes do enter the brain producing a scenario similar to that seen in inflammatory responses in the periphery.

In limited, acute reactions to injury, in the absence of blood–brain barrier breakdown, there is the subtler response of the brain’s own immune system, composed largely of rapid activation of glial cells. These responses represent the other end of the spectrum of CNS injury, where limited neuronal insults trigger glial cell activation without breakdown

of the blood brain barrier and without concomitant leukocytic infiltration. This form of “pure” glial response occurs in neuronal injury caused by either loss of afferents (Kreutzberg 1996b) or loss of efferents (Ito et al. 1997). Axotomy, for instance, results in neuronal chromatolysis, the classic example of potentially reversible neuronal injury (Kreutzberg 1996b). It is in these situations that microglial and astrocytic responses (like their peripheral counterparts) fulfill their evolutionarily programmed functions of a reparative response to the benefit of the organism as a whole.

13.5.1.2 Chronic Neuroinflammation

Chronic inflammation is often associated in the understanding of CNS disease as opposed to acute inflammation which is linked with CNS injury. It is proposed that chronic inflammation is a causative factor to the pathogenesis of neurological diseases and disorders (Eikelenboom et al. 2006; Whitton 2007). The immune cells and pro-inflammatory chemicals involved in neuroinflammation would underlie the mechanisms of diseases and neurodegeneration. The activation, or over activation, of immune cells involved in neuroinflammation and release of pro-inflammatory substances would result in reduced neuroprotection and neuronal repair, and increased neurodegeneration, leading to neurodegenerative diseases (Zilkova et al. 2006). To elaborate, during disease states (for example, Parkinson’s (PD), Multiple sclerosis (MS), Alzheimer’s disease (AD) the inflammatory responses damage the BBB, increase oxidative stress and release pro-inflammatory and pro-apoptotic cytokines and other neurotoxic factors that affect neuronal damage or dropout. The damage and stress signals enhance microglial activation, resulting in positive feedback in the release of chemokines and cytotoxic cytokines that cause further ingress of immune cells into the brain and expand inflammatory responses.

The concept of chronic inflammation (as opposed to acute inflammation) is more relevant in the context of understanding CNS disease (as opposed to CNS injury), as the very term “disease” implies chronicity. Multiple sclerosis is, of course, an unequivocal and long-recognized example of an inflammatory brain disease. Although the underlying cause(s) of multiple sclerosis have not been elucidated, it is probably safe to say that the persistent injurious stimulus that accounts for neuroinflammation in multiple sclerosis is a myelin-related protein that has escaped self-tolerance and become an autoimmunogen. Consistent with the chronic persistence of this autoimmunogen is a persistent accumulation of blood-derived mononuclear leukocytes in the CNS parenchyma, a phenomenon that is similar to what is found in other autoimmune diseases such as rheumatoid arthritis or polymyositis.

Infections are another group of diseases that are classically recognized as inflammatory in nature, with meningeal, perivascular, or even parenchymal infiltrates of peripheral

leukocytes. There are, however, exceptions. Rabies is a disease in which the peripheral immune response is slow and inadequate, and in which classic inflammatory changes are less striking than those found in other viral encephalidites. Babes, in 1897, described microglial activation in rabies infection, although he did not recognize the nodules he found as clusters of activated microglia. Similar small collections of activated microglia were subsequently found to occur in a wide variety of viral brain infections.

Today, the most important example of a chronic brain infection is human immunodeficiency virus (HIV). Chronic HIV encephalitis is characterized by the same nodules of activated microglia that Babes described in rabies. HIV enters and persists in the CNS via myelomonocytic cells: monocytes, perivascular cells, and microglia (Garden 2013). HIV infection is uniquely different from most other infectious diseases affecting the CNS in that the virus targets and disables precisely those cells that are key players in neuroinflammation; microglia in the brain and T lymphocytes in the periphery. It therefore comes as no surprise that prominent T cell infiltrates do not occur in HIV encephalopathy.

Prion diseases represent another chronic infectious CNS disease that is not accompanied by leukocytic infiltrates. Microglial activation, again, appears to be the most prominent inflammatory component of prion diseases (Eikelenboom et al. 2002; Perry et al. 2002), although there are a few reports describing T cell infiltration as well (Betmouni et al. 1996). Prion diseases share interesting parallels to rabies infection in that infected cells are unrecognized by peripheral immune responses. This may explain in part the unusual patterns of neuroinflammation in prion diseases—manifest not only in atypical cellular infiltrates but also in unusual cytokine profiles (Baker et al. 2002). Both HIV and prion infections probably produce an altered microglial physiology that is likely to translate into cycles of neurodegeneration, which could be a contributing factor in the development of dementia that occurs in these conditions.

13.5.2 Neuroinflammation in Neurodegenerative Diseases

Chronic inflammation could influence the pathogenesis of neurodegenerative diseases. It is clearly evident that physiological or pathological responses like neuroinflammation, if goes awry, is tightly linked to the neurodegenerative disorders and diseases. A few examples neuroinflammatory response being the key drivers in disease and infection progression would bring out a better understanding of this concept.

Neurodegenerative diseases particularly Alzheimer’s disease, amyotrophic lateral sclerosis, Parkinson’s disease, and Huntington’s disease (HT) lack the prominent infiltrates of

blood-derived mononuclear cells that characterize autoimmune diseases. On the other hand, there is abundant evidence that many substances involved in the promotion of neuroinflammatory processes are present in the CNS of patients with such neurodegenerative diseases.

Alzheimer's disease (AD) is characterized by the progressive inability to form new memories and access existing ones, mainly because of neuronal cell death in the hippocampus and frontal cortex of the brain (Selkoe 2002). Besides such atrophy in the brain, microscopically there are a number of changes in the AD patient's brain too. The two major findings in the Alzheimer's brain are amyloid plaques and neurofibrillary tangles. β amyloid ($A\beta$) is a peptide that forms insoluble and pathological extracellular aggregates forming plaques, which seem to attract microglial cells, as suggested by the clustering of microglia at sites of $A\beta$ deposition (reviewed by (Streit 2004)). This proinflammatory response of microglial recruitment initially poses as a neuroprotective effect, but when prolonged or continuous turns into a neurotoxic effect. This suggests that CNS inflammation at least participates in amplification of the disease state.

Parkinson's disease (PD) whose clinical symptoms include tremor, postural instability and slowness of movement (Gao et al. 2003) is attributed to the loss of dopaminergic neurons in the substantia nigra pars compacta and the subsequent loss of projecting nerve fibres in the striatum (Block et al. 2004). PD is sporadic, and various environmental agents including pesticides and infections, may contribute to the disease. A role of inflammation has been strongly implicated (reviewed by (Gao et al. 2003)) and activated microglia are found close to degenerating substantia nigral neurones of patients with PD.

Multiple sclerosis (MS) is a chronic disorder in which inflammation plays a clear role. Invasion of the CNS by T cells and macrophages leads to damage to the myelin sheaths surrounding axons, loss of neuronal function and death. Since the injured areas of the CNS vary widely, the clinical symptoms are heterogeneous, and can include fatigue, muscle weakness, areas of numbness and paralysis. Microarray analysis has revealed that many genes related to inflammatory processes are upregulated in the marginal zones of active demyelinating lesions (Mycko et al. 2003).

Autism is a neurodevelopmental disorder characterized by impaired communication and social interaction and may be accompanied by mental retardation and epilepsy. Its cause remains unknown, despite evidence that genetic, environmental, and immunological factors may play a role in its pathogenesis. Recent studies show that in autistic cases, microglial and astroglial activation was present in the absence of lymphocyte infiltration or immunoglobulin deposition in the CNS (Vargas et al. 2005).

Inflammation undoubtedly contributes to other chronic CNS disorders, such as amyotrophic lateral sclerosis (ALS)

and Creutzfeldt–Jakob disease (CJD). ALS, a rapidly progressing motor neuron disease, is associated with mutation of superoxide dismutase (SOD1) gene, and mice that overexpress mutant SOD1 show upregulation of proinflammatory cytokines (Yoshihara et al. 2002), suggesting activation of microglia. Similarly, cytokine levels are elevated in CSF of CJD patients, and activated microglia are detected in mice infected with CJD (Van Everbroeck et al. 2002).

Infections are another group of diseases that are classically recognized as inflammatory in nature, with meningeal, perivascular, or even parenchymal infiltrates of peripheral leukocytes. However there are exceptions, microglial cells have found to be the potential mediator of neurodegeneration in some infections. Rabies is a disease in which the peripheral immune response is slow and inadequate, and in which classic inflammatory changes are less striking than those found in other viral encephalidites. Babes (1892), described microglial activation in rabies infection, although he did not recognize the nodules he found as clusters of activated microglia. Similar small collections of activated microglia are subsequently found to occur in a wide variety of viral brain infections. Presently, the most important example of a chronic brain infection is human immunodeficiency virus (HIV). The virus targets and disables precisely those cells that are key players in neuroinflammation; microglia in the brain and T lymphocytes in the periphery. HIV enters and persists in the CNS *via* myelomonocytic cells: monocytes, perivascular cells, and microglia (Garden 2002). Chronic HIV encephalitis is characterized by the same nodules of activated microglia that was described in rabies. Overall the activated microglial cells contribute significantly to the HIV associated neuropathogenic processes.

Prion diseases represent another chronic infectious CNS disease that is not accompanied by leukocytic infiltrates. Microglial activation, again, appears to be the most prominent inflammatory component of prion diseases (Eikelenboom et al. 2002; Perry et al. 2002), although there are a few reports describing T cell infiltration as well (Betmouni et al. 1996).

Thus it clearly evident that chronic microglial activation is an important component of neurodegenerative diseases, and this chronic neuroinflammatory component likely contributes to neuronal dysfunction, injury, and loss (and hence to disease progression) in these diseases. The recognition of microglia as the brain's intrinsic immune system, and the understanding that chronic activation of this system leads to pathologic sequel, has widened the modern concept of neuroinflammation. The idea of microglia-driven neuroinflammatory responses, with neuropathological consequences, has comprehensively replaced the older vision of passive glial responses inherent in the reactive gliosis hypothesis.

13.5.3 Microglia as Mediators of Inflammation

Once the microenvironment of the CNS becomes activated, local cells also produce proinflammatory cytokines, chemokines and upregulate immunomodulatory surface markers. These changes in turn decrease the stringency of the blood–brain barrier, allowing entry of soluble factors and peripheral immune cells, including macrophages, natural killer cells and lymphocytes. The specific sequence of events demonstrating that microglia activation precedes peripheral cell infiltration has been demonstrated in bone marrow chimeric mice (Schilling et al. 2003). For self-protection against oxidative stress, microglial cells are equipped with efficient antioxidative defense mechanisms. Microglial cells contain glutathione, substantial activities of the antioxidative enzymes, superoxide dismutase, catalase, glutathione peroxidase and glutathione reductase as well as nicotinamide adenine dinucleotide phosphate (NADPH)-regenerating enzymes. Their antioxidative potential protects microglial cells against oxidative damage (Dringen 2005).

Activated microglia cells trigger and maintain an inflammatory response, deluging neurons with a whole host of inflammatory mediators that may ultimately lead to neuronal cell death. Thus microglial activation and chronic inflammation thereafter is the starting point for elevated levels of a wide array of potentially neurotoxic molecules which are believed to contribute to neurodegenerative processes. Several methods have become available for identifying activated microglia, and their presence has been demonstrated in a variety of neuroinflammatory/neurodegenerative diseases such as AD, PD, ALS and MS (Chen et al. 2004); (Turner et al. 2004). This participation of activated microglia and the release of neurotoxic products in the demise of neurons have now been postulated in most, if not all, neurodegenerative diseases.

13.5.4 Signaling Pathways Mediating Microglial Homeostasis and Activation

The transition from the homeostatic microglial phenotype to an activated stage is tightly regulated by several intrinsic (e.g., Runx-1, Irf8, and Pu.1) and extrinsic factors (e.g., CD200, CX3CR1, and TREM2).

The surface molecule CD200 is expressed by neural cells including neurons, astrocytes and oligodendrocytes (Barclay et al. 2002). Its receptor CD200R is expressed on microglia. The interaction of neuronal CD200 with CD200R leads to inactivation of microglia and keeps them in a resting state (Hoek et al. 2000). Following facial nerve axotomy, a model for local neuronal degeneration, CD200-deficient neurons elicited an accelerated microglial response in the lesioned nucleus. In the animal model for multiple sclerosis (MS), experimental autoimmune encephalomyelitis (EAE), defi-

ciency of CD200 resulted in a more rapid onset of disease (Hoek et al. 2000). These findings indicate that without the CD200–CD200R signaling, microglia develop an activated phenotype in the CNS.

The G-protein-coupled seven-transmembrane chemokine receptor, CX3CR1, is expressed on myeloid and natural killer (NK) cells and microglia (Jung et al. 2000). Its ligand, fractalkine or neurotactin, CX3CL1, is expressed on different neuronal subsets (Kim et al. 2011). Binding between neuronal CX3CL1 to the microglial CX3CR1 plays in the interaction of neurons and microglia (Harrison et al. 1998). Furthermore, loss of CX3CR1 in microglia led to an enhanced neuronal cell death in animal models for Parkinson's disease and other motor neuron disorders (Cardona et al. 2006b). However, several studies on the role of CX3CR1-deficiency in animal models for Alzheimer's disease (AD) showed that CX3CR1 deficiency appeared to be beneficial by resulting in reduced neuronal loss and improved behavioral deficits (Fuhrmann et al. 2010; Lee et al. 2010; Liu et al. 2010). These results indicated that CX3CR1-deficiency could play different roles under inflammatory and neurodegenerative CNS conditions. In addition, CX3CR1 is an important regulator of microglial surveillance. Thus, Paolicelli et al. reported CX3CR1-deficient animals showed a reduced number of microglia during the first weeks after birth (Paolicelli et al. 2011). Reduced microglial cell number in CX3CR1-deficient animals resulted in the development of immature neuronal circuits. In contrast, CX3CR1-deficient animals revealed a high density of spines and functional excitatory synapses, which are more known to be related to a mature phenotype than delayed brain development. In addition, another study reported that CX3CR1-deficient animals exhibited an inhibition in microglial recruitment to forming synapses in the barrel field of the somatosensory cortex, leading to an abnormal synapse formation in this area (Hoshiko et al. 2012). Therefore, interaction of neurons and microglia appears to be essential for proper synapse formation in the postnatal cortex. Recent investigations in healthy CX3CR1-deficient animals showed a harmful effect of this mutation for adult neurogenesis and hippocampal circuit integrity. The number of neuronal precursors in the hippocampus was decreased and led to diminished adult neurogenesis (Bachstetter et al. 2011). Moreover, CX3CR1-deficient animals display cognitive impairment (Rogers et al. 2011). These studies support the role of CX3CR1 signaling in keeping microglia in a homeostatic state.

Another glycoprotein identified on microglia is known as the triggering receptor expressed on myeloid cells 2 (TREM2), which was linked to an anti-inflammatory phenotype (Colonna 2003). TREM2 is associated with the adaptor protein DNAX-activating protein of 12-kDa (DAP12), which transmits the signal from the receptor to the intracellular signaling cascade. TREM2 is essential for phagocytosis of apoptotic cell by microglia (Neumann and Takahashi 2007). Furthermore,

TREM2 was shown to have beneficial effects in autoimmune CNS demyelination (Takahashi et al. 2007). Mutations in TREM2 or DAP12 are associated with a severe neurodegenerative disease known as Nasu-Hakola disease, which is further characterized by a form of early onset dementia and formation of bone cysts (Paloneva et al. 2001). Although TREM2 polymorphisms are known to be associated with a higher risk for the development of late onset AD (Guerreiro and Hardy 2013), the role of TREM2 in neurodegenerative diseases remains controversial. Murine studies suggest a beneficial role for TREM2 in suppressing inflammation (Piccio et al. 2007; Takahashi et al. 2005) and promoting phagocytosis of amyloid- β peptide (Wang et al. 2015). However, a recent study reported that *Trem2* deficiency in APP-PS1 mice reduces brain inflammation and plaque burden (Jay et al. 2015). Consistent with this, increased *TREM2* expression is associated with the CD33 AD risk allele (Chan et al. 2015) and recent data show that soluble TREM2 levels in the CSF are increased in the early symptomatic phase of AD in association with neuronal injury markers (Heslegrave et al. 2016; Suarez-Calvet et al. 2016). This may reflect a dysregulation of homeostatic microglia in response to neuronal injury.

Kinase and phosphate cascades mediate microglial response to extracellular stimuli. p38 mitogen-activated protein kinases are a class of mitogen-activated protein kinases (MAPK) that are responsive to stress stimuli. Several reports have demonstrated that p38 and p44/42 families of mitogen activated protein kinase pathways play a significant role in activation of microglial cells which in turn leads to release of neurotoxic molecules and neuroinflammation (Lee et al. 2000; Li et al. 2001; Waetzig et al. 2005). A MAPK pathway generally consists of four sub- pathways: (1) extracellular-signal-regulated kinases (ERK1/2, also known as p44/42 MAPK); (2) c-jun N-terminal kinases/stress-activated protein kinases (JNKs./SAPKs); (3) ERK5/big MAPK 1 (BMK1), and (4) p38 MAPK. Microglia activation could effect through any these if not all of the MAPK pathways. In vivo evidence also implicates that p38 and p44/42 MAPKs play an important role in microglial activation in acute brain injury such as stroke and in chronic neurodegenerative diseases such as Alzheimer's disease (Koistinaho and Koistinaho 2002). The other proinflammatory pathway that could respond to microglia activation is the NF κ B pathway. Any of the microglia mediated pro-inflammatory stimuli can activate NF κ B expression (Sparacio et al. 1992), which can further induce specific genes that regulate inflammation.

13.6 Physiological Functions

The main function of immune cells and in particular microglia is to secrete cytokines to fight first against an invasion and promote an inflammatory reaction. Microglia are also known

to produce cytokines in the context of synaptic modulation. However, microglia also have diverse functions.

13.6.1 Motility/Surveillance

In 2005, discovery of high degree of motility of microglia in the healthy brain brought a new view on their active role in surveying the microenvironment of neurons. These studies revealed that microglia were not static cells as microglia processes protract and retract, scanning the molecular and cellular microenvironment in proximity to each individual microglia. Thus, under physiological conditions microglia present a constant motility of their ramifications in the cerebral cortex (Davalos et al. 2005; Nimmerjahn et al. 2005; Stence et al. 2001). These surveying movements are dependent on ATP and gap junction proteins or connexins in steady-state (Davalos et al. 2005). More recently, the CX3 chemokine receptor 1 (CX₃CR1) also known as the fractalkine receptor, which is mainly expressed by microglia in the CNS, has been shown to regulate microglia surveillance dynamics in the retina. For instance, basal microglia motility is decreased in retina explant of CX₃CR1-knockout mice (Liang et al. 2009). The constant surveillance of specific microenvironments allows microglia to rapidly extend processes toward a lesion site in CNS ($\sim 1.25 \mu\text{m}/\text{min}$) (Davalos et al. 2005; Nimmerjahn et al. 2005). Several extrinsic and intrinsic factors are implicated in the process of microglia extension toward a lesion. Rapid extension of these processes is also dependent on extracellular ATP detected by microglia through the purinergic receptor, P2Y₁₂ (Davalos et al. 2005; Haynes et al. 2006). Activation of P2Y₁₂ receptors is associated with outward potassium current in microglia (Wu et al. 2007). Outward potassium current could contribute to regulation of microglia volume during chemoattraction (Eder 2005). Glutamate also attracts microglia through an ATP independent mechanism as shown in mouse spinal cord (Liu and Kielian 2009). In a model of retina lesion, CX₃CR1 has been shown to be implicated in the fast response of microglia toward the lesion (Liang et al. 2009). Interestingly, in vivo activated microglia by bacterial endotoxin such as lipopolysaccharide (LPS) exhibit retracted ramifications (Madore et al. 2013), this in response to ATP detected by the adenosine receptor 2A (Orr et al. 2009). Activation of this receptor could explain morphological changes from ramified to amoeboid microglia. Microglia are considered as a protective agent in healthy tissues able to very rapidly extend their migrating and converging processes toward a lesion site. Indeed microglia processes convergence is quick after a laser beam lesion on brain slices. This rapid reaction limits lesion propagation to neighboring neuronal tissues (Hines et al. 2009). Moreover, microglia motility is also regulated by neuronal activity. In 2011, Fontainhas dem-

onstrated that microglia motility is regulated by ionotropic glutamatergic neurotransmission and decreased by ionotropic γ -aminobutyric acid (GABA) neurotransmission (Fontainhas et al. 2011). In support of these findings a recent study revealed that in rodent hippocampus, dendritic neuronal N-Methyl-D-aspartate receptor (NMDAR) activation triggers ATP release that in return, induces outgrowth of microglia processes (Dissing-Olesen et al. 2014). These new functions and mechanisms of microglia regulation contribute to the hypothesis that microglia participate in neuronal functions during homeostatic and injury states.

13.6.2 Antigen Presentation

At the periphery, dedicated cells are doing the antigen presentation process, which is to present exogenous antigen to T cells. This constitutes the cellular component of adaptive immunity. Professional antigen presenting cells (APC) such as dendritic cells, macrophages and lymphocytes phagocytose their targets. They will migrate then to lymph nodes where they will present to T cells digested exogenous proteins attached to their cell surface, to specific receptors such as class II proteins of major histocompatibility complex (MHC II). In the CNS, antigen presentation by microglia is debated. In physiological conditions, microglia do not express MHCII. Only a subset of cells, which will be considered as dendritic, cells express co-stimulatory molecules such as CD11c (Bullock et al. 2008). Ford in 1995 showed that microglia to a few extent do an activity of antigen presentation in vivo (Ford et al. 1995). However, after an localized immune challenge with IFN- γ , microglia express high levels of MHCII and CD11c in vivo and will present antigens at their cell surface in vitro (Gottfried-Blackmore et al. 2009). One of the reason of microglia would not be able to present in vivo antigens, would assess that microglia would have to exit the parenchyma to migrate toward lymph nodes. Antigen presentation by microglia in the CNS would not take place in the parenchyma but rather in the meninges and choroid plexus. These structures contain perivascular APCs. Antigen presentation could be assessed by a direct drainage of antigens in the CNS in the cerebro-spinal fluid via the arachnoid space toward channels present at the level of cribriform plate of the ethmoid to finally join lymph nodes in the deep cervical (Galea et al. 2007; Ransohoff and Engelhardt 2012). However, recently, it has been shown that the CNS present a functional and classical lymphatic system, called the glymphatic system (Louveau et al. 2015). Self antigens including CNS antigens do not promote any response since auto-reactive T cells are eliminated by clonal deletion in the thymus. In the case of auto-immune diseases such as MS, reactive T cells against myelin escape from this immune tolerance mechanism and enter the CNS under certain conditions leading to

the demyelination process (Goverman 2011). Microglia seem to play a negative role in EAE progression, animal model of MS since when microglia activity is suppressed and the severity of pathology is reduced (Heppner et al. 2005) (Heppner et al. 2005). However, this deleterious role of microglia could be linked to their defective phagocytic activity or antigen presentation function in disease (Ransohoff and Engelhardt 2012).

13.6.3 Migration (chemotaxis)

Microglia is able to migrate toward a lesional site where they can eliminate debris and contribute to tissue repair. Microglia migration is dependent on gradients of chemokines and cell surface receptor expression and their localization from the injured site (Flynn et al. 2003; Dijkstra et al. 2004; Wang et al. 2008). For example in MS, secretion of CCL2/MCP1 and CXCL10/IP10 and the expression of their receptors is increased and has been associated to an activation of microglial cells (Simpson et al. 2000; Tanuma et al. 2006). CCL2/MCP1 protein is part of the chemokine family CC. CCL2 contains four residues cysteine highly conserved characteristic of the CC chemokine family. In mouse, CCL2 is a protein containing 125 amino acids. A few studies revealed that CCL2 is constitutively expressed by neurons in the CNS and more specifically in inflammatory conditions (Reaux-Le Goazigo et al. 2013). CCL2 is also produced by glial cells (Barna et al. 1994; Berman et al. 1996; Glabinski et al. 1996; Hanisch 2002). Perivascular astrocytes are the main source of CCL2 in the brain and also during inflammatory conditions, Microglia express CCR2 which is the receptor of CCL2 (Conductier et al. 2010). CCL2 was first described for its chemoattractant activity of monocytes toward inflammation sites. Its expression in the CNS is increased in several inflammatory pathologies and notably in Alzheimer's disease. Numerous studies showed that CCL2 is increased at the level of aggregated amyloid plaques associated to a microgliosis (Ishizuka et al. 1997).

13.6.4 Phagocytosis

Endocytosis is defined by internalization of extracellular material into vesicles that are transferred into the cytosol (Napoli and Neumann 2009). This process consists in three mechanisms. Microglia are able to bind extracellular particles through specific receptors which lead to engulfment of these particles. This process is named endocytosis mediated by receptors implying membrane invaginations that are responsible for the formation of the vesicles (Goldstein et al. 1979). A second process is known to engulf extracellular fluids containing single proteins or little molecules and

is named pinocytosis (Glenn et al. 1991). Macropinocytosis has been shown to be responsible of soluble Abeta protein engulfment in a model of AD (Mandrekar et al. 2009). Phagocytosis is the third mechanism and is known to engulf solid particules (Kinchin et al. 2008). The word phagocytosis comes from Ancient Greek meaning eat for phagein and cell for kutos. Pathogen phagocytosis has been discovered by the Russian embryologist Ilya Metchnikoff in the 80s showing that white blood cells could engulf bacteria. Metchnikoff showed that phagocytosis allowed the host defense, that was beneficial for tissue homeostasis and linked to inflammation in humans (Metchnikoff and Binnie 1905). In mammals, professional phagocytes derive from a common myeloid lineage. Phagocytosis is the main function of microglia cells with the actin-dependent engulfment of exogenous particules and debris (Aderem and Underhill 1999) and digest the taken-up material by a professional lysosomal machinery. Depending on the type of the phagocytic receptor microglia responds differently in their downstream cytokine signaling, either pro- or anti-inflammatory. In the presence of apoptotic cells, microglia phagocytose without inflammation and by production of anti-inflammatory cytokines such as transforming growth factor β (TGF β) (Moller et al. 2000; Wu et al. 2002). Also adenosine triphosphate (ATP) released from injured/necrotic neurons can activate microglia through binding to purinergic receptors and convert them to the neurotoxic phenotype (Koutsilieri et al. 2002). Clearance of apoptotic cells, accumulated proteins and exogenous pathogens by microglia is one of the important action to maintain CNS (Chan et al. 2001). Clearance of cell debris following programmed cell death or apoptosis is necessary to limit damages to neighboring cells that are still healthy. Indeed, debris will inhibit growth and tissue repair. Thus phagocytosis is essential during development and during repair after a lesion. However, in case of chronic activation, microglia secrete neurotoxic factors such as inflammatory cytokines and NO. If the phagocytic activity is not controlled and well regulated, the neuroprotective and beneficial effect of microglia can inverse leading to chronic neuroinflammation (Aderem and Underhill 1999). Phagocytosis by microglia is supposed to follow a model in three steps proposed by Savill in 2002. There is a step of chemoattraction in which the phagocyte (microglia) has to find its target by following molecular find-me signals secreted by the target. Once the phagocyte reached its target, it will establish a direct membrane contact via ligand-receptor interactions. Apoptotic cells liberate extracellular nucleotides such as ATP or UTP (Elliott et al. 2009). UDP coming from degradation of UTP will act in P2Y6 receptors which facilitate phagocytosis (Koizumi and Fujishita 2007). CX3CL1 or fractalkine is another signal secreted by apoptotic cells (Truman et al. 2008; Noda et al. 2011). Microglia expressing CX3CR1 will phagocytose apoptotic cells. Eat-me signals are secreted by

microglia and will bind the target to eliminate. For example, apoptotic cells are recognized by microglia through scavenger receptors. “Bridge” molecules or eat-me signals bind phosphatidylserines exposed at the cell surface of apoptotic cells and are detected by receptors in microglia, such as milk fat globule-epidermal growth factor (MGFG-E8) and many others. Different types of phagocytosis exist. Complement cascade play an important role in the phagocytosis of opsonized particules. Complement receptor 3 (CR3 or CD11b/CD18) is expressed by microglia in the CNS and macrophages at the periphery. Complement cascade proteins opsonize targeted pathogens or synapses and participate to their phagocytosis by microglia through CR3 (Aderem and Underhill 1999). Opsonization consists in covering the target with molecules such as C3b or C4b (Brown 1991) in order to facilitate their engulfment by the phagocyte.

Normal microglia phagocytoses injured neurites and myelin debris in a slow process (Gao et al. 2003), whereas activation of microglia increases this ability to phagocytose axonal and myelin debris (Block et al. 2004).

Tremblay and collaborators suggested that microglia would participate to synapse elimination and neuronal circuits remodeling in an experience-dependent manner in a healthy and mature brain (Tremblay et al. 2010). This work also showed that the majority of microglia processes (around 94%) in visual cortex of juvenile mice are juxtaposed to astrocyte and neuronal excitatory synaptic elements including the synaptic cleft. These interactions are done “en passant”. 3D reconstruction of microglia processes shows microglia extending protusions looking like fingers surrounding dendritic spine contacting axons (Tremblay et al. 2010). Using in vivo two-photon imaging of fluorescent-labeled neurons and microglia, it has been demonstrated that the resting microglial processes make brief (approximately 5 min) and direct contacts with neuronal synapses at a frequency of about once per hour (Wake et al. 2009). Microglia preferentially contact small size dendritic spines and remove them (Tremblay et al. 2010). These contacts are activity-dependent, and are reduced in frequency by decreased neuronal activity.

13.6.5 Synaptic Plasticity

Synaptic plasticity corresponds to the ability of synapses to change the strength of their connectivity. These changes can occur during short periods of time, leading to the addition or removal of connections between neurons (Bear 1999; Bliss and Collingridge 1993; Holtmaat and Svoboda 2009; Katz and Shatz 1996; Luscher and Malenka 2012). The main cellular and molecular mechanisms underlying learning and memory abilities rely on neuronal plasticity including synaptic plasticity, which can be studied by looking at the long-

term potentiation (LTP) phenomenon, corresponding to adaptation that occurs when synapses are strengthened following tonic activity. For instance, LTP is induced through high-frequency stimulation (HFS) of neuronal afferents resulting in persistent augmentation of their strength (Bliss and Collingridge 1993; Cooke et al. 2006). Interestingly, recent evidence suggests that microglia can directly modulate synaptic plasticity. Indirect evidences through the effect of inflammatory factors such as interleukin-1 β (IL-1 β) and tumor necrosis factor- α (TNF α), also attest of the modulatory effect of microglia on synaptic plasticity. It is known that IL-1 β gene expression is increased after LTP induction *ex vivo* but also *in vivo* in freely moving rats (Balschun et al. 2003; Schneider et al. 1998). This elevation in IL-1 β expression seems to play a role not only during induction but also during LTP maintenance. Indeed, intracerebroventricular administration of IL-1ra (IL-1 receptor antagonist) after induction of LTP impaired its maintenance. Administration of IL-1ra before LTP induction also seems to be able to impair induction and maintenance of the LTP (Loscher et al. 2003; Schmid et al. 2009). Using transgenic mice, Goshen and collaborators confirmed the involvement of IL-1 β in LTP since IL-1raKO mice do not show LTP induction in the hippocampus after HFS stimulation (Goshen and Yirmiya 2009). TNF α also appears to be involved in synaptic plasticity since *ex vivo* and *in vitro* studies demonstrated that TNF α enhanced synaptic efficacy by increasing surface expression of glutamatergic 2-amino-3-(5-methyl-3-hydroxy-1,2-oxazol-4-yl) propanoic acid (AMPA) receptors and that blockade of TNF α signaling reduced synaptic strength and AMPA receptors expression (Beattie et al. 2002). TNF α also plays a clear role in a form of long-term plasticity called synaptic scaling, a plasticity mechanism able to adjust the strengths in synapses through increased AMPA receptors expression in response to an episode of strong cell activation. This leads to neuronal network stabilization. Indeed it has been shown that TNF α is necessary for increased surface AMPA receptors and synaptic strength after chronic blockade of neuronal activity (Stellwagen and Malenka 2006). Despite the involvement of TNF α in this form of synaptic plasticity, it seems that TNF α is not involved in acute plasticity since most of the studies looking at the role of TNF α in LTP did not find any effect after manipulating TNF α signaling (Albensi and Mattson 2000; Kaneko et al. 2008; Stellwagen and Malenka 2006). Recently CX₃CR1/CX₃CL1 microglial signaling pathway has been investigated and seems to play a role in the modulation of synaptic plasticity, even if contradictory results have been described. Indeed, neuronal activity is known to contribute to synaptic maturation (Hua and Smith 2004; Huberman et al. 2008; Katz and Shatz 1996). *Ex vivo* manipulations demonstrated that administration of fractalkine inhibits LTP induction. This effect was not found in CX₃CR1^{KO} mice (Maggi et al. 2009).

Oppositely, Rogers and collaborators reported complete absence of LTP *ex vivo* in CX₃CR1^{KO} mice (Rogers et al. 2011). No difference were found in LTP in these mice at adulthood whereas during development CX₃CR1^{KO} mice exhibited an increased long-term depression (LTD) and decreased duration and latency of epileptic crises induced by pentylenetetrazol (PTZ), experimental model of epilepsy. Thus, microglial CX₃CR1 is involved in the maturation of hippocampal neurons since CX₃CR1^{KO} mice display increased spine density and PSD95 expression, a post-synaptic protein. The immature synaptic phenotype characterized in CX₃CR1^{KO} mice may correspond to impaired hippocampal development previously discussed (Paolicelli et al. 2011). In the end, these data suggest that CX₃CL1-CX₃CR1 signaling in microglia could play a different role during development and at adulthood in the healthy brain. Less recent *ex vivo* studies demonstrate the role of microglia in maturation of hippocampal synapses. On hippocampal slices from mice lacking KARAP/DAP12 (transmembrane receptor expressed by microglia and known to activate innate immune system) (Hamerman et al. 2005), synaptic maturation is altered (Roumier et al. 2004, 2008). On postnatal day 22, expression of the NR2B subunit of NMDA receptors was increased and Glur2 subunit from AMPA receptors expression was decreased, characteristic of immature synapses (Roumier et al. 2004). Finally, recent results reported the involvement of microglia in synaptic plasticity using the CNS-TGF β -1 transgenic mice, which have a reduced number of microglia cells without affecting neuronal density. Indeed, Koeglspenger and collaborators demonstrated that hippocampal function was altered in these mice (Koeglspenger et al. 2013). The reduced microglial density also was associated with a decreased LTP and increased LTD in the hippocampus. The mechanisms thought to be involved in these effects relied on enhancement of NMDA receptor activation and reduced glutamate recycling. These results are in agreement with the changes observed in mice deficient in CX₃CR1/CX₃CL1 displaying a lack of LTP and hippocampal-dependent learning and memory (Rogers et al. 2011). Altogether, these data emphasized the idea of the key role of microglia in neuronal plasticity.

13.6.6 Exosome

Glia cells and specially microglia require intense cell to cell communication between all partners of the synapse and also intercommunication between structures or even with the periphery. Intercellular communication can be mediated through direct cell to cell contact or paracrine action of secreted molecules. A novel mode of communication relying on the exchange of extracellular vesicles (EVs) between cells has become evident. Various cell types release EVs of

different origin into their environment, which have the potential to transfer a collection of biomolecules between cells locally or over longer distances (Thery 2011; Raposo and Stoorvogel 2013). Extracellular vesicles comprise shedding microvesicles (MVs), exosomes, and apoptotic bodies, which differ in size, cargo, membrane composition, and origin. Apoptotic bodies are released during apoptosis, whereas the other types of vesicles are derived from healthy cells (Thery 2011; Cocucci et al. 2009). While MVs directly pinch off from the plasma membrane and are heterogeneous in size (up to 1000 nm in diameter), exosomes originate from the endosomal system and exhibit a regular shape (50–100 nm in diameter). Exosomes correspond to the intraluminal vesicles of multivesicular bodies (MVBs). Hence their generation involves sorting at the level of the endosomal limiting membrane mediated by the ESCRT (endosomal sorting complex required for transport) machinery (Simons and Raposo 2009; Baietti et al. 2012) and is mediated extracellular ATP (Bianco et al. 2005). Exosomes carry characteristic bioactive lipids, nucleic acids, biogenesis-related proteins (Tsg101 and Alix are classic markers), through which they can influence recipient cells (Tetta et al. 2013). Exosome influence is particularly relevant on immune system (Robbins and Morelli 2014). Reactive microglia were shown to release exosomes and MVs carrying inflammatory cytokines, caspases and P2X7 receptors which may induce and propagate inflammatory reactions throughout the CNS (Prada et al. 2013). Microglia-derived MVs transmit inflammatory signals to recipient microglia which in return upregulate co-stimulatory CD86 molecule and inflammatory factors (iNOS, Cox2 etc) (Verderio et al. 2012). Microglia-derived MVs interact with neurons and can stimulate neurotransmission in vitro and after injection in vivo (Turola et al. 2012). MHCII can be packed into exosomes and its amount is increasing upon stimulation with interferon- γ . It has been suggested that microglia does not release exosomes constitutively (Hooper et al. 2012).

13.7 Role in Neural Development

13.7.1 Elimination of Migrating Stem Cells and Apoptotic Cells

Microglial phagocytosis of newborn neurons has been shown as an important process for the shaping of neural circuitry. During development, programmed cell death occurs among several cells of the neuronal lineage (de la Rosa and de Pablo 2000). These cells undergo apoptosis, triggered by proteolytic cascades mediated by caspases, and characterized by DNA fragmentation and membrane blebbing (Porter and Janicke 1999; Yuan and Yankner 2000). These apoptotic cells include both postmitotic neurons and proliferating neu-

roblasts. In the developing cerebellum, microglia release superoxide anions that trigger cell death in a subset of newborn neurons, and the resulting apoptotic cells are phagocytized by microglia (Marin-Teva et al. 2004). Interestingly, in the adult CNS, microglial-mediated phagocytosis of apoptotic neuroblasts also occurs. In the mammalian brain, two discrete regions exhibit persistent neurogenesis: the subgranular zone (SGZ) in the dentate gyrus of the hippocampus and the SVZ, which lines the walls of the lateral ventricles (LVs) (Whitman and Greer 2009; Ihrie and Alvarez-Buylla 2011). Postnatally generated cells include glutamatergic and GABAergic neurons that populate the dentate gyrus of the hippocampus and are integrated into neural circuitry during learning and memory formation processes. Alternatively, neuroblasts generated in the postnatal SVZ migrate through a long pathway, the rostral migratory stream, towards their final destination in the glomerular and granule cell layers of the olfactory bulb (OB) (Lois et al. 1996). Within the OB, neuroblasts differentiate into GABAergic and to a lesser extent glutamatergic cells, which are integrated as juxtglomerular neurons (Zhao et al. 2008; Brill et al. 2009; Sequerra et al. 2010). These two neurogenic sites both present neural stem cells that in turn are functionally integrated into neuronal circuits (Zhao et al. 2008; Doetsch et al. 1997). Despite the abundant amount of new born neurons, only a small proportion are functionally integrated (Ma et al. 2009). The majority of the new born precursors will undergo apoptosis at early stages and are phagocytosed by microglia (Sierra et al. 2010). Notably, the mechanisms underlying the microglial phagocytosis of newborn cells in this neurogenic niche remain elusive. Tyro3, Axl and Mer (TAM) receptor tyrosine kinases and their ligands Gas6 and protein S have been shown as key elements for the efficient phagocytosis of apoptotic cells in the mature immune, nervous and reproductive systems (Lemke and Burstyn-Cohen 2010). As such, the activity of these signaling pathways might govern microglial-mediated phagocytosis in this adult neurogenic niche. Moreover, whereas several studies have addressed the roles of microglia in shaping adult hippocampal circuitry, only a few have addressed the potentially analogous functions of microglial cells in the neurogenic niches.

13.7.2 Synaptic Pruning

During the initial 2 weeks of post-natal CNS development there is a period of transient synapse formation and elimination dependent on neuronal activity. Synaptic pruning or synapse elimination was initially hypothesized to be dependent on neuronal activity and intrinsic molecular mechanisms (Luo and O'Leary 2005; Katz and Shatz 1996; Huberman et al. 2008; Hua and Smith 2004). This hypothesis was altered when studies showed that during CNS development

microglia play a key role in refinement of neuronal circuits (Marin-Teva et al. 2011). Recent studies demonstrated a role of microglia in the dynamic interactions between microglia processes and synapses resulting in proper pruning (Schafer et al. 2012; Paolicelli et al. 2011). For instance, microglia phagocytose hippocampal synapses during mouse post-natal development (Paolicelli et al. 2011). Immunogold detection of pre- and post-synaptic proteins in microglia confirmed the integral role of microglia in synaptic pruning. Paolicelli and collaborators showed that CX₃CR1 knock-out mice exhibit fewer microglia cells in postnatal hippocampus compared to wild-type mice at the same age. In a pathological context, the CX₃CR1 receptor can modulate microglia in terms of number, activation and recruitment toward lesion sites, by detecting the fractalkine ligand CX₃CL1 expressed on damaged neurons (Jung et al. 2000; Cardona et al. 2006b). In a developing CNS without inflammation, CX₃CL1 would modulate number of microglia, activation and recruitment toward synapses to eliminate. These findings are consistent with previous data suggesting that immune molecules, such as class I molecules of histocompatibility major complex, complement cascade molecules and neuronal pentraxins, contribute to synaptic pruning during development (Stevens et al. 2007; Schafer et al. 2012; Huh et al. 2000; Goddard et al. 2007; Datwani et al. 2009; Corriveau et al. 1998; Boulanger 2009). Recently, immune molecules, including complement proteins C1q and C3, have emerged as critical mediators of synaptic refinement and plasticity (Stevens et al. 2007; Stephan et al. 2012; Schafer et al. 2012). Indeed, pruning of inactive retinal ganglion cells (RGC) synapses in the lateral geniculate nucleus (LGN) is mediated by microglia phagocytosis of the pre- and post-synaptic elements through the complement receptor 3 (CR3) which is activated by the complement cascade beginning with C1q and the opsonization is mediated by C3 (Stevens et al. 2007; Schafer et al. 2012). Recently, retinal TGF- β was identified as a key regulator of neuronal C1q expression and synaptic pruning in the developing visual system. Mice lacking TGF- β receptor II (TGF β RII) in retinal neurons have reduced C1q expression in RGCs and reduced synaptic localization of complement, and pruning defects were observed in complement-deficient mice. TGF- β is implicated in the regulation of neuronal C1q expression in order to initiate complement- and microglia-mediated synaptic pruning.

13.7.3 Synaptogenesis

During CNS development, several studies showed that microglia participate to synaptogenesis regulation. Microglia can stimulate synaptogenesis through secretion of thrombospondins (TSP) (Chamak et al. 1995; Moller

et al. 1996) or extracellular matrix proteins (Christopherson et al. 2005). The absence of these proteins induces a robust decrease of synapses during post-natal period (Christopherson et al. 2005). SIRP α and CD47 are co-localized at synaptic level in retinas for example (Mi et al. 2000). Genetic deletion of CD47 results in a loss of SIRP α localization suggesting that CD47 is necessary for the recruitment and localization of SIRP α . In neuronal hippocampal cultures, SIRP α is localized at the axonal and dendritic level instead of CD47 which is restrained to dendrites (Ohnishi et al. 2005). CD47 improves neurite formation and neuronal arborization in culture (Murata et al. 2006). Interaction between SIRP α and CD47 promotes filopodium formation and spines (Miyashita et al. 2004). Interestingly, a recent study showed that the anti-inflammatory cytokine IL-10 released by microglia increased number of dendritic spines (Lim et al. 2013a). It also showed that IL-10 receptors are present on hippocampal neurons at early stage of brain development (Lim et al. 2013b) suggesting that developing microglia regulated synaptic functions and neuronal development through the interactions of the IL-10 released from the microglia with IL-10 receptors expressed on the hippocampal neurons.

13.7.4 Synaptic Maturation

Neuronal activity is known to contribute to synaptic maturation (Sanes and Lichtman 1999; Katz and Shatz 1996; Huberman et al. 2008; Hua and Smith 2004). Since 2011, microglia has also been showed to contribute to synaptic maturation (Paolicelli et al. 2011). Excitatory synaptic transmission toward CA1 neurons show an immature phenotype in knock out CX₃CR1 mice indexed by increased in long term depression (LTD) and decreased duration and latency of epileptic crises induced by pentylenetetrazol (PTZ), experimental model of epilepsy. These phenotypic characteristics of CX₃CR1-knockout mice are associated with defect in synaptic pruning and immature synapses (Paolicelli et al. 2011). Microglial CX₃CR1, fractalkine receptor, is involved in maturation of hippocampal neurons since CX₃CR1-knockout mice have increased spine density and increased PSD95 expression (Paolicelli et al. 2011). Less recent ex vivo studies demonstrate the role of microglia in maturation of hippocampal synapses. On hippocampal slices from knock out KARAP/DAP12 (transmembrane receptor expressed by microglia and known to activate innate immune system (Hamerman et al. 2005), synaptic maturation is altered (Roumier et al. 2004, 2008). On postnatal day 22, expression of subunit NR2B of NMDA receptors was increased and Glur2 subunit from AMPA receptors expression was decreased, characteristic of immature synapses.

13.8 Molecular Regulation in Development and Survival

Tissue-resident macrophages have many tissue-specific functional characteristics, which are a reflection of distinct gene-expression programs (Okabe and Medzhitov 2015). Thus, microglia express functional and unique molecular characteristics not seen in other tissue macrophage populations (Hickman et al. 2013; Butovsky et al. 2014; Gautier et al. 2012). The mechanism to establish these organ-selective properties is through environmental influences on RNA expression profiles, exerted at the level of epigenetic histone and DNA modification (Amit et al. 2015).

13.8.1 PU.1-, RUNX1- and IRF8-Dependent Microglia Development

Between embryonic days 8 and 9, EMPs migrate to the forming CNS where their further development is regulated by transcription factors that are essential for regulation of microglia cell development are primarily PU.1, RUNX1, and IRF8. PU.1 is a member of the ETS family of transcription factors (Rosenbauer and Tenen 2007), and its targeted disruption leads to the lack of B cells, monocytes, macrophages, and parenchymal microglia (Beers et al. 2006; McKercher et al. 1996). RUNX1 is a critical regulator of microglia during embryonic development (Ginhoux et al. 2010), as well as a modulator of proliferation and homeostasis in the postnatal stage (Zusso et al. 2012). IRF8, similarly to RUNX1, is involved in the regulation of microglia differentiation during development as a heterodimeric partner of PU.1, as well as in microglial activation in adulthood (Kierdorf et al. 2013). These myeloid lineage-determining transcription factors set the stage for cell differentiation throughout a specific cell lineage by establishing common enhancers. Subsequently, these factors cooperate with environment-dependent transcription factors to promote tissue-resident macrophage-specific gene expression.

13.8.2 IL34-, CSF1r- and Tgfb β 1-Dependent Microglia Maintenance and Survival

Microglia express receptors that trigger essential cellular developmental and survival signals. The receptor for colony stimulating factor 1 (Csfr1) plays a major role in peripheral macrophage development and survival (Cecchini et al. 1994; Chitu and Stanley 2006). Dai et al. showed that targeted disruption of the Csfr1 gene results in mononuclear phagocyte deficiency (Dai et al. 2002). Furthermore, Ginhoux et al. showed that the development of microglia and primitive yolk sac macrophages is dependent on Csfr1

signaling (Ginhoux et al. 2010). However, the Csfr1^{op/op} mouse strain with a natural occurring null mutation in Csfr1 did not reveal the same severe phenotype observed in the Csfr1r-deficient animals (Yoshida et al. 1990). Detailed examination of Csfr1^{op/op} mice revealed the presence of microglia but at reduced numbers (Blevins and Fedoroff 1995; Erlich et al. 2011). Thus, survival and maintenance of microglia are majorly influenced by Csfr1r function. However, Csfr1r may have Csfr1-independent functions in microglial homeostasis, suggesting the existence of another ligand for this receptor. Lin et al. discovered another ligand of the Csfr1r known as IL-34 (Lin et al. 2008). Both, IL-34 and Csfr1 share some similar signaling functions via Csfr1r (Wei et al. 2010). However, both ligands showed a differential expression pattern in vivo. Moreover, IL-34 is required for the development of Langerhans cells and microglia (Greter et al. 2012; Wang et al. 2012). IL-34-deficient animals had reduced numbers of microglia and were consequently more susceptible to viral infections in the CNS (Wang et al. 2012). Greter et al. demonstrated that IL-34 is expressed by specific neuronal subsets in the cortex and hippocampus and that microglial development was not influenced by IL-34 deficiency. In contrast, microglial cell number was decreased in specific regions of the adult brain (Greter et al. 2012). These results indicated that IL-34 plays a role in the adult brain for microglial survival and homeostasis. Additionally, a recent study showed that the signaling of both IL-34 and Csfr1 are important for microglial proliferation upon neurodegeneration during prion infection and AD (Gomez-Nicola et al. 2013). Microglial proliferation was induced by administration of Csfr1 and IL-34, whereas IL-34 showed a stronger proliferative capacity than Csfr1. Interestingly, heterozygous mutations in the Csfr1r locus can be found in patients with hereditary diffuse leukoencephalopathy with spheroids (HDLS), characterized by demyelination of the cerebral white matter and formation of spheroids which lead to progressive cognitive and motor dysfunction (Rademakers et al. 2012). However, it is still unclear, what roles IL-34 and Csfr1 play in microglial development or homeostasis in these patients. Future studies will elucidate the detailed function of these important physiological signaling molecules in microglia.

Microglia have a unique homeostatic molecular and functional signature (M0) in the healthy brain (Hickman et al. 2013; Butovsky et al. 2014; Gautier et al. 2012) which is tightly controlled by TGF β 1 signaling (Butovsky et al. 2014; Gosselin et al. 2014). TGF β 1 signaling is required in vitro for microglia to express a partial microglial molecular signature characteristic of acute ex vivo adult microglia. Furthermore, a loss of microglia has been observed in mice deficient for TGF β 1 in the CNS (Butovsky et al. 2014). In support of the role of TGF β 1 on regulation of homeostatic microglia, Gosselin et al. showed that signal-dependent transcription

factors, such as SMAD3, which is triggered by TGF β in the brain, activated a subset of PU.1-poised enhancers and super-enhancers in microglia (Gosselin et al. 2014). Accordingly, TGF- β 1 was found capable of inducing gene expression and enhancer profiles that appeared much more similar to in vivo microglia than in vitro microglia cultured in its absence (Butovsky et al. 2014; Gosselin et al. 2014). Moreover, Tichauer et al., reported that TGF β 1-Smad3 pathway is impaired in aging (Tichauer et al. 2014). Thus, age-related impairment of TGF β 1-Smad3 can reduce protective activation while facilitating cytotoxic activation of microglia, potentiating microglia-mediated neurodegeneration.

13.9 Molecular Signature

13.9.1 Homeostasis

Recent studies reported that microglia have a unique transcriptomic signature, which distinguishes them from other CNS cells and peripheral macrophages or monocytes (Gautier et al. 2012; Chiu et al. 2013), and express a unique cluster of transcripts encoding proteins for sensing endogenous ligands and microbes, defined as the sensome (Hickman et al. 2013). When compared to different tissue-resident macrophage subsets, microglia showed a specific or enhanced expression of genes including *Hexb*, *Tmem119*, *Siglech*, *Olfml3*, *Cx3cr1*, *Gpr84*, *Trem2*, *Socs3*, and *Fcrls* (Gautier et al. 2012). Chiu et al used ImmGen Data to identify 50 genes enriched in microglia as compared to genes expressed within CNS tissues (Chiu et al. 2013). Among them, *Olfml3*, *Siglech*, and *Tmem119* are highly enriched markers for microglia. Hickman et al., identified over 100 genes enriched in microglia as “the microglial toolset for sensing changes in the brain’s milieu” including *Csf1r*, *Cxcr4*, *Cx3cr1*, *Olfml3*, *P2ry12*, *Cd33*, *Siglech*, *Tmem119*, and *Tyrobp* (Hickman et al. 2013). We analyzed mRNA, microRNA and proteomics in adult microglia and identified 239 genes including *Fcrls*, *P2ry12*, *Tmem119*, *Olfml3*, *Csf1r*, *Gpr34*, *Mertk*, *P2ry12*, *Hexb* and eight microRNAs and 74 proteins are uniquely or highly expressed in microglia as compared to their expression in myeloid and other immune cells (Butovsky et al. 2014). Several of these microglial genes were validated in human microglia (Butovsky et al. 2014). Identification of the homeostatic microglia signature will provide robust tools including microglia specific antibodies and genetic mouse models to investigate microglial biology and to generate a more accurate description of microglia phenotypes in disease (reviewed in (Crotti and Ransohoff 2016)).

13.9.2 Aging and Disease

During aging microglia exhibit deramified and fragmented processes in postmortem human brain subjects (Streit et al. 2004). Hickman et al. analyzed the microglia molecular signature in aging mice and found most of the sensome genes are downregulated (Hickman et al. 2013). Furthermore, aging microglia are characterized by expression of cell surface markers like *Lgals3*, *Axl*, *Clec7a*, *MHC class II*, and *Cxcr4* (Holtman et al. 2015b). A similar observation about aged microglia being “immunologically activated but not polarized to a pro- or anti-inflammatory phenotype” at the transcriptional level has been recently reported (Butovsky et al. 2014). Microglia acutely isolated from a murine model of peroxisomal β -oxidation deficiency (*Mfp2*^{-/-}) shows robust and chronic inflammation with increased expression of inflammatory surface and cytokine markers and suppression of the homeostatic purinergic receptor P2ry12, and other cell surface molecules in *Mfp2*^{-/-} model (Verheijden et al. 2015) similar to what was reported in aged microglia (Hickman et al. 2013). A partial explanation of the loss of homeostatic functional phenotypes in aging microglia could be the downregulation of *Tgbr1* observed in *Mfp2*^{-/-} mice (Verheijden et al. 2015), given that TGF β 1 signaling has been reported to be fundamental for microglia expression signature (Butovsky et al. 2014).

Microglia from AD model mice show the upregulation of *Il1b*, *Clec7a*, *Axl*, and *Itgax*. By contrast, the homeostatic genes including *Cx3cr1*, *Tmem119*, and *Csf1r*, as well as some phagocytosis and/or endocytosis genes, were reduced in microglia in the context of AD (Orre et al. 2014).

Similarly, transcriptomics and microRNA analysis of microglia purified from SOD1G93A mice reveals that microglial signature genes are lost during disease progression in this murine model of ALS (Butovsky et al. 2015). P2ry12, transcription factors *Egr1*, *Atf3*, *Jun*, *Fos*, and *Mafb*, and the upstream regulators *Csf1r*, *Tgfb1*, *Tgfb1r*, and *Cd39*—an ATP catabolic ectoenzyme—are downregulated in spinal cord microglia from SOD1G^{93A} mice as compared to those from control mice. In contrast, upregulation of apolipoproteins, including ApoE and miR-155, in microglia from SOD1 mice and human spinal cord from ALS donors were reciprocally upregulated (Butovsky et al. 2015). In particular, ApoE has been proposed to trigger an inflammatory phenotype in microglia, preferentially in male mice. Genetic ablation of miR-155 restores expression of the microglia-specific target genes, attenuates expression of ApoE, and improves survival (Butovsky et al. 2015). Thus, the unique homeostatic microglia gene signature is progressively lost during aging and in neurodegenerative diseases.

13.10 Molecular Signaling in Immunomodulation

13.10.1 Fractalkine/CX3CR1 Signaling

Fractalkine/CX3CL1 protein is the only known member of the chemokine family CX3C and contains 373 amino acids. The protein is synthesized as an anchored membrane protein. It can be converted to a soluble glycoprotein by cleavage of membrane protein form under the action of metalloproteases (Hundhausen et al. 2003) and is secreted by microglia in spinal cord (Meucci et al. 2000; Ransohoff 2002; Clark et al. 2007). CX3CL1 acts like a conventional chemokine, acting locally by direct contact under its anchored form or indirect under its soluble form (Bazan and Allan 1997). Indeed, its increasing the recruitment and activation of many cell populations expressing the receptor CX3CR1, most of them being monocytes. Membrane CX3CL1 act like an adhesive molecule participating to the leukocyte capture and infiltration (Ransohoff 2009). However, it is established that both forms of CX3CL1 bind to CX3CR1 with the same (Harrison et al. 2001). CX3CL1 is one of the chemokine which is constitutively expressed at high levels in the CNS and acts only on the CX3CR1 receptor. The chemokine was cloned from endothelial activated cells and neurons. CX3CL1 and its receptor have been described to play a role in neuron-microglia communication. CX3CL1 is expressed by neurons (Nishiyori et al. 1998; Schwaeble et al. 1998; Hughes et al. 2002) and CX3CR1 is uniquely expressed by myeloid cells including microglia cells (Nishiyori et al. 1998; Hughes et al. 2002; Mizuno et al. 2003). However, CX3CL1 has been shown to be expressed by astrocytes (Mizuno et al. 2003) and some studies have revealed that CX3CR1 could be expressed on neurons (Meucci et al. 2000). CX3CL1/CX3CR1 signaling plays an important physiological role in neuron-microglia communication and in neuroprotection under inflammatory or lesional conditions (Mizuno et al. 2003; Hughes et al. 2002). In vitro and in vivo studies have shown CX3CL1 interaction to its receptor contributes to the attenuation of microglial activation and neurotoxicity under inflammatory conditions. In vitro, soluble CX3CL1 acts like an anti-inflammatory factor through the inhibition of the IL1b, IL6, TNFa, NO and iNOS expression in microglial and mixed glial cultures (Mizuno et al. 2003; Zujovic et al. 2000). In 2009, Lyons showed that both forms of CX3CL1 decrease the expression of IL1b and MHCII in primary cultures of neuron-microglia (Lyons et al. 2009). In vivo, blockade of endogenous CX3CL1 using an anti-CX3CL1 potentiate the increase of TNFa expression and isoprostane-8 (oxidative stress marker), suggesting that CX3CL1 expression is necessary for the control of microglial (Zujovic et al. 2001). Genetic ablation of CX3CR1 showed that the absence of CX3CL1/CX3CR1 signaling exacerbates microglial responses under inflammatory

conditions. Indeed, the mice present a intensive microglia activation and an increase of IL1b production in the hippocampus following LPS stimulation (Cardona et al. 2006a). Moreover, in neurodegenerative disease models such as Parkinson disease or ALS, the absence of CX3CR1 induces a more robust activation of microglia and an important neuronal loss compared to WT mice (Cardona et al. 2006a). During chronic neurodegenerative pathologies or even in a case of acute inflammation, CX3CL1/CX3CR1 signaling regulates microglial activation. It is also the case in diverse physiopathological conditions in which CX3CL1 expression levels are modulated (Hughes et al. 2002; Kastenbauer et al. 2003). CX3CL1 is decreased in the CNS and in the hippocampus of aged rats (Lyons et al. 2009; Wynne et al. 2010) and contributes to low chronic inflammation characteristic in aging. The decrease of CX3CL1 is linked to the increase of activation markers such MHCII and CD40 in microglia and also to an increase of IL1b expression (Wynne et al. 2010). CX3CL1 administrated in the CNS decreases microglial activation and restores synaptic plasticity deficits caused by aging (Lyons et al. 2009). Regarding the receptor CX3CR1, LPS reduces in vitro its expression on microglia cultures (Boddeke et al. 1999). Recently, it was shown that in vivo, peripheral injection of LPS decreases CX3CR1 gene expression on microglia at adulthood and in aged mice (Wynne et al. 2010). CX3CR1 expression is reduced 4 h after LPS injection and restored 24 h later in adult mice. Instead the expression is still decreased in aged mice. This decrease of CX3CR1 expression in aged mice is matching the prolonged expression of IL1b (Wynne et al. 2010). CX3CL1/CX3CR1 signaling modulates microglia and their functions on the CNS.

13.10.2 CD39-ATP Axis

Nucleotides represent a novel and ubiquitous class of extracellular signaling substances in the CNS. ATP can be released from neural and glial cells (Dunwiddie et al. 1997; Pankratov et al. 2006; Koizumi 2010; George et al. 2015). Type 2 receptors for extracellular nucleotides (P2 receptors) function either as ion channels (P2X receptors, permeable for Na⁺, K⁺ and Ca²⁺) (Buell et al. 1998) or are G-protein-coupled (P2Y receptors) (King et al. 1998). They have a broad distribution in embryonic and adult CNS among most cell types. ATP acts as fast as neurotransmitters (Edwards and Gibb 1993; Bardoni et al. 1997) and is stored in vesicles (George et al. 2015). Moreover, ATP can trigger or inhibit neurotransmission by acting on neurotransmitter release via presynaptic receptors (Gu and MacDermott 1997). Microglia present several nucleotide receptors. They respond to ATP with the release of cytokines (IL1b) and undergo apoptosis following activation of P2X7 receptor (Ferrari et al. 1997) acting as a potent cytolytic stimulus. P2X7 receptor is activated in

diverse brain pathologies (Rodrigues et al. 2015). Microglia modulation of neurotransmission is also mediated by binding of ATP to P2RY receptors located on astrocytes. Microglia rapidly release small amounts of ATP and astrocytes in turn amplify this release and this independently of cytokine release.

Ectonucleotidases play a major role in modulating or terminating P2 receptor functions by hydrolysing extracellular nucleotides. Members of the ecto-nucleoside triphosphate diphosphohydrolase (E-NTPDase) family hydrolyse nucleoside 5'-triphosphates and nucleoside 5'-diphosphates. Northern hybridization suggests that the three related family members NTPDase1 to NTPDase3 are expressed in mammalian brain (Zimmermann and Braun 1999). NTPDase1 (CD39) hydrolyses nucleoside 5'-triphosphates and -diphosphates equally well (Kaczmarek et al. 1996). CD39 is a major ecto-nucleotidase expressed by microglia. CD39 and its activity of ecto-nucleotidase have been shown to be upregulated after cerebral ischemia in the hippocampus (Finsen et al. 1993). Under these conditions, considerable ATP is released and possibly other nucleotides may come from damaged cells. Microglia present a high capacity for surface-located nucleotide hydrolysis. CD39 may protect microglia from ATP-mediated overstimulation and would facilitate the formation of final hydrolysis product adenosine that has neuromodulatory and immunomodulatory roles (Di Virgilio 1998). CD39 activity is also present under physiological conditions in microglia. CD39 may be implicated in termination of purinergic signaling at the vicinity of the synapse involving astrocyte and neuronal transmission.

13.10.3 GPR34

G protein-coupled receptors (GPCR) form the largest gene family among transmembrane receptors, including more than 900 genes in humans and other mammals (Fredriksson and Schiöth 2005). A great number of stimuli, such as light, hormones, neurotransmitters, peptides, and nucleotides, activate the distinct receptors. About 155 so-called “orphan” GPCR (Wigglesworth et al. 2006) await identification of their physiological relevance. GPCR control almost every physiological function making this receptor family the most frequently used target for therapeutic drugs. Among the five structurally different GPCR families (Fredriksson and Schiöth 2005), the rhodopsin-like receptors form the largest in humans and other vertebrates. The rhodopsin-like family is divided further into subfamilies and groups. The P2RY12-like receptor group includes the ADP receptors P2RY12 and P2RY13, the UDP-glucose receptor P2RY14, and the orphan receptors GPR87, GPR82, and GPR34 (Schöneberg et al. 2007).

GPR34 is an orphan receptor of the P2RY12-like receptor group and was first discovered by mining GenBank™ for

novel GPCR sequences and homology cloning, assigned to the human X chromosome (Schöneberg et al. 1999a). Phylogenetic studies revealed that GPR34 has been highly conserved over the past 450 million years of vertebrate evolution (Schulz and Schöneberg 2003). To date, there is no report of GPR34 deficiency in humans, and sequencing of more than 100 worldwide samples of human genomic DNA revealed no functionally relevant alleles indicating the physiological importance of the gene (Engemaier et al. 2006). GPR34 shows a ubiquitous expression profile in mouse and human tissues (Schöneberg et al. 1999b). More detailed analyses showed GPR34 expression in the myeloid progenitor cell line HL-60 in K562 cells, and WEHI-3B cells, the macrophage cell line RAW 264.1 (Engemaier et al. 2006), and in the murine mast cell line P815.

GPR34 is implicated in cellular chemotaxis and immune response. Recently, several members of the P2RY12-like receptor group have been assigned to agonists, including nucleotide derivatives and lipids as physiological ligands (Sugo et al. 2006). Specifically, GPR34 has been shown to be a receptor for lysophosphatidylserine (lysoPS) (Kitamura et al. 2012). However, a recent study showed by knocking down *Gpr34* in mice, no evidence that lysoPS are natural agonists of receptor (Liebscher et al. 2011). LysoPS are generated by hydrolysis of membrane lipids through phospholipases A₁ and A₂ when apoptotic cells expose phosphatidylserine at the cell surface. LysoPS are potent activators of histamine release from mast cells (Bellini et al. 1990). Furthermore, they have been described as growth inhibitors of T cells and as chemoattractant molecules for fibroblasts and tumor cells (Bellini et al. 1990). Deficiency in *Gpr34* showed no major alterations but led to improper immune response upon antigen and pathogen challenges (Liebscher et al. 2011).

Microglia expressed highly *Gpr34* (Butovsky et al. 2014). GPR34 function in microglia has not yet been fully understood but one study presented *gpr34* as important for microglia phagocytosis (Preissler et al. 2015). Altered microglia morphology and decreased phagocytosis was reported in CD39 deficient mice (Bulavina et al. 2013). This convergent microglial phenotype in CD39- and GPR34 may point towards unidentified endogenous purinergic agonists of the ADP receptor P2RY12-like GPR34. Future studies need to address GPR34 relevance under pathophysiological circumstances such as EAE and Alzheimer's disease.

13.10.4 TAM System

The TAM system was discovered as a family of receptor tyrosine kinases (RTKs) in 1991. This system is known to modulate the immune system and in particular microglia by helping clearance of apoptotic cells and restoration of homeostasis. The TAM family is composed of three recep-

tors, Tyro3, Axl and MerTK (Lemke and Rothlin 2008). TAM system mediates homeostatic phagocytosis of apoptotic cells and membranes in adult tissues, facilitate also the infection of target cells by virus and contribute to some extent to progression and metastasis of cancer (Lemke and Rothlin 2008). The principal TAM receptors are Axl and MerTK. Activation of MerTK or Axl modulate the activation of the immune system.

13.11 Biomarkers

Because of mesodermal origin, microglia share many features with other myeloid cell populations. Immunohistochemical studies showed microglial expression of macrophage markers, including F4/80, Fc receptor, and CD11b, in mouse (Perry et al. 1985) and, later, in human (Akiyama and McGeer 1990).

As the tissue-resident macrophage of the CNS, murine microglia have since been confirmed to express multiple macrophage markers, including the colony-stimulating factor (CSF)-1 receptor (CSF-1R, CD115), the integrin CD11b, the surface glycoproteins F4/80, the inhibitory immune receptor CD200R, the surface enzyme tyrosine-protein phosphatase nonreceptor-type substrate or CD172 α , the fractalkine receptor CX3CR1, and the calcium-binding protein Iba-1. Microglia also express lower levels of the panhematopoietic marker CD45 compared with tissue macrophages, which also permits their discrimination from monocytes in the bloodstream, whereas the hemoglobin scavenger receptor CD163 enables distinction from perivascular macrophages in the steady state (Dijkstra et al. 1985; Serrats et al. 2010). CD169/Siglec-1 is a marker for mature dendritic cells/macrophages (Davies et al. 2013). It has recently been proposed as a marker for invaded monocyte-derived cells in the CNS, as it has been shown not to be expressed in resident CNS microglia (Butovsky et al. 2012; Gao et al. 2015; Zondler et al. 2016).

Two first microglia-specific antibodies have been generated using adult microglia as “cell-live vaccine”. Rats were vaccinated with CD45^{Low}/CD11b⁺ adult mouse microglia to generate mouse anti-rat antibodies against surface microglial molecules. Two microglia-specific mAbs were identified CD39 (ectonucleoside triphosphate diphosphohydrolase) and 4D4 mAbs which distinguish non-overlapping populations of peripheral inflammatory monocytes and resident microglia in mice (Butovsky et al. 2012). Based on the identification of a unique transcriptomic signature microglia including surface molecules (Butovsky et al. 2014; Chiu et al. 2013; Gautier et al. 2012; Hickman et al. 2013), additional microglia-specific antibodies have been developed including FCRLS (Fc receptor-like S, scavenger receptor) (Butovsky et al. 2014), P2ry12 (Purinergic Receptor P2Y, G-Protein Coupled, 12) (Butovsky et al. 2014; Haynes et al.

2006) and Tmem119 (transmembrane protein 119) (Satoh et al. 2016; Bennett et al. 2016).

13.12 Molecular Targeting

13.12.1 Genetic Manipulation

Genetic manipulation of microglia *in vivo* has led to valuable insights about the origin of microglia and their behavior under steady-state conditions and diseases (for review, see (Wieghofer et al. 2015; Wieghofer and Prinz 2016)). The fractalkine receptor CX3CR1 is highly expressed on microglia but also other macrophages, monocytes and dendritic cells (Jung et al. 2000). The Cx3cr1⁺/GFP mouse line therefore strongly labels microglia and is the best-studied model in microglia research. Constitutive Cre deleter strains are more efficient and lead to a high “accumulative” degree of recombination in the population of interest. Nevertheless, the lack of temporal control of the recombination events is a disadvantage of these lines. Here, the tamoxifen-inducible Cre-ER-T2/Mer-Cre-Mer system comes into play. This system allows the induction of recombination within a short time window by pulsing with tamoxifen. Two tamoxifen-inducible knockin Cx3cr1*CreER* mouse models were established to target microglia specifically (Goldmann et al. 2013; Parkhurst et al. 2013; Yona et al. 2013)). Both lines have in common that only long-lived cell populations are stably labeled, whereas short-lived cells, like monocytes, underlie a turnover and are continuously replenished by hematopoietic stem cells in the bone marrow (for review, see (Wieghofer et al. 2015; Wieghofer and Prinz 2016)). Parkhurst et al. and Bruttger et al. used this model as a tool to deplete microglia by crossing them to the Rosa26-fl-stop-fl-DTR (R26-iDTR) transgenic line to induce the expression of the primate diphtheria toxin receptor (DTR) upon Cre-mediated recombination (Bruttger et al. 2015; Buch et al. 2005; Parkhurst et al. 2013). The DT can cross the blood–brain barrier (BBB) and leads to an arrest of translation after receptor-mediated entering of the cell by blocking the phosphorylation of the elongation factor 2 (EF-2) (Wieghofer et al. 2015). After the administration of DT, specifically microglia are virtually absent after 1 day and only slowly recovered in a time-dependent manner over the course of 1 week while CX3CR1⁺ cells in blood and spleen remained unaffected (Bruttger et al. 2015).

13.12.2 Therapeutic Approaches

Microglia, since it plays so much of a key and critical role in neuroinflammation and thereby neurodegeneration progression has been the reason why they have been put in focus as inter-

vention targets in disease treatment. A corollary of neuroinflammation proposes that suppression of microglial production of neurotoxic mediators will result in neuroprotection. Although several drugs alleviate symptoms of neurodegenerative diseases, chronic use of these drugs is often associated with debilitating side effects, and none seems to dampen the progression of these diseases. So far, the development of effective neuroprotective therapies is impeded by our limited knowledge of the pathogenesis of neurodegenerative diseases. Since several studies have demonstrated that the inhibition of microglial activation control the pathogenesis, thus the activation of counter regulatory mechanisms is essential to avoid the escalation of CNS inflammatory processes (McCarty 2006). This may be possible through the identification of agents that target over activated microglial cells and the determination of their anti-inflammatory mechanisms. This may help development of better therapeutic strategies for neurodegenerative diseases.

Some of the well-studied inhibitors of inflammation are glucocorticoids, minocyclines, vitamin E, D, endocannabinoids, transforming growth factor beta1 and several synthetic drugs (Dheen et al. 2007). Though several anti-inflammatory drugs have been shown to diminish neuroinflammation, a very few have direct functional effects on microglial activity (Lleo et al. 2007).

Non steroidal anti-inflammatory drugs (NSAIDS) which include ibuprofen, naproxen and many other generic drugs, have been identified with a tendency to irritate the stomach, with the possibility of more serious complications such as an ulcer, stomach bleeding, colon or small bowel irritation over long term usage (Silverstein et al. 2000). Though synthetic cyclooxygenase 2 (COX-2) selective NSAIDs were brought into the market as alternatives highlighting its association with less gastrointestinal toxicity than nonselective NSAIDs, recent studies have shown that they cause more serious adverse effects like cardiovascular events and other life threatening side effects (Mukherjee et al. 2001). Therefore, there is an urgent need to develop drugs that have wide spectrum anti-inflammatory effects and which are able to slow down or curtail the progression of the degenerative process without causing any debilitating side effects.

13.13 Pharmacological Targeting

Recent evidence supports that CSF1R inhibitors could cause the depletion of the microglia. Thus, injection of a blocking antibody against Csf1r on activated microglia induced a strong reduction of proliferating cells during prion infection and AD (Gomez-Nicola et al. 2013). Moreover, treatment with the CSF1R/c-kit inhibitor PLX3397 decreased brain microglia by 99% after 21 days (Elmore et al. 2014b). Inhibition of the CSF1R at lower levels in 3xTg-AD mice

with a specific CSF1R inhibitor (PLX5622) prevented microglial association with plaques and improved cognition (Dagher et al. 2015). Prolonged inhibition of CSF1R in APP/PS1 mice by an orally administration of tyrosine kinase inhibitor (GW2580) resulted in the blockade of microglial proliferation and the shifting of the microglial inflammatory profile to an anti-inflammatory phenotype (Olmos-Alonso et al. 2016). Pharmacological targeting of CSF1R in AD mice in both studies resulted in improved performance in memory and behavioral tasks and a prevention of synaptic degeneration, although these changes were not correlated with a change in the number of amyloid- β plaques (Olmos-Alonso et al. 2016). These studies support for the efficacy of CSF1R inhibitory strategies in the treatment of Alzheimer's disease-like pathology to reduce microglia numbers and reduce the potentially damaging components of neuroinflammation, thus underpinning the possible evaluation of CSF1R inhibitors in clinical trials for Alzheimer's disease.

13.14 Review Questions

- What is the origin of microglia?
 - Yolk sac erythromyeloid progenitors*
 - recruited myeloid cells
 - neural stem cells
 - hematopoietic stem cells
 - all of the above
 - None of the above
- Neuroinflammation is occurring in the brain in response to:
 - infection
 - neurodegenerative disease
 - neuronal lesion
 - acute injury
 - all of the above*
 - None of the above
- Microglia in homeostasis are:
 - quiescent
 - neurotoxic
 - neuroinflammatory
 - producing inflammatory cytokines
 - none of the above*
- Modulatory factor involved in induction of homeostatic microglia:
 - PU.1
 - TGF β 1*
 - IRF8
 - RUNX1
 - None of the above
- Microglia physiological functions are:
 - cytokine production
 - antigen presentation
 - brain surveillance

- (d) phagocytosis
 - (e) *all of the above*
 - (f) none of the above
6. Neuron-microglia communication is controlled by:
- (a) CX3CL1
 - (b) CX3CR1
 - (c) SDF-1
 - (d) *all of the above*
 - (e) none of the above
7. Unique microglial biomarkers are:
- (a) CD11b
 - (b) Iba1
 - (c) CX3CR1
 - (d) F4/80
 - (e) P2ry12
 - (f) Tmem119
 - (g) a and b
 - (h) c, e and f
 - (i) *e and f*
8. Targets to pharmacologically deplete microglia:
- (a) Iba1
 - (b) *Csf1r*
 - (c) Cox2
 - (d) CX3CR1
 - (e) None of the above
9. Describe the available animal models to target microglia. What are the limitations of the animal models?
10. Describe the common characteristic of microglia in development and aging.

13.15 Answers

9. There are several mouse models to target microglia have been developed. The most popular are *Cx3cr1Cre* and *Cx3cr1CreER* mice crossed to *Rosa26-fl-stop-fl-DTR* or floxed-genes of interest will serve a model to specifically and conditionally ablate microglia or delete genes in microglia. Limitations: *Cx3Cr1* is a broad myeloid receptor, thus the ablation system is not specific to parenchymal CNS microglia. Therefore, treatment of *Cx3cr1CreER* mice with tamoxifen for 5 days will induce Cre expression in all peripheral myeloid cells and microglia. Due to low rate of microglia proliferation, within 30 days, microglia will continue to express Cre-recombinase, but peripheral myeloid cells will be repopulated with new bone-marrow derived myeloid cells and will not express the Cre-recombinase.
10. Based on morphological and molecular aspects, microglia during development and aging show common amoeboid and inflammatory profile. In addition, the molecular homeostatic signature is not present embryonic microglia and suppressed during aging.

Larisa Y. Poluektova

Abstract

This chapter describes lymphocyte maturation and differentiation. Interactions of lymphoid tissues with the central and peripheral nervous systems play a fundamental role in health and disease. Recent advances in xenobiology has opened new approaches to study relationships between peripheral immunity and nervous system development, homeostasis, response to injuries, and disease in animal models. Humanized animal models help to study the complexity of human immune system development and adaptive immune responses. Humanization of a mouse brain with human glial cells provides an additional tool to study hemato-lymphoid brain interactions in small animals.

Keywords

Antibodies • B cells • Effector memory T cells • Follicular dendritic cells (FDCs) • Immune privileged • Regulatory T cells • Stat4 • Stat6 • T-Bet

14.1 Introduction

For many years, the immune system was studied separate from the nervous system and vice versa. This is for several reasons. *First*, under normal physiological conditions peripheral lymphocytes are not found in perivascular compartments and not within the central nervous system (CNS) parenchyma. This supported the notion that the brain was “immune privileged.” However, the presence of infiltrating immune cells, including lymphocytes, in the CNS is present in most neurodegenerative diseases. *Second*, there is no question about ongoing adaptive immune activities

during CNS infections and autoimmune disorders. *Third*, the functional links between the CNS and lymphoid organs are operative in development, cell to cell interactions, signaling, and modeling. Despite the complete segregation and privileged status of the mammalian CNS, immune-neural interactions have shown common developmental paths and share cell types and regulatory molecules. Similarities between the nervous and immune systems show essential homeostatic and coordinated responses to danger. Both organs are able to establish direct and non-direct connections and carry information from and to distant parts of the body by use of a range of chemical signaling molecules. Both also communicate rapidly through chemical and cellular networks by utilizing shared and conserved second messengers and signaling pathways. They form synapses to facilitate information transmission and have threshold sensitivity of cellular receptors for ligands. Nervous and immune organs acquire memory with maturation, training, and exposure to new signals. *Finally*, studies of human immune system and nervous system development and function became possible in severely immunodeficient mice by transplantation of human hematopoietic and neural stem cells, named humanized animal models.

14.2 Overview of Embryonic Hematopoiesis, Lymphopoiesis and Nervous System Development

Today, the common concept of lymphoid tissue ontogeny relies upon the concept of circulating stem/progenitor cell populations, which migrate from the yolk sack into the aortogonad mesonephros (AGM), then into organ anlagen, initiating hematopoiesis in fetal liver and bone marrow, and lymphopoiesis in thymus [reviewed in (Baron et al. 2012; Jagannathan-Bogdan and Zon 2013; Prinz and Priller 2014; Rodgers and Dizerega 2013)]. Neural crest cells (NCC) are one of the earlier developmental “bridges” between the blood and brain. During early embryonic development, primitive hematopoiesis (erythropoiesis and macrophages) begins in the yolk sac; and the first neuroepithelial and neural crest cells from neural tube provide support by secretion of erythropoietin (Suzuki et al. 2013). NCC are a pluripotent population of cells that migrate from the dorsal neuroepithelium and give rise to multiple cell types including most of the peripheral nervous system (PNS) (neurons of the sensory, sympathetic, parasympathetic and enteric ganglia as well as ganglionic satellite glial cells and Schwann cells lining peripheral nerves), pigment cells and craniofacial bone and cartilage (Takahashi et al. 2013; Theveneau and Mayor 2012).

Similarities between the nervous and immune system development regulation are made accordingly. For example, a regulatory circuit made up of transcriptional factors *Gata2*, *Fli1*, and *Scl/Tal1* and their enhancers, *Gata2-3*, *Fli1+12*, and *Scl+19*, operates during specification of hematopoiesis (Pimanda et al. 2007), as well as *SCL* and *Gata2* are common with midbrain and DA system development (Herberth et al. 2005). Ephrin-B2 is a protein that in humans is encoded by the *EFNB2* gene, a member of the ephrin (EPH) family. The ephrins and EPH-related receptors comprise the largest subfamily of receptor protein-tyrosine kinases and have been implicated in mediating developmental events, especially in the nervous system and in erythropoiesis (Carmeliet and Tessier-Lavigne 2005). During maturation and differentiation of cells and organ structures, some such regulatory genes participate in the regulation of molecules and pathways involved in systemic crosstalk between systems.

14.2.1 T Cells

The thymus is a primary lymphoid organ that is involved in the development of the T cells, which are effectors of adaptive immune responses. The human thymus develops at ~embryonic day 35 from the endoderm with subsequent epithelial–mesenchymal interaction. In regards to the ontogeny of the immune system, most of what is known was derived from rodent studies. Thymic epithelium and surrounding mesenchyme, which derived from the cephalic region of the neural

crest, play an important role in T cell development. At the embryonic stage, lymphomyeloid commitment precedes thymic development in $CD45^+CD117^+CD34^+$ hematopoietic clusters of AGM region. In addition, multilineage progenitors restricted to T, NK (natural killer) and macrophage lineage (pTM) or just T lineage (pT), or B and B plus macrophage (pBM) were identified in the AGM region. At the time of entry into the thymic epithelium, immigrant cells express $CD45^+$, $CD117^+$, $CD44^+$, $CD34^+$, and $\alpha 4$ integrin; but they are negative for $CD62L$, $CD25$, and $Thy-1.2$ in mice. One of the important cytokines that regulates survival of human lymphoid progenitors is interleukin (IL)-7. Before exposure to epithelial inductive influence by thymus epithelial stromal cells (TEC), lymphomyeloid progenitors are IL-7 receptor alpha chain positive ($IL-7R\alpha^+$). Upon differentiation to functionally mature lymphocytes ($CD4$ and $CD8$), $IL-7R\alpha$ appears to be downregulated, and cells lose thymic homing capacity. In knockout models of mice, deletion of *IL-7* gene or related receptors abrogate development of lymphocytes and lymphoid organs (Tsapogas et al. 2011; Liang et al. 2012; Ribeiro et al. 2013). The transmembrane receptor Notch is essential during early T lineage development. In the absence of Notch1-mediated signals, T cell development is arrested at an early stage; and B cells accumulate intrathymically.

14.2.2 B Cells

The precise site of human B cell commitment in ontogenesis is not yet known. The B cell precursors derive from the intraembryonic para-aortic region. B cell commitment might take place in the omentum and fetal liver. These progenitors express $CD117^+AA4.1^+CD34^+CD45^+CD19^+Sca-1^-$. The fetal liver has long been considered the initial site of B cell commitment, and from then on B progenitors expand in a synchronous wave-like pattern reaching a peak in the perinatal stage. Even after birth, B cells may develop at sites other than the bone marrow. The myeloid suppressing transcription factor Pax-5 plays a critical role in B cell commitment, while the chemokine receptor CXCR4 and its ligand SDF-1 α play a pivotal role in B cell development of the fetal liver. Another hypothesis based on mouse development suggests that interleukin-7 receptor- α ($IL-7R\alpha$)-expressing progenitors from mouse fetal liver promotes their development into B cells as well as pre-lymphoid tissue inducers compartment (van de Pavert and Mebius 2010).

14.2.3 Cells Derived from Hematopoietic Precursors are Involved in Immune Responses in the Brain

Brain tissue contains only one type of specialized resident cell of mononuclear phagocyte lineage, which is known as microglia. Several waves of population in the brain by cells of

macrophage lineage have been proposed: primitive macrophages from yolk sac with high proliferation capacity, myeloid precursors from fetal liver with ability to proliferate, and bone marrow derived non-dividing (or very limited division) precursors in adult. Two types of brain macrophage residents exist (microglia and perivascular macrophages) with non-selective but differently expressed human markers. All are CD45^{lo}CD11c⁺CD11b⁺(Mac-1^{+/−})CD64^{+/−}CD68^{+/−}RCA-1^{+/−}MHC-classII^{+/−}Ham56⁺ and belong directly to immune system as effectors of innate immunity. They are major participants in the establishment of adaptive immune reaction and immune privilege in situ in the parenchyma and the meninges. The nature of microglia and other brain residents from monocyte lineage were well explored in mice (Ginhoux et al. 2010; Perdiguero et al. 2014). These cells originate from yolk-sac-derived erythro-myeloid; and the turnover and replacement with bone-marrow derived monocytes/tissue macrophages is extremely limited.

14.3 Postnatal Development of Lymphocytes

14.3.1 Hematopoietic Stem Cells and Lymphoid Cell Lineages

The generation of lymphocytes from adult hematopoietic stem cells (HSCs) is different from the embryonic development. HSCs are defined by their unique capacity to self-renew as well as their multilineage differentiation into all blood cell lineages. Therefore, they are crucial for reconstitution of hematopoiesis on transplantation into recipients with bone marrow (BM) ablation. Although representing approximately only 0.05–0.1 % of total BM cells, virtually all HSC activity has been shown to be contained within the lineage negative or low (Lin^{−/lo}) Sca1⁺c-Kit(CD117)^{lo/hi} (LSK) CD34^{−/lo} HSC compartment. The LSK HSC pool can be further subdivided for short-term repopulating cells using additional markers. As HSCs acquire high levels of CD34 expression, CD27 and another tyrosine kinase type receptor, Flk-2/Flt3, lose long-term repopulating activity.

It is as yet unanswered whether T, B, NK and DCs (dendritic cells) develop from common lymphoid progenitors (CLPs), or whether they are derived from either lymphoid-restricted stem cells or multipotent progenitors. However, at least in the adult murine bone marrow, a population of Lin[−]IL-7R⁺Thy-1[−]Sca-1^{lo}CD117^{lo} cells has been shown to contain CLPs on the basis of their capacity to develop into lymphoid cells, while being unable to support myeloid differentiation. It is possible that between common myeloid precursors (CMP) and granulocyte monocyte precursors (GMP) exist the population of progenitors for monocytes and dendritic cells (MDP), which is positive for CX₃CR1 (fractalkine receptor) (Fogg et al. 2006). The progenitor cell

choice of the T-cell fate is dependent on environmental signals. Identification and characterization of thymus seeding progenitors (TSPs) has been challenging, owing to the rarity of these cells in the BM or blood at any given time; thus, their lineage potential and level of commitment are still largely debated. Potential candidates of TSPs include: lineage marker negative (Lin[−]) Sca-1⁺ cKit/CD117⁺ (LSK) cells; LSK Flt3⁺ multipotent progenitors (MPP) and further subdivided based on the expression of CCR9 and VCAM-1; LSK Flt3^{hi} Rag-1⁺ early lymphoid progenitors (ELP) or lymphoid-primed multipotent progenitors (LMPP); Lin[−] Sca-1^{lo} cKit^{−/lo} Flt3^{hi} IL-7Rα⁺ common lymphoid progenitors (CLP) or their progeny Lin[−] cKit^{−/lo} B220⁺ IL-7Rα⁺ preTα⁺ CLP-2; and, Lin[−] cKit^{lo} CD90⁺ CLP-2-like circulating T-cell progenitors (CTP). However, the identity of the cells that first enter the thymus is generally accepted to be a Lin[−] cKit⁺ Flt3⁺ CD24^{−/lo} PSGL1⁺ CCR9⁺, commonly referred to as the early thymic progenitor (ETP) (Thompson and Zuniga-Pflucker 2011). The generation of B-lymphocytes from HSCs is controlled by two cytokine receptors (Flk2/Flt3 and IL-7R) and six transcription factors (PU.1, Ikaros, E2A, Bcl11a, EBF, and Pax-5). Ikaros and PU.1 act in parallel pathways to control the development of lymphoid progenitors in part by regulating the expression of essential signaling receptors Flt3, CD117, and IL-7Rα. The generation of the earliest B cell progenitors depends on transcriptional factors E2A and EBF that coordinately activate the B cell gene expression program and immunoglobulin heavy-chain gene rearrangements at the onset of B-lymphopoiesis. Pax5 restricts the developmental options of lymphoid progenitors to the B cell lineage by repressing the transcription of lineage-inappropriate genes and by simultaneously activating the expression of B-lymphoid signaling molecules. Two other transcriptional factors LEF1 and Sox4 contribute to the survival and proliferation of pro-B cells in response to extracellular signals. Finally, IRF4 and IRF8 control the termination of pre-B cell receptor signaling, and thus, promote differentiation to small pre-B cells undergoing light-chain gene rearrangements (Singh et al. 2005). Productive variable-region and joining-region rearrangements (VLJL rearrangements) of the immunoglobulin light chain are completed in pre-B cells; expression of the B-cell receptor (BCR) drives pre-B cells to the immature B-cell stage. Newly formed B cells are exported to peripheral lymphoid tissues as functionally immature or transitional intermediates cells.

14.3.2 T Cell, TCR, MHC and CD4–CD8 Development

Intrathymic development of T cells is based on three major sets of genes: promiscuous tissue-specific antigen (TSA) expression on thymic epithelial cells (TEC); MHC class I and II molecules expression on antigen-presenting cells

(APC), such as cortical TEC, medullary TEC, thymic dendritic cells (DCs), and macrophages; and T cell receptor (TCR) molecules.

14.3.2.1 The Thymic Epithelial Cells

The nature of TEC precursors and pathways of maturation is still in debate. The most accepted concept today is the presence of self-renewing precursors of endoderm origin [reviewed in (Anderson et al. 2014)]. These cells undergo a maturation pathway from a cortical TEC (cTEC) without expression of a transcriptional regulator known as an autoimmune regulator (AIRE), to an immature medullary TEC (mTEC) with low levels of AIRE expression, then to mature mTEC AIRE-positive, and finally to Hassall's corpuscles. Expression of TSA is a physiological property of TECs, representing all parenchymal organs, and including up to 5–10 % of all currently known genes, including fetal stage-, tumor- and sex-associated. TSA expression increases with TEC maturation. Brain-, intestine- and liver-related TSA have the highest presentation on mTEC. TECs do not form a static scaffold, but similar to stratified epithelia of the skin and gut have a steady state turnover with a half-life of 3–4 weeks. Together with a turnover rate of 2 weeks for thymic DCs, this makes the APC population in the medulla a highly dynamic compartment (Derbinski and Kyewski 2005; Perniola 2012; Sun et al. 2013).

Interaction with TEC is the major step in T cell education in the thymus and in establishment of self tolerance. The cross-talk between derived early T lineage progenitors (ETPs) with MHC II-positive cTEC give rise to CD4⁺CD8[−] double negative (DN) thymocytes. These cells undergo proliferative expansion and lose B- and NK potential. After that, T cell lineage commitment and the onset of TCR β -chain rearrangement occurs. Then positive selection takes place through interaction of now CD4⁺CD8⁺ double positive cells with cTEC bearing MHC I and II. Then cross-talk between mTEC and DCs expressing TSA and circulating antigens leads to deletion (or induction of anergy) of self-reacting T cells, known as negative selection. These events take place in the corticomedullary junction and medulla; then already single positive CD4 or CD8 cells leave the thymus (Bommhardt et al. 2004; Yui and Rothenberg 2014; Shah and Zuniga-Pflucker 2014).

14.3.2.2 T Cells Receptor and CD4/CD8 Commitment

Signaling through the T cell receptor (TCR) controls key events in the life of T cells: their development in the thymus from common lymphoid progenitors, the survival of naïve T cells following their exit from the thymus, and the differentiation of these cells into effector populations with discrete functional profiles. Mature T cells express either as $\alpha\beta$ - or $\gamma\delta$ - TCRs, which recognize antigens. These receptors are generated by a rearrangement of gene segments that result in

the formation of genes encoding the α -, β -, γ - and δ -chains of the receptors. The choice of $\gamma\delta$ vs. $\alpha\beta$ chains of TCR expression happens at the stage of pre-TCR by selection of cells with productive TCR β rearrangements irrespective of the V β gene segment used. Rearrangement of TCR generates receptors with different affinity and avidity to an unlimited amount of peptides (derived from self and non-self proteins) in the context of MHC molecules expressed on thymic APC/TEC. Thymocyte fate and selection are related to a degree of TCR downregulation and internalization after TCR/peptide/MHC engagement. Maximal TCR downregulation is correlated with negative selection (highest avidity, agonists), and suboptimal TCR down-regulation mediated positive selection (lowest avidity, antagonists). Intermediate stages in development of early thymocytes from triple negative (CD3[−]CD4[−]CD8[−]) into triple positive (CD3⁺CD4⁺CD8⁺) Selection undergoing, in context of MHC class II antigens generates CD4⁺ cells. The Lck protein tyrosine kinase activity upon “strong” TCR signaling favors development of CD4⁺ cells; whereas, “weak” TCR signaling and reduction of Lck activity favors development of CD8⁺ cells. TEC and thymic hematopoietic DCs are able to induce the proliferation and differentiation of CD4⁺CD8[−]CD25[−]T cells into CD4⁺CD25⁺FOXP3⁺ (forkhead box P3) regulatory T cells (Treg). This induction depends on peptide/MHC class II interactions, and the presence of IL-2. Singer et al. summarized the existing models of CD4/CD8 lineage choice (Singer et al. 2008). These mature, but naïve T cells exit peripheral blood and seed lymphoid organs in T-cell specific zones, in order to be acquired by adaptive immune responses for elimination of infected or tumor cells, support for humoral immune responses, formation of immunologic memory, prevention of excessive tissue damage, and facilitation of tissue regeneration.

14.3.2.3 T Cells and Brain

The long living neurons and synapses that provide long-term memory have to be strongly protected from damage by inflammatory/autoreactive CD4⁺ and cytolytic/cytotoxic CD8⁺ T cells. Brain parenchyma does not provide the support for the migration or survival of T cells. The highly specialized nature of the endothelial cell lining, with the cerebral vasculature and tight junctions, forms a physical and functional barrier to lymphocytes. For a short period of time, T cells can be found in perivascular spaces and make parenchymal foci as an inflammatory reaction to acute viral or bacterial infection. However, such physiologic responses in the brain parenchyma are quickly terminated by the down-regulation of MHC class I and II co-stimulatory molecular expression on glial cells (immunosuppressive function of IL-10, TGF- β and prostaglandins), by apoptosis of T cells through Fas-Fas ligand (CD95/CD95L) interaction. Activation of brain microglial cells, DCs, and macrophages

may also be stopped by factors directly produced by neurons, such as CD200 molecules. This protein from the Ig superfamily plays an important role in the downregulation of myeloid cell function, which expresses a receptor to this ligand. Persistence of T cells in the brain is a rare event and is associated with chronic pathology as a tertiary lymphoid structure, with support and activation signals coming from DCs and macrophages.

14.3.3 B Cells

14.3.3.1 Development in Bone Marrow

In adults, B cells are generated from B-lineage committed precursors in the BM. Newly formed B cells express antigen-specific surface antibody (sIgM+ and sIgD+). In the BM, B cells are subjected to multiple selective pressures that purge autoreactive B cells and guide differentiation of the remaining cells into functionally distinct peripheral B cell compartments. The naïve B cells then enter the circulation and migrate to the spleen and lymph nodes. The generation of B-lymphocytes from hematopoietic stem cells (HSCs) is controlled by two cytokine receptors (Flk2/Flt3 and IL-7R) and six transcription factors (PU.1, Ikaros, E2A, Bcl11a, EBF, and Pax-5). Ikaros and PU.1 act in parallel pathways to control the development of lymphoid progenitors in part by regulating the expression of essential signaling receptors Flt3, CD117, and IL-7R α . The generation of the earliest B cell progenitors depends on transcriptional factors E2A and EBF, which coordinately activate the B cell gene expression program and immunoglobulin heavy-chain gene rearrangements at the onset of B-lymphopoiesis. Pax5 restricts the developmental options of lymphoid progenitors to the B cell lineage by repressing the transcription of lineage-inappropriate genes and by simultaneously activating the expression of B-lymphoid signaling molecules. Two other transcriptional factors LEF1 and Sox4 contribute to the survival and proliferation of pro-B cells in response to extracellular signals. Finally, IRF4 and IRF8 together control the termination of pre-B cell receptor signaling, and thus, promote differentiation to small pre-B cells undergoing light-chain gene rearrangements. Productive variable-region and joining-region rearrangements (VLJL rearrangements) of the immunoglobulin light chain are completed in pre-B cells, and expression of the B-cell receptor (BCR) drives pre-B cells to the immature B-cell stage. Newly formed B cells are exported to peripheral lymphoid tissues as functionally immature or transitional intermediates cells (Clark et al. 2014).

14.3.3.2 Distribution of B Cells and Function

Selection from newly formed B cells into transitional, follicular and marginal-zone (MZ) B cells depends on integrated signals from several classes of surface receptors,

such as: the BCR and co-signals, the tumor-necrosis factor receptor (TNFR) family, and the G-protein-coupled receptors (GPCRs). Follicular and MZ long-lived compartments participate differentially in B-cell effector functions such as the germinal-centre (GC) reaction, long-term memory, antigen presentation, and antibody and plasma-cell (PC) generation. Different strengths of BCR signaling are required for the development of the three mature B-cell subsets: peritoneal B cells require the strongest BCR signal, follicular B cells require an intermediate BCR signal, and marginal-zone B cells require a weaker BCR signal. During B lymphocyte development, antibodies are assembled by random gene segment re-assortment to produce a vast number of specificities. A potential disadvantage of this process is that some of the antibodies produced are self-reactive; and in humans, the majority (55–75 %) of all antibodies expressed by early immature B cells displayed self-reactivity, including polyclonal and anti-nuclear specificities. Most autoantibodies are removed from the population at discrete checkpoints during B cell development. Inefficient checkpoint regulation would lead to substantial increases in circulating auto-antibodies. So, an important role of the BCR at the immature B-cell stage is to induce efficient elimination of these potentially harmful cells. This can be achieved in three ways: immature B cells are eliminated through negative selection (BCR-induced cell death), they are inactivated (anergy), or they revise the specificity of their BCRs (receptor editing). Finally, secretion of IgM, IgG1, and IgG2c represents Th1-dependent immune responses; IgG2 and IgE represents Th2-dependent; while IgG3 represents T cell independent immune responses (Hua and Hou 2013).

14.3.3.3 Brain and B Cells

In contrast to T cells, in different immunopathologies, the brain provides a fostering environment to B cells. Primary central nervous system (CNS) lymphomas are usually of B cell origin. The cerebrospinal fluid (CSF) of patients with chronic infectious and autoimmune diseases of the CNS typically contains remarkably stable oligoclonal Ig bands. In the CNS of multiple sclerosis patients, clonally expanded B cells and plasma cells persist, while ectopic B cell follicles develop in the meninges of patients with secondary progressive multiple sclerosis (MS), and B cell differentiation may be recapitulated in the CNS of MS patients (Krumbholz et al. 2006).

14.3.4 Natural Killer and Other Innate Lymphoid Cells

Human NK cells comprise ~15 % of all lymphocytes and are defined phenotypically by their expression of CD56 and lack of CD3 expression. Two distinct populations of human NK

cells could be identified based upon their cell-surface density of CD56. The majority (~90 %) of human NK cells has low-density expression of CD56 (CD56^{dim}) and express high levels of Fcγ receptor III (FcγRIII, CD16); whereas, ~10 % of NK cells are CD56^{bright}CD16^{dim} or CD56^{bright}CD16⁻. Over the past decade a number of phenotypic and functional properties of human NK cells have been characterized. There is now good evidence to suggest that distinct immunoregulatory roles can be assigned to the CD56^{bright} and CD56^{dim} NK-cell subsets. Peripheral NK cells are expressing in addition to CD16 and CD56, CD161 (NKR-P1A). The low-affinity FcγRIII on the surface of NK cells binds to Ab-coated (opsonized) targets and signals through associated subunits containing an immunoreceptor tyrosine-based activation motif (ITAM) to direct antibody-dependent cellular cytotoxicity (ADCC). Of significance, the CD56^{bright} NK-cell subset expresses the high-affinity IL-2R constitutively and can produce interferon gamma (IFN-γ) in response to picomolar concentrations of IL-2. Because IL-2 is produced only by T cells and not NK cells, the expression of high-affinity IL-2Rαβγ on CD56^{bright} NK cells is necessary to promote cytokine cross-talk between NK cells and T cells in secondary lymphoid organs. NK cells constitutively express several receptors for monocyte-derived cytokines (monokines), including IL-1, IL-10, IL-12, IL-15, and IL-18, and most likely receive some of their earliest activation signals from monocytes during the innate immune response. Conventional NK cells now could be classified as population of innate lymphoid cells (ILCs), which belong to group 1 with two other populations that not carry described above receptors but produce IFN-γ. Group 2 ILCs secrete IL-5 and IL-13 following stimulation by IL-25 or IL-33 ("alarmin") released by damaged epithelial cells or activated myeloid cells. Group 3 ILCs include lymphoid tissue inducer (LTi) cells, natural cytotoxicity receptor (NCR)+ and NCR- retinoic acid-related orphan receptor (ROR)γt+ subsets that produce cytokines IL-17A and/or IL-22. Functionally, the ILC family can be considered as "innate" equivalents of T effector cells (cytotoxic CD8 T cells and differentiated CD4 Th subsets), as they secrete a similar array of cytokines and activate an analogous set of target cells (Xu and Di Santo 2013).

14.4 Organization of the Secondary Lymphoid Tissues

14.4.1 Embryonic Development of Lymphoid Tissues

Development of the lymphatic system begins with the invagination of endothelial cells from veins and the formation of lymphoid sacs (Fig. 14.1). At the location of the lymph sacs, connective tissue protrudes into these lymph sacs, forming

the very first anlagen of the lymph nodes. At this moment, differentiation of mesenchymal cells into specialized cells, known as lymphoid organizer cells, which can initiate the formation of lymph nodes, is expected. The platelet-derived growth factor (PDGF), fibroblast growth factor, as well as TGF superfamily of growth factors, which are crucial for the differentiation of mesenchymal cells, are likely to be involved in the earliest phases of lymphoid organ formation. However, no molecules have been identified that direct the early specification of mesenchymal cells into specific lymph node organizer cells. The mesenchymal specification of lymph node organizer cells is expected to be independent from lymphotoxin beta receptor (LTβR) signaling. The stromal organizer cells mediate attraction and retention of hemopoietic cells (lymphoid tissue inducers, LTi), resulting in accumulation and clustering of cells (Lu and Browning 2014; Cupedo and Mebius 2005; Benezech et al. 2010).

For the generation of LTi cells, which are derived from IL-7R-expressing hematopoietic precursors, expression of retinoic-acid-receptor-related orphan receptor-γ (RORγ) by LTi cells is mandatory. LTi cells mediate triggering of the LTβR on stromal cells through expression of LTα1β2, which is induced by ligation of either the TNF-related activation-induced cytokine (TRANCE), which signals through TRANCE receptor (TRANCE) and/or IL-7R. Functional LTi cells need to express CXCR5 as well as CCR7 to respond to CXCL13, CCL19, and CCL21, chemokines involved in lymph node formation. To generate functional lymphoid tissue organizers, LTβR signaling leads to expression of mucosal addressin cell adhesion molecule (MAdCAM-1), intercellular adhesion molecule 1 (ICAM-1), and vascular cell-adhesion molecule 1 (VCAM-1) on these cells, as well as the production of the chemokines CXCL13, CCL19, and CCL21. The mesenchymal cells produce more chemokines, express adhesion molecules and establish the first positive-feedback loop for the recruitment of LTi cells.

Days before birth, lymphocytes and dendritic cells (DCs) are recruited to the lymph node and Peyer's-patch anlagen. Because T cells and B cells themselves express LT-α1β2, recruitment of lymphocytes is amplified by a second positive-feedback loop and culminates in the formation of a mature lymph node or Peyer's patch, consisting of segregated T-cell zones and B-cell follicles, high endothelial venules (HEVs) and additional specialized mesenchymal cells.

IL-7R signaling has been reported to be essential for the development of Peyer's patches, but this pathway is also involved in the generation of some lymph nodes. In the absence of a functional IL-2R common γ-chain (γc) and Janus kinase 3 (Jak3), which are both components of the IL-7R signaling pathway or in the absence of IL-7, no peripheral lymph nodes develop. Although lymphopenia has been suggested as an explanation for the inability to detect lymph nodes in IL-7R-deficient and γc-deficient mice, lymph nodes

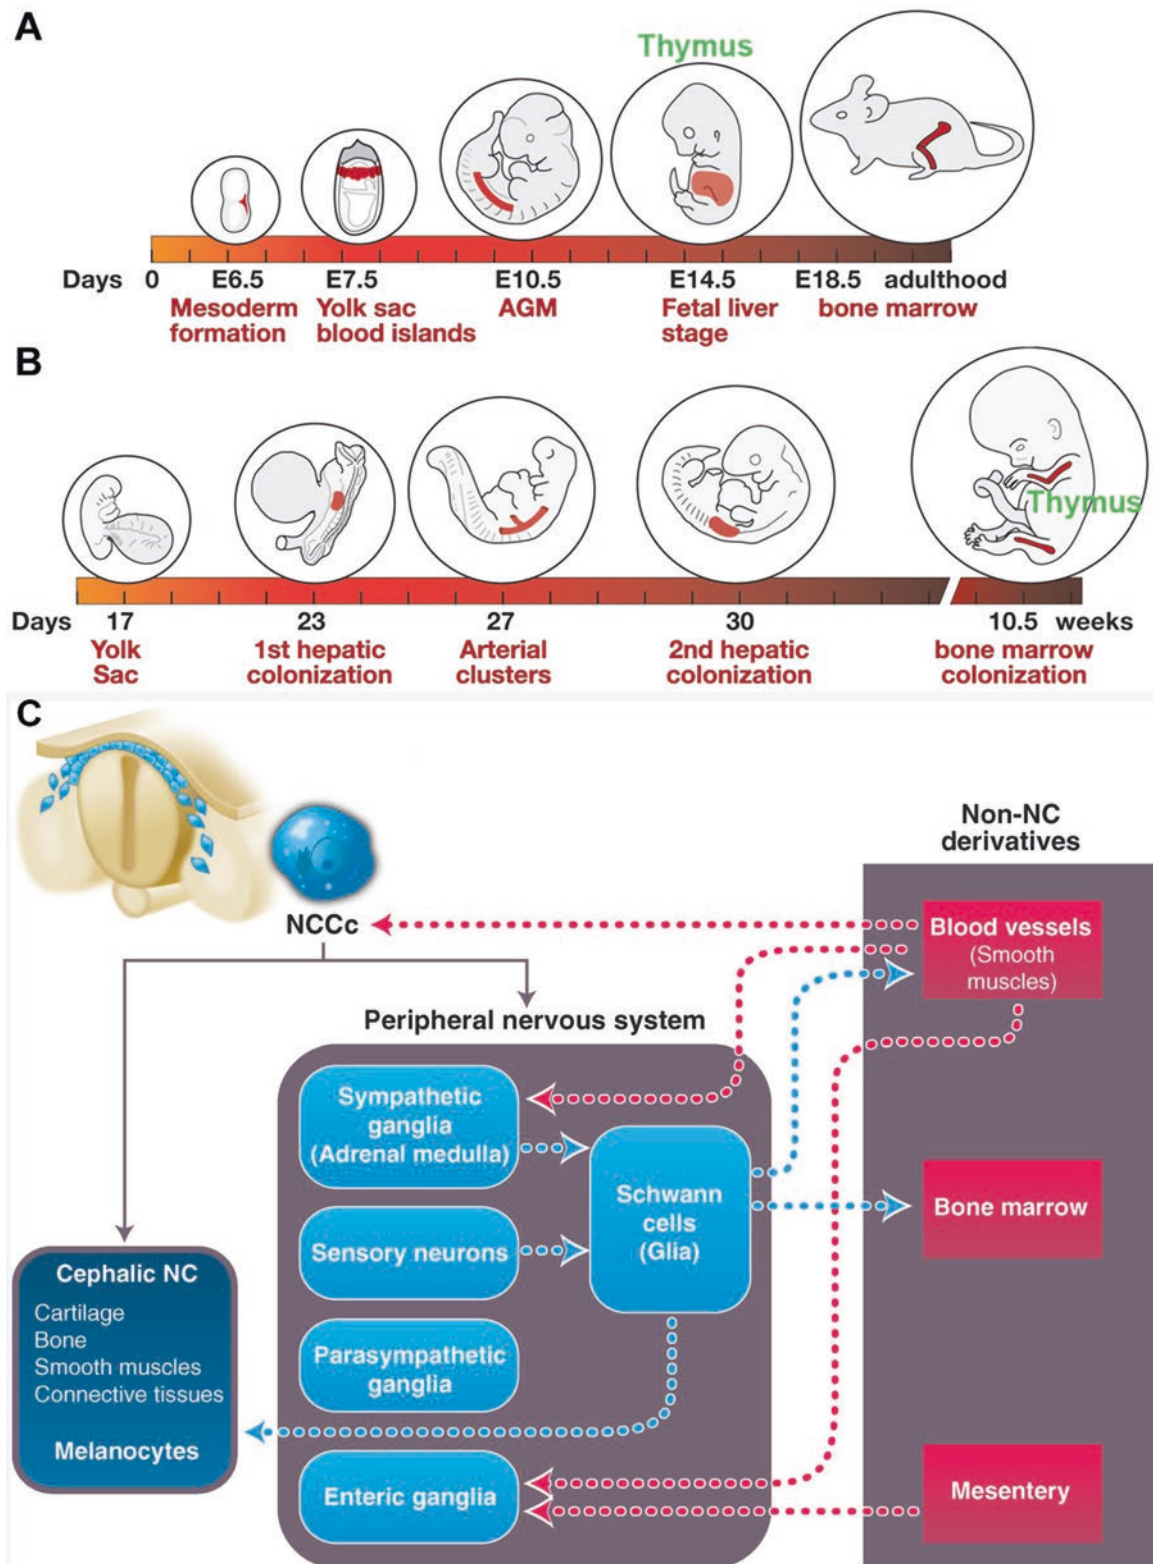

Fig. 14.1 Hematopoiesis during development and neural crest cells as a link to nervous system components. **(a)** Hematopoietic development in the mouse. Formation of mesoderm during gastrulation (around E6.5), development of yolk sac blood islands (~ E7.5), emergence of HSCs in the aorta-gonad-mesonephros region (E10.5; other sites such as large arteries and placenta not shown), active fetal liver hematopoiesis (E14.5), and hematopoiesis in the bone marrow of the late gestation fetus (E18.5) and adult animal. Active circulation begins at approximately E9.0. **(b)** Hematopoietic development in the human embryo. An embryo at yolk sac stage of hematopoiesis (day 17), at the time of the

first hepatic colonization by HSCs (day 23), arterial cluster formation (day 27), second hepatic colonization (day 30), and bone marrow colonization (10.5 weeks). Active circulation begins at approximately day 21. Used with permission and modified from Baron et al. (2012). **(c)** Schematics showing interactions between neural crest- and non-neural crest derivatives. Neural crest-derived cells are presented in blue and light blue boxes. Cell-cell interactions are shown by dotted arrows (light blue and red). Used with permission and modified from Takahashi et al. (2013)

can easily be found in severe combined immunodeficient (SCID), recombination-activating gene (Rag) 1 product and Rag2-deficient mice, which also lack mature lymphocytes.

Inducers CD45⁺CD4⁺CD3⁻ cells that form a precursor population can differentiate to antigen-presenting cells, as well as NK cells, but not to B or T cells. Detailed phenotyping of adult LT_i (or accessory) CD45⁺CD4⁺CD3⁻ cells has shown that they are similar to a CD4⁺ cell population (Brendolan and Caamano 2012).

14.4.2 Adult Lymphoid Tissues

14.4.2.1 Lymph Node Architecture

The lymph nodes have two components: the stroma with its fixed cells and the parenchyma with its migrating cell populations. In contrast to non-lymphoid parenchymal organs, the stromal network has an indispensable functional role. Fibroblastic reticular cells (FRCs) constitute the main stromal population and form its internal three-dimensional network. FRCs express surface molecules and produce ‘homing’ chemokines for T cells, B cells and DCs. They provide anatomical arrangements that influence the traffic patterns of lymphocytes, facilitates lymphocyte ‘crawling’ along preformed ‘corridors’. Moreover, FRCs typically wrap reticular fibers (mainly made up of type III and IV collagen, elastin, and laminin) to form a set of interconnected channels, called the FRC conduit system. This system allows for the efficient and rapid transfer of soluble molecules, such as antigens, chemokines, and immune complexes from the subcapsular sinus to the deeper cortex, the high endothelial venules (HEVs), and perhaps the follicular compartment. Lymph nodes can undergo rapid and profound hypertrophy during an immune response, and FRCs are deeply involved in matrix reorganization and the remodeling of lymph-node architecture.

The conduit system and sinuses are lined by sinus endothelial cells (SECs). These are flattened cells that do not form a continuous layer, especially in the wall of the medullary sinus, but contain intercellular gaps or pores. Gaps have also been demonstrated in the floor of the subcapsular sinus.

FRCs and SECs might be ontogenically related and serve to filtrate lymph fluid collected from all peripheral tissues, including brain interstitial tissue and cerebrospinal fluid. In the subcapsular sinus, macrophages and DCs sample the lymph and remove microorganisms and debris contained there. These cells also transport and/or process antigenic material for presentation to B and T cells. However, soluble lymph-borne material has restricted access to the lymphocyte compartment and the cortex.

Migrating naïve T and B cells (as well as monocytes, NK and DC) enter lymph node via high endothelial venules (HEVs), migrate through the net of dendritic cells and, if not acquired, exit via single (one) for each nodule efferent lymph

vessel back to circulation. The CCR7 chemokine receptor and two of its ligands CCL-19 and 21 have been attributed, but none of them are strongly confirmed to be expressed by human HEVs. Both ligands might be transported to the luminal surfaces of HEVs (Comerford et al. 2013; Pfeiffer et al. 2008). All secondary lymphoid tissues have some structural similarity and major component is a lymphoid follicle with germinal center (GC), follicular mantle and marginal zone (van de Pavert and Mebius 2010).

14.4.2.2 Antigen-Presenting Cells

The lymph node harbors a composite population of dendritic cells (DCs)—residents and emigrants—capable of selection, stimulation and elimination of effector lymphocytes, e.g. trigger adaptive immunity and/or tolerance. In the human lymph node T-cell compartment two primary subsets of DCs, compared to six in mice, have been identified: monocytoïd CD11b⁺CD11c⁺ and plasmacytoïd interferon-(IFN) α producing CD123⁺CD11b⁺CD11c⁻. The last subset clusters with T cells around HEVs. CD11c⁺ DCs are present as stellate cells whose delicate processes or ‘veils’ extend in many directions; these are called interdigitating DCs. In the B cell compartment, follicular DCs (FDCs) orchestrate B cell function. Whether FDCs originate from hematopoietic progenitors or from stromal elements is still a controversy. New evidence suggests the presence of two types of FDCs within human germinal centers: the classic FDCs that express CD21 and fibroblast-related markers represent stromal cells and the CD3⁻CD4⁻CD11c⁻ germinal center dendritic cells (GCDC), which represent hematopoietic cells that may be analogous to the antigen-transporting cells described in mice. Under specific conditions in vitro, human monocytes can downregulate expression of the hematopoietic marker CD45 and function as FDCs. FDC are recognized as a bridging cell between innate and adaptive (B cell) responses (Aguzzi et al. 2014). For example, FDCs are generally considered to be the major source of CXCL13 (also called B cell-attracting chemokine-1) both in normal and aberrant lymphoid tissue. The most CXCL13-expressing cells in rheumatoid arthritis and ulcerative colitis are of monocyte/macrophage lineage. They are located in irregular lymphoid aggregates within an FDC network, but also within and near smaller collections of B cells in diseased tissue where no FDCs are detected. These cells occupy the outer layers of primary and secondary lymph node follicles—the light zone and the follicular mantle. FDCs constitute a three-dimensional sponge-like network formed by interdigitation of adjacent cells. As shown by ultrastructural studies, these cells present filiform or beaded dendrites with characteristic ‘ball-of-yarn’ convolutions. FDCs play a pivotal role in promoting B-cell proliferation and differentiation in germinal centers. They are very efficient in trapping and retaining antigen–antibody complexes through CD21–CD35 and Fc γ RIIB receptors for long periods and presenting them

as iccosomes (immune-complex-coated bodies) to memory B cells. Spleen also contains lymph node-like organized structures, however this organ is multifunctional. For detailed information read (Kain and Owens 2013).

14.4.3 Lymph Node as the Home for Primary Adaptive Immune Responses and Peripheral Tolerance

14.4.3.1 Common Rules of Adaptive Immune Responses

The major function of the immune system is the control of our biologic individuality. The strength and quality of immune responses is based on highly polymorphic MHC molecules and various recombinations of T and B cell receptors. The specificity of proteins expressed by viruses, bacteria and parasites, along with their interaction and processing through host cell antigen-presenting machinery is the second side of the coin. The same is true for changed self-proteins by oxidation, nitration and other types of chemical alterations.

Cytokine/chemokines induced by external, self and self-modified proteins, loaded into DCs/macrophages and delivered from affected tissues (including the brain) by lymphs into regional draining lymph nodes control the balance between induction of immunity or tolerance. Both the induction of antigen-specific immunity and tolerance rely on the direct interaction of DCs with naïve T cells. These interactions occur in the T cell zone of lymph nodes in the vicinity of high endothelial venules (Siebert and Luther 2012; Baaten et al. 2013).

14.4.3.2 CD4⁺ T Cell Polarization

Depending on the co-stimulatory and cytokine signals that are provided by DCs at the time of priming, naïve CD4⁺CD25⁻ T cells differentiate into T helper (Th) cells such as Th1, Th2, Th17 and T follicular helper (Tfh) cells. Activation of naïve CD4⁺ T cells through the TCR elicits low but detectable transcription of both genes, IL-4 and IFN- γ . The expression of T-box transcription factor, T-bet, plays a critical role in Th1 development and supports transcriptional competence at the IFN- γ locus and selective responsiveness to IL-12. As stimulation progresses in the presence of signaling through the essential IL-12 receptor (via transcription factor STAT4), primed cells have IL-4 expression and become Th1 helper cells.

Another transcriptional factor GATA3 is involved in Th2 differentiation and contributes to chromatin remodeling events that favor IL-4 gene stable demethylation and IL-4 production. Signaling through IL-4 receptor and downstream with STAT6 favors stable production of IL-4 (as well as IL-5, IL-13) and differentiation in Th2 cells. It is unclear whether Tfh cells differentiate as a separate lineage at the time of T-cell priming or whether they emerge at a later stage from non-polarized, primed T cells or even from polarized Th2 or Th1

(less possible) cells. IL-6, IL-23 via STAT3 pathway in the presence of TGF- β facilitate differentiation of naïve Th cells into Th17 phenotype to protect against fungal and bacterial infections. As of today, there are at least four different Th cell subsets (Th1, Th2, Th17, and iTreg) that have distinct functions to regulate immune responses. Each cell subset expresses a unique set of transcription factors as well as hallmark cytokines. The cytokine environment created by activated CD4⁺ T cells themselves, by dendritic cells, and/or other cell types during the course of differentiation plays a critical role in the Th fate decisions (Yamane and Paul 2012, 2013).

14.4.3.3 CD4⁺T⁻ B Cell Interactions

A proportion of newly primed T cells that have upregulated expression of CXCR5 migrate toward the T-cell-zone-follicle boundary, where they might provide cognate help to antigen-specific B cells. In this location, they can interact with B cells and also with CD4⁺CD3⁻ accessory cells (LTi cells analogs for development of lymph nodes). The CD4⁺CD3⁻ accessory cells that are present at the T-cell-zone-follicle boundary, and within the follicles, provide signals through CD134 (also known as OX40) and CD30 at the surface of follicular T cells, which direct localization of these cells, maintenance of germinal-centre reactions and the generation of B-cell and CD4⁺ T-cell memory responses.

These follicular T cells strongly express the CD28-related molecule ICOS (inducible T-cell co-stimulator; also known as CD278) and secrete moderate amounts of IL-10, which are co-stimulatory factors with crucial functions in T helper cell and B-cell responses. After stimulation, they express CD134 and rapidly upregulate CD40 ligand (CD40L; also known as CD154) from pre-formed stores. This is consistent with their capacity to induce germinal-centre B cells to survive, secrete antibody and express activation-induced cytidine deaminase (AID). AID is crucial for immunoglobulin class switching and somatic hypermutation. IL-21 co-stimulation potently induces the expression of both B lymphocyte-induced maturation protein-1 (BLIMP-1) and AID, as well as the production of large amounts of IgG from B cells (Ettinger et al. 2005). Tfh, Th1 and Th2 cells can all participate in antibody responses. Th1 and Th2 cytokines guide class-switch recombination to result in particular immunoglobulin classes and subclasses, thereby skewing antibody responses depending on the nature of the stimulus. For example, IFN- γ promotes switching to IgG2a during antiviral responses, and IL-4 promotes the production of IgE during anti-parasite responses. Both Th1 and Th2 cells are crucial helpers in the extrafollicular pathway of B-cell differentiation, and are potent inducers of class switching to T-cell-dependent antibody classes and subclasses outside germinal centers. CD4⁺ Treg cells that suppress Th1/Th2 cells function, expansion of CD8⁺ cells and B-cell production of antibody have also been described. These are

CD4⁺CD25⁺CD57⁻ T cells that co-express CXCR5 and localize to T cell zone and germinal centers. T cells that express NK1.1 (CD4⁺ NKT cells) as well as NK are there.

14.4.3.4 B Cell Differentiation and Humoral Immune Responses

The help that T cells provide to B cells allows the production of high-affinity memory B cells and long-lived plasma cells that are specific for foreign antigens. The T cells independent immune responses usually occurs after direct activation of B cells by bacterial capsular polysaccharides and by microorganism-derived Toll-like-receptor ligands. This is a rapid antibody response to the pathogens through the generation of short-lived, low-affinity extrafollicular plasma cells.

The essential structure for T cell-dependent responses is a germinal center. Germinal centers arise in lymphoid tissues following antigenic stimulation and provide a milieu for proliferation of B cells (known as centroblast), somatic hypermutation that results in an increase in the affinity for antigens for a minority of germinal-center B cells. This process results in B cells becoming self-reactive.

Centroblasts exit cell cycle to become centrocyte and bind antigen that is associated with FDCs using newly expressed cell-surface immunoglobulin, after processing B cells present antigen in MHC II to T helper cells and elicit help. Interaction with T helper cells has several outcomes: (1) survival and selection of high-affinity centrocytes; (2) class-switch recombination of immunoglobulin and differentiation into long-lived plasma cells and memory B cells; (3) perpetuation of germinal-center reactions by stimulating centrocytes to recycle to become centroblasts. In the absence of antigen-specific T cells, centrocytes are eliminated and germinal centers abort early after induction.

Spontaneous ectopic germinal-center formation have long been recognized to occur in human autoimmune diseases and is a source of somatically mutated high-affinity autoantibodies.

14.4.3.5 CD8⁺ T Cells

A small proportion of follicular T cells in human germinal centers are CD8⁺ (less than 5% in tonsils and 10–15% in lymph nodes). Unlike B cells, which require a significant amount CD4⁺ T cell help in order to achieve high specificity, magnitude and stability in antibody production (humoral immune responses), CD8⁺ cell mediated (cytotoxic/cytolytic) cellular immune responses during the first several days after induction are independent from CD4⁺ help. Only memory formation is dependent of CD4⁺ T cell help. Mainly it depends upon CD40 ligation and IL-2 production by CD4⁺ Th1 helper cells, and is regulated by co-stimulatory molecules expressed by DCs.

The effector CD8⁺ T cells possess an arsenal of cellular weapons and are exquisitely refined in their ability to recognize target cells displaying small peptides on a protein scaffold

of MHC. Upon recognition of a foreign peptide, CD8⁺ T cells can use either cytopathic or non-cytopathic mechanisms to rid a cell of an invading pathogen. These mechanisms include deposition of pore-forming molecules and granzyme release, engagement of the apoptosis-inducing ligands (such as Fas ligand), and the release of cytokines such as IFN- γ and TNF- α . All this machinery is programmed in the lymph node during priming and delivered at the site where CD8⁺ cells perform their function. CTLs will eliminate virally or bacterially infected cells (stromal, macrophages/DCs, or lymphocytes) residing in lymph nodes that would have led to lymphopenia and immune-suppression (HIV/AIDS).

14.4.3.6 Adaptive Immunity and the Brain

Just like for any other tissue, the status of post-capillary vein endothelial cells plays a dominant role in penetration of activated lymphocytes into the brain parenchyma. Systemic activation of such cells by exo- and endotoxins via increased production of TNF- α and other pro-inflammatory cytokines, up-regulation of adhesion molecules allows lymphocytes to enter perivascular spaces in the meninges and choroids plexus, neither of which have an established blood–brain barrier. These two compartments contain potential (macrophages) and actual dendritic cells. Following viral and bacterial infections that might affect APC and induce local immune reactions, memory cells are formed. In healthy individuals at middle age, in the CSF very low number of lymphocytes are present, >80% of which are memory T cells (CD4⁺CD45RO⁺CD27⁺CXCR3⁺). Continuous recirculation of these cells between blood and the CSF is supported by low levels of P-selectin expression on endothelial cells of the deep stromal veins of the choroid plexus and the bridging meningeal veins. Engelhardt and Ransohoff (2005) review lymphocyte migration in the brain in great detail. These memory cells will persist through human life and respond in situ to re-appearing antigen (viral, bacterial, etc). Even so, the memory recall in the brain is delayed due to the immunosuppressive brain environment and activation of pro-apoptotic T-cells-glia interactions via CD95/CD95L (Fas/FasL), CD30/CD153 and other probable TNF-family related factors. New technical advances in real-time imaging of the leukocyte behavior in cerebral infection provide insights into these processes (Pai et al. 2014).

14.5 Neuro-Immune Interaction

14.5.1 Innervation of Lymphoid Tissue

The clinical, epidemiological, and experimental data have suggested that factors, hormones, and neural mediators that link the immune and nervous system might involve in the pathogenesis of multiple immune-mediated disorders of the

nervous system. These molecules are members of the same superfamily, which allow the mutual and bi-directional neural-immune interaction (Procaccini et al. 2014).

In lymphoid organs, similar to blood vessels, sympathetic/noradrenergic and sympathetic/neuropeptide Y (NPY) innervation predominate parasympathetic (cholinergic) innervation and are actually located along the vessels. In the thymus at the ultrastructural level, noradrenergic fibers are seen in proximity to thymocytes, mast cells and fibroblasts (Fig. 14.1). Catecholaminergic nerve fibers also run in close contact to TECs. Since TECs form the blood-thymus barrier in the outer thymic cortex, these cells may be targets for circulating epinephrine from the adrenal gland or norepinephrine (NE) released from the perivascular nerves. In spleen the sympathetic nerve fibers are present among cells in the T-dependent area; macrophages and B cells residing in the marginal zone and the marginal sinus, the site of the lymphocyte entry into the spleen. In lymph nodes noradrenergic fibers supply paracortical and cortical zones (T cell-rich regions) but are absent from nodular regions and germinal centers, the B cell-containing areas. The gut, lung and nasal mucosa have the highest intensity of innervation of associated lymphoid tissues. Nerves predominate in T cell zones of lymphoid aggregates where they contain neuropeptides and the sympathetic neurotransmitter NE.

14.5.2 Regulation of Immune Cells Activity by Neurotransmitters and Neuropeptides

As was mentioned above, antigen-presenting cells starting from thymic TECs, and ending with tissue resident macrophages/DCs, play an indispensable role in lymphocyte function from programming central tolerance and immunity to support of their effector function and peripheral tolerance. Cells of macrophage/DC origin express functional receptors for NE ($\alpha 1$, $\alpha 2$, $\beta 1$, $\beta 2$), dopamine (D1-5), neuropeptide Y (Y1), opioids (μ , δ , κ), and parasympathetic nicotinic acetylcholine receptors. Complex signaling through these receptors will affect activation status of APCs, expression of co-stimulatory/co-inhibitory molecules and profile of secreted cytokines/chemokines. Signaling through Ach receptors suppresses TNF secretion following the activation of lymphocytes, so the receptors play an anti-inflammatory role. Macrophages/DCs and lymphocytes express the variety of adrenergic receptors and the co-signaling during antigen presentation in the presence of increased concentrations of NE or dopamine can modulate T cells polarization toward Th2. The same direction influences histamine, serotonin, neuropeptides such as substance P, vasoactive intestinal peptide (VIP), pituitary adenylate cyclase-activating polypeptide, calcitonin gene-related peptide, α -melanocyte-stimulating hormone and leptin (Elenkov et al. 2000; Scheiermann et al. 2013) (Fig. 14.1).

14.6 Humanized Animal Models

14.6.1 Hemato-Lymphoid “Humanization” of Mice

The humanized mouse field is evolving, and has received significant attention as an experimental platform to study human hematopoietic and immune system development (Rongvaux et al. 2013), human stem cells and normal tissues growth in the context of regenerative medicine (Isobe et al. 2014), and human tumor stem cells and tissues biology in cancer-related research (Williams et al. 2013). For such models, scientists use immunodeficient mice. The non-obese diabetic mice (NOD) carrying mutation of DNA-dependent protein kinase (*Prkdc*) (Bosma et al. 1983) and deletion of common cytokine receptor gamma chain (γ), complete loss of common cytokine receptor gamma chain (γ .null) (Cao et al. 1995; DiSanto et al. 1995) for NOD.Cg-*Prkdcscid* *Il2rgtm1Wjl/SzJ* (NSG) or deletion of the intracytoplasmic domain for NOD.Cg-*Prkdcscid* *Il2rgtm1Sug/JicTac* (NOG) (Ohbo et al. 1996; Ikebe et al. 1997; Sugamura et al. 1996) are the most popular. These strains were used for studies of human hematopoietic stem cells (HSC) and immune system development and function (Tanner et al. 2014). A marked increase in engraftment was attributed to the low lytic activity of the C5 component of complement [due to two base-pair deletion in a 5' exon of the murine C5 gene (Baxter and Cooke 1993)] with defects of macrophage function (defective regulation of colony-stimulating factor-1 and interferon- γ receptors, and reduced secretion of IL-1 in response to LPS), and NK cell activity (Shultz et al. 1995). The murine polymorphism of signal regulatory protein- α (SIRP- α , CD172 α)—the region in the insulin-dependent diabetes 13 (*Idd13*) locus on chromosome 2 containing a coding sequence polymorphism of *Sirpa*, was responsible for the survival and subsequent development of human HSC in a murine environment. SIRP- α interacts with the widely expressed cell surface transmembrane glycoprotein CD47 (also called integrin-associated protein, IAP). The interaction of these ligands expressed on surface membranes of mouse macrophages and human HSC surfaces provides a negative “stop” signal for destruction of xenogeneic human cells (Takenaka et al. 2007; Takizawa and Manz 2007). The major characteristics of these types of chimeric animals are (1) the high rate of acceptance of human HSC; (2) stable population of mouse bone marrow; (3) occupancy of murine thymus with human thymocytes and their maturation in $\alpha\beta$, $\gamma\delta$ and regulatory T cells (4) complete reconstitution of residual murine lymph nodes with human T, B and dendritic cells; (5) formation of splenic white pulp (Fig. 14.2); (6) distribution of human cells of macrophage lineage throughout brain meninges and perivascular spaces (Fig. 14.3). These “humanized” mice support chronic HIV-1 replication and recapitulate the course of humankind progression with loss

Fig. 14.2 Humanized hematolymphoid organs mouse model. Human CD34⁺ stem cells (HSC) isolated from umbilical cord blood or fetal liver were injected intrahepatically into 1 day-old irradiated pups. A complete human immune system is developed in NSG/NOG mice. The injected HSC reach mouse lymphoid organs including bone marrow, spleen, lymph nodes, gut and develop into a broad range of immune cell lineages. The presence of human CD34⁺ stem cells, myeloblasts, B cell precursors, erythroblasts, promyelocytes, granulocytes and monocytes

in mouse bone marrow were detected. Human T cell development occurred in the mouse thymus, as evidenced by the presence of CD4/CD8 T cells. In lymphoid tissue, distinct follicles filled with human T, B lymphocytes and macrophages were observed. Lymph nodes were also reconstituted with human lymphocytes, macrophages and dendritic cells. A mature human immune system develops in the mouse by 20–22 weeks. From Gorantla et al. (2012)

of CD4⁺, development of HIV-1-specific CTL, and humoral immune responses (Watanabe et al. 2007; Gorantla et al. 2010; Brainard et al. 2009).

14.6.2 Mouse Brain “Humanization”

In contrast to the biological blocks for postnatal reconstitution of mouse brain resident macrophages by human cells, transplantation and development of neurons and glial populations (astrocytes and oligodendrocytes) is possible and highly efficient in immunodeficient mice with NOD/scid or Rag-knockout backgrounds. Human CD133⁺ neuronal progenitor cells transplanted into irradiated at birth pups by 6

months of age populated multiple mouse brain regions with mature neurons with well-established connections within mouse neuronal network (Uchida et al. 2000; Benninger et al. 2000). Transplantation of human glial progenitors isolated from fetal brain with specific phenoty A2B5⁺/PSA–NCAM–showed replacement of significant proportion of mouse astrocytes with human astrocytes and improved mouse cognitive abilities (Han et al. 2013). The same phenotype progenitors transplanted in mice with immunodeficient deficient background and defects in myelinating cell development (*shiverer*, MBP^{shi/shi}) give rise to oligodendrocytes (Windrem et al. 2014). Moreover, these human glia repopulated mouse brains became permissive for human-specific viral infections like human gliotropic JC virus (Kondo et al. 2014).

Fig. 14.3 Schematic representation of the CNS-immune system cross-talk. There are bi-directional circuits linking CNS and immune system. The CNS can communicate with the immune system to modulate its activity, through different ways: through the autonomic nervous system (via the sympathetic and vagus nerve innervation), the catecholaminergic pathway, or the neuropeptides and hormones release. They modu-

lates immune system, by increasing the activation of T cells and decreasing Treg cells functions, thus representing a key player in the susceptibility to immune-mediated disorders ($\beta 2R$, $\beta 2$ receptor; $\alpha 7$ nAChR, $\alpha 7$ subunit of the nicotinic acetylcholine receptor). From Procaccini et al. (2014)

14.7 Conclusion

In this chapter, we are reviewing the development of immune system, establishment of organs of the immune system and their function as a collector of information about status

(normal or inflamed) of any tissues including brain. There is a strong relationship between development of both systems and separation of nervous and immune system *post partum*. However, innervation of hemato-lymphoid organs regulates development of inflammation in these compartments.

The efferent information actively is coming from the brain, but development of effector reactions is limited by strong central tolerance during education of lymphocyte by TEC expressing brain antigens as well as peripheral tolerance supported by soluble brain antigens filtered through regional lymph nodes and presented by resident DCs in the absence of co-stimulatory signals. Humanized animal models helped to study the complexity of human immune system development and adaptive immune responses *in vivo*. Humanization of a mouse brain with human glial cells provided an additional tool to study hemato-lymphoid tissue and brain interaction in small animal models. The presented review will help to understand brain immunopathology described in the following chapters.

14.8 Review Questions

1. Briefly summarize the major steps in lymphocyte embryonic development.
2. Briefly summarize the major steps in T lymphocyte development.
3. Briefly summarize the major steps in B lymphocyte development.
4. Briefly summarize the distribution of B cells and their function.
5. Briefly summarize the major steps in helper cells polarization.
6. Briefly summarize the major factors that limit T cells survival in the brain.
7. Briefly summarize the major steps in adaptive immune responses.
8. Briefly summarize the major requirements for B cells differentiation and antibody production.
3. The fetal liver has long been considered the initial site of B cell commitment, and from then on B progenitors expand in a synchronous wave-like pattern reaching a peak in the perinatal stage. Even after birth, B cells may develop at sites other than the bone marrow.
4. Selection from newly formed B cells into transitional, follicular and marginal-zone (MZ) B cells depends on integrated signals from several classes of surface receptors, such as: the BCR and co-signals, the tumor-necrosis factor receptor (TNFR) family, and the G-protein-coupled receptors (GPCRs).
5. Depending on the co-stimulatory and cytokine signals that are provided by DCs at the time of priming, naïve CD4⁺CD25⁻ T cells differentiate into T helper (Th) cells such as Th1, Th2, Th17 and T follicular helper (Tfh) cells. As stimulation progresses in the presence of signaling through the essential IL-12 receptor (via transcription factor STAT4), primed cells have IL-4 expression and become Th1 helper cells. Macrophages/DCs and lymphocytes express the variety of adrenergic receptors and the co-signaling during antigen presentation in the presence of increased concentrations of NE or dopamine can modulate T cells polarization toward Th2.
6. The highly specialized nature of the endothelial cell lining, with the cerebral vasculature and tight junctions, forms a physical and functional barrier to lymphocytes. For a short period of time, T cells can be found in perivascular spaces and make parenchymal foci as an inflammatory reaction to acute viral or bacterial infection. However, such physiologic responses in the brain parenchyma are quickly terminated by the downregulation of MHC class I and II co-stimulatory molecular expression on glial cells (immunosuppressive function of IL-10, TGF- β and prostaglandins), by apoptosis of T cells through Fas-Fas ligand (CD95/CD95L) interaction.
7. Cytokine/chemokines induced by external, self and self-modified proteins, loaded into DCs/macrophages and delivered from affected tissues (including the brain) by lymphs into regional draining lymph nodes control the balance between induction of immunity or tolerance. Both the induction of antigen-specific immunity and tolerance rely on the direct interaction of DCs with naïve T cells.
8. B cells require a significant amount CD4⁺ T cell help in order to achieve high specificity, magnitude and stability in antibody production (humoral immune responses).

14.9 Answers

1. The common concept of lymphoid tissue ontogeny relies upon the concept of circulating stem/progenitor cell populations, which migrate from the yolk sack into the aortogonad mesonephros (AGM), then into organ anlagen, initiating hematopoiesis in fetal liver and bone marrow, and lymphopoiesis in thymus.
2. The human thymus develops at ~embryonic day 35 from the endoderm with subsequent epithelial–mesenchymal interaction. At the embryonic stage, lymphomyeloid commitment precedes thymic development in CD45⁺CD117⁺CD34⁺ hematopoietic clusters of AGM region. In addition, multilineage progenitors restricted to T, NK (natural killer) and macrophage lineage (pTM) or just T lineage (pT), or B and B plus macrophage (pBM) were identified in the AGM region.

Abstract

Neural stem cells and neurogenesis are a constitutive part of brain development and homeostasis. Importantly, function of neural stem cells and neurogenesis is how a healthy brain is defined. Decline number of neural stem cells and impaired neurogenesis are observed during aging and neurodegenerative disorders. Therefore, research in the past decades has generated great interest in the understanding of neural stem cells and neurogenesis. Many immunological and pharmacological therapeutic approaches are developed based on this research. In the current chapter, we introduce different types of stem cells relevant to the health and diseases of the nervous system. We discuss critical molecules and cell types involved in adult neurogenesis and how this research can be used to promote neural regeneration and repair during diseases. Additionally, we introduce an exciting new avenue of stem cell therapy based on somatic cell reprogramming strategy and discuss its potential applications in various neurological diseases.

15.1 Introduction

Neurogenesis continues throughout life and contrary to the previously held dogma that no new neurons are produced in the adult human brain. Neurogenesis during development and throughout adult life is a result of the proliferation, migration, and differentiation of neural stem cells (NSCs). NSCs are cells that can differentiate into all central nervous system (CNS) cells and self-renew while retaining their

multipotential capabilities. Numerous factors contribute to NSC survival, proliferation, migration and differentiation. These factors include, but are not limited to, cytokines, chemokines, growth factors, hormones, morphogens, cell adhesion molecules, and neurotransmitters. New neurons and supporting cells are produced in the adult brain on a daily basis. It is estimated that in the human hippocampus, approximately 700 new neurons are added every day (Deng et al. 2010; Spalding et al. 2013). However, it remains unclear how long these new cells survive, how well they integrate into circuitry of the CNS, whether they have any functional impact on memory formation or cognition, and whether alterations in this neurogenesis process could underlie neurological diseases. Notably, considering that human brain has approximately 100 billion neurons, the rate of neurogenesis is extremely low. Therefore, much research has focused on replacing damaged neurons by either transplantation of

embryonic, fetal, adult stem cells, or by stimulation of endogenous NSCs to undergo growth and differentiation. Future research into the mechanisms by which neurogenesis is regulated and investigations on the functional impact of the newly generated neurons are imperative for understanding brain development as well as in treating neurodegenerative disorders.

15.2 Stem Cells, Neural Stem Cells and Neural Progenitor Cells

A stem cell is a special kind of cell that has the unique capacity to continually renew itself and also to give rise to additional specialized cell types. It is now known that stem cells, in various forms, can be obtained from the embryo, fetus, and adult. Stem cell plasticity, the ability to differentiate into more than one kind of cell, may vary depending on where the stem cell originates. Most of what is known about these cells has been learned by studying rodent stem cells. However, emphasis of current research is on the utilization of human stem cells in therapy.

15.2.1 Embryonic Stem Cells

Human embryonic stem cells were first obtained in 1998 by two different research teams. The cells obtained from the inner cell mass of the blastocyst (4 to 5-day embryo) are embryonic stem cells (ESC). In contrast, cells cultured from the primordial germ cells of 5- to 9-week fetuses are embryonic germ cells (EGC). In the laboratory, ES or EG cells can proliferate indefinitely in an undifferentiated state but can also be manipulated to become specialized or partially specialized cell types, a process known as directed differentiation. Both ES and EG cells are pluripotent, meaning they have the potential to develop into more than 200 different known cell types. This class of human stem cells holds the promise of being able to repair or replace cells or tissues that are damaged or destroyed by many of the most devastating human diseases.

15.2.2 Adult Stem Cells

An adult stem cell is an undifferentiated cell that is found in an otherwise differentiated (specialized) tissue in the adult. It can renew itself for the lifetime of the organism and yield the specialized cell types of the tissue from which it originated. Adult stem cells usually divide to generate progenitor or precursor cells, which then differentiate and develop into mature cell types that have characteristic shapes and specialized functions. Adult stem cells have been found in tissues that

develop from all three embryonic germ layers, but these cells are rare. Often they are difficult to identify, isolate, and purify. Most adult stem cells grown in a culture dish are unable to proliferate in an unspecialized state for long periods of time. The plasticity of adult stem cells appears to be less than that of ES cells; to date there is no isolated population of adult stem cells capable of forming multiple kinds of cells of the body.

15.2.3 Neural Stem Cells and Neural Progenitor/Precursor Cells

NSCs are self-renewing, multipotent cells that generate neurons, astrocytes, and oligodendrocytes (Gage 2000). During embryonic development, NSCs arise from generative zones derived from the inner lining of the neural tube that extend from periventricular regions of the telencephalon to the spinal cord within the mammalian CNS. NSCs can be isolated from the embryonic or fetal CNS, including basal forebrain, cerebral cortex, hippocampus, and spinal cord. In the adult nervous system, NSCs can be isolated from neurogenic zones (the subventricular zone and hippocampal dentate gyrus). In addition, more recent evidence suggests that stem cells can be isolated from non-neurogenic areas, e.g., the spinal cord. NSCs can be grown in culture and retain both their pluripotency and ability to self-renew.

Neural progenitor cells (NPCs), in contrast, are multipotent and proliferative cells with only limited self-renewal that can differentiate into at least two different cell lineages ("multipotency," but not "pluripotency", Fig. 15.1) (Gage et al. 1995; Weiss et al. 1996; McKay 1997). Lineage-specific precursors or progenitors are cells restricted to one distinct lineage (e.g., neuronal, astroglial, and oligodendroglial). The term "precursors" is used to encompass both stem and progenitor cells" (Emsley et al. 2005).

Other lineage-specific progenitor cells exist in the adult CNS. For example, oligodendrocyte progenitor cells (OPCs), also known as NG2-glia, are glial precursors to oligodendrocytes but may also be able to differentiate into neurons and astrocytes (Nishiyama et al. 2009). Interestingly, although OPCs account for 5 % of cells, it may be the major dividing population in the adult CNS (Dawson et al. 2003).

15.2.4 Induced Pluripotent Stem Cells (iPSCs)

Through exposure to a specific set of transcription factors adult somatic cells can be reprogrammed into pluripotent stem cells. These iPSCs were first created in 2006 by exposure of adult fibroblast cells to four transcription factors, Oct4, Sox2, c-Myc, and Klf4, via a viral vector (Takahashi and Yamanaka 2006). Since then, many other transcription

Fig. 15.1 Characterization of human cortical neural progenitor cells. (a) Cells were isolated from human fetal cortex and culture in NPIM containing EGF, bFGF, and LIF. Cells expressed Nestin, a neural stem/

progenitor cell marker. (b–c) After switching to a differentiation medium, NPCs were differentiated into neurons (β -tubulin, b) and astrocytes (GFAP, c)

factors have been discovered that alter the epigenetic markers of cells to mimic a stem cell phenotype.

iPSCs have a tremendous capacity to replace injured or defective tissues if they are exposed to the proper transcription factors for differentiation. As they can be derived from the host, the immune system does not respond strongly to them as it would to standard tissue grafts. However, iPSCs are difficult to produce, and both iPSCs and their differentiated progenies have a tendency to be tumorigenic. This had led to further research to reduce tumorigenicity of these cell types (Ruggieri et al. 2014).

The development of iPSCs has tremendously advanced the field of stem cell research. First, it is now possible to create iPSCs cell lines from specific patient tissues. These patient-derived iPSCs cell lines could then be used to model diseases or used for drug screening, which will further the understanding of disease pathogenesis and therapy. Second, iPSCs technology has also been actively used to create tissue-specific stem cells for cell replacement therapies. Both of these advances spark interest in achieving NSCs, NPCs, and lineage-specific NPCs through reprogramming strategies. See Table 15.1 for detailed features of different stem cell types.

15.3 Stem Cells and Neurogenesis During Brain Development

Neurogenesis is primarily a process that involves proliferation, migration, differentiation, and survival of neural stem cells (Palmer et al. 1997; Gage 2000). Multiple factors have been shown to regulate neurogenesis in the developing and adult nervous system including hormones, neurotransmitters, trophic factors, and chemokines (Cameron et al. 1998; Ferguson and Slack 2003).

15.3.1 Determination and Formation on Neural Tube

Developmental neurogenesis begins when a portion of the mesoderm gives rise to the notochord along the anterior-posterior axis of the embryo. This notochord releases factors that cause primary ectoderm multipotent stem cells to differentiate into more fate-restricted stem cells of the neuroectoderm, forming the neuronal plate. The neuronal plate develops along the dorsal surface at the anterior end of the embryo. As the edges of the neuronal plate fold over its center, fuse, and detach from the ectoderm the neuronal plate forms a hollow neural tube with an outer mantle layer and an inner proliferative zone. This neural tube will become the CNS, while a group of cells termed the neural crest on the dorsal side of the neural tube will give rise to the peripheral nervous system.

Upon formation of the neural tube, regionally distinct transcription factors are expressed, designating the configuration of discrete brain regions that will eventually develop into the forebrain, midbrain, cerebellum, hindbrain, and spinal cord (Hatten 1999; Shimamura et al. 1997). Factors from the microenvironment surrounding NPCs in the neural tube direct the differentiation of these cells to regionally specific arrays of neurons. These distinct differentiation events include dorsal-ventral polarization in the spinal cord, segmentation in the hindbrain, and lamination in the cerebral cortex (McConnell 1995).

15.3.2 Neural Stem Cells in CNS Development

The proliferating cells during CNS development reside in the ventricular zone of the neural tube. These cells are a heterogeneous population that exhibits complex patterns of gene expression (Temple 2001; Florio and Huttner 2014). This diversity of gene expression allows differentiation of

Table 15.1 Features of different stem cell types

Cell type	Location	Self-renewal capacity	Differential capacity
Embryonic stem cells (ESCs)	Inner cell mass of the blastocyst (4 to 5-day embryo)	Infinite	Pluripotent (can differentiate into every cell of the organism except for the trophoblast)
Induced pluripotent stem cells (iPSCs)	Somatic cells	Infinite	Pluripotent (can differentiate into every cell of the organism except for the trophoblast)
Embryonic germ cells (EGCs)	Primordial germ cells of 5 to 9-week fetuses	Infinite	Totipotent (can differentiate into every cell of the organism)
Adult stem cell	Specific niches in adult tissue (location varies for each tissue/organ)	Infinite	Multipotent (can differentiate into most cells of the tissue in which they reside. Also, they may have plasticity, which allows them to differentiated into cells of other tissues)
	Embryo: Inner lining of the neuronal tube		
Neural stem cell (NSCs)	Fetus: Basal forebrain, cerebral cortex, hippocampus, and spinal cord Adult: Subventricular zone and hippocampal dentate gyrus	Infinite	Multipotent (can differentiate neurons, astrocytes, and oligodendrocytes)
Neural progenitor cell (NPCs)	Fetus: Basal forebrain, cerebral cortex, hippocampus, and spinal cord Adult: Subventricular zone and hippocampal dentate gyrus	Limited (can self-renew, but only for a limited number of generations)	Multipotent (can differentiate into at least two cell types of the tissue in which they reside)
Lineage-specific precursor cell	Specific niches in adult tissue (Location varies for each tissue or organ)	1. Limited (can self-renew, but only for a limited number of generations)OR..... 2. Cannot self-renew (It no longer retains the ability to differentiate into more than one cell type), but can amplify in cell number	1. Multipotent (Can differentiate along one specific lineage [e.g. neuronal or astroglial])OR..... 2. Unipotent (Can only differentiate into one cell type)

NSCs to astrocytes, oligodendrocytes, and various types of neurons, depending on the signals present in the microenvironment within the developing CNS. As the development of the embryo progresses, multipotent stem cells differentiate into more fate-restricted progenitors, which give rise to macroglial cells and regionally distinct neuron types. These progenitors first give rise to neurons, then to glial cells during embryonic and fetal development, and finally to astrocytes during postnatal growth. Numerous factors have been identified to regulate these mechanisms, including growth factors, neurotransmitters, and chemokines; these are discussed in detail in later sections.

15.3.3 Stem Cells in Adult Neurogenesis

In the adult human brain, neurogenesis is limited to two regions, where two distinct populations of NPCs have been identified: (1) one in the subventricular zone (SVZ) of the

lateral ventricles and (2) another in the subgranular zone (SGZ) of the dentate gyrus of hippocampus. In these neurogenesis areas, primary progenitors give rise to heterogeneous intermediate progenitor cells, which in turn generate large numbers of neuroblasts that migrate and integrate into the neural networks. For example, in the SVZ of the lateral ventricles, type B1 NSCs give rise to type C transit amplifying cells and type A mature neuroblastic cell progenies, which migrate to reach olfactory bulb, differentiate into neurons, and integrate into the existing neural structures. This active neurogenesis are apparently coordinated by a complex interplay of growth factors, morphogens, cell-cell interactions, neurotransmitters, and endothelial signals (Tong and Alvarez-Buylla 2014). Other, but possibly less significant, populations of NPCs may exist throughout the adult CNS. The physiological role of adult neurogenesis and potential to control it for therapeutic benefit are critical areas of current research for the treatment of neurodegenerative disorders and neural damage.

15.4 Stem Cell Signaling Pathways for Migration, Proliferation and Differentiation

Neurogenesis includes proliferation, neuronal fate specification of NPCs (differentiation), migration, maturation, and functional integration of neuronal progeny into neuronal circuits (Ming and Song 2005). A full understanding of the molecular mechanisms regulating proliferation, migration and differentiation of these cells is essential if these cells are to be used for therapeutic applications.

15.4.1 Proliferation

Proliferation and survival of stem cells are important for the maintenance of the neural stem cell pool for neurogenesis. The signals involved include members of the fibroblast growth factor (FGF) family, the transforming growth factor- β (TGF- β) superfamily such as the bone morphogenic proteins (BMPs), the growth and differentiation factors (GDFs), and the Hedgehog family. In addition, many other cues are crucial for neural development.

FGFs constitute a large family of structurally related polypeptide growth factors that signal through receptor tyrosine kinases. It has been suggested that cyclin D2 (intimately involved in driving cells through the G1 phase of the cell cycle) is an effector of the FGF-dependent maintenance of the caudal stem zone (Lobjois et al. 2004). Receptor-mediated regulation of proliferation involves calcium signaling and the cAMP and PKA pathway. Activation of the Ras/Raf/Mek/Erk pathway is coupled to the cell cycle machinery via interactions with p53 retinoblastoma tumor suppressor protein (Rb) and E2F families of proteins.

Wnts are a large family of highly conserved secreted signaling proteins related to the *Drosophila* wingless protein that regulates cell-to-cell interactions during embryogenesis (Willert et al. 2003). In vitro and in vivo studies have shown that Wnt signaling is required to expand and maintain neural precursor populations in the brain and the spinal cord. As currently understood, Wnt proteins bind to cell surface receptors of the Frizzled family and act on multiple disparate signaling pathways. Three major pathways have been identified: (i) the Wnt/ β -catenin pathway also referred to as the canonical Wnt signaling pathway, (ii) the Frizzled/planar cell polarity (Fz/PCP) pathway, and (iii) the Ca²⁺ pathway. The details of these signaling pathways have been reviewed recently (Cayuso and Marti 2005; Ille and Sommer 2005). For the canonical Wnt signaling pathway, extracellular Wnt molecules bind to Fz seven transmembrane receptors on the cell surface; these Fz receptors are structurally similar to G-protein coupled receptors (GPCRs). Through several cytoplasmic relay components, the signal is transduced to

β -catenin, which then enters the nucleus and forms a complex with TCFs (from T-cell factor) to activate transcription of Wnt target genes (Logan and Nusse 2004).

Sonic hedgehog (Shh) is one of the members of the hedgehog family of secreted proteins required for multiple aspects of development in a wide range of tissues including the CNS (Machold et al. 2003). In addition to its fundamental role played in pattern formation of the ventral CNS, the Shh-Gli pathway has been demonstrated to play a major mitogenic role in the development of dorsal brain structures, including the cerebellum, neocortex, and tectum (Dahmane and Ruiz i Altaba 1999; Pons et al. 2001; Wallace 1999; Wechsler-Reya and Scott 1999; Dahmane et al. 2001). Shh mediated proliferation is also required for maintenance of neural stem cells in late development and adult. Shh activity is triggered by the binding of the ligand to its receptor Patched (Ptc), an 11-pass transmembrane receptor, and nuclear translocation of Zinc-finger proteins of the Gli family that activate or repress transcription of specific target genes (Jacobs et al. 2003).

Many of those crucial growth factors and morphogens are provided by the endothelial cells in the neurogenic vasculature. However, dietary restriction, exercise/enriched environment are known to positively modulate NPC proliferation within the neurogenic niche, whereas increased levels of glucocorticoids inhibit NPC proliferation. More recently, systemic factors with immunomodulatory property have also been demonstrated to affect NPC functions in the active neurogenesis areas (Villeda et al. 2011; Katsimpardi et al. 2014).

15.4.2 Differentiation

Differentiation is the process by which unspecialized cells (such as a stem cell) become one of the many highly specialized cells that make up the body. There are two directions of differentiation for neural stem cell: neurogenesis and gliogenesis. Neurogenesis requires a stepwise change of neuronal potential and lineage determination through a network of neurogenic factors (Morrison 2001; Florio and Huttner 2014). Neurogenic factors such as BMPs promote neurogenesis by inducing the expression of proneural basic helix-loop-helix (bHLH) transcription factors to activate the expression of a cascade of neuronal genes. Moreover, the activity of proneural genes inhibits gliogenesis in the CNS. In contrast, mammalian “hairy and enhancer of split homolog” (HES) gene expression promotes a glial fate. It is likely that other genes also influence multipotent stem cells to become glial precursor cells. Olig1 and Olig2 promote the development of oligodendrocytes. Notch activation acts in neural stem cells as a lateral inhibitory switch that terminates neurogenesis and initiates gliogenesis, even in the continued presence of neurogenic growth factors.

It has been shown that multiple bHLH genes play a critical role in regulation of neural stem cell differentiation (Bertrand et al. 2002; Ross et al. 2003). The activator-type bHLH genes *Mash1*, *Math* and *Ngn* are expressed by differentiating neurons. These bHLH factors form a heterodimer with a ubiquitously expressed bHLH factor E47 and activate gene expression by binding to the E box, promoting the neuronal subtype specification. bHLH genes promote neuronal subtype specification later in differentiation as well, as reviewed (Kageyama et al. 2005).

Factors that promote self-renewal include but are not limited to fibroblast growth factor (FGF), the transforming growth factor- β (TGF- β), Wnt signaling, and Notch signaling. NSCs are directed towards differentiating along the neuronal lineage by a decrease in Notch signaling and an increase in basic helix-loop-helix (bHLH) transcription factors. As these immature neurons mature they express activator-type bHLH genes *Mash1*, *Math* and *Ngn*. NSCs are directed towards the glial lineage by a low level of bHLH and a higher level of factors such as Notch, ciliary neurotrophic factor (CNTF), and Nrg-1. As these glial progenitors mature to astrocytes they express *Hes* and as they differentiate into oligodendrocytes they express *Oligo1* and *Oligo 2*. Specific cell markers can identify each of these cell types. Nestin and GFAP are expressed by NSCs, PSA-NCAM, DCX, and Tuj-1 are expressed by NPCs, NeuN and Map-2 are expressed by maturing neurons, GFAP is expressed by glial progenitors and astrocytes, and O4 and Gal-C are expressed by oligodendrocytes.

While *Mash1*, *Math* and *Ngn* promote neurogenesis, the repressor-type bHLH genes, including *Hes* genes, regulate maintenance of neural stem cells and promote gliogenesis. There are seven members in the *Hes* family, from which *Hes1*, *Hes3*, and *Hes5* are highly expressed by neural stem cells. *Hes* factors have a conserved bHLH domain; they form dimers and bind to DNA. The target genes for *Hes* factors include the activator-type bHLH genes such as *Mash1*. *Hes1* represses *Mash1* expression by directly binding to the promoter. The activator-type bHLH factors form a heterodimer with another bHLH activator E47 and promote neuronal differentiation from neural stem cells. *Hes1* forms a non-functional heterodimer with E47 and inhibits formation of *Mash1*-E47 heterodimer. Thus, *Hes1* antagonizes *Mash1* by two different mechanisms: repressing the expression at the transcriptional level and inhibiting activity at the protein-protein level.

It has been suggested that Notch signaling is important for maintaining multipotency in some neural stem cells but promotes glial differentiation in others or at different times during development. The Notch signaling pathway is best characterized as mediating cell-cell signaling between adjacent cells. The ligands are members of the Delta and Jagged gene families and the receptors are single-pass transmem-

brane proteins. Upon ligand binding, the intracellular domain of Notch (NICD) is released from the plasma membrane and translocates into the nucleus, where it converts the CBF1 repressor complex into an activator complex. The NICD/CBF1 activator complex upregulates targets such as the *Hes* and *Herp* (*Hes*-related protein) genes, which block neurogenesis. This is the central mechanism to the inhibition of neuronal differentiation by Notch (Yoon and Gaiano 2005). A proposed mechanism for NSCs/NPCs self-renewal and differentiation has been summarized in Fig. 15.2 to help understand the cell fate decision of NSCs/NPCs.

15.4.3 Migration Signaling

A remarkable feature of the developing CNS is the extensive migration of cells. As specific classes of cells come to reside in specific layers, migration also reflects the programmed control of neuronal fate. Control of these movements is rather complex, involving multiple regulatory genes and several extracellular molecules. Slit, reelin, and doublecortin may all regulate neuronal cell migration (Nadarajah and Parnavelas 2002). Slit and its receptor Robos mediate migration of NPCs crossing the midline in the developing brain (Orgogozo 2004). Doublecortin and reelin regulate cortical neuron migration (Feng and Walsh 2001; Nadarajah and Parnavelas 2002). In addition, chemokines such as CXCL12, also known as stromal cell-derived factor 1 (SDF-1 α), play an important role for NPCs migration during development, as discussed in Sect. 5.1.

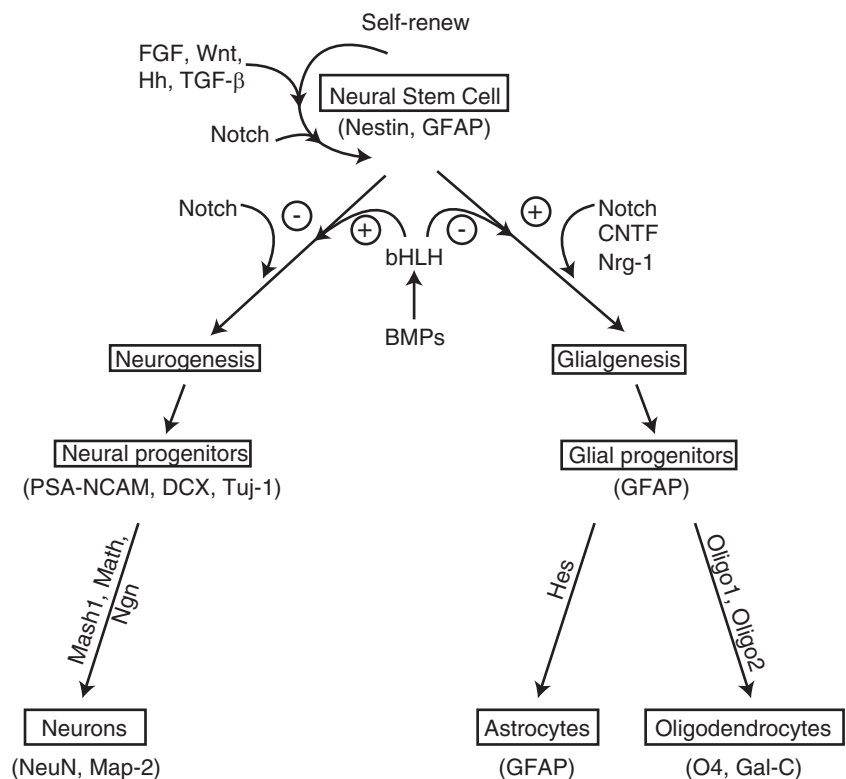

15.5 Chemokines and Neurogenesis

Chemokines constitute a family of structurally related low molecular mass (8–11 kDa) proteins with diverse immune and neural functions. In addition to their well-established roles in the immune system, chemokines play a role in the migration, proliferation, differentiation, and survival of neural stem/progenitor cells (Refer to Chap. 17.1 regarding chemokine and chemokine receptor classification and signaling pathways).

15.5.1 CXCL12 and Its Receptor CXCR4

Studies have shown that chemokine receptors are widely expressed in embryonic and adult neural stem/progenitor cells, including CXCR4, CXCR7, CCR2, CCR5, and CX3CR1 (Ji et al. 2004; Tran et al. 2004; Peng et al. 2004; Widera et al. 2004; Chen et al. 2015). CXCR4 is one of the most highly expressed chemokine receptors. Deletion of the gene for the CXCR4 receptor or of its only known ligand,

Fig. 15.2 A proposed mechanism for a select number of factors that regulate self-renew and differentiation of NSCs/NPCs

CXCL12, results in embryonic lethality. The brains of mouse embryos homozygous for the absence of CXCR4 or CXCL12 have severe abnormalities in the development of the cerebellum (Zou et al. 1998; Ma et al. 1998), hippocampal dentate gyrus (Lu et al. 2001; Bagri et al. 2002) and neocortex (Stumm et al. 2003). In the cerebellum, CXCL12 is highly expressed in the leptomeninges and is the major chemoattractant for external germinal layer cells in the developing cerebellum (Klein et al. 2001; Zhu et al. 2002). In mice lacking CXCL12 or CXCR4, migration of granule cell precursors out of the external germinal layer occurs prematurely, resulting in abnormal development of the cerebellum (Ma et al. 1998). In agreement with a key role for CXCR4, CXCR4 mRNA is expressed at sites of neuronal and progenitor cell migration in the hippocampus at late embryonic and early postnatal ages. The absence of CXCR4 leads to a reduction in the number of dividing cells in the migratory stream and in the dentate gyrus itself. In addition, neurons appear to differentiate prematurely before reaching their target (Lu et al. 2001; Bagri et al. 2002). In the cortex, CXCL12 is highly expressed in the embryonic leptomeninges and is a potent chemoattractant for isolated striatal precursors, while CXCR4 is present in early generated Cajal-Retzius cells of the cortical marginal zone (Stumm et al. 2003). Mice with a null mutation in CXCR4 or CXCL12 show severe disruption of interneuron placement and proliferation, while the submeningeal positioning of Cajal-Retzius cells remains unaffected

(Stumm et al. 2003). In conclusion, CXCL12 likely acts both as a chemoattractant and a mitogenic stimulus for neural stem/progenitor cells in the development of the cerebellum, hippocampus and neocortex.

CXCL12 may also affect spinal cord development. CXCL12/CXCR4 expression is increased in developing spinal cord progenitors. SDF-1 induced chemotaxis in both neural and glial progenitor cell, suggesting that CXCL12/CXCR4 may affect spinal cord development through modulating progenitor cell migration (Luo et al. 2005).

The expression of CXCL12/CXCR4 in the adult CNS suggests that CXCL12/CXCR4 signaling is also important in adult neurogenesis (Tran and Miller 2005; Bagri et al. 2002). In the adult, neurogenesis continues in the dentate gyrus. Adult NPCs in the subgranular zone, which produce granule neurons, express CXCR4 and other chemokine receptors, and granule neurons express CXCL12. The expression of CXCL12 and CXCR4 in adults differs from the embryonic patterns but remains consistent with continued functions in granule cell mitogenesis and/or chemotaxis.

Neural stem cell survival is an imperative issue during neurogenesis. Whether CXCL12-CXCR4 interaction is involved in all three steps of neurogenesis is not clear; however, CXCL12-CXCR4 signaling regulates survival of both NPCs and oligodendrocyte progenitors in vitro (Krathwohl and Kaiser 2004; Dziembowska et al. 2005). In addition to CXCR4, NPC survival also involves CXCR7, which is a

second receptor for CXCL12. Interestingly, although CXCR7 does not mediate classic GPCR signaling, it promotes NPC survival through endocytotic signaling (Zhu et al. 2012).

15.5.2 Other Chemokines and Their Receptors

The role of other chemokines and their receptors in neurogenesis has only recently become realized. For example, it has been suggested that CXCR2 plays a vital role in patterning the developing spinal cord; CXCR2 and its ligand, growth-related oncogene alpha (GRO- α , CXCL1) are crucial in arresting embryonic oligodendrocyte precursor migration (Tsai et al. 2002). Spinal cord oligodendrocytes originate in the ventricular zone and subsequently migrate to white matter, then stop, proliferate, and differentiate (Tsai et al. 2002). Without CXCR2 signaling, a widespread dispersal of postnatal precursors has been seen (Tsai et al. 2002). This shows that GRO- α -CXCR2 interaction plays an important role in holding a population of presumptive white matter (Tsai et al. 2002), thus, creating an organized and functional spinal cord. In young adult mice, increasing peripheral CCL11 chemokine levels in vivo decreased adult neurogenesis and impaired learning and memory, suggesting systemic inflammatory factors may negatively regulate neurogenesis (Villeda et al. 2011). Monocyte chemoattractant protein-1 (MCP-1, CCL2) can also activate the migration capacity of rat-derived neural stem cells. With this in mind, it can be assumed that numerous other chemokines and their receptors will be found to play an important role in regulating NPC function, similar to CXCR4.

15.6 Growth Factors and Neurogenesis

Numerous growth factors regulate neurogenesis in the CNS and are valuable tools in the maintenance and differentiation of NPCs in culture. Ciliary neurotrophic factor (CNTF) released by astrocytes promotes proliferation of NPCs (Emsley and Hagg 2003). Vascular endothelial growth factor (VEGF) in the subventricular zone (SVZ) promotes survival, differentiation, and release of brain-derived neurotrophic factor (BDNF), which will be discussed in detail in Sect. 6.2 (Hagg 2005; Louissaint et al. 2002). Insulin-like growth factor (IGF) produced endogenously in the brain and from circulating blood stimulates proliferation and differentiation of NPCs to a neuronal lineage (Anderson et al. 2002). Transforming growth factor (TGF α) produced by astrocytes promotes proliferation by the activation of epidermal growth factor (EGF) receptor (Hagg 2005; Enwere et al. 2004). Glial-derived neurotrophic factor (GDNF) has been shown

to promote survival of dopaminergic neurons in culture (Nakajima et al. 2001). Platelet-derived growth factor (PDGF) may contribute to survival, differentiation, and migration of NPCs (Kwon 2002). Nerve growth factor (NGF) promotes survival and differentiation (Plendl et al. 1999). Although numerous growth factors are significant in neurogenesis, this section will focus on three growth factors: EGF, basic fibroblast growth factor (bFGF), and BDNF.

15.6.1 Epidermal Growth Factor and Basic Fibroblast Growth Factor

EGF and bFGF regulate survival, proliferation, and differentiation of NPCs. Regeneration of neurons after ischemic brain injury in rats was significantly increased by infusion of EGF and bFGF (Nakatomi et al. 2002). NPC culture systems use EGF and bFGF to maintain the cell pool by increasing proliferation and survival and by preventing differentiation. After NPCs are stimulated to differentiate into neurons, EGF has neurotrophic properties on the newly forming neurons to promote survival. EGF collaborates with sonic hedgehog (SHH) and non-amyloidogenic amyloid precursor protein to promote proliferation (Hagg 2005; Machold et al. 2003; Palma et al. 2005; Caille et al. 2004).

15.6.2 Brain-Derived Neurotrophic Factor

Brain-derived neurotrophic factor (BDNF) promotes survival and differentiation of NPCs to a neuronal lineage (Hagg 2005; Mattson et al. 2004). Infusion of BDNF into the brain of rats has been shown to have antidepressant-like properties, as demonstrated by the learned helplessness test and forced swim test (Siuciak et al. 1997). The antidepressant-like activity may be the result of BDNF-stimulated increase in survival and differentiation of NPCs to neurons in the hippocampus. This is supported by the finding that BDNF infusion into the lateral ventricle increases the number of newly generated neurons in various regions of the rat brain (Pencea et al. 2001). Neurodegenerative disorders like bacterial meningitis may cause an increase in BDNF levels, which correlates with an increase in neurogenesis (Tauber et al. 2005). These support the idea that BDNF is a crucial factor in the regulation of neurogenesis, specifically for persuading NPC cultures to differentiate into neurons. BDNF can come from multiple sources, including but not limited to astrocytes, vascular endothelial cells, neurons, and NPCs. Other growth factors, hormones, and neurotransmitters may use BDNF as a downstream factor to regulate neurogenesis. BDNF expression in astrocytes can be increased by noradrenaline, serotonin, and glutamate (Zafra et al. 1992; Mattson et al. 2004). Testosterone increases the expression of VEGF, which then

stimulates release of BDNF (Hagg 2005; Palmer et al. 2000). Another regulator of BDNF is nitric oxide production by NPCs, which can act in a positive feedback loop with BDNF to shift NPCs from proliferation to differentiation (Cheng et al. 2003).

15.7 The Role of Neurotransmitters in the Regulation of Neurogenesis

Neurotransmitters such as acetylcholine (Mohapel et al. 2005; Harrist et al. 2004; Paez-Gonzalez et al. 2014), dopamine (Hoglinger et al. 2004; Baker et al. 2004; Van Kampen and Robertson 2005), serotonin (Banasr et al. 2004), norepinephrine (Kulkarni et al. 2002), GABA (Wang et al. 2005; Bolteus and Bordey 2004; Overstreet Wadiche et al. 2005), and glutamate (Kitamura et al. 2003; Luk et al. 2003; Brazel et al. 2005), contribute to the regulation of neurogenesis in the dentate gyrus (DG) and the subventricular zone (SVZ) of the lateral ventricles. These neurotransmitters regulate proliferation, differentiation, migration, survival, and synaptic plasticity.

15.7.1 Dopamine in Neurogenesis

Dopamine projections from the midbrain innervate the SVZ and have been shown to promote proliferation and differentiation through the activation of dopamine D2 and D3 receptors (Hagg 2005; Van Kampen and Robertson 2005; Hoglinger et al. 2004; Baker et al. 2004); however, other evidence suggests that activation of D3 receptors does not affect neurogenesis and D2 receptor activation may inhibit neurogenesis (Baker et al. 2005; Kippin et al. 2005). These apparent contradictions reflect the fact that neurogenesis is complex and is dependent on balance among signals that simulate and inhibit neurogenesis (Hagg 2005). Specific D3 activation stimulated proliferation and showed preferential differentiation to neuronal phenotype (Van Kampen and Robertson 2005; Van Kampen et al. 2004), and dopamine D3 activation has been shown to have neuroprotective effects (Carvey et al. 2001; Anderson et al. 2001; Vu et al. 2000).

15.7.2 Serotonin in Neurogenesis

Serotonin projections innervating the SVZ and DG have been shown to influence proliferation and survival (Simpson et al. 1998; Banasr et al. 2004). Serotonin stimulation of 5-HT_{1a} receptors enhances NPC proliferation and increases levels of BDNF, which promotes survival and stimulates differentiation of NPCs to a neuronal lineage (Hagg 2005; Banasr et al. 2004; Mattson et al. 2004).

15.7.3 Norepinephrine in Neurogenesis

Norepinephrine has been shown to influence proliferation, but it has not been shown to affect survival or differentiation in the DG (Kulkarni et al. 2002). Adrenergic receptors are abundant in the CNS; however, their significance in neurogenesis has not been well established.

15.7.4 GABA in Neurogenesis

Maturing neurons receive GABAergic input for 1–2 weeks before they form glutamatergic synapses (Overstreet Wadiche et al. 2005). GABA contributes to the stimulation of proliferation, migration, and neurite outgrowth (Bolteus and Bordey 2004; Owens and Kriegstein 2002). GABA is essential for the maturation of neurons and formation of functional synapses. GABA's role is not simply the creation of new neurons, but also the formation of functional synapses that ultimately lead to repair or improved neurological function.

15.7.5 Glutamate in Neurogenesis

Glutamate is the primary excitatory neurotransmitter in the mammalian CNS, where it has been shown to mediate synaptic transmission, synaptic plasticity, neuronal toxicity, and proliferation and differentiation of NPCs (Dingledine et al. 1999; Arundine and Tymianski 2004). During many neurodegenerative disorders, extracellular glutamate levels are increased in the CNS. This increased glutamate leads to excitotoxicity of neurons, but some of the negative effects may be counterbalanced by increasing neurogenesis and activation of survival pathways in select cells, including NPCs. Glutamate acts on several receptor types, which are classified into “metabotropic” and three “ionotropic” groups: kainate, *N*-methyl-D-aspartate (NMDA), and α -amino-3hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors (Hollmann and Heinemann 1994; Pin and Duvoisin 1995; Monaghan et al. 1989). Metabotropic glutamate receptors are GPCRs whose activation leads to release of Ca²⁺ from intracellular stores or inhibition of adenylyl cyclase (Pin and Duvoisin 1995). Ionotropic receptors are ion channels that open upon binding of glutamate, leading to the influx of sodium and/or calcium and the efflux of potassium, resulting in changes in membrane potential and diverse cellular processes (Arundine and Tymianski 2004).

NMDA receptor antagonist reduced proliferation of striatal neurons, demonstrating that NMDA receptor activation may induce proliferation (Sadikot et al. 1998; Luk et al. 2003). The metabotropic glutamate receptor subtype, mGluR5, is expressed early in development in

regions of active proliferation, suggesting that mGluR5 may play a role in proliferation and/or differentiation (Di Giorgi Gerevini et al. 2004).

Numerous studies have shown beneficial effects to neurogenesis by activating and/or potentiating AMPA receptors. By decreasing the rate of desensitization of AMPA receptors, proliferation of NPCs increases in rat hippocampus (Bai et al. 2003). Multiple mechanisms have been suggested to explain this AMPA receptor-mediated neurogenesis. The increased expression of genes that stimulate proliferation and/or differentiation is one possible method for AMPA-mediated neurogenesis. Activation of AMPA receptors leads to increased expression of immediate early genes, such as: NGFI-A, c-fos, c-jun, and jun-b in oligodendrocyte progenitors (Pende et al. 1994).

Potentiation of AMPA receptors can also increase BDNF expression in the rat hippocampus, especially in the dentate gyrus (Mackowiak et al. 2002). AMPA receptor activation can lead to upregulation of BDNF in a calcium-dependent and calcium-independent manner. Calcium can bind to calcium response elements on the BDNF promoter, resulting in increased BDNF transcription. Also, AMPA receptors can physically associate with the tyrosine kinase Lyn. Lyn activation through AMPA receptors can stimulate mitogen-activated protein kinases (MAPK), leading to increased BDNF expression (O'Neill et al. 2004). As previously described, BDNF promotes survival and differentiation of NPCs to a neuronal lineage (Hagg 2005; Mattson et al. 2004).

15.7.6 Interaction of Neurotransmitters in Neurogenesis

One factor for the creation of the SVZ and DG niches for NPCs and neurogenesis could be the overlap of neurotransmitter systems in these two areas (Hagg 2005; Simpson et al. 1998). Serotonergic and dopaminergic projections converge almost exclusively over the SVZ. Similarly, serotonergic and norepinephrinergic projections congregate over the DG (Hagg 2005). None of these neurotransmitters may be sufficient to stimulate neurogenesis on its own; rather, it is the multitude of neurotransmitters, growth factors, and chemokines that combine to create the niche for NPCs and to stimulate successful neurogenesis.

15.8 Brain Inflammation and Neurogenesis

Previously, the brain was thought to be an immune-privileged organ. Now it is clear that the brain does respond to peripheral inflammatory stimuli through both neural and humoral afferent signals. The concept that the microglia act as the brain's immune system has also become widely accepted.

The inflammatory responses in the brain have different features from those of non-neuronal tissues. Microglia activation and elevated levels of cytokines and adhesion molecules are hallmarks of CNS inflammation (Matyszak 1998).

The likely role of immune cells in regulating neurogenesis is of great interest. Their effects may depend on the timing, dynamics and severity of the inflammation. On the positive side, it has been suggested that the immune system may be protective and even assist regeneration; microglia (Streit 2002) and macrophages (Rapalino et al. 1998) have been shown to facilitate tissue repair after CNS injury. On the negative side, the immune system may also cause "bystander damage" in the inflamed brain. The limited regeneration capacity and extreme vulnerability of CNS neurons to inflammatory conditions make the inflamed CNS a hostile environment for neurogenesis. Pharmacologic approaches to control neurogenesis and/or neuroinflammation are likely to become important areas of research for treatment of CNS injury and neurodegeneration (Whitney et al. 2009; Borsini et al. 2015).

15.8.1 Inflammation Can Suppress Neurogenesis

Accumulating evidence suggests that brain inflammation plays an important role in the pathogenesis of chronic neurodegenerative disease such as Alzheimer's disease, Parkinson's disease and multiple sclerosis (Marchetti and Abbracchio 2005). Acute brain injury from stroke and status epilepticus is also linked to inflammation. Although it has been reported that these insults trigger increased neurogenesis in the subgranular zone of the dentate gyrus, it has also been shown that newly formed dentate neurons were severely lost, which may be associated with brain inflammation. Arvidsson et al. showed that more than 80% of new striatal neurons that are generated from the subventricular zone after stroke in rats die within the first week after the insult (Arvidsson et al. 2002). Systemic inflammation triggered by peripheral infection can cause activation of microglia in the brain of Alzheimer's disease patients, leading to aggravation of the cognition decline. Epidemiological studies suggest that patients on long-term anti-inflammatory treatments have a significantly reduced risk of Alzheimer's disease (Zandi and Breitner 2001).

An invariant feature of damage to the CNS is the migration of microglia to the site of injury and their subsequent activation. However, the specific role of microglia in neurogenesis is still controversial. The activation of microglia can result in either neuroprotective or neurotoxic effects, or both. Previous studies have indicated that microglia are capable of secreting neurotrophic survival factors upon activation, and they can direct neural precursor cell migration and differentiation

(Kim 2005). Yet several publications (Ekdahl et al. 2003; Monje et al. 2003; Hoehn et al. 2005) report pathogenic roles of microglia on neurogenesis, as well as strengthening the traditional view that immune cells in the CNS have an adverse effect on neurogenesis. In lipopolysaccharide-induced inflammation of the rat CNS, basal hippocampal neurogenesis is strongly impaired and the increased neurogenesis triggered by this brain insult is also attenuated. This impairment is associated with microglial activation. Activated microglia were localized in close proximity to the newly formed cells, and the impairment of neurogenesis depended on the degree of microglia activation. Systemic administration of the microglial activation inhibitor minocycline effectively restored neurogenesis, presumably by suppressing inflammation without affecting neurogenesis (Ekdahl et al. 2003).

Using a coculture system, Monje et al. found that activated, but not resting microglia, decreased the differentiation of NPCs to approximately half of control levels. Furthermore, in vivo models of acute and chronic inflammation also demonstrated that inflammation itself suppresses neurogenesis. Neurogenesis and activated microglia show a striking negative correlation, and decreased microglial activation by inflammatory blockade with the nonsteroidal anti-inflammatory drug indomethacin likely accounts for part of its restoration of neurogenesis (Monje et al. 2003). The deleterious effect of activated microglia on neurogenesis is most likely mediated through the action of various factors, such as IL-1 β or IL-6, TNF α , IFN- γ , NO, and reactive oxygen species; all of these factors can be released from microglia and are neurotoxic in vitro (Hoehn et al. 2005). For example, during inflammation, NO is released by microglia and astrocytes at pathological levels via induction of inducible nitric oxide synthase (Bo et al. 1994). Exposure of NO to SVZ NSCs as well as human NSCs has presented a detrimental outcome to neurogenesis while still activating gliogenesis. However, NO has also been shown to promote NSC self-renewal by up-regulating neuron restrictive silencer factor/RE1-silencing transcription factor (NRSF/REST) (Bergsland et al. 2014). The role of NRSF/REST is to maintain the pool of NSCs by repressing neural genes. When homeostasis is lost and NRSF/REST is up-regulated, NSC differentiation is inhibited, leading to diminished neurogenesis (Gao et al. 2011). Therefore, inflammatory response can lead to the inhibition of neurogenesis by pathological upregulation of NRSF/REST (Perez Estrada et al. 2014).

When human neural stem cells were transplanted into the ischemic cortex of rats after distal middle cerebral artery occlusion, transplanted stem cells survived robustly in naive and ischemic brains 4 weeks post-transplant. Survival was influenced by proximity of the graft to the stroke lesion and was negatively correlated with the number of IB4-positive inflammatory cells. The negative correlation of cell survival to lesion size and IB4-positive cells suggests that

inflammatory cytokines are detrimental to be the transplanted cells, in accordance with other studies (Arvidsson et al. 2002). Given that the magnitude of the inflammatory response and the types of cytokines present change with time after ischemia, these data imply that the timing of stem cell transplant could significantly influence cell survival, with greater survival predicted if cells are transplanted after inflammation has subsided (Kelly et al. 2004).

15.8.2 Proregenerative Role of Microglia and Brain Immunity

Microglia have unique characteristic of being both supportive glia and immunocompetent defense cells. Many observations strongly support a neuroprotective and proregenerative role of microglia in the injured CNS. In the facial nerve axotomy model of neuron-microglia interaction and neural regeneration (Streit 2002), microglial cells are found to contact the membrane of neurons that will not undergo apoptosis and will eventually regenerate their axons. Their data suggested that microglia may somehow orchestrate the recovery of these cells by assuming a protective role. Microglia activation after brain injury can also benefit regeneration through the release of neurotrophic molecules and some cytokines.

Schwartz and colleagues bring forward a concept of protective autoimmunity (Moalem et al. 1999). Although an uncontrolled immune response impairs neuronal survival and neurogenesis, a local immune response that is properly controlled can support survival and promote recovery. The immune response that causes cell loss under neurodegenerative conditions also blocks neurogenesis in the adult CNS, while the immune response that protects against cell loss also support neurogenesis (Schwartz 2003).

The mechanisms by which inflammation regulates neurogenesis remain inconclusive. Recently, investigators have begun to dissect out detrimental aspects of the immune system that may be responsible for unnecessary tissue loss and restrictions on axonal regeneration. Early inhibition of TNF or TGF- β 2 significantly decreases scarring and tissue loss, and can lead to improvement in functional outcome after CNS injury (Brewer et al. 1999; Logan et al. 1999). Further investigation of the roles of individual inflammatory factors, growth factors and neurotransmitters in neurogenesis will help to shed light on this important research field.

15.9 Induced Pluripotency and Induced Neural Stem Cells

Because specific neuronal subtypes are irreversibly lost during neurodegenerative diseases, the use of stem cells for cell replacement treatment known as cell therapy has become a

large focus within the research community. The development of iPSCs represents a breakthrough in broadening the feasible cell source for cell therapy. iPSCs were developed by introducing pluripotent associated genes or reprogramming factors into a given cell type, typically somatic cells. To convert these cells, four reprogramming transcription factors were initially used, including Oct4, Sox2, c-Myc, and Klf4, which are commonly referred to as the Yamanaka factors (Takahashi and Yamanaka 2006). These four transcription factors were originally identified for their ability to maintain pluripotency in the development of ES cells. The expression of these transcription factors, through a retrovirus gene delivery system, induces the pluripotency in adult somatic cells. Generating iPSCs through reprogramming strategies avoids the need to destroy embryos for ES cells. Therefore, iPSCs techniques have become a promising alternative strategy for regenerative medicine.

iPSCs and ES cells maintain pivotal features of pluripotency through a network of gene expressions systems and genome wide histone complex modifications (Guenther et al. 2010). There has been active research to use the pluripotency of iPSCs in preclinical animal models and future patient therapy models. In early models, low frequency of reprogramming yielded less than 1 % of somatic cell transformation into iPSCs. Possible reprogramming efficiency issues could be related to expressions levels as well as timing of reprogramming genes (Takahashi and Yamanaka 2006). Avenues to improve reprogramming efficiency toward pluripotency have been explored. For example, the inhibition of Mdb3, a subunit of a nucleosome remodeling and deacetylation (NuRD) complex which is responsible for silencing embryonic stem cell marker genes, has shown to increase reprogramming efficiency while promoting pluripotent stem cells differentiation (Luo et al. 2013). Investigations on epigenetic changes from source somatic cells to iPSCs have identified different combinations of transcription factor(s) for reprogramming (Kim et al. 2009). It is important to note that molecular mechanisms for epigenetic changes of somatic cells into pluripotent states remain unknown. In addition, progenitor cells have been found within fibroblast cultures, cautioning the result of iPSCs from pre-existing progenitor cells.

Somatic reprogramming with transcription factors has been scrutinized for the use of oncogenes. Investigations on the Yamanaka factors have shown that many transcription factors are dispensable when other oncogenes are used. Different sets of transcription factors have shown a reduction in the amount of immature progenitors, improvement of self-renewal, and reduction of allotted time for both proliferation and differentiation; these transcription factors often include Sox2, FoxG1, and Brn2 (Lujan et al. 2012). It is noteworthy that none of these cocktails is free from viral (retroviral and lentiviral) infection systems. The viral vectors may increase the tumorigenicity of iPSCs. Interestingly, increase in efficiency and yield can be achieved through the infection

expressing short hairpin RNA against p53, known as a cellular tumor antigen (Marion et al. 2009). Because Klf4 was previously found to repress p53, the indispensable role of Klf4 on iPSCs generation may be through p53. Overall, tumorigenicity represents the most pressing challenge for the clinical application of iPSCs. To avoid cancerous complications, the new iPSCs generation strategies require reduction of reprogramming transcription factors as well as altering to the source of somatic cells. These new strategies sometimes circumvent the pluripotent state in favor for a direct reprogram to specific phenotypes (Ruggieri et al. 2014).

15.9.1 Induced Neural Stem Cells

Induced neural stem cells (iNSCs) bypass pluripotency to avoid pluripotency-derived complications. However, iNSCs are closer to the post-mitotic cells that have differentiated phenotypes, which may cause problems with cellular proliferation. This has been addressed by using similar reprogramming transcription factors (Oct4, Sox2, Klf4, c-Myc) under different overexpression cultural conditions; iPSC states can be bypassed to direct neural identity (Han et al. 2011). To accumulate large differentiated cultures, patient-specific fibroblast extractions could be utilized and then transformed directly into neural fated stem cells. These iNSCs hold intrinsic potential to differentiate into various lineages such as astrocytes, oligodendrocytes, as well as other neural subtypes. However, since the mechanism behind the differentiation is relatively unknown, direct reprogramming of patient neurodegenerative insults may face numerous challenges. As such, iNPCs with restricted neural identity may be better suited for clinical application (Smith et al., Progress in Neurobiology, In Press).

Comparatively, cultivation of iNPCs opposed to iPSCs, using the four identical iPSC reprogramming factors and a doxycycline induced system, takes 11–12 days from induction to obtain sufficient Pax6+ colonies with similar efficiency. Neuronal markers indicated that transdifferentiation of iNPCs followed a parallel pathway as pluripotent cells (Kim et al. 2011). To explain heterogeneous fates of these induced cells, it has been hypothesized that even though iNPCs were negative for pluripotent markers, they still enter a pluripotent pathway undetectable with current technological means during differentiation. It is possible that cultured iNPCs proliferate in growth factors that promote intermediate progenitors with pluripotency (Ruggieri et al. 2014).

Specific application of transcriptional factors during regulating stages of inductions is able to change the cell lineage and efficacy (Tian et al. 2012). Generation of self-renewal iNPCs has implicated the roles of neuronal specific transcription factors such as FoxG1 and Sox2. FoxG1 and Sox2 are able to reprogram somatic cells into neural precursor states, highlighting the importance of these factors in achieving NPC states. Sox2, first thought as a dispensable factor,

has been shown to be essential for neuronal maturity in a reprogramming system. In the absence of Sox2, FoxG1 and Brn2 will promote differentiation of NPCs into multiple neural lineages but lack maturity (Ruggieri et al. 2014).

It is possible to achieve multipotent NSCs through the direct reprogramming of mice fibroblast cells. Both in vitro and in vivo studies show increase of transdifferentiation efficiency with the help of continued research of molecular mechanistic of pluripotent pathways, using combination of culture stem cells with neural progenitors (Han et al. 2012) or limit expression of Oct4 while regulating Sox2 (Thier et al. 2012). However, these both rely on viral infection system, which are not applicable for clinical treatment of patients. While still addressing the issue of efficiency from proliferation and differentiation, studies have indicated the possibility of reprogramming through messenger RNA to avoid innate antiviral responses. RNA-induced pluripotent stem cells exhibit similar identity of ES cells making them a possible alternative (Warren et al. 2010). Even with similar plasticity, before entering patient treatment, reduction of time between induction and cultivation increase in efficiency yields will have to continue to improve.

15.10 Stem Cell and Neuronal Repair During Brain Injury and Neurodegenerative Disorders

A variety of insults have been shown to be induce neurogenesis within the adult brain (Parent 2003), either in regions that have known neurogenic activity, or even in regions where neurogenesis normally does not occur (Yamamoto et al. 2001).

Damage induced by mechanical injury, prolonged seizures, trauma or stroke increases dentate gyrus cell proliferation, where a majority of the newly generated cells differentiate into granule neurons (Parent 2003). It also has been shown that progenitor cells are capable of proliferation and differentiation into mature myelinating oligodendrocytes in models of acute demyelination (Gensert and Goldman 1997). In various animal models of seizure, such as kainate and pilocarpine models of temporal lobe epilepsy, chemoconvulsant-induced status epilepticus, or electrical kindling models of epileptogenesis, increased dentate granule cell neurogenesis has been observed after stimulation (Parent 2003). Roles in other specific diseases are elaborated below.

15.10.1 Huntington's and Alzheimer's Diseases

Increased neurogenesis has been reported in patients with Huntington's disease and Alzheimer's disease (Jin et al. 2004; Curtis et al. 2003). Compared to control patients,

Alzheimer's disease brains showed increased expression of the immature neuronal marker doublecortin and the early neuronal differentiation protein TUC-4. Expression of doublecortin and TUC-4 was associated with neurons in the dentate gyrus, the physiological destination of these neurons, and in the CA1 region, which is the principal site of hippocampal pathology in Alzheimer's disease. Previously, it has been shown that (Jin et al. 2004) enhanced neurogenesis in Alzheimer's disease transgenic mice, in contrast to other reports (Haughey et al. 2002; Wen et al. 2002). Following those reports, it has been shown that induction of astrocytes in transgenic mice with Neurod-1 encoding retrovirus transformed reactive astrocytes and N2 glia into synaptic responsive neurons. Interesting, reactive astrocytes favored conversion to excitatory glutamatergic neurons, while N2 glia favored heterogeneous conversion to glutamatergic and GABAergic neurons (Guo et al. 2014). This demonstrates the possibility of recovery of neural networks in onset Alzheimer's disease neurodegeneration (Smith et al., Progress in Neurobiology, New Press). Similarly, there is a significant increase in cell proliferation in human subependymal layer in response to neurodegeneration of the caudate nucleus of Huntington's patients compared with control brain. These findings indicate that neuron damage or loss can trigger neurogenesis, and this may represent a mechanism directed toward the replacement of dead or damaged neurons.

15.10.2 Cerebral Ischemia

Recent findings in rodents show that cerebral ischemia is another injury model that stimulates neurogenesis in adult brain. There is evidence that the proliferating cells found after ischemia are NPCs (Yagita et al. 2001). Ischemia can lead to the proliferation of newborn cells that migrate into the zone of ischemic injury, differentiate, and express markers of mature striatal neurons (Arvidsson et al. 2002). In general, global cerebral ischemia induces neurogenesis in the dentate gyrus, whereas focal cerebral ischemia additionally increases new neurons in the SVZ (Zhang et al. 2005). Stroke selectively and significantly increases the number of type A and type C cells, which are more actively proliferating neural stem cells. Infusion with the antimetabolic agent cytosine-arabino-furanoside to the brain almost completely ablates type A and type C cells in the ischemic subventricular zone, thus indicating that neural stem cells contribute to cerebral ischemia-induced neurogenesis (Chen et al. 2004). In a middle cerebral artery occlusion ischemia model, BrdU labeling was increased in the ipsilateral SVZ and rostral migratory stream, indicating directed migration of neural progenitors toward the infarct area from their sites of origin.

15.10.3 Parkinson's Disease

In contrast to cerebral ischemia, Alzheimer's disease and Huntington's disease, which have clear evidence of increased neurogenesis, the question of whether adult brain generates new dopamine neurons is still controversial. Using confocal laser scanning microscope, Zhao et al. found dopaminergic neurons with BrdU-positive nuclei in the substantia nigra (Zhao et al. 2003). But a different conclusion was reported in another study (Frielingsdorf et al. 2004). Kay and Blum also reported the presence of BrdU-positive proliferative cells in the substantia nigra. Some of cells were identified as microglia, and none of them differentiated into dopaminergic neurons (Kay and Blum 2000). Another study (Yoshimi et al. 2005) revealed lack of neurogenesis of TH-positive neurons from proliferative stem cells in the substantia nigra. Most recently, α -Synuclein has been identified for its role in neuroinflammation as well as impairment to nerve repair process in Parkinson's disease. Fan et al. reproduced a transgenic mice model using A53T mutant α -synuclein as well as a caspase-1 knockout model to identify the mechanism of inflammasome related impairment of subventricular zone neurogenesis in mice. Stereotactic injections of microRNA-7 inhibited Nlrp3 inflammasome activation, which lead to improved neurogenesis in the SVZ (Fan et al. 2015). While much is still unknown about α -syn inflammasome mechanism, it has provided a gateway for possible treatment by way of enabling neurogenesis.

15.10.4 Mechanisms of Injury Induced Neurogenesis

The mechanisms that underlie the injury-induced neurogenesis mostly remain unclear. Growth factors and neurotrophic factors are likely candidates. In the case of forebrain ischemia, it has been shown that expression of bFGF and BDNF increase after injury. Normal neurodevelopment is guided by the spatial and temporal expression of trophic and growth factors, so these factors may represent the brain's attempt to protect injured neurons by activating developmental programs. In addition to protecting neurons, trophic and growth factors have also been shown to stimulate proliferation of adult neural stem cells and to direct their differentiation (Pencea et al. 2001; Aberg et al. 2000).

Activated glial cells can direct ischemia-induced neurogenesis. Astrocytes are implicated in the regulation of adult neurogenesis in various settings (Song et al. 2002). Microglia activated during inflammation can be a source of trophic factors and chemokines that influence endogenous stem cell behavior. Endothelial cells are another source of neurotrophic factors, including VEGF, BDNF, bFGF and chemokines that promote the survival and migration of

NSCs. Palmer et al. investigated the relationship of angiogenesis and neurogenesis and referred to the survival coupling of neuroblasts and endothelial cells as the "vascular niche" (Palmer et al. 2000). Treatment with VEGF 24 hours after stroke enhances angiogenesis and neurogenesis, indicating that VEGF plays an important role in brain repair (Zhang et al. 2000).

15.10.5 Functional Significance of Neurogenesis After Injury

Stem cells within the adult brain can be stimulated to replace damaged neurons (as illustrated in Fig. 15.3). Important questions remain: do these newly formed neurons in the adult brain establish appropriate synaptic connections and are they functionally integrated into the existed network? It is still uncertain to what extent neurogenesis contributes to functional recovery. Newly born neurons can establish synaptic contacts and are electrophysiologically functional (van Praag et al. 2002; Carlen et al. 2002). When neurogenesis was blocked, mice exhibited an impaired performance of a hippocampus-dependent memory task, suggesting that the newly born neurons are involved in the formation of certain types of memories (Shors et al. 2001). Using ionizing radiation to decrease neural regeneration after global ischemia, Raber et al. demonstrated that reduction of neurogenesis reduces functional recovery (Raber et al. 2004). Consistent with these data, Stilley et al. reported that transplantation of neuronal cells enhanced cognitive function in patients with basal ganglia stroke (Stilley et al. 2004).

An elaborate study by Ramer et al. finally documented a functional regeneration of sensory axon (Ramer et al. 2000). Not only were specific behavioral tests corresponding to the regenerated fiber phenotypes used, but they also confirmed their findings by re-injury of the regenerated fibers to demonstrate their capability for participation in functional recovery.

15.11 Neural Stem Cells and Their Potential Role in Transplant Therapy for Neurodegenerative Disorders

The use of stem cells to generate replacement tissues for treating neurological diseases is a major focus of stem cell research. Spinal cord injury, stroke, multiple sclerosis, Parkinson's disease, Huntington's disease, amyotrophic lateral sclerosis and Alzheimer's disease would benefit from replacing destroyed or dysfunctional cells in the brain or spinal cord. The potential of several promising cell types to serve as an effective transplant has been evaluated in terms of

Fig. 15.3 A proposed mechanism for the simulation of neurogenesis during brain injury and neurodegenerative disorders. During neuronal injury, neurons produce chemokines, which recruit mononuclear phagocytes (MP) into the brain and to the site of injury. As these MP enter an environment of injury or inflammation, they become activated, subsequently releasing factors that might promote neurogenesis. These factors include but are not limited to neurotrophins, which may act directly to enhance the survival and proliferation of NPCs, and cyto-

kines that might activate astrocytes. These activated astrocytes produce chemokines that could promote the migration of NPCs to the site of injury and they can release neurotrophins that can promote neuronal survival. Once the NPCs receive these migratory and neurotrophic signals, the NPCs can migrate, proliferate, and differentiate into neuronal or astrocyte precursors, which then mature into neurons and astrocytes that may integrate into the CNS circuitry

the cell's ability to survive, differentiate, and migrate in an inflammatory milieu of the adult CNS (Magnus and Rao 2005). Many different cell types, including mesenchymal stem cells (Andre et al. 2016), neural stem cells, precursors, and embryonic stem cells, have been suggested as candidate cells for therapy (Rao and Mayer-Proschel 2000). In recent years, in vitro and in vivo stem cells transplantation studies were performed in cellular models, animal models including non-human primate model which has demonstrated the value of pre-clinical modeling with iPSCs and highlighted the feasibility of therapeutic neuron transplantation (Nguyen et al. 2011; Jiang et al. 2012; Liu et al. 2012; Hallett et al. 2015). Several neurological disorders that show some progress in stem cell therapy are discussed below.

15.11.1 Stem Cells for Transplant Therapy

Embryonic stem cells can proliferate indefinitely and under certain condition they can differentiate to neurons and glia in the laboratory. Even though they hold the promise of being able to repair or replace cells or tissues that are damaged or destroyed in neurodegenerative disorders, transplantation of embryonic stem cells is not feasible. The lines of unaltered human embryonic stem cells that exist will not be suitable for direct use in patients. These cells will need to be differentiated or otherwise modified before they can be used clinically. Simply injecting freshly isolated stem cells into the patient would lead to the formation of teratomas, as it occurs when stem cells are injected into mice. These current problems

have led researchers away from embryonic stem cells and towards NSCs harvested from various somatic locations.

NSCs isolated from fetal nervous tissue have the potential to differentiate into all types of nervous system cells, including neurons, oligodendrocytes, and astrocytes, so NSCs also have the capacity to replace damaged tissue in both the CNS and PNS. NSCs will restore functional neurons and glia and regenerate injured tissue. It is this characteristic of neural stem cells that makes them a potentially valuable transplantation material in a host of disorders.

Although adult neural stem cells might provide medical solutions that avoid the ethical and legal problems of cloning and fetal stem cell approaches, the limiting factor for the use of adult stem cells in future cell-replacement strategies is that there are insufficient numbers of cells available for transplantation. Previously, proliferation, as well as differentiation, presented low yields of unspecialized states that could not be properly directed to neuronal fates. New data on the plasticity of adult stem cells are very encouraging. Several studies have shown that adult stem cells from various organs have the plasticity to differentiate not only into their original source tissue, but also into cells of unrelated tissue. A clear example of such plasticity is mesenchymal stem cells (MSCs, Table 15.2).

MSCs include bone marrow derived MSCs (BM-MSCs) and human umbilical cord derived MSCs (hUC-MSCs). It is accepted that MSCs can differentiate into mature mesoderm cells such as bone, cartilage and fat (Pittenger et al. 1999). MSCs transplantation is applied well in the field of hematology, most often performed for patients with hematologic malignancies (Gong et al. 2012; Ball et al. 2007; Le Blanc and Ringden 2006). Some studies in vitro and in vivo reported that MSCs showed a minimum potential for trans-differentiation into neurons (Subbarao et al. 2015; Bossio et al. 2013). In addition, MSCs can inhibit the proliferation of T cells both in vitro and in vivo (Bowles et al. 2014; Kassis et al. 2008). Despite low differentiated efficacy into neurons,

MSCs transplantation has been performed in patients who suffered from neurological disorders such as multiple sclerosis and spinal cord injury in clinical trials, and almost all trials reported the safety and tolerability of MSCs, as well as stabilization/mild improvement of the disease (Diez-Tejedor et al. 2014; Qiao et al. 2014; Chen et al. 2014; Prasad et al. 2014; Frolov and Bryukhovetskiy 2012; Mendonca et al. 2014; Connick et al. 2012; Bonab et al. 2012; Li et al. 2014; Mancardi et al. 2015).

It has been demonstrated that somatic cells such as human fibroblasts can be directly converted to iPSCs and iNPCs by direct reprogramming (Liu et al. 2016; Colasante et al. 2015; Takahashi et al. 2007; Ring et al. 2012; Tian et al. 2012). With the development of direct reprogramming techniques, transplantations of iPSCs or iNPCs become attractive therapy approaches for various neurodegenerative diseases and brain injuries. iNPCs have the abilities to differentiate into region-specific and subtype-specific neurons. It has been reported that transplantations of iNPCs into the brain contribute to the improvement of the diseases in animal models (Kikuchi et al. 2011; Grealish et al. 2014; Hallett et al. 2015). As discussed in prior sections, low reprogramming efficacy needs to be overcome before clinical application.

15.11.2 Progress in Stem Cell Therapy in Neurological Disorders

15.11.2.1 Parkinson's Disease

Among all the CNS disorders, Parkinson's disease (PD) has the longest history of stem cell transplantation therapy. In Parkinson's disease, the loss of dopaminergic neurons in the substantia nigra is the major pathological change; thus, the major transplant therapeutic strategy has been to restore dopaminergic neurons by fetal tissue throughout the 1990s (Mehta et al. 1998; Dunnett and Bjorklund 1999; Lindvall et al. 1990). However, fetal tissue grafts showed short graft

Table 15.2 Stem cells-based therapies for neurological disorders

Stem cell types	Sources	Advantages for clinical treatment	Limitations
NSCs	Fetal brain	Low immunogenicity	Immune rejection
		Low tumorigenicity	Ethical issues
			Difficult to get enough cells
MSCs	Bone marrow	Low immunogenicity	Low differentiated efficacy into neurons
	Human umbilical cord blood	No ethical issues	Very limited source of hUCB-MSCs
iPSCs	Somatic cells	No immunogenicity	Tumorigenicity
		No ethical issues	Low reprogramming efficacy
		High capacity of pluripotency	Low differentiation efficacy into specific neurons
iNPCs	Somatic cells	No immunogenicity	Low reprogramming efficacy
		No ethical issues	
		Abilities to differentiate into region- and subtypes-specific neurons	

survival and limited integration of the grafts, which appeared to reduce the usefulness of fetal tissue. The use of stem cells has increased recently, since they appear to be far superior to fetal tissue grafts. Several groups have generated highly enriched populations of dopamine neurons from mesencephalic progenitors. Transplantation of expanded mesencephalic precursors resulted in spontaneous transformation into dopaminergic neurons, and functional recovery has been achieved in Parkinsonian rats (Studer et al. 1998; Sawamoto et al. 2001).

Since only limited numbers of NSCs can be purified from the midbrain, stem cells may be another candidate for transplantation in PD (Storch et al. 2004; Snyder and Olanow 2005). McKay's group first generated dopaminergic neurons from mouse embryonic stem cells, with greater enrichment achieved by mimicking the oxygen tension of the developing midbrain. When transplanted into 6-OHDA-lesioned rats, embryonic stem cell-derived dopamine neurons showed functional recovery in this dopamine-depleted animal model (Lee et al. 2000; Studer et al. 2000; Kim et al. 2002). Takagi et al. (2005) generated large numbers of dopaminergic neurons from monkey ES cells in vitro (Takagi et al. 2005). Behavioral studies and functional imaging revealed that the transplanted cells functioned as dopaminergic neurons and attenuated MPTP-induced neurological symptoms. Further in vitro study has shown that a minimal cocktail of transcription factors: ASCL1, NR4A2, and LMX1A are sufficient to convert mice and human fibroblasts into functional dopaminergic neuronal cells (Caiazzo et al. 2011). This same group has shown that this lentivirus system not only can develop induced dopaminergic neurons but they express normal action potentials and regular dopamine release within 21 days of transduction. This indicates possible high throughput screening applications (Theka et al. 2013).

To reach ultimate functional recovery in Parkinson's disease, transplanted dopaminergic neurons must survive, reinnervate the striatum, and integrate into the host nigrostriatal system. Many reports in recent years are encouraging, with advancements in co-transduction protocols such as ones with dominant negative TP53 lentivirus construct which have shown to improve transdifferentiation at least four-fold (Liu et al. 2014).

In 2014, hESCs-derived dopaminergic neurons were grafted in a rat model of PD successfully as a preclinical testing (Grealish et al. 2014). In addition, cynomolgus monkey iPSC-derived dopaminergic neurons were transplanted into the putamen of a non-human primate Parkinsonian brain (Hallett et al. 2015). These in vitro and in vivo studies highlighted the feasibility of stem cells therapy in PD and stem cell-based dopamine replacement therapies are close to clinical trials (Hargus et al. 2010; Kikuchi et al. 2011; Grealish et al. 2014; Hallett et al. 2015).

While the current research focuses on dopaminergic neurons, non-dopaminergic degeneration is also an important part of Parkinson's disease pathology. It remains to be established whether it is favorable to implant a pure population of dopaminergic neurons or whether the graft should also contain a specific mix of other neuron types and glial cells to induce maximum symptomatic relief.

15.11.2.2 Spinal Cord Injury

Spinal cord injury is associated with the loss of both neurons and glial cells; thus, stem cell-based therapy for reconstituting the injured spinal cord could be used to replace multiple cell types.

The extent of spinal cord injury depends on the severity of the initial trauma as well as the level of subsequent injury. The primary impact of contusion injury triggers a cascade of secondary events including hemorrhage, ischemia, excitotoxicity and inflammation, which lead to apoptotic neuronal and oligodendroglial death (Beattie et al. 2002). Transplantation will depend on a thorough understanding of the lesion environment and specific deficits associated with the individual injury. To maximize integration of transplanted cells, a variety of strategies such as reducing inflammation, inhibiting apoptosis of transplanted cells by in vitro preconditioning, and modifying the glial scar are being tested (Ramer et al. 2004).

The potential application of neural stem cells for spinal cord injury has been investigated by numerous studies. It has been reported that neural stem cells induced to neuronal differentiation by neurogenin-2 provided significant functional benefit following transplantation after contusion injury (Hofstetter et al. 2005). Further, undifferentiated cells can achieve the regional appropriate phenotype specification in response to local signals in exclusive niches (Gage 2000).

Embryonic stem cells also have been tested. Myelination in the injured spinal cord by implanted mouse embryonic stem cells was reported (Brustle et al. 1999). It has been reported that oligodendrocytes derived from human embryonic stem cells were able to myelinate demyelinated foci in spinal cord contusions (Nistor et al. 2005). The discovery of NG2-expressing progenitors within the spinal cord stirred the hope for using endogenous stem cells in spinal cord injury (Horner and Gage 2000). Recently, mesenchymal stem cells have been tested with an intrathecal cell delivery system, which has shown neurological improvements in clinical research. Further studies to increase efficacy of treatment are required (Derakhshanrad et al. 2015).

15.11.2.3 Other Diseases

Cholinergic neurons, the major site of degeneration in Alzheimer's disease and motor neuron disease, have become the target for cellular reprogramming in many in vivo experiments. Wu et al. demonstrate that a "priming" procedure,

which involves culturing the fetal human neural stem cells on laminin in the presence of a cocktail of bFGF and heparin *in vitro*, generates a nearly pure population of neurons after transplantation into adult rat brain. Furthermore, adult fibroblasts were induced with a combination of factors Neurog2 and Sox11 and high-efficiency small molecules, forskolin and dorsomorphin, to rapidly generated cholinergic neurons (Liu et al. 2013). Previously, stem cell-derived cholinergic neurons were found following implantation in regions that normally contain many cholinergic neurons, such as the spinal cord and medial septum, but were not seen in regions normally lacking these cells, such as the hippocampus and cortex. In contrast, the human neural stem cells that did not undergo *in vitro* priming produced primarily glia or undifferentiated cells following implantation (Wu et al. 2002).

Stem cell-based therapy for stroke will be more complicated, because the extensive cell death and massive inflammatory response make these brains a more hostile environment for cell grafts. Various sources of cells have

been tested for their ability to reconstruct the forebrain and improve function after transplantation in animal models of stroke (Lindvall et al. 2004). Further studies have shown to alleviate cerebral inflammation and neural degeneration by reducing intracerebral infiltrations in animal intracerebral hemorrhage models (Qin et al. 2015). In most cases, only a few grafted cells could survive. Some recent exciting findings in rodents suggest that stroke can induce an increase in neurogenesis; thus, a new therapeutic approach based on self-repair has been brought forth, as discussed in Sect. 11.1.

Clinical trials, such as those listed in Table 15.3, have entered a stage of using exogenous stem or progenitor cells to treat cerebral ischemic patients (George and Steinberg 2015). The strategies thus far have encouraging results, but much work is still required to achieve a better understanding therapeutic benefits. Taking advantage of treatments in terms of multiple cell injury pathways may be required to improve clinical results.

Table 15.3 Stem cells that have been trialed in neurological disorders

Reference(s)	Disease	Type of trial	Method	Number of patients	General outcome
Mancardi et al. (2015)	MS	Phase II trial	Autologous hematopoietic stem cells transplantation (AHSCT)	21	Improvement in reducing new T2 lesions, Gd+ lesions, as well as the annualized relapse rate. No improvement in the progression of disability
Li et al. (2014)	MS	Clinical trial	Human umbilical cord-derived mesenchymal stem cells (hUC-MSCs) transplantation	23	Improvement in the overall symptoms, the EDSS scores and relapse occurrence lower than those of the control patients
Bonab et al. (2012)	MS	Open label study	Autologous bone marrow derived mesenchymal stem cells (BM-MSCs) transplantation	25	Improvement/stabilization in the course of the disease in progressive MS in the first year after injection with no serious adverse effects
Connick et al. (2012)	MS	Open label phase IIa study	Autologous bone marrow derived mesenchymal stem cells (BM-MSCs) transplantation	10	Improvement in visual acuity and visual evoked response latency, with an increase in optic nerve area
Mendonca et al. (2014)	Chronic SCI	Phase I, non-controlled study	Autologous bone marrow mesenchymal stem cells (BM-MSCs) transplantation	14	Safe, feasible, and may promote neurological improvements
Frolov and Bryukhovetskiy (2012)	Chronic SCI	Clinical trial	Autologous hematopoietic stem cells transplantation (AHSCT)	20	Improvement in electrophysiology
Prasad et al. (2014)	Subacute ischemic stroke	Phase II, randomized trial	Autologous bone marrow mononuclear stem cells (BMSCs) transplantation	120	Safety, but no beneficial effect of treatment on stroke outcome
Chen et al. (2014)	Chronic ischemic stroke	Phase II study	Autologous peripheral blood stem cells (PBSCs) transplantation	30	Safe, feasible, and effective in improving functional outcome
Qiao et al. (2014)	Ischemic stroke	Clinical trial	Neural stem/progenitor cells (NSPCs) and mesenchymal stromal cells (MSCs) transplantation	8	Improvement in the neurological functions, disability levels, and daily living abilities of the patients
Diez-Tejedor et al. (2014)	Acute ischemic stroke	Phase II, double-blind pilot clinical trial	Allogeneic mesenchymal stem cells (MSCs) transplantation	20	Not reported

MS multiple sclerosis, SCI spinal cord injury

15.12 Future Directions in Neurogenesis for Neurodegenerative Disorders

Although current research still focuses on cell-based therapies by transplantation of exogenous stem cells or differentiated neurons for neurodegenerative disorders such as Parkinson's disease, Huntington's disease or amyotrophic lateral sclerosis, which all result from a loss of relatively defined phenotypes of cells, accumulating evidence indicates that endogenous neurogenesis may occur as part of an intrinsic brain self-repair process. This raises the possibility of developing therapeutic strategies based on activation of dormant capacities of endogenous neural stem cells.

15.12.1 Endogenous Adult Stem Cells as a Therapeutic Strategy

Recent evidence confirms the widespread occurrence of neural stem cells and the production of new neurons in many parts of adult brain. Although the regeneration of new neurons has been observed only at a very low frequency and can only replace a small fraction of neurons (Magavi et al. 2000; Fallon et al. 2000), these findings encourage work toward a therapeutic strategy based on neurogenesis, especially in neurodegenerative disease where persistent stimuli for neurogenesis exist or where additional stimulation and regulation are possible. For those neural injuries and neurodegenerative disorders that involve relatively broad areas and many types of neurons, this will be an especially attractive direction. With appropriate manipulation, perhaps many types of neurons that have been considered irreplaceable can be regenerated under the right circumstances (Kruger and Morrison 2002).

Distinct environmental cues may instruct endogenous progenitors to differentiate into specific neuronal subtypes depending on their locations. Adult stem cells can regenerate specific neuronal subtypes appropriate for the sites of damage. For example, targeted degeneration of corticothalamic neurons in the neocortex and dopaminergic neurons innervating the striatum has been shown to induce regeneration of the same cells types.

The strategy of manipulating endogenous stem cell for repairing relies on finding the appropriate factors and signaling molecules that help the patient's own stem cells survive and grow. Previous studies have shown that exogenous growth factors can increase the rate of neurogenesis in the adult brain and a certain combination of exogenous factors and endogenous stimulation may be necessary for boosting the regeneration of neurons at lesion sites (Weiss et al. 1996). By intraventricular infusion of growth factors, CA1 hippocampal pyramidal neurons that were lost to ischemic injury were remarkably regenerated by endogenous NPCs. These new neurons not only survived for a long period of time but

also established synaptic connections and showed functional contributions by ameliorating deficits in hippocampal-dependent spatial cognition in ischemic rat models (Nakatomi et al. 2002).

Although newly born neurons are able to project over relatively long distances to targets, questions remain about whether and how the projections incorporate into local circuits. Given the complexity of the adult brain network, it is no surprise that the synapses of newly born neurons remain immature and exhibited altered electrophysiological properties even 3 months after ischemia. Moreover, not all incorporation of new cells into the brain circuitry is beneficial (Nakatomi et al. 2002). For example, prolonged seizures lead to the generation of ectopic neurons or abnormal projections in the striatum and hippocampus, so abnormal neurogenesis may even worsen seizure damage by its pro-epileptogenic nature (Parent 2003).

While a growing number of studies report injury-induced enhancement of neurogenesis, in most cases endogenous stem cells are unable to replace neurons lost to injury. There is little evidence supporting a major role of endogenous neurogenesis to improve neural functions or slow disease progression in neurodegenerative disease. Indeed, although hippocampus is a known site of active neurogenesis throughout adulthood, newly generated cells beyond the dentate gyrus appear to be very limited (Rietze et al. 2000). Therefore, achieving functional neuronal regeneration is still a challenging task for neuroscientist. It is very important to understand how the brain microenvironment changes as a result of injury, and how stem cells respond to the spatial and temporal signals presented. The successful development of therapeutic applications based on endogenous neurogenesis will depend on our ability to manage the proliferation, migration, differentiation, and functional integration of recruited cells. Much work is still required to fulfill such a strategy.

15.12.2 Other Potential Therapeutic Value of NSCs

The potential therapeutic value of NSCs may be in their basic biology. NSCs are potent vehicles for gene therapy, so NSCs may be useful to carry copies of genes into tissue that will benefit the disease therapy. NSCs are migratory; thus, transplanted NSCs will migrate from the site of delivery to distant areas of active neurogenesis or to the damaged tissue, where they reconstruct both neural networks and glia support. Because NSCs will migrate to distant, multiple, and extensive regions of the nervous system, they may be useful in "global" degeneration, in which all or most of the nervous system is affected. In addition to regenerative capabilities, neural stem cells may have an immunoregulatory potential. Mesenchymal stem cells have been shown to inhibit effector

T-cell activities, reducing autoimmune inflammation of the CNS (Zappia et al. 2005). This immunoregulatory potential of mesenchymal stem cells suggests that NSCs may also possess similar properties. Indeed, transplanted NPCs and their NPC-derived secreted factors such as VEGF are powerful modulators of microglia activation, suggesting that NPCs regulate local immune response (Mosher et al. 2012). These immunoregulatory and trophic effects add to the therapeutic value of NSCs/NPCs.

Much of the biology of regeneration of nervous system tissue has yet to be discovered. Many of the factors that contribute to regeneration and/or that prevent it continue to be discovered. Although neurogenesis in adult brain is limited and may not be sufficient to achieve functional recovery after injury, understanding the mechanism of NPCs, iNPCs, and subtype-specific iNPCs is imperative to promote regeneration of damaged tissue.

15.13 Review Questions

1. What are the two criteria that must be fulfilled in order to identify a cell as a “stem cell”?
2. What is the difference between a stem cell and a progenitor cell?
3. Discuss the positive and negative effects inflammation has on neurogenesis.
4. List some of the roles of stromal cell-derived factor 1 (SDF-1/CXCL12) in CNS development and homeostasis.
5. What are the effects of brain-derived neurotrophic factor (BDNF) on NPCs?
6. List the processes that a neural stem cell must undergo to become a functional neuron.
7. Discuss the role of Notch signaling in regulating stem cell self-renewal versus differentiation.
8. Discuss the advantages and shortcomings of embryonic, fetal, and adult stem cells for transplantation therapies.
9. Discuss the benefits and problems associated with therapies using exogenous stem cells as compared to targeting endogenous stem cells to promote neurogenesis.
10. Discuss the advantages and shortcomings of induced pluripotent stem cells for transplantation therapies.

15.14 Answers

1. The cell must be able to self renew and differentiate into multiple lineages or cell types.
2. Stem cells are capable of self renewing indefinitely, whereas progenitor cells can only divide a limited number of times while retaining identical properties and differential capabilities as the parent cell. Alternatively,

a progenitor cell may be defined as a cell that can self renew, but can only differentiate into one cell type.

3. This area remains a controversial topic with no definite consensus. Many researchers have provided evidence that microglial activation and inflammation have both pro- and anti-neurogenic effects. It is possible that signals from damaged tissues or the factors causing injury would also be the signals that induce repair. This may be the case for acute damage, although, it is less likely that chronic, more widespread, or more severe damage will induce significant neurogenesis. Factors produced during severe inflammation may directly inhibit neurogenesis, or it may induce neurogenesis but provide a harsh environment that is detrimental for the survival of the newly developed neurons as well as existing neurons.
4. Stem and progenitor cell survival, mitogenesis, and migration; neuronal axon migration guidance; peripheral macrophage recruitment into the CNS.
5. Increased survival of NPC and directed differentiation to neurons; neuronal axon migration guidance.
6. The stem cell must migrate, proliferate, differentiate along the neuronal lineage, mature from a precursor to a fully functional neuron, integrate into the neuronal circuit, and survive.
7. Upon binding of a ligand to the Notch receptor, the intracellular portion of Notch is cleaved and translocates into the nucleus where it induces the transcription of genes that prevent differentiation. By preventing differentiation, Notch promotes self-renewal or quiescence.
8. The three cell types face the problem of possible rejection but immune suppression therapies may be used to overcome this. Embryonic stem cells are advantageous due to their great potential to expand their cell numbers and to differentiate into all the cells of the CNS. Embryonic stem cells have many problems, including ethical objections and limitations from society and government and the fact that embryonic stem cells will form teratomas if not differentiated prior to transplantation. Also, the embryonic stem cells currently approved for federal funding can never be used for human transplantation due to contamination by mouse feeder layers used in the earlier culture of these cells. Fetal stem cells can easily be isolated from aborted fetuses, expanded in culture, and transplanted in an undeveloped or fully differentiated state. These fetal stem cells still face the problem of ethical objections, although these objections may be less than the difficulties faced when using embryonic stem cells. Adult stem cells do not share the same ethical objection as do embryonic and fetal stem cells, but they are much more difficult to isolate and it is almost impossible to expand the cell number in culture and successfully direct their differentiation. Perhaps the most promising use of adult stem cells would be to use stems

cells from tissue other than the CNS for example hematopoietic stem cells which can be easily isolated from the patient. These cells can be expanded and possibly trans-differentiated into neurons.

9. The stimulation of endogenous stem to promote neurogenesis is beneficial because it does not have the risks associated with transplantation of exogenous stem cells. These include damage caused by the surgical procedure to implant the exogenous stem cells and donor versus graft rejection. But transplantation of exogenous stem cells may allow for the correction of problems associated with endogenous stem cells. These endogenous stem cells may have some genetic problem which prevents successful neurogenesis, whereas, the exogenous stem cells would not have this same genetic disability.
10. Generating iPSCs through reprogramming strategies avoids the need to destroy embryos for ES cells. Furthermore, iPSCs has low immunogenicity and high capacity for pluripotency that provide advantages for transplantation therapies. However, tumorigenicity represents the most pressing challenge for the clinical application of iPSCs. In addition, reprogramming efficiency toward iPSCs is historically low and the differential efficiency of iPSCs to specific neurons is also low.

Acknowledgments We thank Drs. Nicholas Whitney, Dr. Kang Tang, Dr. Myron Toews for the scientific editing of the previous edition of this book chapter; Julie Ditter, Lenal Bottoms, Myhanh Che, Johna Belling, and Robin Taylor for the outstanding administrative and secretarial support. Abstract

Innate immunity response is an ancient self-defence mechanism, which is conserved across a very broad spectrum of species. The innate immune system constitutes the first line of host defense during infection or homeostatic regulatory activities and therefore plays a crucial role in the initial recognition and regulation of immune responses to invading organisms. Peripheral mononuclear phagocytes (MP; monocytes, tissue macrophages and dendritic cells) respond to pathogens but in molecular pattern-specific manners using phagocytosis and clearance mechanisms for intracellular killing. In the central nervous system (CNS), those are perivascular and brain macrophages and microglia. Of relevance they are separated from the antigen specific and long-lasting adaptive immune system, thus MP provide immediate surveillance responses against invading microbial pathogens and cancerous cells in the CNS. Of particular importance to the CNS, innate immunity can be both neuroprotective or neurodestructive contingent on the activation responses and phenotype that has emerged. In reference to phylogeny, MP-governed innate immunity strongly recapitulates ontogeny as it represents evolutionary primitive defense that is self-contained at a single cell level. It is operative in all species from single cell organisms to plants and, insects and inevitably conserved to man.

Damage-associated molecular patterns • Domain-like receptors • Nucleotide oligomerization • Pathogen-associated molecular patterns • Phagocytosis • Phosphatidylserine receptors • Scavenger receptors • Toll-like receptors • Triggering receptor expressed on myeloid cells 2 • TYRO protein tyrosine kinase binding protein

16.1 Introduction for the Innate Immune Responses

The innate immune response of the CNS follows a well-characterized signaling pathway in response to tissue injury, cell death, and pathogens (Olson and Miller 2004).

The functions of the innate immune system include phagocytosis, intracellular killing, secretion of biologically active factors, cell migration, barrier protection and mobility. There are a number of factors that are intrinsic to the MP and govern its function. *First*, rests in the MP's ability to secrete chemokine and other chemical factors that enable entry of inflammatory cells into areas of tissue injury. The ability to recruit a repertoire of immunocytes to damaged and infectious tissue sites, activate the complement cascade and promote clearance of injurious microbes and debris of dead cells and of tissue metabolism together with antibody complexes and subsequent removal are part of the MP's demanding

functional repertoire. *Second*, the cells that also provide chemical barrier to spread of infectious agents are the MP. *Third*, CNS MP's not only function as sentinels but express and engage specific signaling pathways that facilitate the cells' surveillance functions. These include pattern-recognition receptors (PRRs) that recognize signaling pathways initiated by dying or damaged cells referred to as pathogen-associated molecular and damage-associated molecular patterns (PAMPs and DAMPs). PRRs include Toll-like receptors (TLRs), Nucleotide Oligomerization Domain (NOD)-like receptors (NLRs) and Retinoic acid-Inducible Gene 1 (RIG1)-like receptors (RLRs). TLRs are ubiquitously expressed and are often expressed on the plasma membranes of immune cells and glial cells, including microglia, astrocytes, and neurons (Bsibsi et al. 2002). *Fourth*, misfolded and aggregated proteins engaged in common degenerative disorders of the nervous system can affect MP signaling. Indeed, A β itself can act as a PAMP and interact with TLRs (Lotz et al. 2005; Stewart et al. 2010). NLRs are the major component and inflammasomes and found in the cytoplasm. Some NLR ligands, such as muramyl dipeptide (MDP), are also expressed in microglia, astrocytes, and neurons. NLR ligands have been shown to activate inflammasomes the neuronal cells (Chauhan et al. 2009; Ransohoff and Brown 2012). When stimulated by a ligand, such as lipopolysaccharide (LPS, a TLR ligand) or MDP, TLRs or NLRs MP's become activated and initiate transcriptional up-regulation and release of pro-inflammatory cytokines and chemokines. Other major innate immune response in the CNS is phagocytosis, which is rapidly expanding to three distinct categories: (1) phagocytosis of opsonized microbes and particles, by antibodies and complements (2) phagocytosis of non-opsonized molecules, by scavenger receptors and (3) phagocytosis of apoptotic cells, by phosphatidylserine receptors. The first group includes Fc and complement, integrin family and C-type lectin receptors. The second includes newly standardized class A-J scavenger receptors, including SR-A1 (MSR1), SR-B2 (CD36), SR-D1 (CD68), SR-E2 (Dectin-1), SR-F3 (MEGF10), SR-I1 (CD163), SR-J1 (RAGE). The third includes phosphatidylserine receptors, including BAI1, TIM-1, Tyro3, Axl, MerTK, STAB2/SR-H2, α v β 5 integrin, MEGF10, TREM2 and TYROBP. Newly discovered phagocytosis receptor signaling leads to activation of CrkII, Dock180 and Rac1, which are homologue of *C. elegans* CED-2, CED-5, and CED-10. MEGF10 activation of GLUP are homologue of *C. elegans* CED-1 and CED-6. These diverse receptors transmit innate immune response known as antiviral response, inflammatory activation, phagocytosis.

16.2 Pattern-Recognition Receptor Signaling: Receptors for PAMPs and DAMPs and Consisted of TLRs, NLRs, and RLRs

16.2.1 Pathogen-Associated Molecular Patterns (PAMPs) for Innate Immunity Signaling

The innate immune response relies on recognition of evolutionarily conserved structures on pathogens, including viruses, bacteria, fungus and yeast, termed PAMPs, through a limited number of germ line-encoded pattern recognition receptors. PAMPs are characterized by being invariant among entire classes of pathogens, essential for the survival of the pathogen, and distinguishable from "self" (Janeway and Medzhitov 2002). PAMPs are mostly recognized by TLRs through: Glycoproteins, lipoproteins, peptidoglycans, lipoproteic acid, porin, zymozan, β -glycan and protozoa GPI-anchors to TLR2, DNA to TLR9, RNA to TLR3 and TLR7/8, Gram⁻ bacterial lipopolysaccharide (LPS) to TLR4, Gram⁻ bacterial flagellin to TLR5, and fungal mannan to TLR2 and 4 (Table 16.1). An important property of this system is that no single class of pathogen is sensed by only one type of PRR. Rather, a number of different PRRs are engaged by a given pathogen via various PAMPs, hence securing a rapid and potent inflammatory response and also allowing for some specificity of the response. Please refer to Mogensen's review article for more details about PAMPs (Mogensen 2009).

16.2.2 Damage-Associated Molecular Patterns (DAMPs) for Innate Immunity Signaling

The concept of DAMPs was introduced by Matzinger proposed as the "Danger Theory" in which the injured tissues were postulated to release intracellular molecules, DAMPs, that activate the immune system (Matzinger 1994). The "Danger Theory" remained a theoretical model until High Mobility Group Box 1 (HMGB1) and uric acid crystals were recognized as DAMPs (Scaffidi et al. 2002; Shi et al. 2003). Since then, many more DAMPs were identified and their roles in health and disease are now partially understood (Table 16.2). DAMPs are normally invisible to the immune cells, and become visible only when exposed to the extracellular environment. DAMPs can be secreted from not only dead cells but also living cells under the stress. Exemplary

Mitochondria	mtDNA	TLR9		+
	TFAM	RAGE TLR9		
Endoplasmic reticulum	Calreticulin	CD91		

DAMPs include HMGB1 and ATP. As a representative DAMP, HMGB1 is a mobile chromatin protein that acts as a DNA chaperone by binding DNA transiently and bending it reversibly. HMGB1 is released by the activation of inflammasome (Lu et al. 2013). Secreted HMGB1 binds to receptor for advanced glycation endproducts (RAGE), TLR2 and TLR4, which trigger activation of many signaling molecules, such as nuclear factor-kB (NF-kB) pathway, as well as c-jun kinase and p38 mitogen-activated protein kinase (MAPK) pathways (Andersson and Tracey 2011; Kierdorf and Fritz 2013; Urbanaviciute et al. 2008; Wang et al. 2013; Yang et al. 2013; Maroso et al. 2010).

ATP is also a major and time-sensitive DAMP. ATP can be released at nerve terminals and several other cell types under inflammatory, ischemic, and hypoxic conditions (Garg et al. 2012; Junger 2011). ATP acts as a signaling molecule through the activation of purinergic P2 receptors, which are involved in innate and adaptive immune responses (Junger 2011; Eltzschig et al. 2012). P2 receptors can be further subdivided into metabotropic P2Y receptors (P2YRs), which are G-protein-coupled, and ionotropic P2X receptors (P2XRs), which are nucleotide-gated ion channels. P2Y2R signaling causes production of pro-allergic mediators (for example, IL-33, IL-8, eosinophil cationic protein) during allergic

airway disease (Kouzaki et al. 2011). P2XR channels are opened by the binding of ATP, allowing sodium and calcium influx and potassium efflux. Among P2XRs, P2X7R is predominantly expressed on immune cells such as mast cells, macrophages, microglia, and DCs, and its signaling has been linked to inflammatory and infectious disorders (Junger 2011). The binding of extracellular ATP to P2X7R elicits NLRP3 and inflammasome activation (Gombault et al. 2012).

Other known DAMPs are histones, genomic DNA, IL1 α and IL33 as a result of transcriptional induction from nucleus (Schaefer 2014; Bianchi 2007; Lopetuso et al. 2012), F-actin, cyclophilin A, heatshock proteins (HSPs), uric acid crystals, S100s and A β from cytoplasm (Krysko et al. 2012; Bianchi 2007; Stewart et al. 2010), mitochondrial DNA, mitochondrial transcription factor A (MTFA) from mitochondria (Zhang et al. 2010), and calreticulin from endoplasmic reticulum (Krysko et al. 2011, 2012). Please refer to the references for more detailed review.

16.2.3 Toll-Like Receptors (TLRs) for DAMP- and PAMP-Mediated Signaling

One of the most important findings in the effort to understand innate immunity has been the identification of Toll-like receptors (TLRs). TLRs define a major class of PRRs and are critical to the initiation and tailoring of both innate and subsequent adaptive immune responses (Beutler 2004; Iwasaki and Medzhitov 2004). DAMPs and majority of DAMPs signal through TLRs. For example, bacterial cell wall components are recognized by TLR2, and lipopolysaccharide and viral envelope proteins are recognized by TLR4. Double strand RNA, single strand RNA, and unmethylated CpGs are recognized by TLR3, TLR7/8, and TLR9, respectively (for review, see (Akira et al. 2006)). Primary cultured human and mouse microglia express mRNA for TLR1-9, whereas human and mouse astrocytes express high levels of TLR3, and low-level TLR 1, 2, and 4-6 (Jack et al. 2005; Olson and Miller 2004; McKimmie and Fazakerley 2005; Carpentier et al. 2005). A study on aged mouse brains demonstrated that TLR1, TLR2, TLR4, TLR5, TLR7 and CD14 expression were up-regulated in correlation with age, whereas TLR9 was down-regulated (Letiembre et al. 2007). Interestingly, a TLR4 polymorphism was also associated with successful aging (Candore et al. 2006).

TLR-induced signaling pathways can be broadly classified on the basis of their utilization of different adaptor molecules, i.e., dependent on or independent of the adaptor MyD88, Mal or TIR domain-containing adaptor inducing IFN- γ (TRIF), and, additionally, their respective activation of individual kinases and transcription factors (Akira and Takeda 2004; O'Neill and Bowie 2007). Three major signal-

ing pathways responsible for mediating TLR-induced responses include NF- κ B, p38 MAPKs, and IFN regulatory factors (IRFs) (Akira and Takeda 2004; Akira et al. 2006; Kawai and Akira 2007). Whereas NF- κ B and MAPKs play central roles in induction of a proinflammatory response, IRFs are essential for stimulation of IFN production (Akira and Takeda 2004; Kawai and Akira 2007). These receptors are primarily responsible for canonical antiviral response or inflammatory activation of variety of cells.

16.2.4 Nucleotide Oligomerization Domain-Like Receptors (NLRs) for Inflammasome Signaling

NLRs belong to a family of innate immune receptors which have gained increasing interest are now considered key sensors of intracellular microbes and danger signals. NLRs are defined by a centrally located NOD that induces oligomerization, a C-terminal LRR that mediates ligand sensing, and an N-terminal CARD responsible for the initiation of signaling (Kanneganti et al. 2007).

There are two well-characterized members of the NLR family: NOD1 and NOD2. They sense bacterial molecules derived from the synthesis and degradation of peptidoglycan (Kanneganti et al. 2007). NOD1 recognizes diaminopimelic acid produced primarily by Gram⁻ bacteria (Chamaillard et al. 2003; Girardin et al. 2003a), and NOD2 is activated by muramyl dipeptide (MDP), a component of both Gram⁺ and Gram⁻ bacteria (Girardin et al. 2003b). Activation of NODs induces oligomerization and recruitment of signaling molecules and transcriptional activation of inflammatory genes (Kanneganti et al. 2007). NOD1 and NOD2 primarily activate gene expression of proinflammatory, while other NLRs mainly activate of caspases (such as caspase-1), which catalyzes the cleavage of the IL-1 precursor pro-IL-1 β (Mariathasan et al. 2006; Martinon et al. 2002). This IL-1 cleavage complex was termed the inflammasome and consist of the adaptor ASC (apoptosis-associated speck-like protein containing a CARD), pro-caspase-1, and an NLR family member, such as Ipaf (Ice protease-activating factor), NALP1, or NALP3/Cryopyrin (Mariathasan et al. 2006; Martinon et al. 2002). Several families of inflammasomes have been identified, each recognizing different danger signals or PAMPs through their respective NLR (Kanneganti et al. 2007). For instance, NALP3 plays a role in recognition of ATP (Mariathasan et al. 2006), uric acid crystals (Martinon et al. 2006), viral RNA (Kanneganti et al. 2006), and bacterial DNA (Muruve et al. 2008), whereas both NALP3 and NALP1 mediate caspase-1 activation in response to bacterial MDP (Faustin et al. 2007; Martinon et al. 2004). The major signaling output of inflammasome activation is the maturation and secretion of IL-1 β and IL-18.

16.2.5 Retinoic Acid-Inducible Gene 1 (RIG1)-Like Receptors (RLRs) for dsRNA Signaling

RIG-I and melanoma differentiation-associated gene 5 (MDA5) are IFN-inducible RNA helicases and play a pivotal role in sensing of cytoplasmic RNA (Yoneyama et al. 2004, 2005). RIG-I and MDA5 contain an N-terminal caspase recruitment domain (CARD) and a central helicase domain with ATPase activity required for RNA-activated signaling (Yoneyama et al. 2004). Binding of dsRNA or 5'-triphosphate RNA to the C-terminal domains of RLRs triggers signaling via CARD-CARD interactions between the RNA helicase and the adaptor protein IFN- β promoter stimulator 1 (IPS-1), ultimately resulting in an antiviral response mediated by type I IFN production (mainly IFN- α and IFN- β among others) (Yoneyama et al. 2004; Kawai et al. 2005; Kato et al. 2005; Meylan et al. 2005; Xu et al. 2005). RIG-I and MDA5 have viral specificity: RIG-I is essential for the response to paramyxoviruses and influenza virus, whereas MDA5 is critical for the response to picornavirus and norovirus (Kato et al. 2006; McCartney et al. 2008). In addition to viral RNA, RLRs can recognize self-derived small RNAs generated by RNase L, thus amplifying the IFN response (Malathi et al. 2007). The major signaling output of RLRs is the expression and production of type I IFN.

16.2.6 Protein Kinase R (PKR) for dsRNA Signaling

Viral RNA can also be recognized by the IFN-inducible dsRNA-activated PKR, which represents a major mediator of the antiviral and antiproliferative activities of IFN (Nallagatla et al. 2007; Sadler and Williams 2007). Binding of dsRNA, 5'-triphosphate RNA, or poly(I-C) induces conformational changes in PKR, resulting in autophosphorylation, dimerization, and subsequent substrate phosphorylation (Carpick et al. 1997; Nallagatla et al. 2007; Romano et al. 1995). The best-characterized PKR substrate is the eukaryotic initiation factor eIF2 α , the phosphorylation of which leads to inhibition of protein synthesis (Sadler and Williams 2007). Moreover, PKR has been assigned a role in proinflammatory signal transduction as an upstream kinase involved in mediating dsRNA-dependent NF- κ B activation (Zamanian-Daryoush et al. 2000). However, although PKR was originally considered the principal molecule responsible for cellular recognition of dsRNA, the prevailing view is that the major contribution to dsRNA-activated responses is mediated by RLRs, with recent data suggesting that PKR may be able to amplify RLR signaling (McAllister and Samuel 2009; Zhang and Samuel 2008), thus illustrating cross talk between these different cellular dsRNA-sensing systems involved in antiviral defense.

16.2.7 DNA Sensors for dsDNA Signaling

Cytoplasmic localization of DNA is recognized by the innate immune system independently of TLRs, RLRs, and NLRs (Soulat et al. 2006; Stockinger et al. 2004) and involved in a response to both bacteria and DNA viruses (Charrel-Dennis et al. 2008; Leber et al. 2008; Nociari et al. 2007; Rasmussen et al. 2007). The first cytosolic DNA sensor, DAI (DNA-dependent activator of IFN-regulatory factors), was reported in 2007 (Takaoka et al. 2007). DNAs from various sources were demonstrated to bind to DAI, thereby inducing DNA-mediated induction of type I IFN and other inflammatory genes involved in innate immunity (Takaoka et al. 2007). DAI is probably not the only cytosolic DNA receptor triggering the IFN response. AIM2 (absent in melanoma 2) is a recently reported cytosolic DNA receptor stimulating proinflammatory signaling and maturation of pro-IL-1 β (Hornung et al. 2009). Leucine-rich repeat flightless-interacting protein 1 (LRRFIP1) is the third IFN-inducer DNA sensor and can recognize AT-rich B-form dsDNA as well as GC-rich Z-form dsDNA (Yang et al. 2010). LRRFIP1 triggers the production of IFN- β in a β -catenin-dependent manner. β -Catenin binds to the C-terminal domain of IRF3, inducing an increase in IFN- β expression. Considering the large and heterogeneous group of proteins belonging to the family of PRRs, even more cytoplasmic DNA sensors are likely to be identified.

16.3 Phagocytosis: A Principal Innate Immune Response in MPS

Phagocytosis is the fundamental defense mechanism of innate immune system and is one of primary functions of mononuclear phagocytes. It was first described in the late nineteenth century by that mobile phagocytic cells survey tissues for foreign particles and engage in pitched battles with potential pathogens (Gordon 2008). This process can be classified as (1) phagocytosis of opsonized microbes and particles, mostly by antibodies and complements, (2) phagocytosis of non-opsonized molecules, mainly by scavenger receptors, and (3) phagocytosis of apoptotic cells (efferocytosis), mainly by phosphatidylserine receptors. Many of the receptors activate innate immune signalings important for the inflammatory regulation of immune cells. This part will briefly overview the representative molecules and their intracellular signaling to understand the basic of the molecular mechanism of phagocytosis.

16.3.1 Phagocytic Receptors for Microbe Uptake

Phagocytes express a broad spectrum of receptors that participate in particle recognition and internalization. These receptors include Fc-receptors, complement receptors,

Table 16.3 Adapted from Underhill and Ozinsky (2002)

Receptor class	Phagocytic receptors	Ligands
Fc-receptors	FcγRI (CD64)	Opsonized particles with IgG, CRP or SAP
	FcγRII (CD32)	
	FcγRIII (CD16)	
	FcεRI	Opsonized particles with IgE
	FcεRII (CD23)	
	FcαRI (CD89)	Opsonized particles with IgA
Complement receptors	CR1 (CD35)	Opsonized particles with MBL, C1q, C4b or C3b
	CR3 (αMβ2 integrin, CD11b/CD18, or Mac1)	Opsonized particles with iC3b
	CR4 (αXβ2 integrin, CD11c/CD18, or gp150/95)	
Integrin family	α5β1 (CD49e/CD29)	Opsonized particles with fibronectin or vitronectin
	α4β1 (CD49d/CD29)	
	αvβ3 (CD51/CD61)	
C-type lectin receptors	Mannose receptor 1 (CD206)	α-mannan
	Dectin-1	β-glucan
	Dectin-2	

integrin family, scavenger receptors, and mannose receptors (Table 16.3). Full descriptions of every receptor implicated in phagocytosis are beyond the scope of this review.

Fcγ-Receptors recognize Fc region of IgG, which opsonizes particle (Ravetch and Bolland 2001; Daeron 1997). FcγRs fall into two classes: (a) activating receptors that contain ITAM motifs in their intracellular domains that recruit kinases and activate phosphorylation cascades (FcγRI, FcγRIIA and FcγRIIIA), and (b) inhibitory receptors that contain ITIM motifs that recruit phosphatases that inhibit signaling (FcγRIIB) (Ravetch and Bolland 2001; Daeron 1997). Activating receptors bind IgG-opsonized particles and trigger particle engulfment (Aderem and Underhill 1999). Inhibitory receptors regulated this process by coligation that recruits the phosphatase SHIP that blocks phosphoinositide signaling (Ravetch and Bolland 2001). Thus, relative expression level of activating and inhibiting FcγRs can determine the threshold for phagocytosis and inflammatory responses to IgG-opsonized particles.

Complement receptors (CRs) recognize and internalize complement-opsonized particles. CRs include CR1, CR3 (αMβ2 integrin, CD11b/CD18, or Mac1), and CR4 (αXβ2 integrin, CD11c/CD18, or gp150/95) (Ross 2000). CR1 binds a broad spectrum of microbial opsonins including complement components C1q, C4b, and C3b, as well as mannan-binding lectin (MBL) (Ghiran et al. 2000; Klickstein et al. 1997). The integrins CR3 and CR4 are both heterodimers consisting of a shared beta chain (β2, CD18) paired with specific alpha chains, αM/CD11b, and αX/CD11c, respectively, and both receptors recognize iC3b. Both CR1 and CR3 require additional signals in order to mediate internalization of complementopsonized particles. Inflammatory cytokines, microbial products, and adhesion molecules stimulate phagocytosis through CR3, demonstrating the broad spectrum of extracellular molecules to influence phagocytosis (Wright and Griffin 1985; Pommier et al. 1983).

Integrin family recognizes fibronectin and vitronectin-opsonized molecules. These are primarily α5β1 and αvβ3 integrins (Blystone et al. 1994, 1999). Particle ingestion requires a second signal that can be provided by activation of protein kinase C (Blystone et al. 1994, 1999). α5β1 primarily mediates internalization. However, αvβ3 sometimes delivers an inhibitory signal that blocks internalization through α5β1 (Blystone et al. 1994, 1999). Inhibitory signaling may, in part, be due to the association of α5β1 with CD47 (also called integrin associated protein, IAP). Through its ligand SIRPα, CD47 inhibits both Fc- and complement receptor-mediated phagocytosis (Demeure et al. 2000; Oldenborg et al. 2001). Conversely, αvβ3 and another vitronectin-binding integrin, α5β1, can interact with CD36 (a class B scavenger receptor) to mediate phagocytosis of apoptotic cells, which is accompanied by anti-inflammatory signals (Albert et al. 1998; Fadok et al. 1998).

C-type lectin receptors (CTLRs) are expressed on phagocytes and mediate detection of self and foreign carbohydrates of microbes. Zymosan is a *Saccharomyces cerevisiae* yeast cell wall particle that is made up primarily of α-mannan and β-glucans (Di Carlo and Fiore 1958). The macrophage mannose receptor (CD206) binds to α-mannan and dectin-1 binds to β-glucan, which mediate phagocytosis of yeast and zymosan (Ezekowitz et al. 1990; Brown and Gordon 2001). The macrophage mannose receptor is a type I transmembrane protein with an extracellular domain consisting of eight C-type lectin carbohydrate recognition domains, a short amino terminal cysteine rich domain, and a fibronectin type II repeat (Stahl and Ezekowitz 1998; Fraser et al. 2000). There is no signaling motif in the short cytoplasmic tail and the exact signaling is yet to be determined. Dectin-1 was originally defined as a dendritic cell-specific receptor with a short extracellular domain consisting of a single C-type carbohydrate recognition domain and a short cytoplasmic tail containing an ITAM (Ariizumi et al. 2000a, b).

Subsequent analysis determined that dectin-1 is widely expressed on cells of myeloid lineage and may be the predominant β -glucan receptor for phagocytosis (Brown and Gordon 2001; Willment et al. 2001). Dectin-2 was recently isolated and classified as a different activation receptor via association with ITAM-bearing Fc γ R adaptor molecules (Dambuza and Brown 2015). Now dectin-1 comprise a clusters of many CTLRs: dectin-1 cluster (ITAM-1-containing Dectin-1, CLEC-2 and CLEC-9A, ITIM-1-containing MICL and MAH, and DDD/DDL motif-containing LOX-1 and CLEC-1) (Plato et al. 2013).

16.3.2 Scavenger Receptors for Exogenous and Endogenous Molecule Uptake

Scavenger receptors (SRs) comprise a diverse array of integral membrane proteins and soluble secreted extracellular domain isoforms. The first scavenger receptor was identified for the internalization of oxidized low-density lipoprotein into macrophages by Brown and Goldstein in the 1970s.

We have termed these proteins as belonging to the ‘SR super-group’ (Table 16.4), which is standardized according to the recent review by Prabhudas et al. (2014). Based on our current understanding of SR structure and biological function, these proteins were subgrouped into Classes A–J (Zani et al. 2015).

Class A proteins are Type II membrane proteins with an N-terminus comprising a short cytoplasmic domain followed by a single transmembrane region and a large extracellular domain that has a collagen-like domain and collagen-binding activity. Members include SR-A1, SR-A3, SR-A4, SR-A5 and SR-A6. Class A proteins form homotrimers at the cell surface (Gowen et al. 2001). SR-A1 binds to oxidized LDL, and activates JNK and p38 MAPK, leading to apoptosis or foam cell formation (Ricci et al. 2004).

Class B proteins comprise of SR-B1, SR-B2 and SR-B3. These molecules have two transmembrane regions located close to the N- and C-termini which straddle a central domain that is glycosylated and mediates ligand recognition. SR-B1 is originally cloned as HDL receptor, and SR-B2 binds to oxidized LDL, A β , and trigger immune signaling via Fyn/JNK/p38 MAPK for apoptosis, angiogenesis, and foam cell

Table 16.4 Adapted from Prabhudas et al. (2014)

Class	Receptors	Alternative protein names	Gene names
Class A	SR-A1	SR-A1, CD204, SCARA1, SR-AIII, MSR1	MSR1
	SR-A3	MSRL1, SCARA3	SCARA3
	SR-A4	SCARA4, SRCL, CL-P1, COLEC12	COLEC12
	SR-A5	TESR, NET33, SCARA5	SCARA5
	SR-A6	MARCO, SCARA2	MARCO
Class B	SR-B1	SR-BI, CD36L1, SCARB1	SCARB1
	SR-B1.1	LIMP2, CD36L2, LGP85, SCARB2	SCARB2
	SR-B2	CD36, SCARB3, FAT, GPIV, PAS	CD36
Class C	dSR-C1	dSR-C1	Sr-CI
Class D	SR-D1	CD68, gp110, SCARD1, LAMP4	CD68
Class E	SR-E1	LOX-1, SCARE1, CLEC8A, OLR1	OLR1
	SR-E2	Dectin 1, CLEC7A	Dectin1
Class F	SR-F1	SREC-1, SCARF1	SCARF1
	SR-F2	SREC-II, SR-F2, SCARF2	SCARF2
	SR-F3	MEGF10, EMARDD	MEGF1
Class G	SR-G	CXCL16, SR-PSOX	CXCL16
Class H	SR-H1	STAB1, FEEL-1	STAB1
	SR-H2	STAB2, FEEL-2	STAB2
Class I	SR-I1	CD163, M130	CD163
	SR-I2	CD163L1, M160, CD163B	CD163L1
Class J	SR-J1	RAGE, AGER (membrane form)	RAGE
	SR-J1.1	RAGE, AGER (secreted form)	RAGE
Unclassified	TBA	CD14	CD14
	TBA	Ly75, CD205	CD205
	TBA	MRC1, CD206	CD206
	TBA	Langerin, CD207	CD207
	TBA	DC-SIGN, CD209, CLEC4L	CD209/ DC-SIGN
	TBA	S4D-SRCRB	SRCRB4D
	TBA	unknown	SSC5D

formation, and Lyn/FAK/Vav for cell adhesion and migration (Silverstein et al. 2010; Liani et al. 2012).

Class C proteins are specific to insects, not present in mammals, and are involved in the innate immune response against pathogens such as bacteria (Ramet et al. 2001).

The **Class D** protein SR-D1 (CD68) is a Type I membrane protein and is heavily glycosylated. SR-D1 contains an N-proximal mucin-like domain, a proline-rich hinge region followed by a lysosome-associated membrane protein (LAMP) homology domain, a single transmembrane region and a short 12-residue cytoplasmic domain (Holness and Simmons 1993). SR-D1 can bind to oxidized LDL, lectins, selectins and also mediate phagocytosis and bone resorption (Ramprasad et al. 1996; da Silva and Gordon 1999).

Class E proteins are comprised of SR-E1 and SR-E2. SR-E1 is also known as lectin-like oxidized low-density lipoprotein receptor (LOX-1/OLR1). SR-E1 binds to oxidized LDL (oxLDL) and stimulates activation of p42/44 MAPK, p38MAPK and NF- κ B (Biocca et al. 2009; Khaidakov et al. 2011), triggering a key feature of pro-inflammatory response in immune and vascular cells. SR-E2 is dectin-1, which is discussed above as a C-type lectin receptor.

Class F proteins include SR-F1 (SREC1), SR-F2 (SREC2) and SR-F3 (MEGF10/EMARDD). Human SR-F1 and SR-F2 are Type 1 membrane proteins, an extracellular domain containing multiple EGF-like repeats, a single transmembrane region and a relatively large cytoplasmic domain. SR-F1 binds to carbamylated LDL (cLDL), AcLDL or OxLDL particles. However, SR-F2 lacks SR activity and suggested to suppresses the ligand-binding properties of SR-F1. SR-F1 not only recognizes a wide variety of modified lipid particles but also heat-shock protein HSP90 complexes (Murshid et al. 2010; Sano et al. 2012). SR-F3 is an ortholog of *Drosophila* Draper and *C. elegans* CED-1, and involved in the phagocytosis of apoptotic cells (Ziegenfuss et al. 2008; MacDonald et al. 2006; Zhou et al. 2001). This molecule will be described in more detail in the following section 16.3.3.

The **Class G** protein SR-G is also called chemokine 16 (CXCL16) or scavenger receptor for phosphatidylserine and oxidized lipoprotein (SR-PSOX). The SR-G extracellular domain mediates endocytosis of phosphatidylserine or OxLDL, and delivery to endosome-lysosome system. SR-G has important innate immunity functionality through recognition of bacteria and CpG-rich DNA found in other pathogens (Gursel et al. 2006; Sheikine and Sirsjo 2008). This molecule may play a vital role not only in recruiting but also promoting interaction of both T and natural killer cells to dendritic cells (Shimaoka et al. 2004).

Class H proteins include SR-H1 (stabilin 1/STAB1) and SR-H2 (stabilin 2/STAB2). The SR-H1 and SR-H2 membrane proteins are Fasciclin, EGF-like, laminin-type EGF-like and link (FEEL) domain-containing scavenger receptors. SR-H1 and SR-H2 bind to AcLDL, advanced glycation end-products (AGE) and bacteria. Macrophage SR-H1 mediates

recognition of matricellular secreted protein acidic and rich in cysteine (SPARC), a potent angiogenesis inhibitor, to promote endocytosis and lysosomal degradation (Kzhyshkowska et al. 2006). SR-H1 can also promote the clearance of apoptotic and necrotic bodies (Park et al. 2010; Kim et al. 2012). Macrophages also express SR-H2 to promote phagocytosis and clearance of aged cells, apoptotic bodies and heparin-linked proteins. These are also listed as phosphatidylserine receptors in the following section.

Class I proteins comprise of SR-I1 (CD163) and SR-I2 (CD163L). These receptors contains type B scavenger receptor cysteine-rich (SRCR) domain. SR-I1 is a single transmembrane Type 1 membrane glycoprotein and is primarily expressed in monocytes and macrophages. SR-I1 helps the removal of haptoglobin-hemoglobin (Hp-Hb) complexes via the heme oxygenase-1 (HO-1) pathway to reduce pro-inflammatory haem in the circulation (Thomsen et al. 2013). This indicates the role of SR-I1 in anti-inflammatory response by mediating the uptake of toxic haem in macrophages (Kristiansen et al. 2001). SR-I1 also has a role as a PAMP receptor: SR-I1 binds to both Gram⁻ and Gram⁺ bacteria (Fabriek et al. 2007). The expression of SR-I2 is uniquely restricted to tissue-resident macrophages with an anti-inflammatory or anergic phenotype (Gonzalez-Dominguez et al. 2015).

The **Class J** proteins SR-J1 and SR-J1.1 are membrane-bound or secreted form of the receptor for advanced glycation end-products (RAGE). SR-J1 is a 32 kDa multi-ligand transmembrane receptor that belongs to the immunoglobulin gene superfamily. SR-J1 is a PRP: SR-J1 can interact and be activated by a number of DAMPs such as A β (Yan et al. 1996), S100/calgranulin (Hofmann et al. 1999), phosphatidylserine (He et al. 2011) and HMGB1 (amphoterin) (Hori et al. 1995). Under physiological conditions, the expression of SR-J1 is low, but can be aggravated in response to chronic conditions. These pro-inflammatory endogenous molecules are involved in inflammation and physiological stress. AGE-bound SR-J1 is implicated in signal transduction mediating processes such as oxidative stress, apoptosis and inflammation (Xie et al. 2013).

Other unclassified proteins include CD14 (a co-receptor of TLR4 complex), CD205 (lymphocyte antigen), CD206 (macrophage mannose receptor), CD207 (Langerhans cell marker), CD209 (DC-SIGN), and S4D-SRCRB (scavenger receptor cysteine-rich superfamily, Group B 4 Domains) (Table 16.4).

16.3.3 Phosphatidylserine Receptors for the Phagocytosis of Apoptotic Cells

Apoptotic cells expose 'eat-me' signals so that phagocytes can recognize and distinguish them from their healthy counterparts. The most classic 'eat-me' signal is phosphatidylserine (PtdSer). PtdSer is normally sequestered on the inner

Table 16.5 Adapted from Penberthy and Ravichandran (2016)

Names	PtdSer recognition	Signaling pathway	Other ligand	SR classification
BAI1	Direct	ELMO-Dock180-Rac1	LPS	
TIM-1/HAVCR1/KIM1	Direct	p85/LC3	LDL, oxLDL, HAV	Proposed as Class J
TIM-4/SMUCKLER		Integrin signaling		
Tyro3	Via Gas6/Protein S	TK domain		
Axl	Via Gas6	TK domain		
MerTK	Via Gas6, Protein S, Tubby and Tubby-like protein	Integrin signaling		
STAB1/SR-H1	Direct	GULP/Rac1	oxLDL, AGE, Gram+ and Gram- bacteria	Class H
STAB2/SR-H2		Integrin/FAK/ELMO-Dock180-Rac1		
$\alpha\text{v}\beta 3$	Via MEGE8	CrkII/Dock180/Rac1, FAK/ELMO-Dock180-Rac1		
$\alpha\text{v}\beta 5$				
SREC-1/SR-F1	Via C1q		AcLDL, calreticulin	Class F

MEGF10/SR-F3			A β	Class F

leaflet of the plasma membrane, and during apoptosis PtdSer is exposed on the outer leaflet of the plasma membrane, where it can be directly or indirectly detected by numerous PtdSer receptors on phagocytes. Ligation of PtdSer receptors on phagocytes triggers phagocytic cup formation, which then facilitates the engulfment of the dying cell. PtdSer receptors come in a variety of different molecular formats, with the only commonality being their ability to directly or indirectly recognize PtdSer. It should be noted that majority of PtdSer receptors recognize multiple ligands and play roles other than apoptotic cell clearance (Table 16.5). Several PtdSer receptors have already been categorized as scavenger receptors (Table 16.4). We will mainly discuss Brain angiogenesis inhibitor 1 (BAI1), T-cell immunoglobulin and mucin receptor 1 (TIM-1)/hepatitis C virus receptor (HAVCR1)/kidney injury molecule 1 (KIM1), TIM-4/spleen, mucin-containing, knockout of lymphotoxin (SMUCKLER), tyrosine-protein kinase receptor Tyro3, Tyrosine-protein kinase receptor UFO (Axl), Tyrosine-protein kinase Mer (MerTK), STAB2/SR-H2, multiple epidermal growth factor-like domains protein 10 (MEGF10)/SR-F3 and $\alpha\text{v}\beta 5$ integrins.

BAI1 is a type II adhesion G-protein coupled receptor (GPCR) family Das et al. (2011). Human BAI1 is a 1584 amino acid protein with a large extracellular region, and a seven transmembrane region, followed by a long intracellular tail. The cytoplasmic tail of BAI1 can directly interact with engulfment and cell motility protein (ELMO). ELMO form a complex with dedicator of cytokinesis protein 1 (Dock1/Dock180), a guanine nucleotide exchange factor (GEF), which activates Rac Rho small GTPases by exchanging bound GDP for free GTP. Activation of Rac leads to cytoskeletal reorganization and importation of phagosomes. BAI1 is essential for the engulfment of apoptotic cells Park et al. (2007). BAI1 also recognizes LPS Das (2011).

TIM-1/HAVCR1/KIM1 is a prototypical member of a novel class of scavenger receptors. It directly binds to PtdSer, oxLDL, and hepatitis A virus (HAV) Ichimura (2008); Kim et al. (2011); Feigelsstock et al. (1998); Curtiss (2011). Recent publication shows that binding to PtdSer to TIM-1 induces tyrosine phosphorylation of the cytoplasmic tail and its association with p85, which results in encapsulation of phagosomes by lipidated LC3 in multi-membrane organelles (Brooks et al. 2015).

TIM-4/SMUCKLER is structurally similar to TIM-1 and can directly bind to PtdSer Miyashita et al. 2007. TIM-4 uses integrin $\beta 1$ as a co-receptor in the process of apoptotic cell clearance Flannagan et al. 2014 and contributes to phagosome stabilization Mazaheri F et al. (2014).

Tyro3 is one of three TAM receptors (Tyro3, Axl, and MerTK) and has tyrosine kinase domain in the cytoplasmic tail Seitz et al. (2007). Tyro3 indirectly bind to PtdSer via Gas6 or protein S Lew et al. (2014); Lu et al. (1999), and signals through ELMO/Dock180/Rac1 pathway.

Axl also belongs to TAM receptor family and indirectly bind to PtdSer via Gas6 Abu-Thuraia et al. (2015); Seitz et al. (2007). ELMO2 is essential for Axl signaling Abu-Thuraia et al. (2015).

MerTK is another TAM receptor and binds to PtdSer via bridging molecules including Gas6, Protein S, Tubby, and Tubby-like protein 1 Wu et al. (2005); Caberoy et al. (2010); Burstyn-Cohen et al. (2012); Lew et al. (2014). Bridging elicits homo-dimerization of Mer and trans-phosphorylation of the cytoplasmic tyrosine kinase domain Tibrewal et al. (2008). This subsequently drives phosphorylation of phospholipase $\text{C}\gamma 2$ (PLC $\gamma 2$) Todt et al. (2004). PLC $\gamma 2$ can then recruit p130CAS to $\beta 5$ integrin and subsequently activate the CrkII-ELMO-Dock180 complex Wu et al. (2005).

STAB2/SR-H2 possesses multiple EGF-like repeat domains in its extracellular region that mediate direct

interaction with PtdSer Park et al. (2008a). Upon binding to PtdSer, STAB2/SR-H2 has been reported to promote corpse internalization via two independent, but parallel pathways. In the first signaling pathway, STAB2/SR-H2 binds to the PTB domain of the adapter protein GULP via an NPXY motif Park et al. (2008b). The *C. elegans* ortholog of GULP, CED-6, activates the Rac1 ortholog, CED-10 Kinchen et al. (2005). GULP can activate Rac1 as downstream signaling of SR-B1 Osada et al. (2009), it has not been shown in STAB2/SR-H2 signaling. Alternatively, STAB2/SR-H2 interacts with the $\alpha\beta 5$ integrin in the process of erythrocyte engulfment Kim et al. (2012). As discussed below, $\alpha\beta 5$ integrin can signal via the ELMO/Dock180 complex to activate Rac1, suggesting that STAB2/SR-H2 might utilize this downstream signaling module via cooperation with $\alpha\beta 5$ integrin Albert et al. (2000); Akakura et al. (2004).

MEGF10/SR-F3 and **LRP-1** are structurally similar to the *C. elegans* membrane receptor CED-1 Su et al. (2002); Suzuki et al. (2007). CED-1 clusters around apoptotic cells on the phagocyte membrane and is crucial for the clearance of apoptotic cells Ellis et al. (1991); Hedgecock et al. (1983); Zhou et al. (2001). CED-1 functions upstream of CED-6, the *C. elegans* ortholog of GULP Ellis et al. (1991); Su et al. (2002). Both MEGF10/SR-F3 and LRP-1 are capable of signaling via GULP, suggesting that this apoptotic cell recognition and signaling mechanism is evolutionarily conserved and utilized by a multitude of PtdSer receptors Su et al. (2002); Scheib et al. (2012).

$\alpha\beta 5$ integrin indirectly recognizes PtdSer through the soluble bridge, milk fat globule-EGF factor 8 (MFG-E8) or lactadherin Shi et al. (2004); Hanayama et al. (2002); Andersen et al. (1997); Andersen et al. (2000). Interestingly, $\alpha\beta 5$ integrin activates ELMO/Dock180 complex to elicit Rac activation and apoptotic cell engulfment Albert et al. (2000); Akakura et al. (2004). FAK is phosphorylated and recruits p130CAS that binds to CrkII Albert et al. (2000). CrkII then recruits Dock180 and triggers Rac1 activation Albert et al. (2000); Akakura et al. (2004). Overall, these molecules mediate phagocytic cytoskeletal changes via converging intracellular signaling.

16.3.4 TREM2/TYROBP Pathway for Sensing Apoptotic Cells and Diseases

Triggering receptor expressed on myeloid cells 2 (TREM2) belongs to the immunoglobulin superfamily based on shared structural features with immunoglobulin domain or fold. Members of the immunoglobulin superfamily include cell surface antigen receptors, co-receptors and co-stimulatory molecules of the immune system, molecules involved in antigen presentation to lymphocytes, cell adhesion mole-

cules, and certain cytokine receptors. TREM2 is thought to be involved in phagocytosis of damaged cells (Hsieh et al. 2009; Kawabori et al. 2015).

TREM2 is mostly expressed in myeloid cells (immature dendritic cells, microglia and osteoclasts). In the CNS, TREM2 is expressed at levels greater than 300-fold in microglia compared to astrocytes (Hickman and El Khoury 2014). Inflammation decreases TREM2 expression in microglia and their ability to phagocytize apoptotic neurons (Takahashi et al. 2007). TREM2 requires the interaction with the adaptor protein, TYRO protein tyrosine kinase binding protein (TYROBP; formerly DAP12) that facilitates the downstream signaling of phagocytosis (Paloneva et al. 2000). Thus, healthy coupling of TREM2 and TYROBP is essential for the phagocytic function of myeloid cells. No endogenous ligand has been confirmed for TREM2, but TREM2 is shown to bind to Gram⁺ and Gram⁻ bacteria and yeast in a charge-based method (Daws et al. 2003). Stimulation of TREM2 by a cross-linked TREM2 antibody is shown to activate TREM2. This activation causes actin polymerization and restructuring of the cytoskeleton (Takahashi et al. 2005).

TYROBP is a transmembrane adaptor protein that binds to TREM2 and signals through immunoreceptor tyrosine-based activation motifs (ITAMs). The ITAM signal is important for phagocytosis activation in microglia (Linnartz and Neumann 2013). Tyrosine phosphorylation of ITAM by Src family proteins activates TYROBP. The phosphorylated ITAM binds to protein spleen tyrosine kinase (Syk). Syk activates many downstream cascades linked to phagocytosis (Linnartz and Neumann 2013). The ITAM activation is negatively regulated by the immunoreceptor tyrosine-based inhibition motifs (ITIMs). When a regulatory ligand binds to receptor containing an ITIM, recruitment of SHP1/SHP2 occurs. SHP1/SHP2 can dephosphorylate and inhibit ITAM activation and other downstream cascades (Linnartz and Neumann 2013). TYROBP deficient mice show enhanced inflammatory phenotypes (Hamerman et al. 2005).

Mutations in TREM2 or TYROBP are thought to be the main cause of Nasu-Hakola (Paloneva et al. 2003). Nasu-Hakola diseases is polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy (PLOS), a rare autosomal recessive disease (Paloneva et al. 2003). Patients who are diagnosed with Nasu-Hakola disease suffer from bone cyst-like lesions and bone fractures often on their lower legs and also experience rapid pre-senile dementia (Paloneva et al. 2001, 2003). Around the age of 40, patients have severe neurodegeneration and suffer from severe dementia, gait disturbances, sensory agnosia, agraphia and in some cases develop tumors in the CNS (Hakola and Puranen 1993). The link between neurodegeneration and TREM2/TYROBP function provided by Nasu-Hakola disease indicates that the phagocytic and anti-inflammatory function of TREM2/TYROBP signaling is important for healthy brain function.

The missense R47H mutation in TREM2 is associated with LOAD, has an effect on both folding and ligand binding, and decreases the clearance of damaging debris (Abduljaleel et al. 2014). Similarly, FTDL-linked missense mutations in TREM2 (T66M and Y38C) also reduce phagocytic activity (Kleinberger et al. 2014). TYROBP is recently highlighted as one of the central genetic nodes and networks in LOAD (Paloneva et al. 2000, 2001; Zhang et al. 2013). Since both TREM2 and TYROBP are specifically expressed in myeloid cells and physically interact to transduce phagocytosis and anti-inflammatory signaling (Linnartz and Neumann 2013; N'Diaye et al. 2009; Paradowska-Gorycka and Jurkowska 2013), the TREM2/TYROBP pathway may play an important role for regulating peripheral or central inflammation.

16.4 Review Questions

1. Describe the difference in pattern recognition among Toll-like receptors (TLR) 2, TLR4 and TLR in terms of (1) ligand distinction, (2) intracellular signaling, and (3) co-activation signaling
2. Describe the representative danger-associated molecular pattern molecules (DAMPs) from nucleus, cytosol, and mitochondria in terms of (1) exact DAMPs, (2) corresponding receptors, and (3) co-activation signaling
3. Describe subclass of phagocytic receptors for microbes in terms of (1) receptor class, (2) representative receptors, (3) ligands
4. Describe the representative class of scavenger receptors for non-opsonized molecules in terms of (1) scavenger receptor classes, (2) representative receptors, (3) ligands
5. Describe the representative phosphatidylserine (PtdSer) receptors and their intracellular signaling

16.5 Answers

1. Listed in Table 16.1
2. Listed in Table 16.2
3. Listed in Table 16.3
4. Listed in Table 16.4
5. BAI1 is a type II adhesion G-protein coupled receptor (GPCR) family. The cytoplasmic tail of BAI1 can directly interact with engulfment and cell motility protein (ELMO). ELMO form a complex with dedicator of cytokinesis protein 1 (Dock1/Dock180), a guanine nucleotide exchange factor (GEF), which activates Rac Rho small GTPases by exchanging bound GDP for free GTP. Activation of Rac leads to cytoskeletal reorganization and importation of phagosomes. BAI1 is essential for the engulfment of apoptotic cells.

Yunlong Huang and Jialin Zheng

Abstract

The role of cytokines and chemokines in neuroimmune regulation is highly broad and complex, due to the overwhelming number of molecules and their overlapping, synergizing and antagonizing effects of various factors. Classifying any individual factor or family of factors as beneficial or detrimental oversimplifies the interactions between various cell types and the signaling cascades initiated by them. Instead, cytokines need to be considered as a balanced network, where subtle modifications can shift cells towards different outcomes such as death, proliferation, migration, and induction of inflammation or inhibition of immune responses. Prolonged inflammation has a profound impact on the cytokine network and the cells they target, consequently altering the outcome of cell populations. The central nervous system is a unique environment that is exquisitely sensitive to cytokines, growth factors, and chemokines; the dysregulation that is rampant during neurodegenerative diseases permanently transforms brain function. The profile of cytokines, growth factors, and chemokines presented in the brain likely dictate the fate of neurons in the diseases. The understanding of cytokines, growth factor, and chemokine effects and how the expression or activity of those factors can be manipulated may provide the key to diagnosing or treating neuroimmunological diseases.

Keywords

Alzheimer's disease • Chemokine • Chemotaxis cytokine • Growth factor • Inflammation • Multiple sclerosis

17.1 Introduction

Communication between cells takes place either via direct cell-to-cell contact, extracellular vesicles, or soluble factors such as cytokines. Originally thought to be limited to the immune cells, cytokines are soluble protein messengers now known to be produced by a broad range of cells beyond the immune system, regulating key aspects of development,

homeostasis, inflammation, response to infection, and tumor. Among various families of cytokines, chemokines are a unique family in that all family members are primarily involved in cellular migration. Cytokines and chemokines are particularly relevant to neuroimmunology due to their critical role in communication between immune system and central nervous system (CNS). Aberrant regulation of cytokines and chemokines may facilitate the development of several CNS diseases. For example, HIV-1 associated neurocognitive disorders (HAND), Alzheimer's disease (AD), and multiple sclerosis (MS) share certain characteristics in their pathogenesis that include the production of high levels of proinflammatory cytokines. The elevation of proinflammatory cytokines within the CNS is commonly regarded

as a perpetrator to the eventual impairment of neuronal function. Therefore, cytokines and chemokines are the subject of intense investigations for pharmacological intervention. This chapter provides an overview of cytokines, chemokines, and their roles in various pathological conditions. Understanding the involvement of chemokines and cytokines in the pathogenesis of CNS diseases may help identify novel therapeutic targets for the treatment of neurodegenerative disorders and neuronal injury.

17.1.1 Classification of Cytokines and Chemokines

Most cytokines are single polypeptide chains of various sizes, although they may form multimers in biological fluids. To learn about this exceedingly large group of proteins, it is helpful to classify them into families. The classification of cytokines and chemokines is typically based on the structure homology of their receptors (Vilcek 2003). It is important to note that while many of them share structural similarities or have functional homologues; most generalizations are riddled with exceptions. Similarly, the term “growth factors”, used in this chapter, also refers to a broad range of structurally diverse molecules. However, there are clearly some overlaps in term of terminology between cytokines and growth factors. These growth factors are introduced in individual cytokine families in this chapter.

17.1.2 Cytokine Families

When grouped into families based upon the structural homology, most cytokines and their receptors fall into the same family with few exceptions. Below is an effort to group cytokines and their families based on the structural homology of their receptors. This classification helps provide a foundation for thinking about these factors and their role in the brain.

17.1.2.1 Type I Cytokine Receptor Family

Also known as hemopoietic growth factor family, Type I cytokine family share a characteristic three-dimensional motif consisting of an extracellular region containing four α helices. Members of this family include receptors to interleukin-2 (IL-2), IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-12, granulocyte-colony stimulating factor (G-CSF) and granulocyte macrophage-colony stimulating factor (GM-CSF). Subfamilies of Type I cytokine receptor family exist. For example, IL-2 receptor subfamily includes IL-2, IL-7, IL-9, IL-15, and IL-21 receptors; IL-4 receptor subfamily includes IL-3, IL-4, IL-5, IL-13, and GM-CSF receptors; IL-12 receptor subfamily includes IL-12, IL-23, and IL-27 receptors. Among them IL-2, IL-3, IL-4 and IL-7 are T cell growth

factors; IL-6 and IL-12 are pro-inflammatory cytokines; and G-CSF and GM-CSF are important for survival and differentiation of hematopoietic lineages. It is important to note that Type I cytokine receptors are not to be confused with Th1 cytokine receptors. Classification of Type I cytokine receptors is based on structural biology, whereas classification of Th1 cytokine receptors is based on function. Type I cytokine receptors include both Th1 cytokine receptor (IL-2) and Th2 cytokine receptors (IL-4 and IL-5). In addition, members from the same subfamily do not necessarily exert similar biological effects.

17.1.2.2 Type II Cytokine Receptor Family

Also known as interferon family, Type II cytokine receptor family includes receptors to IL-10, IL-19, IL-20, IL-22, and interferons (IFN- α , - β , - ϵ , - κ , - ω , - δ , - τ and - γ). Subfamilies of Type II cytokine receptor family include IL-10 receptor subfamily, which comprises IL-10, IL-19, IL-20, IL-22, IL-24, IL-26, IL-28A, IL-28B, and IL-29 receptors (Sabat 2010); IFN receptor subfamily, which comprises IFN- α/β receptor and IFN- γ receptor. Functions of this group include induction of cellular antiviral states, modulation of inflammatory responses, inhibition or stimulation of cell growth and production or inhibition of apoptosis, as well as affecting many immune mechanisms (Pestka et al. 2004; Renauld 2003). Notably, IL-10 is a potent anti-inflammatory, immunomodulatory cytokine. The IFN system is an important contributor to innate immunity with IFN- γ serving as a potent pro-inflammatory cytokine. The type II cytokine receptor family is also comprised of both Th1 and Th2 cytokine receptors; IFN- γ receptor is a Th1 cytokine receptor while IL-10 receptor is a Th2 cytokine receptor.

17.1.2.3 TNF Receptor Superfamily (TNFRSF)

TNF receptor subfamily is comprised of at least 29 type II transmembrane proteins that have partial homology in their extracellular domains. The ligands for these receptors include 19 members of TNF superfamily. Active TNF receptors typically form trimeric complexes on the plasma membrane. Members of this superfamily include TNF receptor 1 (TNFRSF1A), TNF receptor 2 (TNFRSF1B), Fas receptor (FasR, TNFRSF6), CD40 (CD40, TNFRSF5), and TNF-related apoptosis-inducing ligand receptors (TRAILRs, TNFRSF10A-D). Members of the TNF receptor superfamily are known for their apoptosis-inducing ability, though they have additional biological effects. TNF- α is an inflammatory Th1 cytokine released during infection; CD40 ligand (CD40L) is a strong activator of macrophages; FasL and TRAIL modulate immune responses and induce apoptosis in immune cells and tumor cells. In addition, TNF receptor superfamily also has been suggested to be involved in destructive effects toward tissue in many disease settings.

17.1.2.4 IL-1 Receptor Family

IL-1 receptor (IL-1R) family comprises ten members: IL-1R1, IL-1R2, IL-1R accessory protein (IL-1RAcP), IL-18R α , IL-18R β , IL-33R, IL-36R, single Ig IL-1R-related molecule (SIGIRR), three Ig domain-containing IL-1R related-2 (TIGGIR-2), and TIGGIR-1 (Palomo et al. 2015). Members of IL-1R family typically comprise three extracellular immunoglobulin domains. Therefore, the IL-1 receptor family belongs to the immunoglobulin superfamily. IL-1 β and IL-18, two prominent members of this cytokine family, are produced as biologically inactive pro-peptides that need to be cleaved by caspase-1 upon inflammasome activation in order to bind to their receptors. These IL-1 receptor ligands are potent pro-inflammatory cytokines that induce genes associated with inflammation and autoimmune disease. IL-1Ra, on the other hand, is the specific receptor antagonist for IL-1 α and IL-1 β but not for IL-18.

17.1.2.5 Transforming Growth Factor Beta (TGF- β) Receptor Superfamily

Based on structural and functional properties, TGF- β receptor family can be further divided into type I and type II receptor subfamilies (Herpin et al. 2004). In vertebrates, there are five type II receptors and seven type I receptors in the TGF- β receptor superfamily. However these receptors are paired up with the TGF- β superfamily members, including TGF- β , Activins, Nodals, Bone Morphogenetic Proteins (BMPs), and Growth and Differentiation Factors (GDFs) of a total of at least 30 secreted factors, remain unclear (Weiss and Attisano 2013). The receptors of TGF- β family have characteristic cysteine-rich extracellular domains and either a GlySer (GS) domain or a serine/threonine kinase domain. TGF- β has numerous functions including regulation of embryonic stem cell self-renewal, gastrulation, differentiation, organ morphogenesis, and adult tissue homeostasis. In immune system, TGF- β regulates both anti-inflammatory and proinflammatory T cell responses with the presence of other cytokines (Travis and Sheppard 2014).

17.1.3 Important Sub-families of Cytokines and Growth Factors

The five cytokines families based on their receptor structural homology are a broad term. Smaller groups of cytokines and growth factors may form more function-related sub-families and are discussed below.

17.1.3.1 IL-17 Family

IL-17 cytokine family includes IL-17A (previously referred to as IL-17), IL-17B, IL-17C, IL-17D, IL-17E (also known as IL-25) and IL-17F. All IL-17 family members bind to their receptors, which comprises five receptor subunits from

IL-17RA to IL17RE. These cytokines and their receptors have little homology to other cytokine and receptor families and therefore form a distinct group. The biological function and regulation of IL-17A, IL-17B, IL-17C, IL-17D, and IL-17F are best understood for their pro-inflammatory responses, whereas IL-17E plays distinct roles in immunity by regulating the Th2 response (Gaffen et al. 2014; Jin and Dong 2013).

17.1.3.2 Neurotrophin Family

The neurotrophin family includes nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), NT-4. All neurotrophins are neurotrophic factors capable of binding to a receptor called p75NTR (also known as TNFRSF16) and to one of the three tropomyosin-related kinase (TRK; also known as NTRK) receptors - NGF binds to TRKA, BDNF and NT4 bind to TRKB, and NT3 binds to TRKC (Park and Poo 2013). Neurotrophins secreted by cells protect neurons from apoptosis and are also important for differentiation and maintenance of nerve cells (Korsching 1993; Lewin and Barde 1996).

17.1.3.3 Growth Factor Families

Growth factor families include many each with unique functions. Members of vascular endothelial growth factor (VEGF) and platelet derived growth factor (PDGF) families are potent mitogenic and angiogenic factors with critical roles in embryonic development, wound healing, as well as the integrity of blood brain barrier (BBB). Epidermal growth factor (EGF) family members include EGF, neuregulins, amphiregulin, and betacellulin. These EGF family members mediate their growth and proliferate effects on cells of both mesodermal and ectodermal origin. Insulin-like growth factor (IGF)-I and IGF-II belong to the family of insulin-like growth factors that are structurally homologous to proinsulin. IGF-1 has a much higher growth-promoting activity than insulin and is highly expressed in all cell types and tissues. IGF-2 is expressed in embryonic tissues and is related to development. Fibroblast growth factors (FGF) constitute a large family of proteins involved in many aspects of development including cell proliferation, growth, and differentiation. They act on several cell types to regulate angiogenesis, cell growth, pattern formation, and embryonic development. Notably, EGF and basic FGF are commonly used for the culture of neural stem cells.

17.1.4 Structure and Classification of Chemokines and Their Receptors

First discovered in 1987 (Walz et al. 1987; Yoshimura et al. 1987), chemokines include a group of secreted proteins within the family of cytokines that by definition relate to the

induction of migration. These “**chemotactic cytokines**” are produced by and target a wide variety of cells, but primarily address leukocyte chemoattraction and trafficking of immune cells to locations throughout the body via a concentration gradient. There are two general categories of biological activity for chemokines, the maintenance of homeostasis and the induction of inflammation (Moser and Loetscher 2001; Balkwill 2012). Homeostatic chemokines are involved in roles such as immune surveillance and navigation of cells through hematopoiesis, and are typically expressed constitutively. Inflammatory chemokines are produced in states of infection or following an inflammatory stimulus. By targeting cells of the innate and adaptive immune system, inflammatory chemokines facilitate an immune response.

Chemokine activity is mediated by activating a family of seven transmembrane G-protein coupled receptors (GPCR). GPCRs interact with and signal through heterotrimeric guanine-nucleotide-binding regulatory proteins (G-proteins). Upon stimulation by a ligand, GPCRs undergo a conformational change that leads to activation of the G-protein by GDP-GTP exchange, followed by uncoupling of the G-protein from the receptor. Upon activation, G-proteins trigger a cascade of signaling events that regulate various cellular functions (Devi 2000).

Chemokine receptors are classified into four families based on the number and position of the N-terminal-conserved cysteine residues within the receptor-binding domain. These families include: α -chemokine receptors (such as CXCR2 and CXCR4); β -chemokine receptors (such as CCR5, CCR4, CCR3 and CCR2); γ -chemokine receptor (XCR1) and δ -chemokine receptors (CX3CR1) (Gabuzda et al. 1998; Hesselgesser and Horuk 1999; Klein et al. 1999; Miller and Meucci 1999; van der Meer et al. 2000; Cotter et al. 2002). Additionally, receptors that structurally resemble chemokine receptors but lack classical chemokine receptor signaling include Duffy antigen receptor for chemokines (DARC), D6 (also known as CCBP2), CC-chemokine receptor-like 1 (CCRL1; also known as CCXCKR and CCR11) and CXC-chemokine receptor 7 (CXCR7; also known as RDC1) (Nibbs and Graham 2013). These receptors are now grouped as the family of atypical chemokine receptors (ACKRs). DARC is known as ACKR1, D6 is known as ACKR2, CXCR7 is known as ACKR3 and CCRL1 is known as ACKR4 (Bachelier et al. 2014).

17.1.4.1 CXC Chemokines

These include CXCL1 to CXCL17 and CXC chemokine receptors include CXCR1 to CXCR7. CXC chemokines are further separated into two groups based upon the presence or absence of a specific three amino acid sequence found adjacent to the CXC. The Glu-Leu-Arg residues constitute the ELR motif, and if present, the CXC chemokine is considered to be ELR(+). The general function of ELR(+) chemokines

revolves around neutrophils inducing chemotaxis and promoting angiogenesis (Strieter et al. 1995). Chemokines in this group include CXCL1, CXCL2, CXCL3, CXCL5, CXCL6, CXCL7, CXCL8, and CXCL15; unlike ELR(-) members, these factors interact primarily with neutrophils via CXCR1 and CXCR2 receptors. In contrast, ELR(-) chemokines attract lymphocytes and monocytes with little affinity for neutrophils. This subgroup including CXCL4, CXCL9, CXCL10, CXCL11, CXCL12, CXCL13, CXCL14 and CXCL16, has a wider variety of activities, but generally have angiostatic properties and induce chemotaxis in mononuclear cells.

17.1.4.2 CC Chemokines

These include CCL1 to CCL28, CCL3L1 and CCL4L1, whereas CC chemokine receptors include CCR1 to CCR10. CC chemokines target primarily mononuclear cells and serve in both homeostatic and inflammatory capacities. The family can be divided into five functional groups including allergenic, pro-inflammatory, HCC, developmental and homeostatic groups. The developmental and homeostatic factors are, as expected, constitutively produced, whereas the other groups contain largely inducible signals. Allergenic CC chemokines target eosinophils, basophils and mast cells accounting for their name, and are both potent attractors and stimulants of histamine release. Both inflammatory and HCC subgroups are participants in inflammation but are separated because of phylogenetics.

17.1.4.3 CX3CL1 (Fractalkine, FKN)

CX3CL1 is the lone member of the CX3C subfamily with three intervening residues between the first two cysteines. FKN, the ligand for CX3CR1, is a 373-amino acid, multi-domain molecule found in a wide variety of tissues, including liver, intestine, kidney, and brain. Structural components of FKN include a 76-amino acid chemokine domain (CD) at the N-terminus, which is important in the binding, adhesion, and activation of its target cells (Harrison et al. 2001; Mizoue et al. 1999, 2001; Haskell et al. 2000; Goda et al. 2000). FKN also has an 18-amino acid stretch of hydrophobic residues that spans the cell membrane, and an extended carboxyl-terminus that anchors it to the cell surface (Hoover et al. 2000; Lucas et al. 2001; Cook et al. 2001), thus allowing a membrane form as well as a shed soluble form targeting monocytes and T cells (Bazan et al. 1997).

17.1.4.4 XCL1 (Lymphotactin)

XCL1 is the only representative of the C family. The chemokine targets CD4+ and CD8+ lymphocytes, but does not act on monocytes, and acts through a unique receptor, XCR1. Although having some homology to ligands CCL3 and CCL8, XCL1 lacks the first and third cysteines characteristic of the CC and CXC chemokines.

All of the above families are imperative for homeostatic functions as well as the orchestration of response to pathogenic insult by the immune system. As investigations carry on, this large family will likely see the emergence of additional cytokines and growth factors, and the family and sub-families of cytokine, growth factor, or chemokine receptors will continue to evolve and expand.

17.2 Cytokines and Growth Factors in the CNS

Cytokines and growth factors are an important element in the brain's immune function, serving to traffic leukocytes, maintain immune surveillance, and regulate inflammatory factors. Cytokines and their receptors that are detectable in brain tissues or neuronal and glial cultures under pathophysiological conditions are summarized in Table 17.1. The view of neuro-immunology has evolved from the early belief that regarded the CNS as an absolute immune privileged site to a view of significant CNS-immune system interactions. In the normal

physiological state, T cells, macrophages and dendritic cells readily cross the BBB and transverse specific parts of the healthy CNS (Hickey 1999; Louveau et al. 2015). As discussed in Sect. 17.3, CNS inflammation is unique due to the presence of the BBB. A restricted inflammatory process in the CNS is initiated upon encountering foreign antigen, inducing the production of recruitment factors (Irani 1998). Upon recruitment, monocytes and lymphocytes cross through the BBB to mount immune responses in the CNS. Recruitment is dependent upon the presence of chemotactic factors produced within the CNS that facilitate the crossing of the BBB. This inflammatory state is highly regulated, usually self-limited, and differs from the inflammation in peripheral tissues. The threshold to initiate immune responses against antigens in CNS is much higher than that in periphery (Matyszak 1998; Perry 1998). Avoidance of uncontrolled activation, release of toxic factors, edema and other effectors of robust inflammation is crucial to the maintenance of microenvironment in the CNS.

CNS-immune system interactions are regulated by cytokines, chemokines, and growth factors. Immune cells,

following interactions with pathogens or abnormal cells, release cytokines, which then interact with immunosensory tissues associated with the brain. Cytokines activate these tissues directly via specific receptors, or via diffusible mediators such as prostaglandins. Immunosensory structures respond to cytokines, then activate brain neuro-immune circuits responsible for the induction of the defensive response. Microglia are the resident macrophage of the CNS and present antigen, orchestrating the innate immune responses. Astrocytes have also occasionally been postulated to have a role in antigen-presentation to CD4⁺ T cells. Other resident cells, such as neurons or oligodendrocytes, are all capable of recruiting immune cells, modulating the immune response through cytokines, chemokines, or growth factors. In addition, neurons may also modulate the antigen-presenting function of microglia. For example, neuronal production of neurotrophins also suppresses IFN- γ induced MHC class II expression (Neumann et al. 1998).

Disease states within the CNS can lead to dysregulation of the inflammatory process. Continual activation and

recruitment of effector cells may establish a positive feedback loop that perpetuates inflammatory processes and can ultimately lead to neuronal injury and dropout. Similar yet distinct processes occur in multiple CNS disorders such as MS, HAD, and AD. One underlying similarity in each disease state is the cytokine driven inflammatory response (see Fig. 17.1). Numerous studies have demonstrated that microglia/macrophage and astrocytes are major sources of inflammatory mediators, including TNF- α and IL-1 β , IL-10, and nitric oxide (NO). Those mediators initiate or regulate inflammatory processes in the CNS (Aloisi 2001; Dong and Benveniste 2001; Hanisch 2002). In addition to the beneficial effects that glia have in initiating protective immune responses in the CNS, these cells have been implicated in contributing to tissue damage when chronically and/or pathologically activated. For example, many reports demonstrate that activated microglia may exacerbate AD and MS, as described later in this chapter, through secretion of a battery of inflammatory cytokines and cytotoxic agents (Benveniste 1997; Renno et al. 1995; Meda et al. 1995).

Fig. 17.1 Cytokine-driven inflammatory process in multiple disease states. Multiple disease states have similar cytokine-driven inflammatory processes. In HAND, HIV-1 infection of macrophages in the CNS leads to the activation of macrophages and microglia. Activated macrophage and microglia release cytokines and chemokines, which could be detrimental to neuron. Neuron injury further recruits macrophages.

This injury, recruitment, activation process forms a positive feedback loop and deteriorates the disease states. In AD and MS, either A β priming or T cell-mediated of macrophage/microglia activation may elevate similar inflammatory cytokines, chemokines to cause the pathogenic effects on the CNS

17.3 Molecular Mechanisms of Cytokine and Growth Factor Activity and Signaling

Multiple signaling pathways have been observed for various cytokines. We will first discuss the molecular signaling of neuronal survival and cell death to better understand the molecular mechanisms involved in cytokine-induced neurodegeneration.

The signaling events leading to apoptosis can be divided into two distinct pathways, involving either the mitochondria (*intrinsic*) or death receptors (*extrinsic*) [for reviews, see Green (2003) and Green and Reed (1998)]. The mitochondrial pathway is initiated through various stress signals that impair the mitochondrial membrane integrity. BCL-2 family proteins, including the anti-apoptotic members, i.e. BCL-2 and BCL-XL, and pro-apoptotic members, i.e. Bax, Bak, play a critical role in this pathway (Danial and Korsmeyer 2004; Gross et al. 1999; Wang 2001; Green 2003). The BH3-only BCL-2 family proteins, such as Bid, Bad, Bim, and PUMA, serve as sentinels to these stress signals. Once activated, BH3-only proteins translocate to the outer membrane of mitochondria, where they trigger the oligomerization and activation of both Bax and Bak. In turn, Bax and Bak cause the release of cytochrome c (cyto c) and other apoptogenic factors, including second mitochondrial-derived activator of caspase (SMAC), Htr2, apoptosis inducing factor (AIF), and endonuclease G (EndoG) (Green and Reed 1998). Cyto c then binds the cytosolic adaptor protein, Apaf-1, mediating the formation of the apoptosis complex “apoptosome”. Such complexes lead to the activation of caspase-9, which further processes and activates the effector caspases, pro-caspase-3, 6, or 7. Effector caspases then cleave death substrates and complete apoptosis. The death receptor pathway is initiated through interaction with death receptors and the recruitment of cytoplasmic proteins to specific regions in the intracellular domains of these receptors. The receptor adaptor protein complex then binds pro-caspase 8 and forms a death-inducing signaling complex (DISC) that subsequently releases active caspase 8. Active caspase 8 then activates a caspase cascade and eventually leads to apoptosis of the cell. Many cytokines influence the activation of apoptotic pathways. Members of TNF superfamily, such as TNF- α , TRAIL, or Fas ligand are able to interact directly with death receptors on neurons initiating neuronal apoptosis through activation of the caspase cascade.

In contrast to the apoptotic pathway, some cytokines and growth factors are able to induce survival and proliferation of neurons through survival pathways. The phosphatidylinositol-3-kinase (PI3K) pathway and Ras- or protein kinase C (PKC)-dependent mitogen-activated protein kinase (MAPK) pathway have been extensively studied as survival pathways. Activated PI3K leads to downstream Akt phosphorylation and activation. Notably, Akt activation con-

verges with death receptor mediated receptor interacting protein (RIP) activation on the phosphorylation of the IKK complex and the resulting IKB degradation. IKB degradation releases active nuclear factor κ B (NF- κ B) leading to transcription of genes necessary for cell survival. Similarly, activation of MAPK will lead to nuclear translocation of MAPK together with other transcription factors and co-activators and initiate the transcription of a variety of survival genes. Though not limited to those survival pathways, cytokines and growth factors such as NGF, GDNF, and BDNF play a role in protecting, repairing, or regenerating neurons. Neurons constantly receive survival and apoptotic signals from the extracellular environment, influencing the lifespan of each individual cell. Various cytokines such as BDNF or NGF increase during diseases and may be a compensatory mechanism to the neural injury of the CNS (Soontornniyomkij et al. 1998; Boven et al. 1999). IL-1 β from the IL-1 family or IL-6 from the Type I cytokine family can activate the NF κ B pathway, thus potentially promoting survival of neurons. Interestingly, IL-1, TNF and even TRAIL signaling pathways also converge on IKB degradation and NF κ B activation. IL-6 also activates the Ras-dependent MAPK pathway. Regarding IL-1 β , the activation of NF κ B and MAPK initiates transcription of a variety of genes for either survival or the inflammatory response, dependent upon cell type (Srinivasan et al. 2004).

In summary, various families of cytokine and growth factor may greatly influence the apoptotic or survival pathways of neurons and inflammatory state in the CNS. Extensive crosstalk occurs among signaling pathways activated by cytokines and growth factors. As a result, pathways regulate inflammatory process in neurodegeneration and neuroimmunologic diseases are often not exclusive.

17.4 Cytokines in Neurodegenerative and Neuroimmunologic Disorders

Many cytokines have been suggested to participate in neurodegeneration and neurotoxicity. Increases in factors such as TNF- α and IL-1 β have been observed before neuronal death (Esser et al. 1996; Guo et al. 1998; Little and O’Callaghan 2001; Matusevicius et al. 1996; Meda et al. 1999). However, a simple interpretation of such a pro-inflammatory cytokines effect is controversial. These same cytokines appear to present at least at part of the healthy CNS and has physiological functions. In experimental animals, forced IL-1 β or TNF- α expression does not universally lead to neuronal loss (Akassoglou et al. 1997; Shaftelet al. 2007), suggesting that the action of these cytokines in the CNS is more complex. However, prolonged expression of these cytokines is believed to compromise neuronal functions in disease states. The effect of cytokines in each individual disease will be discussed in the following sections.

17.4.1 Cytokines in HIV Associated Neurocognitive Disorders (HAND)

HIV-1 infection notoriously attacks the immune system in the periphery, but also often leads to neurocognitive impairment in the brain. HIV-1 enters the brain shortly after initial infection, crossing the BBB through peripherally infected monocytes (Koenig et al. 1986). Brain macrophages and microglia, unlike other cellular residents in the CNS, are able to sustain a productive infection within the brain (Eilbott et al. 1989). Although neurons are not infected by HIV-1, without antiretroviral therapy (ART), a dementia specific to HIV has been described as HIV associated dementia (HAD) (Navia et al. 1986; McArthur 1987). Application of antiretroviral therapy has dramatically lowered the rates of HIV-1 replication and HAD. However, substantial numbers of patients are still affected by mild or asymptomatic neurocognitive disorders after apparently successful ART. These disorders, along with HAD, were collected termed HIV associated neurocognitive disorders (HAND) (Sacktor et al. 2016; McArthur et al. 2010). The persistence of HAND indicates an ongoing impairment of neuronal function that cannot be fully restored by ART. The precise mechanism(s) of neuronal injury and dropout in HAND is still unclear. Notably, limited CNS penetration of antiretroviral drugs, presence of viral proteins, the neurotoxicity of ART drugs, co-morbidities with other infection and drugs of abuses may contribute to the neuronal injury associated with the cognitive impairment.

Although recent evidence suggests that HAND showed decreased association with immune activation (Sacktor et al. 2016; McArthur et al. 2010), mononuclear phagocytes (MP, perivascular and brain macrophages and microglia) are known to remain in a chronic state of inflammation (Gendelman and Folks 1999), particularly in the increasing HAND population of older individuals and drug abusers (Valcour et al. 2004; Bell et al. 1998). Pathological examination of patient tissues has revealed characteristic activated macrophage and microglia, as well as damage of neuronal dendrites, axons, and synaptic structure in the brain. Chronic inflammation has both detrimental and beneficial effects. On one hand, these responses are essential in limiting viral spread; yet on the other hand, excessive inflammation is detrimental to resident cells such as neurons. HAD was common in HIV-1-infected individuals who were naïve to ART. In the CNS, infected macrophages and microglia become the major cytokine producer (Meltzer et al. 1990; Wiley et al. 1986; Fischer-Smith et al. 2004; Griffin 1997; Kaul et al. 2001). Two distinct models have been proposed as mechanisms in HAD pathogenesis. The first is the direct neuronal injury model, where viral proteins (gp120, Tat and Vpr) directly interact with neurons causing neuronal injury through various mechanisms. The role of cytokines in this model has been controversial. On one hand, cytokines like

TNF- α have a synergistic apoptotic effect with viral proteins Tat (Shi et al. 1998) and gp120 (Kast 2002). However, other cytokines inhibit the effects of viral proteins on neurons. For example, TGF- β 1 prevents gp120-induced neuronal apoptosis by restoring calcium homeostasis (Scorziello et al. 1997); BDNF and IL-10 can inhibit gp-120 mediated cerebellar granule cell death by preventing gp120 internalization and caspase 3 activation in vitro (Bachis et al. 2001, 2003). The second model, referred to as the indirect neuronal injury model, proposes that neurons die as bystanders when excessive local concentrations of soluble pro-inflammatory and neurotoxic factors are released by infected MP and astrocytes. Studies have supported this notion including the observation that viral protein levels do not correlate with neuronal injury (Petito et al. 1994), while neuronal apoptosis correlates well with microglial activation (Adle-Biassette et al. 1995; Glass et al. 1993). Furthermore, studies have shown that cognitively impaired patients have elevated levels of inflammatory markers and activators in contrast to HIV patients without CNS impairment (Tyor et al. 1992; Sippy et al. 1995).

Although proinflammatory cytokines such as TNF- α and IL-1 β are key molecules in the pathogenesis of HAD, other cytokines may play their role as well. Elevated levels of IL-6, IL-2 and decreased levels of IL-4 have been reported in both CSF and brain sections of HAD patients (Perrella et al. 1992; Wesselingh et al. 1993; Griffin 1997). These factors are directly related to the inflammatory state of brain. The activation of a TH1 immune response by infected macrophages results in the synthesis of cytokines such as IL-2 and IL-6 that activate macrophage and coordinate the immune response towards HIV-1 infection. IL-2 induces T-cell proliferation and potentiates the release of other cytokines. IL-3 and GM-CSF stimulate the production of new macrophages by acting on hematopoietic stem cells in bone marrow. New macrophages are recruited to the site of infection by TNF- α and other cytokines on the vascular endothelium that signal macrophages to leave the bloodstream and enter the tissue. Moreover, many inflammatory signals have been shown to increase HIV replication. IL-2 and GM-CSF are both potent stimulators of HIV-1 replication in activated CD4+ T cells, and GM-CSF increases HIV-1 replication in macrophage cultures (Perno et al. 1990). The activity of type I cytokines during HIV-1 infection promotes the inflammatory response in an effort to eliminate virus, however in the CNS during HAD, type I cytokine mediated inflammation results in neuronal damage as well as facilitating the replication of HIV.

Type II cytokines are key to the balance of inflammation and regulation of response in HAD. Increased levels of IL-10 in the CSF have been reported in individuals with HIV-1 encephalitis (Gallo et al. 1994). In a study in an murine HIV-1 encephalitis model, mRNA levels of IL-10 were increased five-fold as compared to uninfected controls,

and this change is concurrent with down-regulation of proinflammatory cytokines (IL-1 β and IL-6) (Poluektova et al. 2004). Moreover, pretreatment with IL-10 attenuated the neurobehavioral damage induced by HIV-1 gp120 in an animal study (Barak et al. 2002). In addition to IL-10, IFN- α and IFN- β are induced by HIV-1 infection and suppress HIV replication at multiple steps of the viral life cycle in macrophage (Gessani et al. 1994; Gendelman et al. 1992). Levels of IFN- γ have been shown to be elevated in HAD patients (Shapshak et al. 2004). IFN- γ enhances HIV-1 replication in CD4 $^{+}$ T cells in an autocrine manner, while in macrophage culture IFN- γ enhances HIV-1 replication when added prior to infection but inhibits replication when added post-infection. The active effects of these immunomodulatory and antiviral cytokines suggest that their increase may be an attempt to control inflammation and infection, and to restore tissue to homeostasis.

Among the pro-inflammatory cytokines, TNF- α is the most studied. Elevated levels of TNF- α mRNA is seen in brain tissue collected from HAD patients (Wesselingh et al. 1993). Studies have shown that TNF- α levels in vulnerable brain regions correlate with neurological disease severity in HIV patients (Gelbard 1999). During HAD, microglia, macrophages and monocytes show increased expression of TNF- α and TNF receptors (Tyor et al. 1992), an effect promoted by both IFN- γ and IL-1. Under ART, HAD patients have a marked decrease in soluble TNF- α levels in the cerebrospinal fluid; this drop in TNF- α coincides with decreased viral load and marked improvement in the neurological function of patients (Gendelman et al. 1998). TNF- α may promote neuronal demise through various mechanisms. Increased BBB permeability and recruitment of activated immune cells facilitates viral invasion of the CNS. Synergy of TNF- α , viral proteins and excitotoxic glutamate activates glia to produce neurotoxins or leads to neuronal apoptosis directly [see review Saha and Pahan (2003)]. The effects of TNF- α are complex; differing experimental systems or approaches have also shown TNF- α to assume a neuroprotective role. TRAIL, another member of TNF family, is not normally expressed in the CNS. However, upon HIV-1 infection of CNS, TRAIL was upregulated primarily by infiltrated macrophages. Neurons express TRAIL-receptors and have been indicated as a target of TRAIL (Cantarella et al. 2003; Aktas et al. 2005; Ryan et al. 2004). We have demonstrated that TRAIL is upregulated on the cell surface of HIV-infected or immune-activated macrophages (Ryan et al. 2001, 2004). Also, TRAIL has been reported to be expressed on the cell membrane of MP, Natural killer cells, and CD4 $^{+}$ T lymphocytes and can be cleaved into a soluble, secreted form (Ehrlich et al. 2003). The plasma level of TRAIL is increased to ng/ml ranges in HIV-1-infected patients, particularly those with high viral loads (Herbeuval et al. 2005). Thus TRAIL may be one of the neurotoxic mediators in the pathogenesis of HAD.

Another proinflammatory cytokine IL-1 β is rapidly produced upon HIV-1 infection within the CNS. The induction of IL-1 β has been shown to be associated with HAD (Zhao et al. 2001). IL-1 β in this case serves as an upstream signal for multiple proinflammatory cytokines, notably TNF- α and IL-6, initiating and amplifying inflammation in the brain, which is responsible for the global activation of macrophage and microglia (Chung and Benveniste 1990; Aloisi et al. 1992; Lee et al. 1993). IL-1 β directly activates HIV-1 replication in a monocytic cell line by transcriptional and post-transcriptional mechanisms independent of NF- κ B. IL-1 also synergistically enhances HIV-1 replication with multiple cytokines including IL-4 and IL-6 (Kedzierska et al. 2003).

TGF- β is expressed in the brain by astrocytes, MP and oligodendrocytes, and has been shown to exert multiple effects on neurons and glial cells both in vitro and in vivo. Effects of TGF- β include cell cycle control, differentiation, extracellular matrix formation, hematopoiesis, and chemotaxis. Importantly in the CNS, TGF- β has key a role in regulating neuron survival and repair processes. TGF- β has also been shown to play a role in several varieties of CNS pathology including ischemia, excitotoxicity and neurodegenerative diseases such as multiple sclerosis. In mild HAD, the cerebral levels of TGF- β has an inverse correlation to IFN- α and HIV RNA; while in the severe form of HAD, TGF- β is undetectable (Perrella et al. 2001). In specific culture conditions, TGF- β has neurotrophic effects similar to BDNF and NGF, but a change in conditions can shift the effect of TGF- β towards neurotoxicity (Prehn and Miller 1996).

In summary, various cytokines are upregulated and strongly associated with brain inflammation and neurological symptom in HAD patients. However, introduction of ART has reduced such cytokine dysregulation in HAND patients. This trend of cytokine regulation is consistent with the clinical and pathological manifestation of HAND.

17.4.2 Cytokines in MS

MS is a chronic neurological disease with the hallmark pathological findings of perivascular inflammation and demyelination. Histological sections from MS patients show demyelinating plaques are distributed within the white matter of the CNS, but the most frequently affected sites are the optic nerves, the brainstem, the cerebellum and the spinal cord. Although the pathological hallmark of the MS lesion is focal demyelination, axonal damage and neuronal dysfunction are also found in the pathology of MS (Trapp et al. 1999; De Stefano et al. 2001; Bjartmar et al. 2003). The selective loss of axons and myelin sheaths has been postulated to occur via a variety of different mechanisms. Traditionally, MS has been considered an autoimmune disorder consisting of myelin auto-reactive T-cells that drive an inflammatory process, leading to

secondary macrophage recruitment and subsequent myelin and oligodendrocyte destruction. However, recent detailed studies on a large collection of MS lesions have indicated that structural features of the plaques are extremely variable and the events involved in the immunopathogenesis of MS may be more complicated (Carson et al. 2005).

Cytokines are extensively involved in the pathogenesis of MS. Generally, Th1 of activated CD4⁺ cells produce IL-1 β , IL-2, IFN- γ , and TNF- α to mediate inflammatory pathological processes in immune-mediated tissue damage seen in MS and experimental autoimmune encephalomyelitis (EAE), a mouse model of MS (Adorini and Sinigaglia 1997). In contrast, Th2 cells produce IL-4, IL-6, and IL-10 to mediate antibody production and downregulation of Th1 cellular responses (Adorini and Sinigaglia 1997). The inflammatory reaction in MS and EAE is associated with the upregulation of a variety of Th1 cytokines, including IL-2, IFN- γ , and TNF- α . Adaptive transfer of IFN- γ -producing Th1 cells but not Th2 cells induce EAE, suggesting the pathogenic role of Th1 cells in EAE. However, cells other than the classical Th1 T-cells may contribute to the inflammatory process in autoimmune disease. Studies in the last decade led to the identification of a functionally distinct T cell subset called T helper type 17 (Th17) cells that produce a signature cytokine, interleukin-17A (IL-17A), which play a crucial role in EAE pathogenesis (Korn et al. 2009). Furthermore, IL-23, a cytokine from IL-12 subfamily, has been identified to be a pivotal factor in inducing Th17 cells into a more pathogenic phenotype (Gaffen et al. 2014). This is also evidence suggesting that IL-9-producing Th9 cells can also induce EAE upon adaptive transfer, albeit with a different phenotype (Jager et al. 2009). These data suggest that the heterogeneity of multiple sclerosis lesions may relate to different disease-causing T cells and their associated effector cytokines.

Many inflammatory cytokines from TNF superfamily, such as fas ligand and TNF- α , are important effectors for neuronal death in EAE. Overexpression of Bcl2, an anti-apoptotic protein that blocks death receptor-initiated signaling events, protects mice primed to develop EAE (Offen et al. 2000). Further, elevated death ligand TRAIL expression level in the blood MP of MS patients had been reported (Huang et al. 2000). Oligodendrocytes and neurons have recently been shown to be one of TRAIL's targets (Matysiak et al. 2002; Wosik et al. 2003; Aktas et al. 2005). Although inflammatory mechanisms seem to be an important aspect contributing to tissue injury in MS, whether the degree to which demyelination and axonal injury are a direct consequence of inflammation, is still not clear.

Although pro-inflammatory cytokines associated with type I, IL-1 β , and TNF receptor families are thought to play an important role, characterization of MS and EAE animal model generally support the pathogenic role of IL-17A in the pathogenesis of MS (Korn et al. 2009; Glass et al. 2010).

Th17 cells and IL-17A are frequently detected in lesions from patients with multiple sclerosis and mice with EAE. The differentiation and activation of Th17 cells requires not just IL-17A and IL-17F but cytokines including IL-1 β , IL-6, TGF- β as well as IL-23 and other cytokines. Therefore, targeting IL-17A with neutralizing antibodies has become a new therapeutic approach in treating multiple sclerosis (Gaffen et al. 2014). An ongoing clinical trial with the IL-17A-specific antibody secukinumab in active relapsing-remitting multiple sclerosis has now provided preliminary results that support the role of IL-17A in multiple sclerosis in humans (Baeten and Kuchroo 2013).

In addition to cytokines, T cells, macrophage, and microglia also produce neurotrophic factors and other neuroprotective factors during inflammation, which indicates an important role for inflammation in the repair of MS lesions (Stadelmann et al. 2002; Hohlfeld et al. 2000; Gielen et al. 2003). FGF2 and PDGF have been demonstrated to be the factors regulating remyelination (Frost et al. 2003). CNTF family factors, such as CNTF, leukemia inhibitory factor, cardiotrophin-1, and oncostatin M have been reported to induce a strong promyelinating effect in a myelination model (Stankoff et al. 2002). NGF enhances neural growth and also has the ability to switch the T-cell phenotype from Th1 to Th2, which reduces CNS tissue damage (Villoslada et al. 2000). Interestingly, IL-1 β is crucial to the remyelination of the CNS and this action is suggested to the induction of astrocyte and microglia-macrophage-derived IGF-1 (Mason et al. 2001). IGF-1 may, in addition, have antiapoptotic properties for oligodendrocytes (Mason et al. 2000).

Cytokines has a long history to be used for MS therapy. IFN- β has been in clinical use as an immunomodulatory drug for the treatment of MS for more than 10 years. Administration of IFN- β decreases the relapse rates and new MRI lesions in patients with relapsing/remitting MS (The IFN- β Multiple Sclerosis Study Group 1993) or delay disease progression in patients with secondary progressive MS (Jacobs et al. 1996; George C Ebers et al. 1998). However, the exact mechanisms of action of IFN- β in MS are unknown. IFN- β is effective in preventing the IFN- γ -induced upregulation of MHC-II on antigen-presenting cells (Yong et al. 1998). In an earlier study, patients treated with IFN- γ exhibited an alarmingly high relapse rate during the initial month of treatment (Panitch et al. 1987). IFN- β can also downregulate the expression of costimulatory molecules and inhibit the activation and proliferation of T cells. Another effect of IFN- β is the alteration of cytokine levels. IFN- β decreases the level of Th1 cytokine such as IFN- γ , IL-12 and TNF- α (Yong et al. 1998). IFN- β treatment of astrocytes has been reported to stimulate production of NGF in-vitro (Boutros et al. 1997) and may thus promote remyelination in the CNS.

In summary, cytokines and growth factors are very important mediators in the pathogenesis of MS. More effort should

be brought to explore the complex interactions among immune cells, cytokines, growth factors and CNS resident cells to identify the main perpetrator(s).

17.4.3 Cytokines in AD

AD is the most common chronic neurodegenerative disorder characterized by plaque deposits comprised of highly insoluble β -amyloid peptides ($A\beta$), cleaved products of the amyloid precursor protein (APP), intracellular neurofibrillary tangles (NFTs) generated by hyperphosphorylated forms of the microtubule-binding protein tau, and inflammatory proteins in the cerebral cortex and hippocampus (Ringheim and Conant 2004; Selkoe 2001; Glass et al. 2010). A number of factors have been thought to contribute redundantly to pathogenesis of AD, including unbalanced calcium homeostasis, cell-cycle protein dysregulation, excitatory amino acids, as well as DNA damage. Deposition of $A\beta$ and hyperphosphorylated tau in the brain parenchyma appears to be the crucial factor for the onset of AD, although mechanisms underlying $A\beta$ effects are far from understood. $A\beta$ at high concentrations (generally $>10 \mu\text{M}$) has been found to act as a potent neurotoxic agent to both neuronal and non-neuronal cells. Furthermore, $A\beta$ formation and hyperphosphorylated tauopathy appear to be sufficient to cause stress response in neurons. The stress response in neurons could further activate microglia and astrocytes and to local inflammation that may further amplify neuronal injury and loss.

Inflammation has been suggested to contribute to the $A\beta$ deposition and neuropathology associated with AD. For example, many clinical studies have indicated that anti-inflammatory drugs have a protective effect upon the development of AD (Stewart et al. 1997; Broe et al. 2000). AD is associated with the increase of pro-inflammatory cytokines including IL-6, TNF- α , M-CSF, IL-1 β , TGF- β , PDGF (Griffin et al. 1989, 1995; Akiyama et al. 2000; van der Wal et al. 1993; Tarkowski et al. 1999). These cytokines are produced by activated glia and some (IL-1 β and TNF- α) are capable of perpetuating glial activation, leading to a cycle of overproduction of these potentially neurotoxic molecules. Microglia isolated post-mortem from AD patients have been shown to either constitutively express cytokines, including IL-1 β , IL-6, and TNF- α , or produce these cytokines in response to $A\beta$ (Lue et al. 2001). It should be noted that a complex relationship seems to exist between $A\beta$ deposition and the $A\beta$ -induced inflammatory response.

IL-1 β regulates the synthesis of the APP from which the pathologic and diagnostic amyloid plaques of AD originate (Goldgaber et al. 1989). The functions of IL-1 β and its association with AD pathology suggest that this cytokine plays a key role in the pathogenesis of AD. Brain tissue levels of IL-1 β are markedly elevated in AD, and the numbers of IL-1-

immunoreactive microglia are markedly increased in tissue sections of Alzheimer brain, mirroring the distribution of microglia within cerebral cortical layers in brains of normal controls (Sheng et al. 1998), suggesting that the distribution of microglia within the brain determines in part the distribution of $A\beta$ plaques in AD.

In summary, cytokines and growth factors discussed in this section are implicated in the pathophysiological processes of AD, likely amplifying inflammatory response that ultimately causes neuronal injury. Although the extent of involvement by cytokines, chemokines, and growth factors in AD is still up to debate, many clinical studies will be directed to address this question.

17.5 Chemokine in the CNS

While produced most often by immune cells, chemokines are also expressed by cells within the brain including endothelial cells, neurons, astrocytes, microglia and oligodendrocytes. They regulate a number of brain functions including the migration, recruitment, accumulation, and activation of leukocytes in the brain (Wu et al. 2000). For a summary of chemokines in the CNS, see Table 17.2. Some chemokines such as stromal derived factor-1 alpha (SDF-1 α , CXCL12) and FKN (CX3CL1) are constitutively produced in the brain and likely play an important role in CNS homeostasis and development. Others, such as macrophage inhibitory proteins - one alpha and one beta (MIP-1 α , CCL3 and MIP-1 β , CCL4), monocyte chemotactic protein-1 (MCP-1, CCL2), and the regulated upon activation normal T-cell expressed and secreted (RANTES, CCL5), are induced by inflammatory stimuli. These chemokines are likely involved in the pathogenesis of a variety of neurodegenerative diseases, where inflammation plays a role in pathogenesis, such as MS, AD, and HAND.

The inflammatory response manifested in the brain during HIV-1 infection leads to the development of a chemo-attractant gradient to facilitate the formation of multinucleated giant cells in HIV encephalitis (Williams et al. 2002). This enables inflammatory monocytes to enter the brain, become activated and expand the sources of neurotoxic secretory factors that lead to the pathological and clinical aspects of disease (Gendelman et al. 1997). Moreover, chemokine receptors are critical for infection in perivascular macrophages and microglia. Studies have shown chemokines and their receptors play a more direct role in the neuropathogenesis of HIV-1 infection. It is now clear that neurons, glia and neural stem cells express chemokine receptors and the interactions of HIV-1 gp120 with neuronal chemokine receptors leads to apoptosis of neurons (Cotter et al. 2002; Ryan et al. 2002; Peng et al. 2004; Tran and Miller 2003; Kaul et al. 2001). These effects may be manipulated by chemokines

Table 17.2 Chemokine ligand and receptor expression in CNS

Cell type	Ligands chemokine (systematic name)	Receptors	
Monocytes/macrophages	MCP-1 (CCL2)	CCR2	Bernasconi et al. (1996), Cinque et al. (1998), Kelder et al. (1998), Collman et al. (2000), and Gabuzda et al. (2002)
	MIP-1 α/β (CCL3/CCL4)	CCR3, CCR5	
	RANTES (CCL5)	CCR3, CCR5	
	IL-8 (CXCL8)	CXCR3	
	IP-10 (CXCL10)	CXCR4, CCR4	
Microglia	MIP-1 α/β (CCL3/CCL4)	CCR3, CCR5	Bernasconi et al. (1996), Cinque et al. (1998), Kelder et al. (1998), and Harrison et al. (1998)
	RANTES (CCL5)	CCR3, CCR5	
	MCP-1,3 (CCL2,CCL7)	CCR2	
	IL-8 (CXCL8)	CXCR3	
	IP-10 (CXCL10)	CCR4, CXCR4, CX3CR1	
Astrocytes	MCP-1 (CCL2)	CCR2	Conant et al. (1998) and Zheng et al. (1999b)
	MIP-1 α/β (CCL3/CCL4)	CCR3, CCR5	
	RANTES (CCL5)	CCR3, CCR5	
	SDF-1 α (CXCL12)	CXCR4	
	IL-8 (CXCL8)	CCR4	
	IP-10 (CXCL10), FKN (CX3CL1)		
Neurons	FKN (CX3CL1)	CCR2	Coughlan et al. (2000), Erichsen et al. (2003), and Cook et al. (2001)
	MCP-1 (CCL2)	CCR5, CXCR4	
	GRO- α (CXCL2)	CXCR2	
		CXCR3	
Endothelium	IL-8 (CXCL8)	CXCR4, CXCR7	Gabuzda et al. (2002) and Stumm et al. (2002)
	IP-10 (CXCL10)	CCR5	
	MGSA- α , - β , - γ (CXCL1, 2, 3)		
	MIG (CXCL9)		
	MCP-1,3,4 (CCL2, 7, 13)		
	SDF-1 α (CXCL12)		

that act on the same receptors. The presence of chemokine receptors on neural cells also supports the notion that chemokines modulate neuronal physiological functions. Thus, chemokine receptors might have a crucial role in the balance between neuronal protection and injury.

17.6 Chemokines and Their Receptors in Neurodegenerative and Neuroimmunologic Disorders

17.6.1 Chemokines and Their Receptors in HAND

17.6.1.1 HIV-1, Chemokines and HIV-1 Co-receptors

As previously discussed, chemokines are important players in immune homeostasis and inflammatory response. Their essential roles in immune system have made them targets of invading pathogens. Studies have shown multiple viruses including herpesvirus, poxvirus, retrovirus, and lentivirus take advantage of the chemokine system, posing as analogs, to presumably gain a survival advantage by avoiding or altering immune detection and elimination (Murphy 2001).

Another manipulation of chemokine immune defense first described in 1996, is the use of a chemokine co-receptor in HIV infection (Feng et al. 1996). Initially, HIV was assumed to rely solely on the CD4 surface protein found on T-cells and macrophages for entry into host cells [CD4 as an HIV receptor is reviewed in Sattentau and Weiss (1988)]. However, CD4 alone did not accurately predict the cell interactions of HIV. This eventually led to the breakthrough revealing that chemokine receptor-mediated viral membrane fusion with human host cells. Each HIV strain has different specificities and interactions with various chemokine receptors, but the two primary HIV coreceptors are CCR5 and CXCR4. Macrophage or M-tropic viral strains utilize CCR5 for infection; T-cell or T tropic viral strains rely upon CXCR4. There is another viral subset, dual tropic or R5X4 strain that employs both coreceptors. Further, additional receptors have been shown to have more limited viral interactions including CCR2, CCR3, CCR8, CX3CR1 and others, but the pathophysiological relevance has yet to be determined (Gabuzda and Wang 2000).

The co-receptor requirement is a result of receptor ligand interactions between the chemokine receptors and the HIV coat protein gp120. Virus-cell interactions characteristically begin with gp120 binding CD4, inducing a conformational

change in gp120. This change alters the affinity of gp120 for a coreceptor, either CCR5 or CXCR4, resulting in a trimolecular interaction between gp120, CD4 and the coreceptor (Berson and Doms 1998; Dimitrov et al. 1998; Berger et al. 1999). The multi-molecular interaction then permits fusion of HIV viral membrane to the host cell, permitting entry and consequent integration into the host DNA. Chemokine receptors play a critical role, particularly in the early stages of HIV cell entry both in protective and liable capacities. CCR5 and CXCR4 are the major co-receptors for viral entry into CD4+ cells (Feng et al. 1996; Cocchi et al. 1995; Dragic et al. 1996; Deng et al. 1996), whereas the presence of their ligands can sometimes help prevent infection. In contrast, a deletion within the CCR5 gene confers resistance to HIV-1 infection (Samson et al. 1996). Furthermore, transplantation with stem cells from homozygous CCR5 deletion has produced a first function cure HIV-1 patient, demonstrating the critical role CCR5 plays in maintaining HIV-1 infection (Hutter et al. 2009). These observations have elicited intense interest in using CCR5 as a drug target for the treatment of HIV-1 infection.

Neurons express both chemokines and chemokine receptors, and although not infected by HIV, neurons do express the coreceptors CXCR4 (Zhang et al. 1998) and CCR5 (Rottman et al. 1997). Similar to cells infected by HIV, the neuron coreceptors have affinity for HIV envelope protein gp120, regardless of CD4. Many groups have since shown neuronal toxicity mediated by viral proteins, particularly gp120 (Hesselgesser et al. 1998; Ohagen et al. 1999; Kaul and Lipton 1999; Zheng et al. 1999b; Chen et al. 2002; Garden et al. 2004). Upon interaction with coreceptors, gp120 induces signaling cascades that may play a role in promoting apoptosis. Blocking of these cascades can block neuronal death in some cases. Interestingly, different viral strains induce varying levels of neuronal toxicity (Gabuzda and Wang 1999; Zheng et al. 1999a).

17.6.1.2 Neuroprotective and Neurotoxic Effects of Chemokines and Their Receptors in HAND

In contrast to HIV-1 coreceptors, some chemokine ligands have the ability to reduce or ablate neuron toxicity. High levels of chemokines RANTES, MIP-1 α , and others have been shown to reduce neuron death (Meucci et al. 1998; Kaul and Lipton 1999), while SDF-1, at higher concentrations may actually promote neuronal death (Kaul and Lipton 1999; Hesselgesser et al. 1998; Zheng et al. 1999b). The mechanism is not yet completely understood, but may rely upon simple competitive inhibition, receptor expression changes on the cell surface, or other unknown mechanisms.

FKN (CX3CL1): In the CNS, FKN is constitutively produced by neurons, and its receptor (CX3CR1) is predominantly expressed in the microglia. FKN appears to have

physiological functions since mice lacking the chemokine receptor Cx3cr1 exhibit a transient reduction of microglia during the early postnatal period and a consequent deficit in synaptic pruning (Zhan et al. 2014). FKN levels are higher in the CSF of cognitively impaired HIV patients than in infected subjects without cognitive impairment. Moreover, FKN can affect the chemotaxis of primary monocytes across an artificial blood brain barrier, and is neuroprotective to cultured neurons (Meucci et al. 2000; Tong et al. 2000). Thus, this neuronal chemokine may serve as a damage signal to recruit macrophages and microglia to the site of injury (Jung et al. 2000; Tong et al. 2000; Zujovic et al. 2000; Erichsen et al. 2003). Subsequent chemokine-MP interactions can initiate inflammatory responses through the production of chemokines/cytokines or protective responses through the production of neurotrophins (Xiao and Link 1998; Cotter et al. 2002; Kaul et al. 2001).

MCP-1 (CCL2): Despite some association of chemokines and neuroprotection, there are also detrimental effects of chemokine function during HAD pathogenesis. Shown to be expressed in the brains of HAD patients (Conant et al. 1998), MCP-1 (CCL2) is a potent chemoattractant for monocytes and may help fuel the positive feedback loop of inflammation in the HAD brain. MCP-1 recruits monocytic phagocytes to sites of inflammation as was evidenced by a study using a mouse system with elevated levels of MCP-1 resulting in increased phagocytic cells at lesion sites (Fuentes et al. 1995). A high level of MCP-1 in CSF versus plasma was shown to be predictive of dementia development in monkeys (Zink et al. 2001). While clearly possessing chemotactic properties, the ability of MCP-1 to recruit phagocytes through the BBB was further elucidated with a study showing changes in BBB permeability in the presence of MCP-1 (Song and Pachter 2004). Increased levels of MCP-1 were shown to result in initial protection from infection, however, upon successful HIV-1 infection, increased MCP-1 was shown to lead to increased susceptibility to the development of HAD (Gonzalez et al. 2002).

Interferon gamma inducible protein 10, (IP10, CXCL10): IP-10 is a CXC chemokine. As indicated by its name, IP-10 is highly induced by interferon as well as other factors, yet is also produced constitutively throughout the body. IP-10 targets multiple subtypes of activated T-cells and macrophages for migration. IP-10 has been found in very high levels in CSF as well as shown to recruit cells into the CNS in the setting of HAD. While clearly a player in recruitment and inflammation, IP-10's role has also been shown to include cytotoxic effects towards neurons (van Marle et al. 2004) and may stimulate HIV-1 replication in macrophages (Lane et al. 2003).

IL-8 (CXCL8): An endogenous ligand for CXCR2, IL-8 is secreted in high levels by HIV-1 infected lymphocytes and macrophages. Although expressed constitutively, immune activation potentiates IL-8 production from infected or uninfected

macrophages by agents such as LPS or CD40L (Zheng et al. 2008). IL-8 levels are increased in the CSF of HAD patients, more so than those lacking cognitive symptoms, supporting the role IL-8 in HAD (Zheng et al. 2008).

SDF-1 (CXCL12): Chemokines have also been shown to have a neuromodulatory capacity, in some cases decreasing excitation and avoiding toxicity. A complicated example is the effect of SDF-1 on glutamate toxicity and uptake, specifically as regulated through astrocytes. SDF-1 is a member of the C-X-C chemokine subfamily and is the only known physiological ligand for CXCR4 (Rossi and Zlotnik 2000). SDF-1 is a potent chemoattractant for resting lymphocytes, monocytes, and CD34-positive hematopoietic progenitor cells (Kim and Broxmeyer 1999). CXCR4 is upregulated in HIV and SIV encephalitis, experimental allergic encephalitis (EAE), and brain tumors (Jiang et al. 1998; Sanders et al. 1998; Vallat et al. 1998; Westmoreland et al. 1998). SDF-1 transcripts are predominantly expressed by oligodendrocytes, astrocytes and neurons in the cortex, hippocampus and cerebellum (Gleichmann et al. 2000; Stumm et al. 2003). SDF-1 has been shown to be upregulated in the brain of patients with HIV encephalitis (Langford et al. 2002; Rostasy et al. 2003). Studies conducted in different settings have shown SDF-1 to promote neuronal survival, reducing glutamate toxicity (Meucci et al. 1998), while another study has shown SDF-1 to increase neuronal death by increasing the release of glutamate and TNF- α from glial cells (Bezzi et al. 2001). This may be due to experimental variation or a concentration dependent effect of SDF-1 and glutamate regulation. Recently, it was suggested that SDF-1 could be cleaved to SDF-1 (5-67) and mediate direct neurotoxicity (Zhang et al. 2003).

17.6.1.3 Therapeutic Avenues Directed Toward Chemokines and Their Receptors

Because HIV requires coreceptors for the induction of productive viral infection, and naturally occurring alleles have been shown to effectively limit HIV entry [reviewed in Tang and Kaslow (2003)], potential therapies may rely upon exploitation of CXCR4 and CCR5. However, the ability of HIV to mutate presents a great hurdle in the development of effective therapeutic receptor antagonists. Another layer of complexity is the potential side effects of blocking one or multiple chemokine receptors that have homeostatic and inflammatory roles. Despite the inherent difficulties, multiple approaches have been studied that led to the development of a new class of HIV drugs called CCR5 antagonists (Flexner 2007). Among these new drug maraviroc was approved in 2007 for the treatment of HIV-1 infection. Since then, maraviroc has become one of the two chemokine receptor-targeting drugs that are approved for clinical use. New approaches are also begin developed to target CCR5 for

anti-HIV treatment, which include siRNAs, engineered zinc finger nuclease, and CRISPR/Cas9 (Zhou et al. 2004; Gu and Chen 2014; Saayman et al. 2015).

Some chemokine ligands inherently disrupt viral pathogenesis or provide protection against cell death during the disease process. Ligands of HIV co-receptors, such as SDF-1 and RANTES, have been shown to block infection of cells in different systems (Bleul et al. 1996; Lederman et al. 2004). Similarly, ligands to co-receptors have been shown to block HIV envelope protein induced toxicity to neurons (Alkhatib et al. 1996; Meucci and Miller 1996). The mechanism may be simple blocking or internalization of receptors, or may rely upon the signaling downstream of chemokine interaction.

17.6.2 Chemokines and Their Receptors in MS

Similar to cytokines, the chemokine expression pattern is also a Th1-mediated response in MS. Pro-inflammatory cytokines activate resident macrophages and microglia within the CNS. Recruitment and attraction of these cells occurs via integrins and chemokines and is believed to contribute to tissue injury and demyelination. Selective expression of individual chemokines may influence the cellular composition of inflammatory lesions because chemokine receptors are associated with either Th1 or Th2 responses. Th1 proinflammatory cells may express CCR5 (receptor for chemokines RANTES, MIP-1 α and MIP-1 β) and CXCR3 (receptor for IP-10 and MIG), whereas Th2 inflammatory cells may shift toward the display of CCR3 (receptor for MCP-3, MCP-4, and RANTES) and CCR8. MCP-1, MCP-2, and MCP-3 were found to abundantly express within the lesion center, with more intense staining apparent for MCP-1 and MCP-2 (McManus et al. 1998; Van Der Voorn 1999; #5468).

In MS autopsy brain sections, CCR5 and CXCR3 are overexpressed in peripheral and lesion associated T-lymphocytes (Balashov et al. 1999; Simpson et al. 1998). The ligands for CCR5 and CXCR3, RANTES and IP-10, also increase in the CSF (Lucchinetti et al. 2003). For the cell source of chemokines, IP-10 was associated with astrocytes and perivascular astrocytic processes within MS lesions (Sorensen et al. 1999; Balashov et al. 1999; Simpson et al. 1998). These results suggested that interaction between IP-10 and CXCR3 might be the mechanism that traffic T-cells into MS lesions. Similarly, the elevated CCR5 in activated macrophages was found to be in MS lesions, these results indicated RANTES might mediate the recruitment and activation of monocytes and macrophages in MS (Sorensen et al. 1999).

Chemokines play an important role in remyelination of MS. Chemokine CXCL12 regulates remyelination through oligodendrocyte progenitor cells (OPCs) (Patel et al. 2010).

Blockade of CXCL12 and its receptor CXCR4 signaling limits OPC maturation during remyelination (Carbajal et al. 2010). Interestingly, antagonism of CXCR7, an atypical chemokine receptor that binds CXCL12, augments OPC proliferation, leading to increased numbers of mature oligodendrocytes within demyelinated lesions (Williams et al. 2014). These results suggest that CXCR7 could serve as a new therapeutic target to promote remyelination in MS.

Taken together, existing literature suggests extensive chemotactic interactions between the glia cells in MS lesion and the infiltrating cells. Whether these interactions ultimately promote destructive inflammation or recruitment of protective regulatory cells that enhance tissue repair is still not clear. This is a crucial question to answer before potential pharmacological intervention based on chemokines and their receptors could be used.

17.6.3 Chemokines and Their Receptors in AD

Immunohistochemical analysis of tissue from human brains with AD have revealed that in AD, there is increased expression of MIP-1 β and IP-10 by activated astrocytes, and of the chemokine receptors CCR3 and CCR5 on activated microglia, adjacent to A β deposits in AD (Xia et al. 1998, 2000). Dystrophic neuritis has been shown to express the IL-8 receptor CXCR2 within the A β plaques of AD (Xia et al. 1997). A β is capable of modulating the inflammatory processes involved in AD through chemokine production. MCP-1 is found in activated microglia and within neuritic A β plaques, but not in early plaque forms (Ishizuka et al. 1997). A β promotes production of MCP-1, MIP-1 α , MIP-1 β , or IL-8 by monocytes and microglia (Meda et al. 1999; Fiala et al. 1998); A β also promotes expression of MCP-1 and RANTES by astrocytes (Johnstone et al. 1999). These observations collectively suggest that chemokines may play a role in the pathogenesis of AD (Xia and Hyman 1999). Indeed, Ccr2-deficient mice are viable and in mouse model of AD, Ccr2-deficiency blocks microglial accumulation in the brain, suggesting that CCL2 and CCR2 are pathogenic in Alzheimer's disease. Production of this chemokine promotes the recruitment and accumulation of astrocytes and microglia in senile plaques (Cartier et al. 2005).

Although the exact role of chemokines in the AD is still not yet well defined, neuroprotective effects of chemokine have also been noted thus make chemokines double edged roles in the AD. Fractalkine/CX3CL1 is suggested to have a protective role in AD. It has been reported that Fractalkine/CX3CL1 inhibits the production of IL-6, TNF- α and NO with A β -primed microglia, thereby improving the neuronal survival rate (Mizuno et al. 2003; Zujovic et al. 2000). GRO- α (CXCL2), the ligand for CXCR2 has been suggested to trigger ERK1/2 and PI-3K pathway in a way similar to

BDNF, thus indicates GRO- α , or perhaps other CXCR2 ligands, could have neurotrophic effect on neurons and other cell types (Xia and Hyman 2002). Neuroprotective effects of other chemokines, such as RANTES, SDF-1 α , IP-10, and MIP have also been documented (Meucci et al. 1998).

With the current understanding of the dual roles of chemokines and their related regulations, it is not likely that the pharmaceutical intervention will soon be used to treat the AD. New therapeutic modalities targeting chemokines and their receptors may become available with a more detailed understanding of these agents and their receptors in the inflammatory changes responsible for the CNS degeneration.

17.7 Review Questions

1. What are the difference between type I cytokines and Th1 cytokines?
2. How does IL-1 β contributes to the development of HIV-1 associated dementia, Alzheimer's disease, and multiple sclerosis?
3. Why does signaling of TNF family of cytokine need to be tightly regulated during CNS inflammation.
4. Why are there more chemokines than chemokine receptors.
5. How do different stimuli lead to CNS inflammation in the pathogenesis of HIV-1 associated dementia, Alzheimer's disease, and multiple sclerosis?
6. Briefly discuss the approach to classify chemokines and provide an example for each type.
7. Which chemokine receptors have been identified as coreceptors for HIV?
8. Many cytokines and chemokines are upregulated during the pathogenic processes in MS and AD, what is the best approach to identify them as therapeutic targets?
9. Which of the following statements about chemokines is correct?
 - (a) Chemokines and chemokine receptors play a significant role in pathogenesis of inflammatory disorders.
 - (b) Stromal derived factor-1 α (SDF-1 α , CXCL12) and fractalkine (FKN, CX3CL1) are constitutively produced in the brain.
 - (c) Macrophage inhibitory proteins-one alpha and one beta (MIP-1 α , CCL3 and MIP-1 β , CCL4), and monocyte chemotactic protein-1 (MCP-1, CCL2) are induced by inflammatory stimuli in the CNS.
 - (d) All of the above are correct.
10. Propose a potential therapeutic approach using a cytokine or chemokine in HIV-1 associated neurocognitive disorders.

17.8 Answers

1. Classification of Type I cytokine receptors is based on structural biology, whereas classification of Th1 cytokine receptors is based on function. Type I cytokine receptors include both Th1 cytokine receptor (IL-2) and Th2 cytokine receptors (IL-4 and IL-5).
2. IL-1 β is a potent proinflammatory cytokine. HIV-1 infection, A β deposition, and the infiltration of activated T cell into the CNS will lead to IL-1 β production in microglia and macrophage. IL-1 β induces genes associated with inflammation and amplifies inflammation in the CNS particularly in the chronic state.
3. This inflammatory state is highly regulated, usually self-limited, and differs from the inflammation in peripheral tissues. The threshold to initiate immune responses against antigens in CNS is much higher than that in periphery.
4. There are few chemokine receptors that bind to a single ligand, and several chemokines can bind to multiple receptor
5. In HAD, HIV-1 infection of macrophage in the CNS leads to the activation of macrophage and microglia. Activated macrophage and microglia release cytokines, and chemokines that can be detrimental to neurons. Neuronal injury recruits additional macrophages. This process of injury, recruitment, and activation forms a positive feedback loop and advancing the disease state. In AD and MS, either A β priming or T cell-mediated of macrophage/microglia activation may utilize similar inflammatory cytokines and chemokines to cause the pathogenic effects on the CNS.
6. Chemokines are classified based upon the arrangement of two N-terminal cysteine pairs. Chemokines with two cysteines separated by one amino acid are called CXC or α with examples being SDF-1 (CXCL4) and IL-8 (CXCL8). Chemokines with two cysteines immediately next to each other are called CC or β chemokines, with examples including MCP-1 (CCL2), MIP-1 α/β (CCL3,4), and RANTES (CCL5). The two remaining groups are called C or δ chemokines and CX3C or γ chemokines and are represented by Lymphotactin (XCL1) and Fractalkine (CX3CL1).
7. CCR5, CXCR4, and CX3CR1.
8. Targeting IL-17A with neutralizing antibodies has become a new therapeutic approach in treating multiple sclerosis.
9. Because of the great diversity among cytokines, there are nearly limitless potential therapeutic avenues through their manipulation. The use of anti-inflammatory cytokines such as TGF- β and IL-10 may be useful for preventing or limiting excessive inflammation in some neurodegenerative disorders. On the other hand, inflammatory cytokines such as IFN- γ or TNF- α may potentially be used to enhance the immune response, perhaps

facilitating the removal of immune insults such as HIV or A β protein aggregates. One final approach may be through the manipulation of survival pathways; for instance, pro-apoptotic factor TRAIL may have therapeutic uses for clearance of infected cells, whereas BDNF may be a useful agent to enhance neuron viability. It is important to keep in mind a major pitfall is the means of delivery for this type of treatment and ensuring the specificity of response to the area of insult.

Acknowledgments This work was supported in part by research grants by the National Institutes of Health: R01 NS41858-01, 2R56NS041858-15A1 (JZ), and R03 NS094071-01 (YH). We thank Drs. Nathan Erdmann and Terry D. Hexum for the scientific editing of the previous edition of this book chapter; we thank Julie Ditter, Robin Taylor, Myhanh Che, Lenal Bottoms, Johna Belling, and Kimberley Morrison for the outstanding administrative and secretarial support.

Growth and Neurotrophic Factors in HIV-Associated Neurocognitive Disorders

18

Palsamy Periyasamy, Ming-Lei Guo, and Shilpa Buch

Abstract

The advent of combination antiretroviral therapy (cART) has successfully controlled replication of the human immunodeficiency virus (HIV) leading to reduced morbidity and increased longevity of infected people. Paradoxically however, as patients live longer lives, the prevalence of HIV-associated cognitive impairments has risen due to drug toxicity and its limited cART central nervous system (CNS) penetrance. Additionally, the presence of HIV proteins, which are not impacted by antiretrovirals, are a source of neuroinflammation. As a result, almost 50 % of infected individuals on effective cART exhibit various forms of HIV-associated neurocognitive disorders (HAND) whose mechanism(s) include deficits in calcium flux, excitotoxicity, cell signaling, oxidative stress and autophagy. Additionally, defects in the processing and functioning of neurotrophic factors such as fibroblast growth factors, brain-derived growth factor, insulin-like growth factor, platelet-derived growth factor, and glial cell derived neurotrophic factor have also been implicated in disruption of neuronal function. Importantly, these factors have been shown to interfere with the fundamental mechanism of apoptotic cell death, the underlying feature of HAND and other neurodegenerative diseases. Additionally, neurotrophic factors are also capable of promoting neuronal differentiation, neurogenesis and angiogenesis, thereby facilitating repair. Currently, there are no effective adjunctive treatments for disease. Thus, identifying novel neuroprotective molecules for treating such diseases is highly warranted in this field. This chapter discusses the beneficial roles of those neurotrophic and growth factors in the context of potential HIV therapies.

18.1 Introduction

Currently over 40 million people are living with HIV-1 worldwide. The advent of combination antiretroviral therapy (cART) has successfully controlled replication of the virus leading to increased longevity of those infected. As a result, disease morbidities and mortality rates for patients with HIV has improved dramatically. Paradoxically however, increased survival rates resulting from broad cART availability and usage have also resulted in an undesirable increase in the

prevalence of mild neurocognitive impairments collectively referred to as HIV-associated neurocognitive disorders (HAND). Clinically, HAND is associated with reduced quality of life, memory loss, and social and occupational disabilities. Pathologically, in the most severe forms, patients can exhibit protracted forms of HIV-encephalitis (HIVE) and in the most mild subtle evidence gliosis. Pathological findings, however, do not always correlate with disease signs and symptoms and patients manifest with common and subtle cognitive deficits rather than overt dementia. When neurodegenerative pathology is seen it is characterized by involvement of cortical and subcortical regions (milder phenotypes) and simplification of the synaptodendritic structure of neuronal populations in the neocortex and hippocampus.

Central nervous system (CNS) homeostasis is a fine balance between the presence of neurotrophic and neurotoxic factors. While there is abundant information on the neurotoxic factors, the neurotrophic factors have been rather understudied and include brain derived neurotrophic factor (BDNF), fibroblast growth factor (FGF), nerve growth factor (NGF) and glial cell derived neurotrophic factor (GDNF) have been implicated in the protection of neurons against various neurotoxins (Alzheimer and Werner 2002; Deierborg et al. 2008; Almeida et al. 2005; Colafrancesco and Villoslada 2011). Downregulation of BDNF follows HIV infection leading to imbalance of anti- and pro-apoptotic neurotrophins (Avdoshina et al. 2011; Bachis et al. 2012; Mocchetti et al. 2007; Nosheny et al. 2007; Bachis and Mocchetti 2005). Findings from our lab have identified yet another factor, platelet-derived growth factor (PDGF) that plays a crucial role in reversing neuronal toxicity mediated by HIV proteins, Trans-activator of transcription (Tat) and HIV-1 gp120 (Yao et al. 2009). Neurotrophic factors exert their effects by preventing synaptic and axonal degeneration that follows neurotoxin exposures. These factors interfere with the fundamental mechanism of apoptotic cell death; the underlying feature of many neurodegenerative diseases. Additionally, neurotrophic factors are also capable of promoting neuronal differentiation, neurogenesis and angiogenesis, thereby facilitating repair (Avdoshina et al. 2011; Bachis et al. 2012; Mocchetti et al. 2007; Nosheny et al. 2007; Bachis and Mocchetti 2005). Neurotrophic factors can promote axonal growth and maintain normal neuronal morphology. For HAND, a loss of expression of neurotrophic factors and/or their receptors can impair neural signaling and affect disease. Although cART can inhibit systemic virus replication, HIV proteins (not impacted by cART) such as Tat or HIV-1 gp120 present in CNS and the lymph node tissues can induce neurotoxicity. Viral proteins interfere with neuronal survival by a number of mechanisms including the production of free radicals, nitric oxide, and the release of glutamate, inflammatory cytokines or other excitotoxins (Kaul et al. 2001). Additionally, neurotrophic factors are also capable of promoting neuronal

differentiation, neurogenesis and angiogenesis, thereby facilitating repair. Currently, there are no effective treatments for most neurodegenerative diseases. Thus, identifying novel neuroprotective molecules for treating such diseases is highly warranted. This chapter discusses the beneficial roles of several neurotrophic factors such as FGF, BDNF, IGF, PDGF, and GDNF in the context of HIV infection.

18.2 Fibroblast Growth Factor (FGF)

The superfamily of FGF encompasses 18 family members that are grouped into several subfamilies based on their sequence homology and phylogeny. Originally this superfamily included four additional ligands, now termed FGF homologous factors (previously FGF11-14; now FHF1-4), that have since been removed (Goldfarb et al. 2007) as they are not capable of activating FGF receptors although they share structural similarity with other member ligands. The 18 ligands bind to four distinct membrane-bound FGF receptor subtypes with differing affinities (Reuss and von Bohlen und Halbach 2003). Following binding to the ligand, FGF receptors undergo dimerization and phosphorylation followed by activation of three primary downstream signaling pathways: RAS/mitogen-activated protein kinase (MAPK), phosphatidylinositol 3-kinase (PI3K)/AKT and phospholipase gamma (Fig. 18.1).

Ten of eighteen FGFs are expressed in the brain (Goldfarb et al. 2007) with the highest abundance for FGF1 and FGF2 in the adult brain (Turner et al. 2006; Wilcox and Unnerstall 1991; Gomez-Pinilla et al. 1992). FGF2, also known as basic fibroblast growth factor, was the first FGF to be cloned in the rat (Kurokawa et al. 1988). Among the various brain regions, hippocampus and the cortical regions exhibit the highest expression of FGF2 (Gomez-Pinilla et al. 1994). At the cellular level, FGF2 is expressed in both neurons and glial cells with astrocytes representing increased expression (Gonzalez et al. 1995). FGF1, known as acidic fibroblast growth factor, is predominantly expressed in neurons and relatively little outside of the nervous system (Goodrich et al. 1989). FGFs have been well characterized for their multifarious roles in neuronal differentiation, survival as well as angiogenesis in the CNS. FGFs have also been shown to promote gliogenesis and neurogenesis when added to cultures of precursor cells from various brain areas (Vescovi et al. 1993; Qian et al. 1997) or when expressed in developing (Raballo et al. 2000) or adult brains in vivo (Shihabuddin et al. 1997; Yoshimura et al. 2001). Additionally, the neuroprotective roles of FGFs have also been demonstrated in neurons exposed to toxic insults (Frim et al. 1993; Zechel et al. 2010). Specifically, FGF2 has been demonstrated to inhibit excitotoxicity associated with excessive glutamatergic stimulation (Fernandez-Sanchez and Novelli 1993; Kirschner et al. 1995; Brandoli

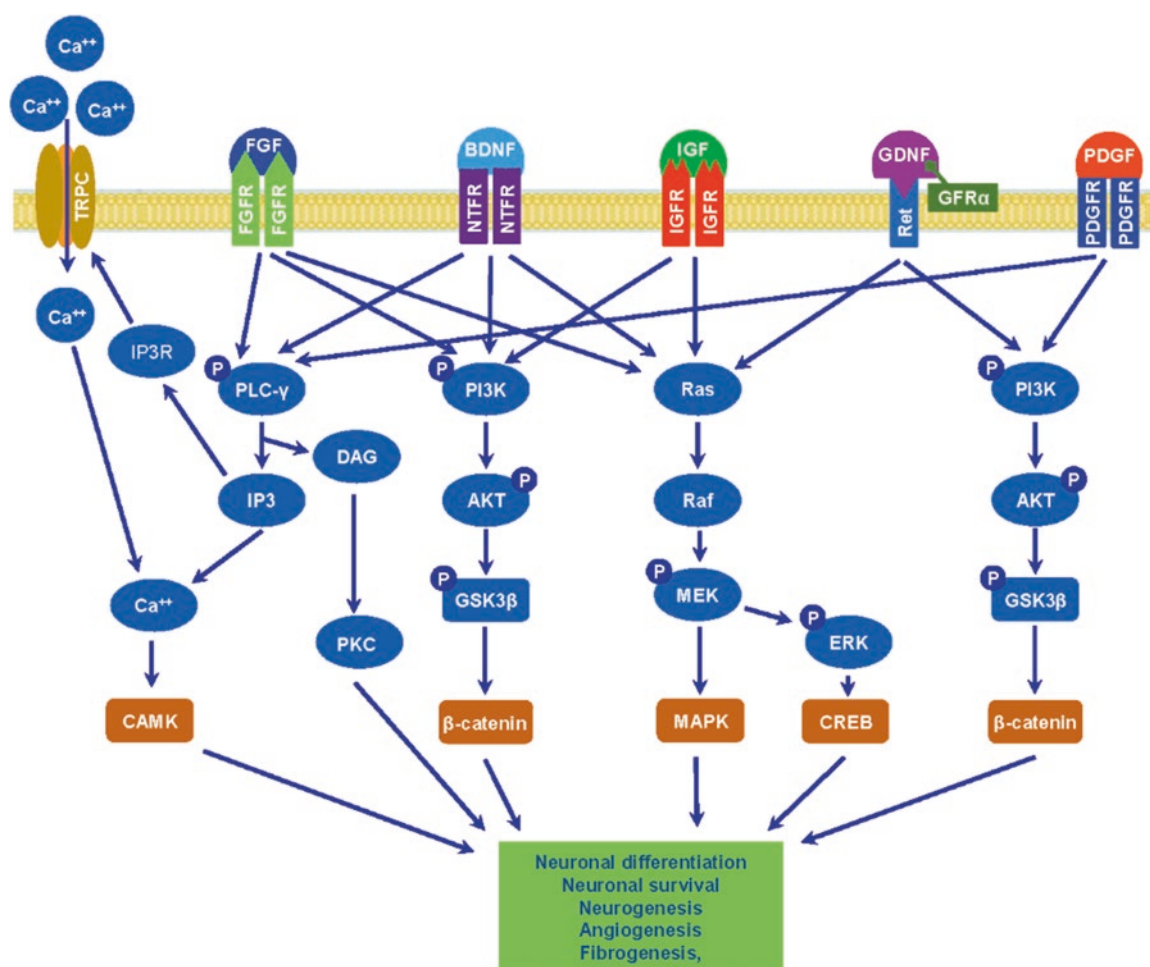

Fig. 18.1 Schematic representation of growth and neurotrophic factors signaling in HAND. After HIV infection, the HIV proteins and other cellular neurotoxins involved in the activation of various signaling

through its receptor interactions thereby affecting/modulating the downstream signaling processes as an outcome these pathways intensify the neurotoxic effects of HIV proteins

et al. 1998) while also reducing inflammatory responses and improving recovery of neuronal function following mechanical injury or stroke (Peterson et al. 1996; Kawamata et al. 1997; Teng et al. 1999).

Based on the ability of FGFs in exerting protective effects on mature neurons exposed to toxic stimuli, it has been proposed that enhanced expression of these neurotrophic factors could be of therapeutic value as a mechanism to protect the CNS against toxicity mediated by HIV proteins such as Tat and gp120 (Everall et al. 2001; Langford et al. 2002). In fact, FGF1 levels have been shown to inversely correlate with neurotoxic effects observed in HIV patients (Everall et al. 2001). For example, in archived brain tissues from HIV positive encephalitic patients with no obvious signs of neurodegeneration, FGF1 levels were significantly elevated compared with the levels of the neurotrophic factor in HIV positive individuals exhibiting both encephalitis and signs of neurodegeneration (Crews et al. 2009; Everall et al. 2001). In vitro studies using primary human neuronal cultures have

also demonstrated that FGF1 protected the neurons against gp120 toxicity in a dose-dependent manner (Everall et al. 2001) and that FGF1 overexpression ameliorated neurodegeneration in gp120 expressing transgenic mice in vivo (Crews et al. 2009). In addition to the damage to neurons, gp120 also mediates injury to endothelial cells lining the blood-brain barrier (BBB). This in turn leads to breach of the BBB integrity resulting ultimately into enhanced migration of HIV-infected cells from the periphery into the brain (Nakamuta et al. 2008; Yang et al. 2009a).

FGF2 that is produced primarily by astrocytes has the ability to promote endothelial cell fitness and angiogenesis. For example, pretreatment of human umbilical vein endothelial cells with FGF2 protected cells from gp120-induced angiotoxicity. It was demonstrated that ERK signaling pathways was responsible for these protective effects of FGF2 (Langford et al. 2005). Other possible protective roles for FGFs in the CNS include the dampening of the pathology and symptomatology resulting from excessive glutamate and

the ensuing neuroinflammation in HIV patients. In fact, both FGF1 and 2 have been shown to reduce the expression of CXCR4, a chemokine receptor that mediates the entry of T-tropic HIV (Dittmar et al. 1997). Furthermore, it was also shown that FGFs levels inversely correlated with CXCR4 expression in postmortem AIDS brains (Sanders et al. 2000). This could explain in part, why reduced expression of FGFs, in turn, lead to enhanced neuroinflammation and increased virus replication, thereby contributing to exacerbated progression to HAND.

HIV patient brains exhibit not only morphological and structural alterations in mature neurons, such as decreased synapse numbers, reduced spine density and neuronal loss, but also significant defects in adult hippocampal neurogenesis (Avraham et al. 2014; Lee et al. 2013). Similar defects in neurogenesis that are observed in HIV patient brains have been also recapitulated in a rodent model of HAND—the gp120 transgenic mice (Okamoto et al. 2007). Interestingly, over-expression of FGF1 (Crews et al. 2009) diminishes these neurogenesis defects as indicated by increased numbers of doublecortin expressing neurons (Langford et al. 2005). Based on these findings, it has been suggested that the mechanism(s) responsible for impaired neurogenesis during HIV infection involve neurotoxic effects of HIV proteins such as gp120, vpr, and Tat on neuronal progenitor cells through dysregulation of the neurotrophic factor signaling pathways. In the setting of HIV-mediated encephalitis, alterations in GSK3 β (Maggirwar et al. 1999; Nguyen et al. 2009; Kehn-Hall et al. 2011) and abnormal activation of CDK5 (Patrick et al. 2011; Lee et al. 2013) have also been suggested to play important roles in the culmination of neurodegeneration and ultimately HAND. It was shown that over-activation of CDK5 resulted in hyperphosphorylation of collapsing-response mediator protein-2 (CRPM2) and decreased neurite outgrowth. Reciprocally, inhibition of CDK5, or expression of a non-phosphorylatable (S522A) CRPM2 construct in adult hippocampal neurons reversed neurite outgrowth deficits (Lee et al. 2013). Likewise, CDK5-mediated CRPM2 phosphorylation was significantly increased in the hippocampus of HIV positive subjects and in gp120 transgenic mice, and these effects were rescued by genetic down-modulation of CDK5 in the mouse model (Crews et al. 2011). These results thus underscore that abnormal CDK5 activation and CRPM2 hyperphosphorylation could contribute to defective neurogenesis in neurodegenerative disorders such as HIVE (Crews et al. 2011).

Taken together, these reports highlight the fact that FGFs, especially FGF1 and FGF2 play critical roles in the CNS, not only by supporting the survival of mature neurons exposed to toxic stimuli, but also by promoting neurogenesis and angiogenesis to ensure normal brain functioning and homeostasis. FGFs are also beneficial in enhancing neuronal survival and protection against toxic insults in the HIV infected brain.

Development of FGFs as therapeutic agents could thus serve as alternative approaches for ameliorating functional deficits associated with HAND.

18.3 Brain-Derived Neurotrophic Factor (BDNF)

BDNF is a member of the neurotrophin family that includes NGF and the neurotrophins NT-3 and NT-4. In general, BDNF supports the survival of mature neurons and promotes the neurogenesis and differentiation of new neurons in the CNS and the peripheral nervous system. In the brain, BDNF is expressed in the hippocampus, cortex, and basal forebrain—areas vital for learning and memory. BDNF primarily binds to two types of receptors: TrkB and the LINGFR (low-affinity nerve growth factor receptor, also known as p75). Pro-BDNF and mature BDNF have different binding affinities for TrkB and p75. Pro-BDNF binds with a higher affinity to p75 while mature BDNF has a preference for TrkB. Such distinct binding patterns could likely explain the differences in cellular fates induced by pro- or mature BDNF exposure; with pro-BDNF binding to p75 resulting in pro-apoptotic signaling while mature BDNF predominantly supporting neuronal survival. Mechanistically, BDNF executes its functions by enhancing glutamatergic excitatory signaling (elevations of NMDA and AMPA Receptors activity) and preventing the GABAergic inhibitory signaling strength. BDNF play critical roles in neuronal survival and growth. Impaired functioning of BDNF has been implicated in many neurodegenerative disorders including Alzheimer's disease (AD), drug addiction and schizophrenia. For example, in the brains of AD patients, there is alteration in BDNF transport resulting in degeneration of selected neuronal populations located in the basal nucleus of Meynert and hippocampus (Mufson et al. 1989; Mufson and Kordower 1992; Poon et al. 2013). Furthermore, reduced BDNF release/levels have also been shown to closely correlate with depression (Duman 2004) and Huntington's disease (Zuccato and Cattaneo 2009).

Recent evidence has also shown that BDNF may play a neuroprotective role in the context of HIV-1. BDNF has been shown to protect neurons against gp120-mediated toxicity both in vivo and in vitro (Bachis et al. 2003) by regulating neuronal expression of the HIV co-receptor, CXCR4. This receptor is abundant in neurons and areas of the CNS such as the cortex, hippocampus and striatum (Ahmed et al. 2008). Increasing evidence shows that neuronal CXCR4 is a target of BDNF. Indeed, previous studies have shown that BDNF decreases the expression of CXCR4 (Nosheny et al. 2007; Bachis et al. 2003). Conversely, heterozygous BDNF knockout animals exhibited increased levels of CXCR4 mRNA in the cortex, hippocampus and striatum compared with the wild type controls (Ahmed et al. 2008). Moreover, in these mice,

increased CXCR4 expression correlated with a more robust neurotoxic effect of gp120 (Nosheny et al. 2004). Thus, BDNF is particularly important as a neuroprotective factor against HIV envelope gp120 mediated neurotoxicity, which is primarily transmitted via the CXCR4 receptors. Furthermore, BDNF has also been shown to reduce glial expression of CXCR4, leading in turn, to effective blocking of virus infection in microglia and astrocytes in the CNS (Nosheny et al. 2004). Mechanistically, BDNF initially binds to the tyrosine kinase receptor, TrkB, followed by induction of receptor dimerization (Fig. 18.1). This in turn, leads to increased activation of ERK signaling which culminates in decreased expression of CXCR4, blocking of caspase-3 and decreased gp120-mediated neuronal apoptosis (Bachis et al. 2003). CXCR4 internalization is important for BDNF-mediated down-regulation of CXCR4 levels (Bachis et al. 2003; Mocchetti and Bachis 2004; Mocchetti et al. 2007, 2008). Intriguingly, another study validating these findings demonstrated that BDNF was not able to prevent gp120 neurotoxicity in neurons that did not express TrkB (Ahmed et al. 2008).

There are other mechanisms as well, by which BDNF exerts its beneficial effects in the context of HIV. BDNF supports the survival of T cells (Maroder et al. 1996; De Santi et al. 2009), which are the key cells that are depleted in AIDS patients. BDNF thus exerts its effects by maintaining the pool of CD4⁺T cells thereby delaying the progression to AIDS. Preservation of CD4⁺T cells can in turn, can have broader implications for CNS functioning. It has been demonstrated that onset of severe immunodeficiency precedes progressive neurological deficits. For example, it has been shown that during a state of chronic inflammation induced in a non-human primate following infection with simian immunodeficiency virus, the brain is positive for peripheral circulating monocytes trafficking from the bone marrow (Burdo et al. 2010). Inflammation in this case correlated with the severity of encephalitis. It has been shown that uncontrolled activation of cytokine and chemokine receptors in the context of HIV infection leads to dendritic beading and loss of dendritic spines (Suzumura et al. 2006). These changes are accompanied by failure of long-term potentiation (LTP), which in turn, underlies learning and memory deficits. BDNF rescues neuronal deficits by promoting dendritic branching and spine morphology (Horch and Katz 2002; Tanaka et al. 2008), which are crucial for BDNF-mediated LTP (Figurov et al. 1996). This in part, explains how BDNF maintains neuronal structural integrity and morphology while abrogating memory and learning deficits.

HIV proteins have been shown to regulate BDNF levels in the brain. For example in the HIV brain, gp120 and TNF α antagonized BDNF functions by inhibiting the anterograde transport of BDNF, reducing the intracellular stores and stimulating the NMDA receptor activity (excitotoxicity), leading in turn, to reduced neuronal survival (Bachis et al. 2003;

Nosheny et al. 2004). HIV also inhibits BDNF activity via an indirect mechanism via stimulation of TNF α . TNF α has been shown to prevent glucocorticoid receptor (GR) activity, leading to reduction of hippocampal neurogenesis. HIV-induced neuroinflammation thus indirectly leads to neurodegeneration by silencing GR activity (Suri and Vaidya 2013). Additionally, BDNF pro-survival effect is also reduced as HIV downregulates its levels in lymphocytes, which in turn, leads to T-cell apoptosis and neurodegeneration (Avdoshina et al. 2011). The molecular mechanism(s) underlying down-regulation of BDNF by HIV remain unclear. Recent data however, suggests that gp120 reduced pro-BDNF processing in neurons by decreasing furin levels and by effectively altering the balance of anti- and pro-apoptotic neurotrophins (Bachis et al. 2012). Another study also showed that in the older patients with HIV or with HIVE exhibited decreased levels of BDNF and increase levels of pro-BDNF protein.

Several cellular mechanisms are involved in the processing of pro-BDNF into mature BDNF. ProBDNF is cleaved within the endoplasmic reticulum by furin and in regulated secretory vesicles by proconvertase enzymes. If proBDNF reaches the extracellular milieu, it is processed by plasmin, and the mature BDNF produced then activate cell surface TrkB receptors (Pang et al. 2004). On the other hand, extracellular proBDNF binds with p75NTR and become endocytosed and then cleaved to produce mature BDNF that either activates TrkB within endosomes (Nykjaer et al. 2004) or is recycled to the cell surface (Pang et al. 2004). The site of BDNF translation within the neuron determines the form of BDNF released. BDNF mRNA with a short 3' UTR accumulates in the neuronal soma, whereas BDNF mRNA with a long 3' UTR is trafficked to dendrites. The soma supports BDNF cleavage within the Golgi, but the majority of dendrites lack Golgi elements necessary for processing of proBDNF, and therefore proBDNF is the predominant form released (Barker 2009; Yang et al. 2009b). Conversion of pro-BDNF to mature BDNF is an important process for synaptic plasticity. In fact, pro-BDNF can bind with high affinity to p75NTR (Greenberg et al. 2009) and promote neuronal loss (Teng et al. 2005). The altered mBDNF/proBDNF ratio in HAND could thus compromise synaptic connections and neuronal survival. These findings were recently corroborated by a report demonstrating that reduced neurite out growth and impaired neurogenesis was reversed by exercise via the production of BDNF in a gp120 transgenic mouse model (Lee et al. 2013).

Taken together, it is reasonable to suggest that HIV promotes neuronal degeneration by lowering BDNF levels and that BDNF treatment could be considered a beneficial therapeutic approach for ameliorating complications of the CNS in HIV-infected patients. Corroborating this was the observation that both brain (Bachis et al. 2012) and serum (Avdoshina et al. 2011) BDNF levels were significantly lower in HIV positive individuals compared with the HIV

negative subjects. Furthermore, low levels of BDNF have been shown to impair the innervation of the cortex by serotonergic fibers (Lyons et al. 1999). Similarly, gp120-mediated reduction of BDNF levels appears to cause neuronal degeneration even in the absence of inflammation (Nosheny et al. 2004). In summary, these findings suggest that low levels and activity of BDNF could be a risk factor for the development of HAND and that delivery of BDNF to neurons could be an effective means of treating HIV-associated neurodegeneration.

18.4 Insulin-Like Growth Factors

Insulin-like growth factors (IGFs) are signaling protein molecules that regulate key cellular activities, specifically cell proliferation, differentiation, and apoptosis. Recent reports have shown that IGFs are potential neurotherapeutic agents that modulate brain development and plasticity (Bondy and Cheng 2002; Ciucci et al. 2007; Tropea et al. 2006). IGF signaling is an intricate system, comprises of two ligands, IGF-1 and IGF-2, two-cell surface receptors (IGF1R and IGF2R), and a family of six high-affinity IGF-binding proteins (IGFBPs) and four low-affinity IGFBPs. The sequence homology of IGF-1 and IGF-2 are similar to each other as well as with proinsulin (Daughaday and Rotwein 1989; Rotwein 1991). IGF-1 and IGF-2 normally bind to the insulin/IGF family of cell surface receptors and activate their intrinsic tyrosine kinase activities. Since IGF-1 has a higher binding affinity to IGF1R than that of insulin receptor, IGF1R is commonly referred to as a physiological receptor. IGF2R on the other hand is commonly referred as a clearance receptor, because IGF2R can only bind with IGF-2 thereby sequestering the IGF-2 and preventing IGF-2 mediated downstream signaling (Nakae et al. 2001). IGF signaling elicits pleiotropic activities such as proliferation, maturation, survival, and/or growth of most neural cells including neural stem cells, lineage restricted neural precursor cells, post-mitotic neurons, oligodendrocytes and astrocytes in the developing brain. The biological activities of IGFs however, seem to vary based on the specific cell types, the local microenvironment, and the stage of development (O'Kusky and Ye 2012).

IGF-1, a small polypeptide trophic hormone, is mainly synthesized in the liver and is transported to the brain simply by IGFBPs, found in the plasma and cerebrospinal fluid (Jones and Clemmons 1995). IGF1 is also produced by all the cell types in the brain, and its expression is highest perinatally in regions such as the brainstem, cerebellum, cortex, hippocampus, hypothalamus and the spinal cord. The primary functions of IGF-1 include regulation of development, cell differentiation, plasticity, and survival of the nervous system (Benarroch 2012). In addition, IGF-1 is involved in regulating brain development and promoting neuroprotection following cellular

insult, neurogenesis, myelination and synaptogenesis. IGF-1 binds to the cell surface IGF1R, which is expressed specifically during the development of the brain or in response to injury, thereby producing growth-promoting signals. IGF-1 mediated canonical signaling through the IGF-1 receptor comprises of phosphoinositide-3-kinase-AKT-FOXO, and RAS-MAPK signaling pathways (Fig. 18.1). These signaling pathways modulate active gene transcription and activate numerous downstream kinases and phosphatases, that eventually perturb vital cellular functions including protein synthesis, autophagy, apoptosis and protection from oxidative stress associated with immunity and inflammation (Fernandez and Torres-Aleman 2012). In addition, IGF-1 has an essential role in the promotion of dorsal root ganglion neuronal development and peripheral axonal regeneration as well as neuritogenesis (Kimpinski et al. 1997; Jones et al. 2003). Essentially, the effects of IGF-1 are more prominent in the adult brain than in the developing brain (Bondy and Lee 1993).

The association between IGF axis and HIV is very complex. HIV infection is frequently interconnected with a notable decline in the IGF-1, IGF-2, and IGFBP-3 levels with a significant elevation in IGFBP-1 and IGFBP-2 concentrations. In recent years, IGF-1 has gained significant attention for its modulatory role in adult neurogenesis (Aberg et al. 2000, 2003; Lichtenwalner et al. 2001). In addition, circulating IGF-1 plays an essential role in the mediation of exercise-induced augmentation of hippocampal neurogenesis in the adult brain (Trejo et al. 2001). IGF-1 also acts as a neuroprotective agent against neuronal death induced by supernatants from HIV-1-infected macrophages in vitro (Ying Wang et al. 2003). Low levels of IGF-1 in conjunction with elevated levels of TNF- α are known to exacerbate HIV-1 mediated neurodegeneration (Kumar et al. 2003). In addition, low levels of peripheral IGF-1 have been reported in HIV-patients with wasting syndrome and in children with failure to thrive. Since IGF-1 acts as a primary mediator for growth hormone action, its role in anabolic effects has encouraged studies on IGF-1 levels in HIV-infected patients and the use of IGF-1 and growth hormone in the treatment of cachectic patients (Wilk et al. 2011; Mynarcik et al. 1999). However, few studies suggest limited resistance to IGF-1 and growth hormone therapies in the setting of HIV-1 wasting syndrome (Jain et al. 1998). Therefore, diminished levels of IGF-I in the CNS or alternatively development of insulin resistance may compromise neuronal survival during HIV infection.

18.5 Glial-Derived Neurotrophic Factor

Glial-derived neurotrophic factor (GDNF) was originally isolated from the supernatant fluids of cultured rat glioma cells and was shown to have profound effects on the survival and

differentiation of motor, and dopaminergic neurons of the midbrain and striatum (Henderson et al. 1994; Yan et al. 1995). GDNF exerts its neurotrophic effects on variety of cells such as the sensory and autonomic ganglia (Buj-Bello et al. 1995; Ebendal et al. 1995), Purkinje cells of the cerebellum (Mount et al. 1995), hippocampal neurons (Martin et al. 1995), as well as noradrenergic (Arenas et al. 1995), serotonergic (Ohta et al. 2002), and cholinergic neurons (Williams et al. 1996). GDNF belongs to a family of neurotrophic factors, which are comprised of four proteins—artemin, GDNF, neurturin, and persephin. These neurotrophic factors belong to the transforming growth factor- β (TGF- β) superfamily. GDNF however, is distinct and demonstrates limited amino acid sequence homology with other members of the superfamily. The conformational similarity of GDNF is significantly conserved with other members of the superfamily. All the members of this family function as homodimers to elicit both protective and restorative signaling in the developing and adult CNS (Allen et al. 2013; Airaksinen and Saarma 2002). GDNF and its associated family members mediate their signaling through the canonical signaling receptor Ret and a glycosyl-phosphatidylinositol-anchored co-receptor, GDNF family receptor α (GFR α) (Fig. 18.1). There are four isoforms of GFR α such as, GFR α 1, GFR α 2, GFR α 3 and GFR α 4 and that have been shown to bind to the ligands artemin, GDNF, neurturin and persephin, respectively (Naveilhan et al. 1998).

This family of neurotrophic factors has been shown to play key roles in diverse biological processes including cell survival, differentiation and migration, as well as neurite outgrowth (Lin et al. 1993; Tomac et al. 1995). GDNF has been demonstrated to promote exclusively the survival of dopaminergic neuronal cells in a mouse model of Parkinson's disease (Hegarty et al. 2014; Zhao et al. 2014). These studies implicate GDNF as a promising therapeutic agent for the treatment of Parkinson's disease (Yasuda and Mochizuki 2010; Hegarty et al. 2014). GDNF has also been shown to protect neonatal and adult facial motor neurons from axotomy-mediated cell death (Yan et al. 1995). Similar to GDNF, neurturin has also been shown to protect non-human primate dopaminergic neurons from 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) induced neurotoxicity (Grondin et al. 2008).

The neurotrophic potential of GDNF is specifically important for HAND, especially in the late phase of HIV-associated dementia (HAD). During this late stage, the manifested clinical features of HAD resemble to those observed in Parkinson's disease, such as bradykinesia, loss of fine motor skills, involuntary movements and postural instability (Berger and Nath 1997; Mocchetti et al. 2014). It can be envisioned that GDNF can be considered a potential therapeutic agent for HAD. Along these lines and similar to the findings for PDGF

(described above), intrastriatal microinjections of HIV-1 envelope protein gp120 significantly reduces levels of GDNF in the rat substantia nigra thereby causing retrograde degeneration of nigrostriatal neurons (Nossheny et al. 2006). Using the same model the authors have demonstrated chronic and progressive neurodegeneration mediated by gp120 (Nossheny et al. 2006). Interestingly similar to the experimental model, GDNF expression was notably diminished in the substantia nigra in patients with as compared to those without dementia. Altogether, the neurotrophic potential of GDNF is vital for protecting the survival of substantia nigra neurons in HIV-1 patients (Mocchetti et al. 2014).

18.6 Platelet-Derived Growth Factor

Platelet-derived growth factor (PDGF) is a family of mesenchymal cysteine-knot-type mitogens and is synthesized in several tissues including brain cells such as neuronal progenitors, neurons, astrocytes, oligodendrocytes, and Schwann cells in the peripheral nervous system. This growth factor acts in an autocrine and paracrine manner and plays a key role from gastrulation period to adult neuronal maintenance. This growth factor family consists of four chains (five isoforms), which are disulfide-linked to form homo- or heterodimers of A-, B-, C-, and D-polypeptide chains, i.e. PDGF-AA, PDGF-AB, PDGF-BB, PDGF-CC, and PDGF-DD (Heldin and Westermark 1999). These growth factors elicit their biological functions on cells through binding with their cognate receptors, namely PDGF receptor (PDGFR)- α , and PDGFR- β by their receptor tyrosine kinase activity. Binding of PDGF stimulates PDGFR dimerization, which further initiates downstream signaling. Based on PDGF isoforms and the pattern of receptor expression, specific receptor dimers play key roles in eliciting signaling specific to a particular cell. Typically, PDGFR- α binds to the A-, B-, and C-chains of PDGF, while PDGFR- β binds to the B- and D-chains of PDGF (Andrae et al. 2008; Chen et al. 2013).

Though the mitogenic activity of PDGFs in most of the cell types has been well studied, their key roles in various disorders of the CNS are a subject of extensive exploration. PDGF-A is also shown as a potent mitogen for oligodendrocyte progenitors, whereas postnatally surviving PDGF-A null mice are developed tremor owing to severe deficiency of myelination in the central nervous system (Betsholtz 2004; Fruttiger et al. 1999). In addition, PDGF-BB has been shown to protect primary hippocampal neurons from glutamate-induced neuronal injury by up-regulation of PDGFR- β signaling, especially targeting NR2B receptors (Beazely et al. 2009). Several studies have demonstrated the neuroprotective potential of PDGFs via their role in guarding neuronal/brain cells from direct in vitro glutamate-induced

excitotoxicity and hypoxic-ischemic injury (Egawa-Tsuzuki et al. 2004; Tseng and Dichter 2005; Ishii et al. 2006). In addition, PDGFs and PDGFR activation is essential for neuronal progenitor cells differentiation into neurons (Erlandsson et al. 2001; Williams et al. 1997) and is shown to protect hippocampal neurons from oxidative insults and energy deprivation (Cheng and Mattson 1995). Additionally, PDGFR activation has also been shown to be protective in the context of Alzheimer's disease pathology, possibly by inhibiting NMDA receptors. Taken together these studies suggest a neuroprotective effect of PDGF produced by neurons themselves.

HIV infection primarily targets the basal ganglia region of the brain leading to dopaminergic neuron degeneration (Nath et al. 2000) with the development of HIV-associated dementia and other neurological complications at the end stage of disease (Mocchetti et al. 2007). Recent investigations have also revealed the novel neuroprotective role of PDGFs that function by reversing neuronal toxicity induced by HIV-1 proteins Tat and gp120 in the primary midbrain neurons (Yao et al. 2009, 2014) as well as in the SHSY-5Y neuroblastoma cells (Peng et al. 2008a, b; Zhu et al. 2009). Furthermore, it was also shown that the neuroprotective potential of PDGF was mediated through the transient receptor potential canonical channels (TRPC), which are Ca^{2+} -permeable, non-selective cationic channels that play key roles in various physiological functions including neuronal survival (Fig. 18.1). In keeping with the cell culture findings, it was further validated that PDGF-mediated neuroprotection was attenuated in mice pretreated with the TRPC blocker. Additional molecular mechanism(s) underlying PDGF-mediated neuroprotection against HIV-1 protein toxicity include activation of PI3K/AKT and ERK/CREB pathways and concomitant inactivation of the mediators of the proapoptotic pathway. In addition to its role in neuroprotection, PDGF-BB also promotes differentiation of rat hippocampal neural progenitor cells through activation of TRPC channels, influx of calcium, and activation of ERK signaling and the downstream transcription factor, CREB thereby reversing the impairment mediated by HIV-1 Tat protein (Yang et al. 2015). PDGF exposure of neurons has also been shown to decrease the release of extracellular glutamate and induce upregulation of the synaptic plasticity proteins (Peng et al. 2008a, b; Tseng and Dichter 2005; Yao et al. 2009, 2014). Arc/Arg3.1 is one such synaptic plasticity protein, whose expression in the neurite has been implicated as an index of synaptic activation. Interestingly, it has been demonstrated that PDGF-BB regulates the expression of *Arc/Arg3.1* gene in the rat hippocampal neurons (Peng et al. 2010). Furthermore, it has been shown PDGF-CC also protects the rat cortical neurons against HIV-1 Tat protein-mediated neurotoxicity through activation of the TRPC and AKT signaling (Peng et al. 2012).

18.6.1 PDGF Paradox in HAND

While the PDGF family members play protective roles on neuronal fitness and survival, in the endothelial cells (Mermis et al. 2011; Yao et al. 2011) and astrocytes (Bethel-Brown et al. 2011, 2012) their effects are more cytotoxic. For example in the context of pulmonary hypertension associated with HIV-infection, it has been shown that exposure of HIV-1 proteins to pulmonary endothelial cells induced oxidative stress with subsequent activation of hypoxia inducible factor-1 α leading in turn, to increased expression of PDGF, that functions as a mitogen for the neighboring smooth muscle cells (Mermis et al. 2011). In addition, HIV-1 infection of human primary astrocytes resulted in increased expression of PDGF, which in turn, led to increased expression of the chemokine MCP-1 through the ERK1/2, JNK MAPK and NF κ B activation pathway. Increased MCP-1 expression, ultimately resulting in increased monocyte transmigration and disruption of the endothelial barrier permeability in the brains of individuals infected with HIV-1 (Bethel-Brown et al. 2012). Upregulated expression of PDGF in astrocytes is thus deleterious for endothelial cells.

Among all the cells of the CNS, the pericytes are known to express high constitutive levels of PDGF receptor. However, their role in the context of HIV infection is rather understudied (Nakagawa et al. 2012). It has been shown that pericytes potentiate and enhance the transcytosis of HIV-1 across brain microvascular endothelial cells via lipopolysaccharide-mediated release of inflammatory cytokines (Dohgu and Banks 2013). New findings have also shed light on the role of PDGF-BB in pericyte functioning under both physiological as well as pathological conditions (Lindahl et al. 1997; McCarty et al. 2007). For example, PDGF has been shown to increase the migration of retinal microvascular pericytes and plays an essential role in pericyte maintenance (Nadal et al. 2002). On the other hand, exposure of pericytes to HIV-1 Tat protein was shown to induce the expression and release of PDGF-B, which in turn, via the autocrine loop resulted in increased loss of pericytes from the endothelial barrier resulting in increased neuroinflammation (Niu et al. 2014). The mechanism of HIV-1 Tat-mediated expression of PDGF-BB in pericytes involved activation of the ERK and JNK MAPK pathways along with the downstream activation of NF- κ B (Niu et al. 2014).

18.7 Future Perspectives

The key challenge in the field of growth factor therapy is drug delivery to the CNS. Though these factors cross the BBB minimally via peripheral administration, direct administration of these factors into the CNS is essential in order to reach neurons of the brain or spinal cord. Furthermore, when these

growth and neurotrophic factors ‘flood’ the nervous system after direct administration into the CNS, they cause adverse effects that are intolerable over extended time-periods. Thus, the ideal system for administration of growth factors to the nervous system must achieve effective concentrations at precise sites of degenerating neurons, while limiting the spread to distant sites, which could generate adverse effects. In addition, delivery must be sustained over time. The absence of a safe and reliable delivery system for growth factor treatment in humans has limited the ability to investigate whether these proteins can effectively treat neurological diseases. Potential approaches that could solve the delivery problem of growth factors to the nervous system include intraparenchymal protein infusion, gene delivery using viral vectors, drug-induced increases in growth factors, and the use of peptide mimetics. Ongoing research in the field is aimed at addressing these challenges by improving gene therapy vectors to achieve persistent, safe and regulatable growth factor expression in the CNS; by enhancing the accuracy of vector and growth factor targeting to the brain using real-time monitoring during treatment; and by developing peptide mimetics of growth factors with specificity for degenerating cell systems. This could replace the need for invasive central administration and avoid adverse effects of non-targeted growth factor distribution.

18.8 Conclusions

Taken together the neurotrophic factors play critical role in the rescuing neurons from HIV protein mediated toxicity. So an effective therapy for HAND will require both cART and adjunct therapies that include neuro-protective and neuro-regenerative agents. Neurotrophic factors are well known for their pro-survival and pro-neurogenesis of neurons that make them perfect candidates as alternative agents for individuals living with HIV. Further effective treatment for HIV-mediated CNS diseases will definitely entail both cART and adjunctive therapies with neurotrophic factors, because these factors are considered as potent modulators of synaptic plasticity and neurogenesis in the adult CNS. Additionally, the biological effects mediated by these factors definitely play significant role in limiting the HIV-mediated neuronal degeneration following with stimulation of neuronal function. Though the effects of these agents are only examined in the cell lines/animal models of HAND, the therapeutic properties of neurotrophic factors provide incentive for further research and raise hope for the therapeutic possibilities in the near future. However, more research on this field is still needed for their clinical use in the future. Additionally, based on the paradoxical nature of most of these factors, caution needs to be exerted in the development and delivery of these agents in the CNS to avoid off-target effects.

18.9 Review Questions

1. Loss of expression of neurotrophic factors and/or their receptors in HIV-associated neurocognitive disorders results in:
 - (a) *Impaired neuronal signaling*
 - (b) Axonal growth
 - (c) Maintenance of normal neuronal morphology
 - (d) Neuronal differentiation
2. Which of the following downstream signaling pathways are activated following fibroblast growth factor binding to its receptors?
 - (a) RAS/mitogen-activated protein kinase signaling
 - (b) Phosphatidylinositol 3-kinase/AKT signaling
 - (c) Phospholipase gamma signaling
 - (d) *All the above*
3. Brain-derived neurotrophic factor primarily binds to:
 - (a) TrkB receptor
 - (b) Low-affinity nerve growth factor receptor
 - (c) Dopamine receptor
 - (d) *a and b*
4. In the context of HIV-1 infection, brain-derived neurotrophic factor elicits neuroprotective effects through:
 - (a) Superactivation of ERK signaling
 - (b) Blocking of caspase-3 expression
 - (c) Decreased expression of CXCR4
 - (d) *All the above*
5. HIV-1 mediated neurodegeneration is exacerbated by:
 - (a) *Low levels of IGF-1 with elevated levels of TNF- α*
 - (b) High levels of IGF-1 with low levels of TNF- α
 - (c) Low levels of TNF- α
 - (d) None of the above
6. GDNF belongs to a family of neurotrophic factors:
 - (a) Belong to the transforming growth factor- β superfamily
 - (b) Mediate their signaling through the canonical signaling receptor, Ret
 - (c) Promote exclusively the survival of dopaminergic neuronal cells
 - (d) *All the above*
7. Platelet-derived growth factors are produced by:
 - (a) Neuronal progenitor cells
 - (b) Neurons
 - (c) Oligodendrocytes
 - (d) *All the above*
8. Exposure of HIV-1 proteins to pulmonary endothelial cells induces oxidative stress with subsequent activation of hypoxia inducible factor-1 α leading to:
 - (a) *Increased expression of PDGF*
 - (b) Increased expression of BDNF
 - (c) Decreased expression of GDNF
 - (d) None of the above

Tara E. Vanderweyde and Benjamin Wolozin

Abstract

Studies of the molecular genetics for Amyotrophic lateral sclerosis (ALS) and other motor neuron disorders have thrust a class of proteins, termed RNA binding proteins (RBPs), into the limelight. A striking number of mutations linked to motor neuron diseases occur in RBPs. The reason appears to derive from the unique structures and biology of RBP, as well as the unique abundance of these proteins in the extra-nuclear domains of neurons. The material discussed in this chapter will explicate the biology of RBPs, provide insight into how this contributes to the pathophysiology of neurodegenerative diseases, and also speculate on potential roles of RNA binding proteins in the inflammatory response.

Keywords

Aggregation • Amyotrophic lateral sclerosis • Prion • Protein synthesis • RNA binding proteins • RNA translation • Stress granules • Stress response

19.1 Overview

Regulating mRNA translation and protein synthesis allows a cell to rapidly alter the proteome in response to various signals. The discovery of RBPs, RNA granules, and their critical role in determining the fate and activity of mRNA transcripts has brought the importance of translational control into sharp focus. The interaction between RBPs and the

types of granules described here controls the stability and translational activity of mRNAs and plays a critical role in fine-tuning protein expression under both normal conditions and under conditions of stress (Adeli 2011).

The RBP family is comprised of about 800 proteins that share conserved domains structures and related functions. These RBPs generally contain two types of conserved domains: glycine rich domains and RNA recognition motifs (RRM). The glycine rich domain is hydrophobic and mediates the reversible aggregation of these proteins. The RRM have broad specificity, but differ in the spectrum of transcripts bound, and this specificity can also be dependent on the type of stress presented to the cell (Wolozin 2012; Paz et al. 2014). RBPs and the granules they form regulate all aspects of RNA biogenesis including RNA maturation, surveillance, transport, subcellular localization, translation, and RNA degradation. RBPs form dynamic interactions with coding, untranslated, and non-protein-coding RNAs in functional units called ribonucleoprotein (RNP) complexes. The RBPs within RNP complexes can remain stably bound to the RNA throughout its journey from synthesis to degradation, or associate with the RNAs selectively in a temporal and spatial manner (Lukong et al. 2008).

The functions of RBPs can generally be divided into nuclear and cytoplasmic activities. In the nucleus, RBPs regulate mRNA maturation, including splicing, RNA helicase activity, RNA polymerase elongation, and nuclear export. In the cytoplasm, RBPs regulate RNA transport, silencing, translation, and degradation. These cytoplasmic RBPs regulate transcript activity and distribution by forming RNA granules that are macromolecular complexes containing RBPs, translational machinery, and mRNA transcripts consolidated to form granules through protein/protein interactions mediated by the glycine rich domains and protein/mRNA interactions mediated by RRM. RNA granules vary by molecular composition and function. RNA degradation is mediated by a type of RNA granule, termed Processing-bodies or P-bodies (PBs). Transport granules play important roles in neurons, where they move transcripts from the soma into the dendritic, and possibly axonal, arbors. Stress granules (SGs) are important for the mammalian stress response, sequestering mRNAs and allowing for dynamic sorting of mRNAs for translation, storage, or degradation to allow for cell survival (Wolozin 2012) (Fig. 19.1).

19.2 RBPs Exhibit Reversible Liquid to Solid Phase Transitions

The ability of RBPs to form granules represents a fundamental aspect of their biology. RBPs have an innate tendency to self-aggregate (Alberti et al. 2009). This ability is mostly determined by the low complexity glycine rich domains. For many RBPs, such as TIA1 cytotoxic granule associated protein (TIA1), these low complexity domains resemble the low complexity region of the yeast prion protein, Sup35, which is also a RBP (Phillips et al. 2004). The prion-like nature of these proteins provides insight into how the low complexity domains impact on RBP biology. Mathematical modeling shows that the low complexity domains function on the cusp of aggregation, so that small changes in their structure or environment can cause them to aggregate (Alberti et al. 2009).

Work by the McKnight group highlights the propensity of these proteins to aggregate (Han et al. 2012; Kato et al. 2012). The group generated recombinant forms of the low complexity domains from many different RBPs, but particularly focused on fused in sarcoma (FUS), which is linked to ALS. They showed that the low complexity recombinant protein could reversibly aggregate in a manner that was controlled by temperature and concentration (Han et al. 2012; Kato et al. 2012). The biological function of this aggregation propensity translates to an ability to serve as a scaffold for binding and sequestering transcripts. The McKnight group used this RNA binding ability to concentrate transcripts selectively bound by specific RBPs, such as FUS. This concept of reversible aggregation directly translates to disease. Several teams analyzed FUS and hnRNPA1, and showed that

disease-linked mutations shift the aggregation characteristics such that the liquid to solid phase transition occurs more quickly and becomes persistent after several transitions (Patel et al. 2015; Nott et al. 2015; Molliex et al. 2015; Lin et al. 2015). The persistence of the FUS granules suggests a mechanism through which mutations might cause disease by inducing formation of persistent FUS granules in the brain; the abnormal stability of these granules would lead to persistent sequestration of transcripts bound by FUS and proteins associated with FUS into the pathological granules (Patel et al. 2015). Thus, a gain of FUS aggregation would cause a loss of function by sequestering FUS, FUS binding proteins and FUS binding transcripts into pathologically persistent RNA granules (Patel et al. 2015). Multiple proteins that accumulate in neurodegenerative diseases contain prion-like and poly-glycine rich domains, and their aggregation mirrors that of proteins linked to neurodegenerative diseases (Gilks et al. 2004). Neurodegenerative-linked proteins Huntingtin, Prion Protein (PrP) and TAR DNA-binding protein 43 (TDP-43) have all been shown to associate with SGs, and mutations or malfunctions in some of these RBPs can directly cause neurodegeneration (Lukong et al. 2008).

19.3 RNA Granules

RBPs regulate all aspects of RNA biogenesis including RNA maturation, surveillance, transport, subcellular localization, translation, and RNA degradation. RBPs are able to interact with mRNA and other protein components and consolidate to form discrete granules in the cytoplasm, and based upon their composition and function can be identified as transport RNPs, SGs, or P-bodies. These RNA granules share common protein components, but each kind of RNA granule contains a distinct population of proteins and performs separate functions: (i) RNA transport granules deliver transcripts to dendrites while inhibiting RNA translational activity. RBPs such as fragile X mental retardation protein (FMRP) and Pumilio (PUM1) participate in dendritic transcript transport and function as translational repressors. (ii) Stress granules (SGs), which will be the main focus of this review, form transiently to reprogram RNA translation under stressful conditions. The primary nucleating SG proteins include TIA-1, G3BP, TIA-1 related protein (TIAR), FMRP, and survival of motor neuron protein (SMN), but a number of disease-linked proteins also associate with SGs as they expand; these proteins include fused in sarcoma (FUS), TDP-43, and ataxin-2 (ATXN2). (iii) Processing-bodies (PBs) are the sites for mRNA degradation, often integrating with miRNA machinery. Dcp1a (decapping enzyme 1a) is a RBP that is classically used to identify PBs. These granules are dynamic and are able to interact with each other and with active polysomes; this regulated trafficking can allow the cell to tailor translation to changes in its environment (Adeli 2011).

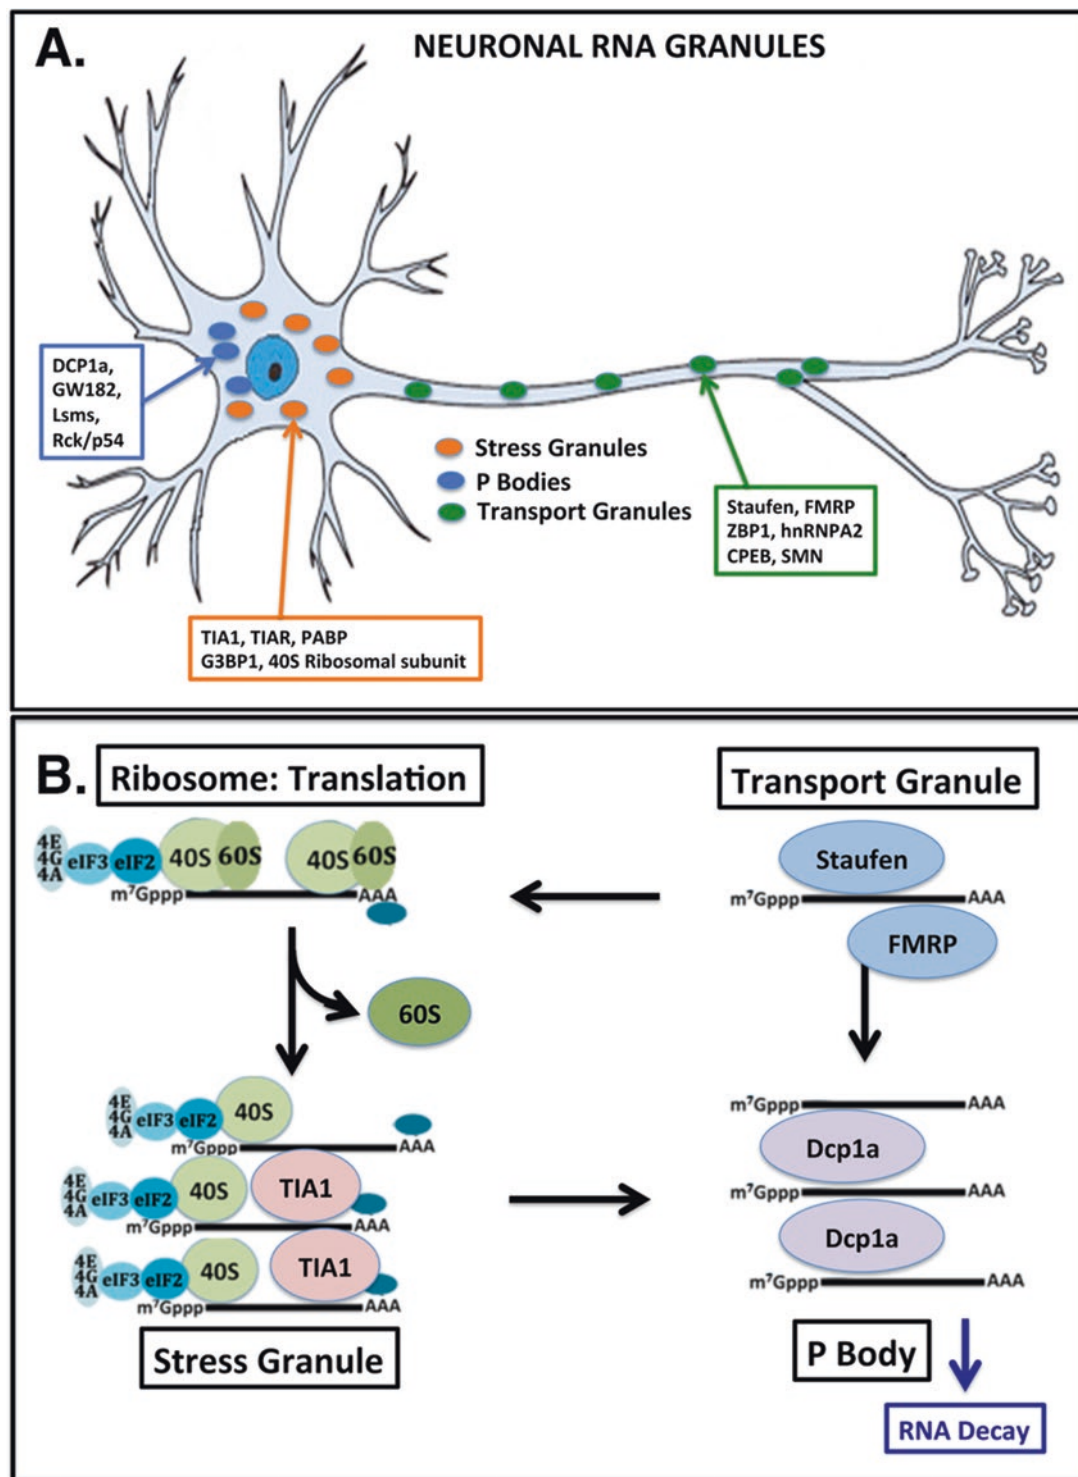

Fig. 19.1 Relationship between SGs, PBs and transport granules in neurons. (a) Types and locations of RNA granules in neurons. Neurons are atypical for having abundant cytoplasmic granules. They have a strong need for neuronal transport granules, in addition to having P-bodies and stress granules. (b) Relationship between the differing

types of RNA granules. Transcripts translocate to the cytoplasm where they are transported to polysomes for translation (protein synthesis). Transcript levels can be regulated by degradation in P-bodies. Stress leads to stalling of translation and formation of stress granules, which lack many (but not all) ribosomal components

19.3.1 Neuronal Transport Granules

Many mRNAs have localization elements within their 3' or 5' untranslated regions (UTRs); RBPs are able to recognize these elements and direct message localization while suppressing translation until the message is delivered to its destination. These mRNAs are delivered by transport granules composed of RBPs and silenced transcripts. Transcripts may also be stored in the cytoplasm in a repressed state by similar RNA storage granules, which act as a pool of mRNA that, depending on metabolic state and environmental changes, can be directed for activation, repression, or decay (Adeli 2011).

Normal neuron physiology largely depends on the presence of these types of granules, which are the functional units for transport and translation regulation of mRNAs from the soma out into the dendrites to synapses. These RBPs also mediate the process of activity dependent protein synthesis, which is critical in all aspects of biology, but has attracted particularly strong attention at the synapse where it controls synaptic plasticity, habituation and memory. For example, the synaptic function of FMRP has been studied extensively and is known to regulate dendritic sprouting.

Neuronal RNA transport granules are distinct from other RNA granules, although they can share some components and get in close contact with other RNA granules likely allowing a flow of mRNAs and proteins. There is also an apparent relationship between neuronal RNA granules and SGs, as both contain polyadenylated mRNAs, ribosomal subunits and a number of common RBPs, including SMN, Staufen, FMRP, Pumilio, TDP-43, and FUS, among others (Thomas et al. 2011).

19.3.2 Stress Granules

The stress response in eukaryotic cells involves the activation of defense mechanisms that either promotes survival or the initiation of apoptosis. The cellular response depends on the type of stress presented. Type I stress, including hypoxia, heat-shock, and oxidative stress, inhibits translation initiation and induces the formation of SGs as a defense mechanism promoting cell survival (Arimoto et al. 2008). SGs contain non-translating mRNAs, translation initiation components, and many additional proteins effecting mRNA function (Buchan and Parker 2009).

In metazoans, five eukaryotic initiation factor 2 alpha (eIF2 α) kinases monitor environmental stress and directly modulate the translation machinery. These include: (i) PKR (protein kinase R), a double-stranded RNA-dependent kinase that is activated by viral infection, heat and UV irradiation; (ii) PERK (PKR-like endoplasmic reticulum kinase, also known as PEK, or pancreatic eIF2 α kinase), a resident endoplasmic reticulum (ER) protein that is activated when unfolded proteins accumulate in the ER lumen; (iii) GCN2

(general control nonderepressible 2), a protein that monitors amino acid levels in the cell and responds to amino acid deprivation; (iv) HRI (heme-regulated initiation factor 2 α kinase), a protein that ensures the balanced synthesis of globin chains and heme during erythrocyte maturation and senses oxidative stress produced by arsenite; and (v) Z-DNA kinase, an enzyme involved in the host antiviral response. Stress-induced phosphorylation of eIF2 α on Ser51 inhibits global protein translation through depletion of the eIF2–GTP–tRNA-met ternary complex, thus permitting the RBP TIA-1 to bind the 48S complex instead of the ternary complex. This promotes polysome disassembly and the consequent recruitment of mRNAs to SGs (McDonald et al. 2011; Kedersha et al. 1999).

These non-translating mRNAs are necessary for SG formation and lead to primary nucleation of SGs involving RBPs including TIA-1, TTP, and G3BP, with specific mRNA transcripts (Fig. 19.4, stage 2). This family of proteins contains prion domains and poly-glutamine rich domains, which confer the ability to reversibly aggregate (Gilks et al. 2004). The primary aggregation of mRNA binding proteins with stalled mRNA transcripts induces protein-protein interactions and cross-linking by proteins such as poly-A binding protein (PABP-1) that seed an increase in aggregation with non-mRNA binding proteins (Fig. 19.2, stage 3). This results in the secondary aggregation of proteins with diverse physiological roles that can be modulated by SGs. The composition of SGs includes translation initiation components, small ribosomal subunit (40S), PABP, other RBPs, and mRNAs coding for most cellular proteins except those involved in the stress response. There is also piggy-back recruitment of many important signaling proteins into these granules that may affect cell signaling and survival (Fig. 19.2, stage 4) (Anderson and Kedersha 2008). However, SG composition may be subtly different according to the nature of the stress stimulus, and it may also change progressively during the response (Thomas et al. 2011).

Once formed, SGs serve as centers of mRNA triage by dynamically sorting sequestered mRNAs for re-initiation, storage, or degradation, and may be required to allow optimal translation of stress-responsive anti-apoptotic mRNAs and thus appear to be protective. SGs have been shown to associate with PBs, with TTP proposed to play an integral role in the shuttling of mRNAs destined for decay from SGs to PBs. Once the stress is removed there is rapid translational recovery in concert with SG disassembly. The mechanism of SG disassembly is poorly understood, but may be dependent upon interactions with heat shock proteins, and active transport by dynein and kinesin motors (Kedersha and Anderson 2007). SGs can also be disassembled chemically via treatment with emetine and cycloheximide. These drugs inhibit translational elongation and block the disassembly of polysomes, thereby preventing the translocation of mRNA into SGs and PBs. Additionally, the drug puromycin promotes premature translation termination and promotes SG and PB assembly (Kedersha et al. 2005).

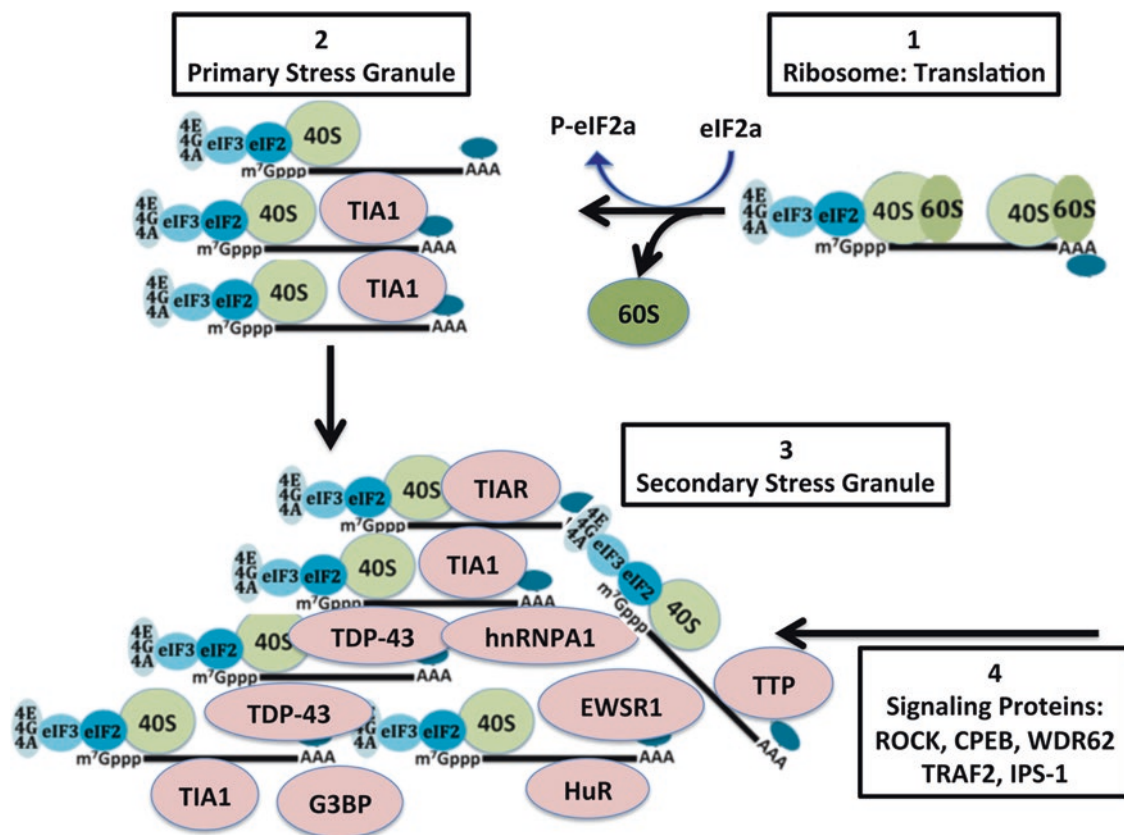

Fig. 19.2 A model of stress granule assembly. The process of SG assembly can be divided into discrete stages that are marked by the specific composition and localization of mRNPs subject to translational arrest. Adapted from Anderson and Kedersha (2008)

SGs have been suggested to suppress apoptosis by suppressing the stress-activated mitogen activated protein kinase (MAPK) pathway (Dewey et al. 2012). Additional cell survival mechanisms linked with SG formation are likely to occur, and an emerging example is the sequestration of proapoptotic molecules. The TNF receptor associated factor 2 (TRAF2) was the first case reported. TRAF2 facilitates apoptosis by two independent pathways: TNFR activation and caspase activation upon ER-stress induction. TRAF2 interacts with eukaryotic initiation factor 4G (eIF4G) and is therefore retained in SGs, thus avoiding apoptosis. More recently, two key molecules that activate the p38/JNK apoptotic pathway, namely RACK1 and ROCK1 were shown to be localized in SGs, thus favoring cell survival (Thomas et al. 2011).

An interesting possibility is that formation of SGs is required to allow optimal translation of stress responsive mRNAs. The translational arrest that accompanies environmental stress is potentially selective: one study shows that the translation of ~25 % of mRNAs is significantly reduced, whereas the translation of another 25 % of mRNAs (including transcripts encoding heat-shock proteins) is significantly enhanced. Stress-induced reprogramming of protein expression also entails stabilizing or destabilizing selected groups

of mRNAs. Thus, post-transcriptional reprogramming of mRNA translation and decay reconfigures the proteome during adverse environmental conditions (Anderson and Kedersha 2008).

The importance of SGs for cytoprotection is highlighted by the effects of knockout of SG proteins, such as TIA-1, or inhibition of eIF2 α phosphorylation, which render cells more vulnerable to acute stresses. Conversely, inhibiting eIF2 α dephosphorylation protects against some forms of stress. However, the actual mechanisms by which SGs mediate protection are poorly understood (Wolozin 2012).

19.3.3 Processing Bodies

P-bodies are another dynamic structure that contains mRNA decay machinery components. Core components of PBs are translationally inactive mRNA and the decapping factor, which induces mRNA decay and blocks translation by decapping and induction of 5'-3' mRNA decay. Key to these complexes are Dcp1/2 (decapping enzymes), the Lsm1-7 complex (activators of decapping), Xrn1 (5'-3' exonuclease), and nonsense mediated decay machinery. P-body

assembly factors recruit mRNA into P-bodies through multimerization domains (Adeli 2011).

P-bodies are often observed juxtaposed to SGs but are also present in cells not under stress. Several observations demonstrate that SGs interact with PBs and are likely to exchange mRNAs between them: (i) mammalian PBs and SGs transiently dock with one another during arsenite treatment and can show prolonged docking when TTP is overexpressed and (ii) PBs and SGs share many protein components and the same mRNA species (Buchan and Parker 2009). In neurons, FRAP analysis indicates that the turnover of DCP1a in PBs is dramatically enhanced by synaptic stimulation, indicating that PB dynamics and the release of mRNAs to allow their translation are controlled by neuronal activity, likely playing a role in regulating local protein synthesis at the post-synapse (Thomas et al. 2011).

19.3.4 Microtubule Dependence

The formation and persistence of RNA granules depends on the movement of RNA and proteins in the cytoplasm and their accumulation in particular cytoplasmic foci. It has been shown that SG formation is microtubule-dependent process and likely is facilitated by the motor protein-driven movement of individual SG components along microtubules. Disruption of MT array with nocodazole treatment abolished the formation of SGs in response to a stressor (Ivanov et al. 2003). Thus it is possible that the distribution of SGs in cells might correlate with the distribution of MTs, and any dysfunction in the MT network would prevent normal SG formation and dynamics.

19.4 RNA Granule Markers

19.4.1 TIA-1

19.4.1.1 Gene and Protein Structure

T-cell intracellular antigen-1 (TIA-1) is a RBP of the RNA recognition motif (RRM)/ ribonucleoprotein (RNP) family that regulates pre-mRNA splicing, mRNA translation, stress-induced translational arrest, and has been implicated as an

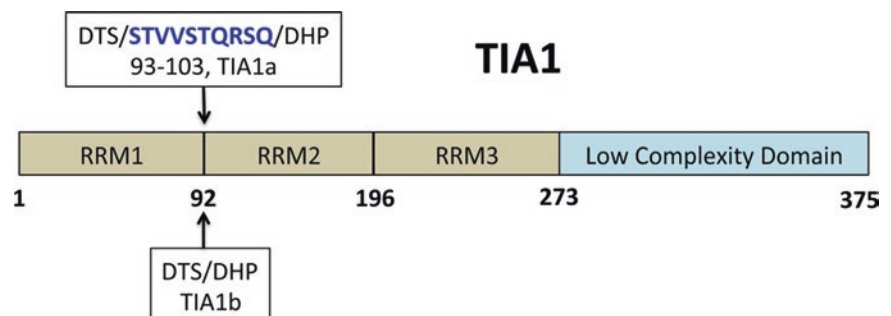

effector of apoptotic cell death (Beck et al. 1996; Gilks et al. 2004). The gene encoding the 43 kDa TIA-1 protein locates at chromosome 2p13.3 (Kawakami et al. 1994). TIA-1 has 3 RRM domains at its N-terminus that confer high-affinity binding to AU-rich motifs, and a glycine-rich, low complexity, carboxyl-terminal domain that allows it to reversibly aggregate, as shown in Fig. 19.3 (Wolozin 2012). The low complexity domain share homology to yeast prion proteins, such as Sup35 (Phillips et al. 2004).

TIA-1 presents in two major isoforms (TIA-1a and TIA-1b) generated by alternative splicing of exon 5 that differ by 11 amino acids as shown in Fig. 19.3. Exon 5 inclusion generates TIA-1 isoform a, whereas exon skipping produces the shorter b isoform. The 11-amino acid peptide encoded by exon 5 is located between RRM1 and 2. The relative expression of TIA-1 isoforms varies in different human tissues and cell lines, suggesting distinct functional properties and regulated isoform expression. Both TIA-1 isoforms show similar subcellular distribution and RNA binding, but TIA-1b displays enhanced splicing stimulatory activity compared with TIA-1a (Izquierdo and Valcarcel 2007).

19.4.1.2 General Biological Functions

TIA-1 is known to regulate pre-mRNA splicing, mRNA translation, stress-induced translational arrest, and has been implicated as an effector of apoptotic cell death (Beck et al. 1996; Gilks et al. 2004). TIA-1 regulates the alternative pre-mRNA splicing of various human and *Drosophila* genes (FGFR-2, msl-2, TIAR, cystic fibrosis transmembrane conductance regulator, and Fas) through binding to U-rich stretches, facilitating atypical 5'-splice site recognition by U1 small nuclear ribonucleoprotein (snRNP) (Izquierdo and Valcarcel 2007). TIA-1 has also been well characterized as a translational regulator. This protein has been implicated in stress-induced translational arrest, colocalizing after stress with poly(A)⁺ RNA in the cytoplasmic foci known as stress granules. TIA-1 is able to bind to the 3'-untranslated regions (UTRs) of the translational regulatory AU-rich elements of tumor necrosis factor α (TNF α), human matrix metalloproteinases-13 (MMP13), cyclooxygenase-2 (COX2), β 2-adrenergic receptor, mitochondrial cytochrome c, GADD45 α , and β -F1-ATPase mRNAs (Izquierdo and

Fig. 19.3 The structure of human TIA-1 gene and protein. Domain structure of human TIA-1 isoforms (Kawakami et al. 1994). The 11-amino acid peptide encoded by exon 5 is shown in *bold*. TIA-1 proteins include three RRM domains and a carboxyl-terminal glutamine-rich domain. Numbers indicate amino acid residues corresponding to each RRM and carboxyl-terminal domain of the TIA-1b isoform. Adapted from Izquierdo and Valcarcel (2007)

Valcarcel 2007). As a translational silencer, TIA-1 binds to these transcripts and suppresses their translation. Thus, mutant mice lacking TIA-1 have a hyperinflammatory phenotype because of the lack of suppression of TNF α and COX2 that results in increased cytokine levels (Yamasaki et al. 2007; Piecyk et al. 2000; Anderson and Kedersha 2008).

Interestingly, the aggregation of TIA-1 is regulated by molecular chaperones (Gilks et al. 2004) and is blocked by HSP70 overexpression. Minimal constitutive levels of HSP70 are continuously required to prevent TIA-1 aggregation. Stress-induced denaturation of other cytoplasmic proteins recruits HSP70 for protein renaturation, thus diverting HSP70 away from TIA-1, promoting TIA-1 aggregation and consequent SG nucleation. The successful refolding of denatured proteins releases HSP70 and the free HSP70 then solubilizes TIA-1, the subsequent TIA-1 disaggregation promotes SG disassembly (Anderson and Kedersha 2008).

19.4.1.3 Mutations Linked to Disease

Recently, a single missense mutation in TIA-1 (p.E384K) was found to cause Welander Distal Myopathy (WDM). WDM is a dominant late-onset muscular dystrophy mainly found in Finland and Sweden. Onset is usually at 40–60 years of age, presenting with weakness and atrophy in the fingers, progressing to the hand muscles and lower legs. Rare homozygotes exhibit earlier onset, faster progression, and proximal muscle involvement. These homozygous patients become wheelchair-bound by age 50 (Hackman et al. 2013).

Pathologically there are myopathic changes and prominent rimmed vacuoles in distal muscles. TIA-1 increased cytoplasmically and granules or bulky aggregates appeared in some atrophic and rimmed-vacuolated fibers. These rimmed vacuoles consistently showed strong LC3b, ubiquitin, and p62 reactivity indicating a potential deficit in protein clearance mechanisms. The mutation in TIA-1 is present in the glutamine-rich C-terminal domain, this domain is both required for enhanced interaction with the U1 splicing complex as well as the self-assembly of TIA-1, thus an assessment of both of these functions was necessary. Assessments of splicing patterns in known TIA-1 splice targets (FAS, PLOD2, and TIAR) suggested that there was no splicing abnormality associated with the mutation. In vitro assessments of mutant E384K TIA-1 indicates that the mutation is able to increase SG formation slightly, and that these stress granules exhibit altered trafficking (Hackman et al. 2013).

19.4.2 TTP

19.4.2.1 Gene and Protein Structure

Tristetraprolin (TTP) is an mRNA-binding protein containing tandem CCCH zinc fingers, involved in post-transcriptional regulation of AU-rich element (ARE)-containing mRNAs.

The gene encoding the 34 kDa protein is located on chromosome 19q13.2. TTP protein has two tandem CCCH zinc finger motifs that allows it to bind mRNAs (Kawakami et al. 1994).

19.4.2.2 General Biological Functions

TTP binds mRNAs through two tandem CCCH zinc finger motifs and promotes their decay. TTP target mRNAs typically contain the AU-rich sequence, where TTP can bind and destabilize its targets including TNF- α , granulocyte macrophage colony stimulating factor (GM-CSF), COX-2, Interleukin 3 (IL-3), IL-10, and interferon- γ (IFN- γ). Mice that lack TTP spontaneously develop erosive arthritis, cachexia, alopecia, dermatitis, autoantibodies, and myeloid hyperplasia indicating its importance in regulating the inflammatory response. TTP is a protein associated with PBs, and may receive transcripts from TIA-1 positive SGs in a hand-off mechanism (Rigby et al. 2005).

Although TTP is a phosphoprotein reported to be a substrate for multiple kinases including ERK, JNK, p38, and MAPKAP kinase 2 (MK2), the role of phosphorylation in regulating TTP function is unclear (Mahtani et al. 2001). While extensive TTP phosphorylation has been mapped, only the serine–threonine phosphatase PP2A has been established as promoting TTP dephosphorylation. TTP can be phosphorylated by MK2, a downstream target of p38, at serines 52 and 178 in mouse, 60 and 186 in humans. mRNA binding was not altered in response to phosphorylation, but it did prevent mRNA decay by preventing TTPs association with SGs or PBs, instead promoting its association with 14-3-3 proteins (Stoecklin et al. 2004; Rigby et al. 2005). Thus, exclusion of TTP from SGs correlates with inhibition of TTP activity, which suggests that TTP induces the degradation of translationally stalled mRNAs via its association with PBs.

19.4.3 G3BP

19.4.3.1 Gene and Protein Structure

G3BP was initially characterized through its interaction with a Ras-GTPase-activating protein (RasGAP p120), and is known to both activate and repress mRNA transcripts in a transcript dependent manner. There are three isoforms of G3BP: 1, 2a, 2b, which are products of two distinct genes. G3BP1 and 2 are encoded by distinct genes on human chromosomes 5 and 4. There is a 74 % similarity between G3BP1 and G3BP2a protein. G3BP2b is a splice isoform of G3BP2a, lacking 33 amino acids in the central region.

G3BP's C-terminus is comprised of two motifs traditionally associated with RNA binding. These are a RRM, and a loosely conserved RGG (arginine-glycine rich) box (Kennedy et al. 2001; Irvine et al. 2004). The N-terminus of G3BP is a nuclear transport factor-2 (NTF-2)-like domain, which influences the cellular localization of proteins and its

oligomerization with itself or with other partners. G3BP's central regions comprise varying numbers of proline-rich (PxxP) motifs and an acid-rich domain (Rigby et al. 2005; Irvine et al. 2004).

19.4.3.2 General Biological Function

The majority of publications concerning G3BP1 support a function in cell proliferation and/or survival downstream of Ras, and this is dependent on regulation of phosphorylation/dephosphorylation at S149. Thus, G3BP is very important in embryonic development and knockout is embryonically lethal (Tourriere et al. 2003). Both G3BP1 and G3BP2 are dramatically overexpressed in human cancers, in particular breast cancers. Over-expression of G3BP1 has been demonstrated in a range of human tumors, including breast, head, neck, colon, and thyroid (Guitard et al. 2001; Irvine et al. 2004).

G3BPs are also found to be components of mRNPs and are necessary to form SG complexes. In response to stress, G3BP becomes dephosphorylated at S149 allowing it to aggregate. The RRM domain mediates the binding of G3BP to specific mRNA sequences so that G3BP can exert its function as a dinucleotide-specific single-strand-specific endoribonuclease. G3BP can bind to the 3' untranslated region (3'UTR) of human c-Myc mRNA in a phosphorylation-dependent manner to increase its degradation in vitro (Cohen et al. 2003). *Supporting this*, several studies implicate G3BP1 in cell cycle regulation, with G3BP1 over-expression increasing S-phase entry and this was dependent on an intact RNA-binding domain (Guitard et al. 2001; Irvine et al. 2004).

There is also an interaction between G3BP1 and the de-ubiquitinating enzyme, USP10. Two substrates for the USP10/G3BP1 de-ubiquitinating complex have been discovered so far: Sec23, a component of the COPII complex involved in anterograde protein export from the endoplasmic reticulum (ER) to the Golgi network and β -COP, a component of the COPI complex required for retrograde protein transport from the Golgi to the ER. De-ubiquitination of Sec23 and β -COP rescues them from degradation by the proteasome, thereby maintaining the activity of the retrograde and anterograde protein secretion pathways (Irvine et al. 2004; Cohen et al. 2003).

19.5 RNA Binding Proteins and Inflammation

Very little is known about the role of RNA granules in inflammation, however it is very clear that RNA granules occur in inflammatory cells, and that they regulate the process. Proteins such as PARP12 localize to SGs in inflammatory cells and stimulate their formation (Welsby et al. 2014).

SG formation is stimulated by cytokines, such as TNF α . Formation in monocytes appears to suppress HSP70 synthesis and promotes apoptosis (Qi et al. 2011). In contrast, formation of a different kind of RNA granule, termed the anti-viral granule (AVG) plays an important role in virtually every viral infection. This field is vast and best addressed by reading current reviews that specifically address this important topic (Onomoto et al. 2014).

19.6 RNA Binding Proteins and Neurodegeneration

Stress granules are also important in the context of unfolded protein diseases. Many aspects of SGs resemble aggresomes and unfolded protein aggregates present in neurodegenerative pathologies (Thomas et al. 2011). For example, both are mediated by specific prion-like and poly-glutamine containing protein-aggregation domains, the dissolution requires molecular chaperones; they contain ubiquitinated proteins and are enhanced by inhibitors of protein degradation machineries. These commonalities make it tempting to speculate that SGs and intracellular protein aggregates may interact. However, the aggregation processes characterizing the biology of RBPs differ from the conventional models of protein aggregation in that they serve distinct biological functions and are reversible. In addition, aggresomes tend to form a single large inclusion, originating at the microtubule-organizing center, whereas SGs occur as multiple complexes scattered throughout the cytoplasm.

19.6.1 RNA Binding Proteins in Neurological Diseases

Perhaps most convincing of the increased recognition of RBPs in neurodegeneration is that mutations or malfunctions in some of these proteins can directly cause neurological disorders. For instance, impaired expression of FMRP, due to trinucleotide repeat expansions is the cause of fragile X mental retardation syndrome (FXS), which is the most common cause of inherited mental retardation, and with aging also leads to a related neurodegenerative condition. Expanded trinucleotide repeats in several different ataxin genes are the cause of spinocerebellar ataxia. Mutations in survival of motor neuron (SMN1) are linked to spinal muscular atrophy (SMA), and mutations in TDP-43, FUS, ATX2, optineurin (OPT) and angiogenin (ANG) all cause motor neuron diseases including amyotrophic lateral sclerosis (ALS). These disease processes have now been linked to dysfunctional or dysregulation of neuronal RNA granules and SGs (Wolozin 2012; Liu-Yesucevitz et al. 2011).

19.6.2 Regulated Protein Aggregation

The potential importance of SGs for neurodegenerative disease becomes apparent because the process of SG formation presents a biological pathway that could be vulnerable to the protein aggregates that accumulate in disease. RBPs are a group of proteins that naturally form insoluble aggregates, yet the aggregated material can disperse and resolubilize. Most, if not all, RBPs linked to neurodegenerative diseases associate with SGs in cell culture. TDP-43, FUS, ATX2, SMN, OPT, and ANG have all been shown to co-localize with classic SG markers (TIA-1, TTP, and/or G3BP) in cells undergoing stress. SG proteins such as TIA-1, eIF3, and PABP also co-localize with neuropathology in brain tissue of subjects with FTDP-17, FTLDP, and ALS, or animal models of these diseases. In addition, as mentioned above with respect to ALS, SMA, and FFR the dysfunctions of the disease may actually be linked to dysregulation of RNA granules (Wolozin 2012).

Recently our lab (Wolozin 2012), proposed that the aggregation of many pathological, intracellular proteins, including TDP-43 and FUS, proceeds through the SG pathway. Mutations in genes coding for SG associated proteins or prolonged physiological stress, lead to enhanced SG formation, which accelerates the pathophysiology of protein aggregation in neurodegenerative diseases. Alternatively, the formation of long-lived stable insoluble protein aggregates seen in disease may lead to accelerated, long-lived SG formation. These highly insoluble aggregates could also serve as a nidus for further aggregation of SGs, by binding with other RBPs and also binding RNA as part of the process of SG maturation. The result would be an overactive SG pathway. Over-active stress granule formation could act to sequester functional RBPs and/or interfere with mRNA transport and synthesis, each of which might potentiate neurodegeneration (Fig. 19.4a—normal, Fig. 19.4b—stress/normal SG formation, Fig. 19.4c—chronic stress/pathologic SG formation). The reversibility of the SG pathway also offers novel opportunities to stimulate endogenous biochemical pathways to reverse these pathological stress granules and also perhaps delays the progression of disease (Wolozin 2012; Vanderweyde et al. 2012).

19.6.3 Potential for Pharmacological Intervention

The RBPs addressed in this section (TIA-1, G3BP, TTP, SMN, and TDP-43) are essential players in RNA metabolism, with the RNPs forming a dynamic regulatory system for all aspects of the life of an mRNA, including nuclear processing,

transport, translation, and decay. These proteins are essential in the coordination of gene expression of many proteins, and their disruption could impair cell function and interfere with appropriate distribution and translation of mRNA in response to signaling (Vanderweyde et al. 2012). Protein levels of RBPs are known to change with aging perhaps making cells more susceptible to dysfunction and disease processes.

Whether hyperactive SG formation is good or bad remains to be determined. Acutely SG formation is known to be protective and anti-apoptotic, until the stress is resolved. In neurodegeneration and other aging-associated diseases, there is no resolution and the stress is chronic. At this point SG formation and recruitment of RBPs from their normal functions act as a loss of function situation where RNPs become dysfunctional, and RNA metabolism is no longer in check. Neurons require SGs for an effective stress response, but overactive, overly stable SG complexes could easily interfere with neuronal function by silencing transcripts and sequestering important proteins. Mutations associated with disease-linked RBPs increase the aggregation propensity or cause dysfunctional RNPs, which provides a direct mechanism for overactive SG formation. Chronic stressful diseases or environmental conditions might also stimulate overactive SG formation. For instance, the oxidative stress associated with aging, the trophic stress associated with diabetes, or the cellular stress associated with cancer all enhance SG formation creating the conditions for overactive SG aggregation (Wolozin 2012).

The effect of modulating the protein synthesis/SG pathway was recently evaluated in an animal model of Creutzfeldt Jacob disease, where pathological misfolding of PrP precipitates neurodegeneration. Mallucci and colleagues forced expression of GADD34, a phosphatase to reduce eIF2 α phosphorylation, inhibit SG formation and stimulate protein synthesis (Moreno et al. 2012). This intervention reduced PrP-induced neurodegeneration. In contrast, salubrinal, which increases and prolongs eIF2 α phosphorylation, increased SG formation, inhibited protein synthesis, and accelerated neurodegeneration (Moreno et al. 2012). These results suggest that inhibiting the SG pathway and stimulating protein synthesis can inhibit PrP-mediated neurodegeneration. The discovery of over-active SG formation in other diseases raises the possibility that these pathways are over-active in multiple neurodegenerative diseases and other aging processes, and pharmacotherapy that targets SG formation might be protective (Wolozin 2012). A major challenge in the future will be to define the components of each RNP complex and pinpoint the defects associated with RBP dysfunction. An important issue to resolve is why the absence of certain RBPs or accessory proteins leads to cell-specific defects (Lukong et al. 2008).

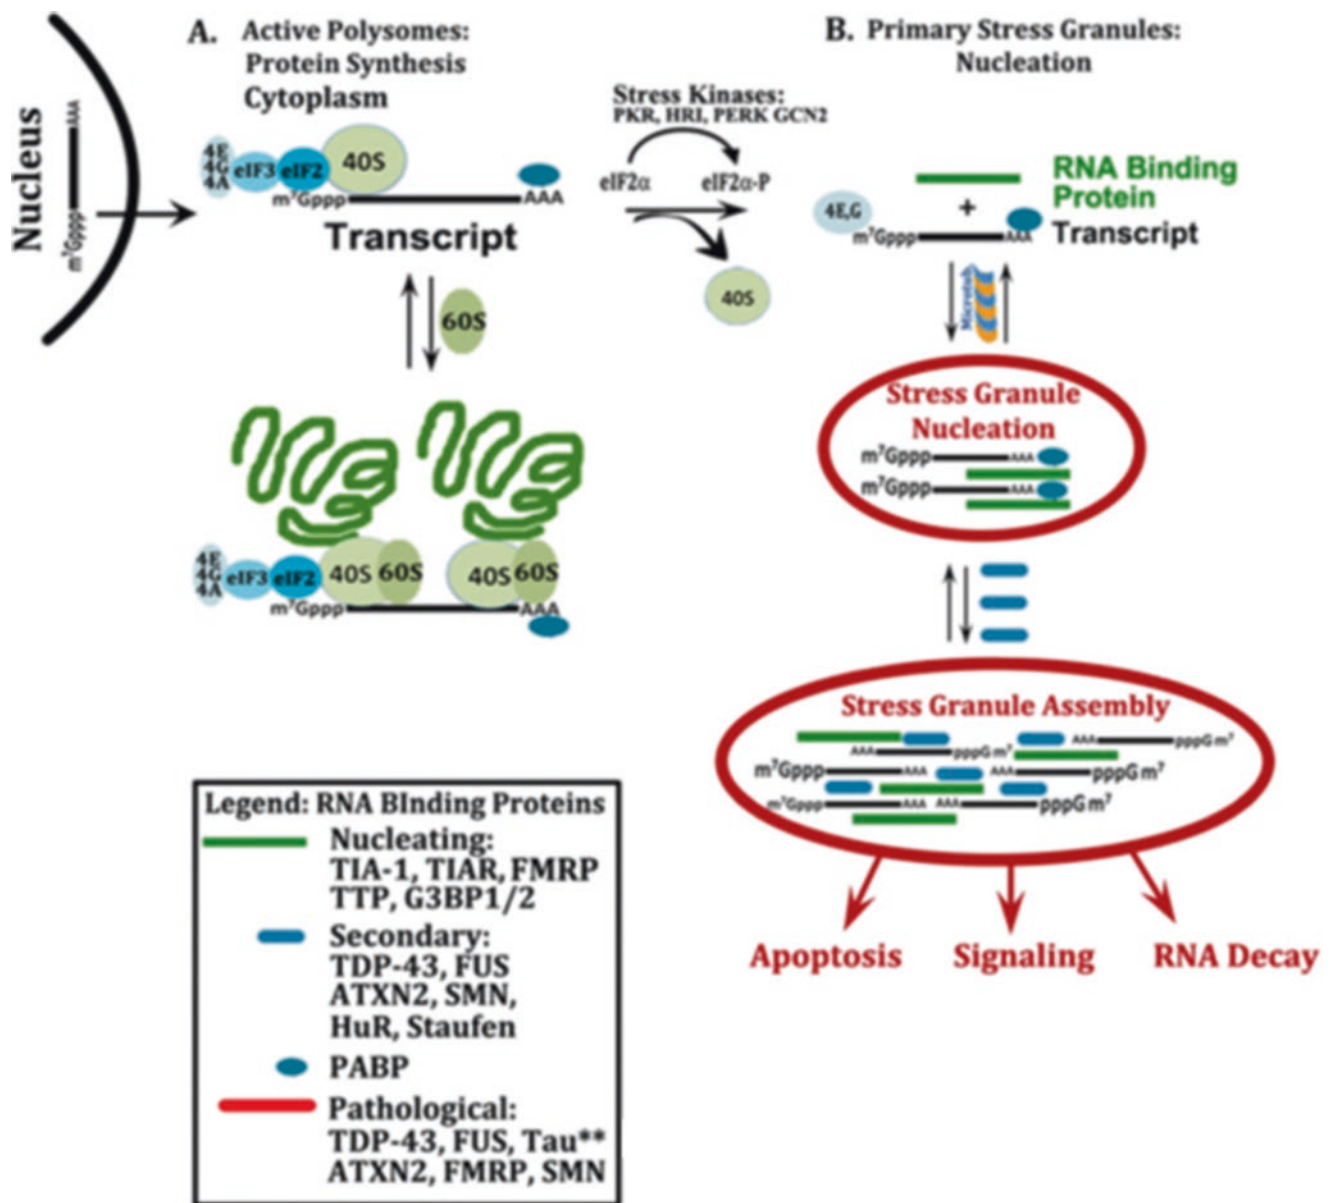

Fig. 19.4 Mechanism of normal and pathological stress granule formation. (a) Under normal, physiological conditions, neurons synthesize specialized proteins from capped transcripts. The proteins eIF4A, E and G complex to form the eIF4F pre-initiation complex, which interacts with the ribosome (40S) as well as other translational regulators to synthesize proteins. Association with the 60S ribosome complex allows protein synthesis to begin. (b) Stress leads to phosphorylation of eIF2 α , dissociation of ribosomes and many of the translation initiation factors, leaving mRNA bound eIF4G and poly-A binding protein. Nucleating RBPs bind the free RNA and also form protein/protein complexes, which initiate SG formation. Once initiated, other RBPs bind to the

mRNA and to the nucleating RBPs to increase the size and complexity of SGs. These SGs are rapidly reversible upon removal of the stress; however prolonged SG formation affects cell biology by interacting with biological systems regulating apoptosis, signaling and RNA decay. (c) Pathological proteins, such as TDP-43, FUS and tau, have a strong tendency to form oligomers, and then fibrils. The consolidation of RBPs during SG formation might promote oligomerization by creating cellular domains with higher concentrations of these proteins. Conversely, the increased stability of oligomers and fibrils might serve as a nidus for SG formation, leading to over-active SG formation. Adapted from (Wolozin 2012)

Fig. 19.4 (continued)

19.7 Major Points

The biology of RBPs provides three novel concepts for the field of neurodegeneration:

1. “Regulated Protein Aggregation”—RNA binding proteins use protein aggregation as part of a normal regulated, physiological mechanism controlling protein synthesis. Increasing evidence indicate that dysfunction

of the RBP regulated protein aggregation pathway strongly contributes to the pathophysiology of neurodegenerative diseases.

2. Recent studies indicate that exposure to extracellular pre-aggregated tau and pre-aggregated α -synuclein can induce further aggregation of tau in cell culture (Guo et al. 2013). However, the initial mechanism through tau might become aggregated remains a mystery. The process of regulated protein aggregation of RBPs provides such a mechanism.

3. The link between tau pathology and RBPs raises the possibility that the pathophysiology of tauopathies affects patterns of RNA splicing, degradation and translation. How ribostasis is altered via the pathophysiology of tau represents a novel line of investigation for the field, which will undoubtedly identify many novel changes occurring during the course of tauopathies

19.8 Conclusions

The high prevalence of prion-like domains in RBPs creates a large genetic target for pathogenic mutations that create hyper-aggregation variants with downstream toxic effects. The role of RBPs in degenerative pathologies may be quite common, as 10 of the top 20 human RBPs predicted to have prionogenic domains have been linked to some form of degenerative disease (Ramaswami et al. 2013). This prevalence suggests that hyperassembly or persistence of SG aggregates may be a causative event in disease progression. The self-perpetuation of such toxic assemblies might be pathological, at least in part, because they disrupt RNA homeostasis. First, pathogenic SG formation could reduce the functional pool of the RBPs. Second, by sequestering associated mRNAs, SG aggregates could alter the population of mRNAs available for translation. Third, pathologic SG aggregates could sequester other mRNA-binding regulatory factors, including other mRNA-binding proteins, miRNAs, and recruited signaling proteins, such that they are not available for their normal functions (Wolozin 2012; Ramaswami et al. 2013). Thus the elucidation of the mechanisms of toxicity in RBP-linked diseases may provide opportunities for pharmacological intervention that will be broadly applicable to many neurodegenerative conditions.

The biology of RBPs and RNA granules presents a new paradigm for understanding the genesis of many neurodegenerative diseases, including motor neuron diseases and tauopathies, which focuses on regulated protein aggregation, implicates tau in this process, and provides a biological context in which these misfolding processes occur. It is well known that aggregation-prone and prion-related domains from different proteins have a propensity to interact with one another (Wolozin 2012). That prion-like aggregation of RBPs appears to provide a seed for the misfolding and aggregation. In disease, aberrant post-translational modifications or other signaling pathways might cause RBPs to lose their normal functions, resulting in their aggregate forming persistent, pathological stress granule complexes. Thus, the discovery intersecting the fields of tauopathies and RNA granule biology shedding light on critical unanswered research questions that may be highly relevant to a further understanding the pathophysiology of neurodegeneration.

19.9 Review Questions

1. What is the role of RNA granules in the stress response?
2. What are the conserved domains in RNA binding proteins and what are their functions?
3. How are mutations in RNA binding proteins thought to contribute to neurodegenerative diseases?
4. What are anti-viral granules?
5. List three core nucleating RNA binding proteins, two RNA binding proteins linked to RNA transport and an RNA binding protein involved in activity dependent translation.

19.10 Answers

1. SGs serve as centers of mRNA triage by dynamically sorting sequestered mRNAs for re-initiation, storage, or degradation, and may be required to allow optimal translation of stress-responsive anti-apoptotic mRNAs and thus appear to be protective. SGs have been shown to associate with PBs, with TTP proposed to play an integral role in the shuttling of mRNAs destined for decay from SGs to PBs.
2. RRM: RNA recognition motif, The RRM domains confer high-affinity binding to specific RNA sequence motifs.
Prion like domain: glycine-rich, low complexity domain that allows RNA binding proteins to reversibly aggregate.
NLS: Nuclear localization signal
3. Mutations in genes coding for SG associated proteins appear to lead to enhanced SG formation. The formation of long-lived stable insoluble protein aggregates seen in disease may lead to accelerated, long-lived SG formation. These highly insoluble aggregates could also serve as a nidus for further aggregation of SGs, by binding with other RBPs and also binding RNA as part of the process of SG maturation. The persistent, pathological SGs appear to be detrimental partly by sequestering RNA binding proteins which prevents them from doing their normal physiological activity.
4. Anti-viral granules are types of RNA granules that form in response to viral infections. In some cases they represent the cellular defense against the virus, which acts by binding viral RNA binding proteins. In other cases they represent the viral machinery used to take over the cellular protein synthesis and anti-viral machinery.
5. Core nucleating RNA binding proteins: TIA1, TTP and G3BP.

RNA binding proteins linked to RNA transport: Staufen, fragile X mental retardation protein (FMRP) and Pumilio (PUM1)

RNA binding proteins involved in activity dependent translation: FMRP

Denise A. Cobb and Howard E. Gendelman

Abstract

Exosomes are extracellular vesicles and regulators of tissue homeostasis, immune effectors, disease biomarkers and drug delivery vehicles. Primarily they serve as vesicular carriers for intercellular communication by bringing nucleic acids, proteins, carbohydrates and drugs to injury action sites. As such, by acting as vesicles for tissue repair and delivery for disease combating therapies they can ameliorate tissue injuries and attenuate microbial infections. On balance, they can perpetuate disease by serving as carriers for infectious agents. In contrast, they can control inflammatory responses through the delivery of tumor necrosis factor alpha (TNF- α) and interleukin-6, ultimately affecting survival during a myriad of infectious, inflammatory and degenerative diseases. Exosomes may also speed engulfment of apoptotic cells and clearance of debris, and reduce systemic inflammatory responses. How exosomes are synthesized, secreted and regulate cellular and tissue function is a key part of understanding immunity and the nervous system. To such ends this review devotes itself to an understanding of the biology and function of exosomes in both health and disease with a special focus on their role as new therapeutic delivery vehicles.

Keywords

Apoptotic cells • Biomarkers • Exosomes • Human immunodeficiency virus • Oligodendrocytes

20.1 Introduction

Exosomes are cell-secreted microvesicles that serve as drug, RNA, microbial and protein transporters. Transport is enabled through bodily fluids and actions facilitate intercellular communication and immune homeostasis responses. Both the cell source and the physiological state and can determine composition and cargo of exosomes, and thus how cells communicate with one another. Exosomes are released into the extracellular environment when multi-vesicular bodies (MVBs) fuse with

the plasma membrane. The first images of a multivesicular body (MVB) exocytotic event appeared in Harding et al. (1983): an example is shown in Fig. 20.1. Exosomes carry cellular components with specialized functions for intercellular signaling, cell homeostasis, growth, differentiation, antigen presentation, microbial infection and tumor proliferation. The first notion for the existence of exosomes was based on an observed vesicular release from maturing reticulocyte endosomes into the extracellular environment (Harding et al. 1983; Lachenal et al. 2011; Pan and Johnstone 1983). Previously thought to be purely waste management in function, exosomes have recently generated intense interest largely based on their role as signaling mediators.

Exosomes are small, 30–150 nm membrane-bound vesicles, that are constitutively secreted by most cell types in the body. These vesicles are found in most bodily fluids including blood, saliva, urine, colostrum, semen and

cerebrospinal fluid (Johnstone et al. 1987; Street et al. 2012; Madison et al. 2014; Dear et al. 2013). Of the exosomes in circulation, an estimated two-thirds originate from platelets (Hunter et al. 2008). After they are released into extracellular spaces, exosomes can interact with adjacent cells, travel an intermediate distance, or enter the circulation. Exosomes then exert their effects by interacting with specific target cells. Their major role is cell-to-cell communication that occurs by binding then signaling through cell receptors and/or by transferring functional proteins, RNA, metabolites and lipids. Delivery of these bioactive molecules is essential for normal function of the target cells but may also contribute to the progression of disease. Because of these features, exosomes appear attractive as both a biomarker source and therapeutic delivery vehicle. Furthermore, exosomes exhibit immunomodulatory and regenerative properties that encourage their application for other therapeutic purposes.

20.1.1 Exosome Biogenesis

Exosomes are defined by their specific physical properties as part of greater populations of secreted vesicles. Notably, they differ from other shedding vesicles on their mode of biogenesis. Three main types of vesicles were described so far: microvesicles (100 nm–1 μ m) which directly bud from the plasma membrane, apoptotic blebs (50–500 nm), which are released by cells undergoing apoptosis, and exosomes (30–100 nm), released by exocytosis from MVBs of late endosomes (Urbanelli et al. 2013).

The current dogma of exosome biogenesis involves their generation through endocytic pathways. First, the plasma membrane invaginates to form an intracellular vesicle. The resulting vesicle fuses with endosomal compartments. When the endosomal membrane bubbles

inward, the MVB forms, an organelle characterized by multiple internal vesicles enclosed within a single outer membrane. The MVBs generated in the endocytic pathway move along microtubules and fuse with the plasma membrane. Upon fusion of the MVB with the plasma membrane the intraluminal vesicles (ILVs) are released as exosomes into the extracellular environment (Dragovic et al. 2011; Théry et al. 2002b).

The mechanisms underlying exosome biogenesis and trafficking are an area of active investigation. Currently, two models have been proposed. One mechanism of exosome biogenesis involves the endosomal-sorting complex required for transport (ESCRT) system. In this model, MVB formation occurs when membrane proteins are ubiquitinated and internalized into the early endosome. Here, ubiquitinated to be recognized by ESCRT-0, -I and -II and enter MVBs (MacDonald et al. 2012). Exosomes are also generated through an ESCRT-independent pathway. The concentration of various membrane lipids may allow for raft-based segregation of cargo within the endosomal membrane. Presence of a ceramide micro-domain has been shown to trigger budding of the endosomal membrane, and consequently the formation of the MVB (Trajkovic et al. 2008) (Fig. 20.2).

Physiological conditions such as increased intracellular calcium, UV irradiation, decreased membrane cholesterol, or free radical stress can increase exosome secretion. Conditions dictating exosome release are thought to be cell-type dependent. Upon release from cells, exosomes can follow one of these three pathways: (1) they can be captured by nearby cells, (2) they can be internalized by cells within an intermediate distance, or (3) they can enter circulation and travel to distant tissues (Pant et al. 2012). Exosomes' mode of action ultimately occurs by affecting intercellular communication. This occurs through transfer of bioactive molecules to their target cells.

Fig. 20.2 Schematic representation of exosome biogenesis. Exosome biogenesis occurs when plasma membrane proteins and lipid are endocytosed. Endocytotic vesicles are delivered to the early endosomes, which fuse with each other, forming late endosomes. When the late endosomal membrane blebs inward, multivesicular bodies (MVB) are formed. MVB may mature into lysosomes, where the degradation of their content occurs, or fuse with the plasma membrane and release internal vesicles (exosomes) to the extracellular space

20.1.2 Composition

20.1.2.1 Lipid Content

The exosomal membrane is enriched with lipid-rafts including cholesterol, sphingolipids, ceramide and glycerophospholipids containing long and saturated fatty-acyl chains (Théry et al. 2009). The concentration of various membrane lipids may allow for raft-based segregation of cargo within the endosomal membrane. Presence of a ceramide micro-domain has been shown to trigger budding of the endosomal membrane, and consequently the formation of the MVB (Trajkovic et al. 2008). Exosomes contain cell-type specific lipids that reflect host cell identity. Oligodendrocytes release exosomes that include the lipids galactocerebroside, sulfatide, and cholesterol which are also prominent in oligodendroglial lipid rafts and characteristic myelin lipids (Krämer-Albers et al. 2007). Similar to plasma membranes, exosomes are organized in a bilayer. But unlike plasma membranes, the exosomal membrane is relatively rigid at pH 7. This rigidity may protect exosomes from lipolytic or proteolytic degradation in circulation (Sampey et al. 2014).

20.1.2.2 Protein

Exosomes of different cellular origins sequester a common set of molecules involved biogenesis, fusion, transport, and vesicle structure. They also carry cell-type specific components, which may reflect the biological function of the parent cell. Proteins from incorporated from the plasma membrane retain the same topological orientation as at the cell surface (Simpson et al. 2008).

Because exosomes are generated in the endocytic pathway, neither nuclear, mitochondrial, nor endoplasmic proteins have been observed in exosomes (Keller et al. 2006). Also due to

their endosomal origin, exosomes contain proteins involved in membrane transport and fusion such as flotillin, Rab-GTPases, and annexin. The presence of such proteins may also be important for fusion of the exosomal membrane with the target cell (van Niel et al. 2006). Adhesion molecules such as tetraspanins and intercellular adhesion molecules (ICAMS) may also be functionally important for the fusion and trafficking of exosomes (Théry et al. 2002b).

Exosomes contain cell-type specific proteins from the originating cell. For instance, exosomes derived from antigen presenting cells also carry MHC I and II on the surface as well as co-stimulatory molecules. Additionally, neuronal exosomes carry the cell adhesion molecule L1, the GPI-anchored prion protein, as well as the GluR2/3 subunits of the α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPA) receptor (Fauré et al. 2006; Lachenal et al. 2011) (Table 20.1).

Normal cellular components such as cytoskeletal proteins and metabolic enzymes are also common to the exosomal membrane. Proteome studies have revealed that exosomes contain a conserved set of proteins across species. For example, nearly all exosomes contain cytoplasmic proteins such as tubulin, actin, as well as the signal transduction proteins, kinases, heterotrimeric G-proteins. Proteins most commonly found associated with exosomes include heat shock proteins such as Hsp70 and Hsp 90, and certain members of the tetraspanin superfamily, especially CD9, CD63, CD81, and CD82 (Théry et al. 2002b). For this reason, the trinity of CD9, CD63, and CD81 is often used as an exosome marker.

Proteins may be trafficked to exosomes in a variety of mechanisms. As previously discussed, ubiquitinated proteins are internalized and transported to the endosome where they interact with members of the ERSCT complex involved in

MVB formation. Due to the location of MVB biogenesis, components of the endosomal compartments are also likely to be incorporated into ILVs. Last, it has been shown that proteins that are capable of higher-order oligomerization and membrane binding target proteins to the exosomal membrane (Fang et al. 2007).

20.1.2.3 Exosome Cargo

Proteins, mRNA, miRNA and DNA have all been identified in exosomal cargoes (Valadi et al. 2007; Kadiu et al. 2012; Kahlert et al. 2014). Cargoes are both cell-type and cell-state specific. Studies have shown that physiological conditions and the cellular microenvironment heavily influence content of exosomes. For example, it was shown that mouse mast cells exposed to oxidative stress released exosomes that differed in their mRNA content compared to their normal counterparts (Eldh et al. 2010). In another study, when retinal pigment epithelial cell cultures were stressed, α B-crystalline, an antiapoptotic protein, was released via exosomes (Biasutto et al. 2013). Release of the molecule provided neuroprotection for the light-sensitive photoreceptors in the retina (Biasutto et al. 2013).

The mechanisms underlying the sorting of nucleic acids and proteins into exosomes are far from being unraveled. Recent studies have demonstrated that lipid rafts have the ability to sort proteins into exosomes (de Gassart et al. 2003).

Alternatively, the ESCRT complex may also be able to sort exosomal cargoes. Reports have demonstrated that the sorting of trans membrane proteins into the MVB pathway relies on the activity of various ESCRT components (Katzmann et al. 2001; Babst et al. 2002). Though, ESCRT machinery has not yet been studied specifically in relation to exosomal cargo packaging, this finding encourages further investigation.

A mechanism for exosomal microRNA sorting has also been suggested. Recent studies indicate that the shuttling of miRNAs into exosomes is a selective process where specific miRNA motifs are recognized by the heterogeneous nuclear ribonucleoprotein A2/B1 (hnRNP A2/B1), an ubiquitously expressed RNA binding protein (Villarroya-Beltri et al. 2013). Other reports find that 3'-end uridylated miRNA isoforms are over-represented in exosomes and facilitate selective miRNA sorting into exosomes, while 3'-end adenylation increases the probability for retention within the cell (Koppers-Lalic et al. 2014). Consistent with these findings, exosomal miRNAs are composed of a distinct set of miRNAs, different from the miRNA signature of the parent cell (Squadrito et al. 2014). In all, the evidence may imply that certain miRNAs have evolved to be packaged into exosomes to carry out a specific biological function.

20.1.3 Functions

Exosomes have pleiotropic biological functions and are involved in a wide variety of physiological processes. Both cell autonomous and cell non-autonomous activities are mediated by exosomes. Cellular processes such as establishment of cell polarity and differentiation involve exosomes. In cancer, exosomes mediate Wnt-directed cell polarization (Luga et al. 2012). During reticulocyte maturation, exosomes are used in the shedding of the transferrin receptor (Johnstone et al. 1989). Cell non-autonomous functions include intercellular communication, a topic to be detailed in the length of the chapter. In brief, exosomes mediate intercellular communication through the shuttling of active biomolecules to recipient cells. Currently, interaction of exosomes with target cells under physiological conditions is not well understood. Three different models of exosome function have been proposed: (1) internalization by target cells, (2) binding to the cell surface and triggering second messenger pathways, and (3) releasing the components into the extracellular matrix (Frühbeis et al. 2012).

20.1.4 Exosomes and Immune-Modulation

Through a variety of mechanisms, exosomes regulate host immunity. As previously detailed, exosomes derived from antigen presenting cells (APCs) express MHC class I and II,

and co-stimulatory molecules. Because exosomes carry immunorelevant structures, they are suggested to participate in immune response (Admyre et al. 2007). Studies have demonstrated that exosomes are involved in both innate and adaptive immune responses.

Exosomes may directly or indirectly stimulate T-cell activation. Several studies have reported activation of CD4⁺ and CD8⁺ T cells by exosomes originating from APCs (Théry et al. 2002a; Andre et al. 2002; Morelli et al. 2004). Interestingly, exosomes may elicit an immune response using two methods, either through direct antigen presentation or by an indirect presentation through transfer of antigenic peptides to APCs. One study found that peptide-bearing exosomes could not induce antigen-dependent T-cell stimulation unless mature CD8⁺ DCs were also present in the cultures. This suggests that in addition to carrying antigen, exosomes promote the exchange of functional peptide-MHC complexes between DCs (Théry et al. 2002a). Several studies have also reported instances of direct antigen presentation without the need of antigen transfer to an APC. For example, exosomes derived from mature DCs were observed to induce an APC-independent antigen-specific T-cell response in vitro (Segura et al. 2005). Similarly, monocyte derived DC-exosomes can induce IFN- γ production in CD8⁺ T cells in the absence of DC (Admyre et al. 2006). B cell exosomes isolated from patients with birch pollen allergy have also demonstrated an ability to induce T-cell proliferation and TH2-like cytokine production independent of peptide transfer to APCs (Admyre et al. 2007).

Some exosomes have inherent immunological activity. For instance, natural killer (NK) cells release exosomes that carry granzyme and perforin, and exert a cytotoxic activity against target cells (Lugini et al. 2012). Mast-cell (MC)-derived exosomes also elicit immune response. In a study, MC-exosomes stimulated immature DCs to up-regulate antigen presentation molecules such as MHC class II, CD80, CD86, and CD40 (Skokos et al. 2003). This demonstrates that exosomes can modulate immune responses by increasing antigen presentation capacity.

During infection, exosomes may be able to recruit or activate host immune cells. Hollow fiber-based experiments indicate that macrophages treated with exosomes released from *Mycobacterium tuberculosis* (*Mtb*)-infected cells can promote recruitment of macrophage and CD11b⁺ cells into the lung in vivo (Singh et al. 2012). This suggests that exosomes may participate in recruiting and regulating host immune cells during infection.

Exosomes can induce immune activation. One study showed that Hsp70 present in renal tumor-derived exosomes could induce production of pro-inflammatory cytokines and tumor growth factors in myeloid-derived suppressor cells (MDSCs). Furthermore, the exosomal Hsp70 was able to suppress MDSC activity via phosphorylation of Stat3; the tran-

scription factor activated through a TLR2-MyD88 pathway (Diao et al. 2015). Lancaster and Febbraio also determined that exosomal Hsp70 could activate NK cells and macrophages (Lancaster and Febbraio 2005). In all, exosomes may be able to initiate host immune responses.

Exosomes may also play a role in immune tolerance. In a recent study, investigators found that exosomes derived from CD8⁺ suppressor T cells were able to act in an antigen-specific manner to suppress allergic cutaneous contact sensitivity in mice. The authors found that the surface of exosomes collected from tolerized mice was coated in immunoglobulin light chains, accounting for antigen specific targeting (Bryniarski et al. 2013).

Inflammatory responses may also be mediated by exosomes using a variety of mechanisms. For example, exosomes may accelerate engulfment and clearance of apoptotic cells, and in this manner serve to reduce systemic inflammatory responses. Additionally, in vitro studies suggest that exosome-delivered miR-155 can increase inflammatory response to endotoxin in primary bone marrow-derived DCs (Alexander et al. 2015). Exosomes may also modulate inflammatory responses through integrin trafficking, a process crucial for the regulation of leukocyte extravasation and migration, a mechanism essential for immune surveillance. One study demonstrated that exosomes released from human macrophages have the ability to negatively regulate endothelial cell migration through integrin trafficking in primary HUVECs. The macrophage-derived exosomes promoted internalization and lysosomal degradation of integrin β 1 (Lee et al. 2014). Because leukocyte recruitment is dependent on the association of epithelial cell and leukocyte integrins, modulation of integrin trafficking suggests that exosomes may mediate the balance of leukocyte recruitment and inflammation expansion.

20.1.5 Exosomes in CNS Communication

In the CNS, neurons, microglia, astrocytes and oligodendrocytes secrete exosomes into the extracellular environment (Glebov et al. 2015), raising the possibility that communication mediated via extracellular vesicles is a common mechanism in the CNS. It has been reported that exosomes are involved in the normal development and physiology of the nervous system (Hooper et al. 2012; Goetzl et al. 2016). One study demonstrated that mature hippocampal and cortical neurons released exosomes in response to calcium and glutamatergic synaptic activity, which suggests a role in normal physiology (Lachenal et al. 2011).

Additionally, oligodendrocytes release exosomes upon stimulation with the neurotransmitter glutamate. The exosomes are readily internalized by neurons, and enhance neuronal tolerance to oxidative stress and oxygen-glucose

deprivation through the transfer of superoxide dismutase and catalase (Fröhlich et al. 2014). Oligodendroglial exosomes also have an impact on neuronal physiology. Electrophysiology studies revealed an increased firing rate of neurons exposed to oligodendroglial exosomes (Fröhlich et al. 2014). Exosomes not only altered neurons physiologically, but also on a molecular level. Differential gene expression and altered signal transduction pathways were observed in neurons following exosome treatment (Fröhlich et al. 2014). Oligodendrocytes also secrete exosomes to deliver neuroprotective proteins, glycolytic enzymes, mRNA, and miRNA to axons in response to neuronal stress signals (Frühbeis et al. 2013).

Astrocytes also respond to neuronal stress signals by releasing exosomes containing neuroprotective Hsp70 and synapsin 1, facilitating the neuronal survival (Taylor et al. 2007). In primary culture, cortical astrocytes and microglial cells have been shown to release exosomes via ATP activation of P2X7 receptors and the downstream activity of acid sphingomyelinase (Bianco et al. 2009). Additionally, microglial microvesicles have been reported to interact with neurons and enhance spontaneous excitatory transmission through the stimulation of sphingolipid metabolism (Antonucci et al. 2012).

Proteomic and functional analyses of microglial exosomes indicate that they may have a role in neuronal metabolic support and neuropeptide catabolism. One study concluded that microglia-derived exosomes expressed metabolically active CD13, an aminopeptidase involved in cleaving leucine- and methionine-enkephalins peptides. The CD13-cleaved neuropeptides were unable to bind to the neuronal opioid receptor as assessed by cAMP response (Potolicchio et al. 2005). In all, exosomes may represent a previously unrecognized form of CNS communication, a significant finding in an organ restricted by cellular motility.

20.2 Exosomes in Disease Pathogenesis

Though exosomes mediate processes in the CNS required for normal function, they also contribute to the pathogenesis of several neuroinflammatory disorders, cancer, and viral infections. Several studies have demonstrated that exosomes play a role in prion and virus trafficking. Proposed by Gould, the “Trojan exosome” hypothesis describes that exosomes have the capacity to facilitate viral spread, a receptor-independent, and Env-independent mode of infection. Currently, this Trojan exosome model is also being evaluated in protein-misfolding neurodegenerative diseases as a possible mechanism for the spread of pathogenic proteins involved in neurodegeneration. Understanding the role of exosomes in the progression of human disease is important for developing novel therapeutic strategies. Potentially, exosome biogenesis, release, and fusion pathways could become novel pharmacological targets.

20.2.1 Exosomes and Infectious CNS Diseases

20.2.1.1 Transmissible Spongiform Encephalopathies (TSE)

Transmissible spongiform encephalopathies (TSE) or prions are transmissible, fatal neurodegenerative disorders that include Creutzfeldt-Jakob disease, fatal familial insomnia, Gertsmann-Straussler-Scheinker syndrome, kuru, and variably protease-sensitive prionopathy in humans, as well as bovine spongiform encephalopathy and scrapie in sheep (Monari et al. 1994; Collinge et al. 2006; Gambetti et al. 2008; Prusiner 1982; Wells et al. 1987). It has been a long-standing question as to how prions spread between cells and throughout the body. Currently, three mechanisms have been proposed, including (1) direct cell-cell contact, (2) tunneling nanotubes, and (3) extracellular vesicles such as exosomes (Kanu et al. 2002; Gousset et al. 2009; Fevrier et al. 2004). The ability of exosomes to travel over relatively long distances within the body makes them an ideal vehicle for infectious pathogens to exploit. Indeed, a number of studies have implicated exosomal vesicles with prion infectivity. Cellular prion protein (PrP^C) is a known constituent of the protein cargo in blood-circulating extracellular vesicles. Moreover, exosomes isolated from conditioned media of TSE-infected cells produced disease when injected into mice (Saá et al. 2014). Another study concluded that the dissemination of prions in N2a cell culture is mediated through the exosomal pathway (Alais et al. 2008).

Recent *in vitro* studies elucidate how PrP^C and PrP^{Sc} are packaged into exosomes (Fevrier et al. 2004). In cultured cell lines, PrP^C is tethered to the plasma membrane by a glycosylphosphatidylinositol anchor and predominantly associated with lipid rafts, especially microdomains of sphingolipids and cholesterol. The conversion of PrP^C to PrP^{Sc} has been suggested to occur in these lipid raft regions (Taylor and Hooper 2006). The presence of such lipid rafts in exosomes suggests a possible role in prion transmission (Baron et al. 2002). Studies have demonstrated that ESCRT machinery is essential for prion trafficking in exosomes. In Mov neuroglial cells, silencing of the HRS-ESCRT-0 or Tsg101-ESCRT-I subunits drastically impairs the formation of cellular infectious prions. Altered trafficking of cholesterol or impaired production of ceramide also significantly decreases infectious prion release (Vilette et al. 2015). Reports also indicate that inhibition of the neutral sphingomyelinase (nSMase), an enzyme associated with lipid-raft dependent endosomal sorting, impairs both exosome formation and prion packaging, suggesting that the nSMase pathway regulates both exosome formation and packaging of infectious prions (Guo et al. 2015).

20.2.2 Viral Infections

Retroviruses exploit the host cell's intercellular communication machinery to evade immune surveillance and facilitate viral spread. This can be accomplished through several mechanisms including tunneling nanotubes and extracellular vesicles (Kadiu and Gendelman 2011). HIV-1 virus has developed many exosome-mediated strategies to manipulate the host's cell machinery. Recently, exosomes have emerged as novel facilitators of HIV-1 infection (Kadiu et al. 2012; Nguyen et al. 2003). Exosomes may mediate infection in a variety of ways. One mechanism follows the "Trojan exosome" hypothesis, in which exosomes have the capacity to facilitate viral spread through a receptor-independent, and Env-independent mode of infection. This model provides retroviruses the ability to exploit intracellular pathways of vesicular biogenesis and transport, allowing for viral dissemination via exosomes (Nguyen et al. 2003). It is worthwhile to note that HIV and exosome bear a great number of similarities. For instance, HIV and exosome particles share similar lipid content, size, topology, carbohydrate profile, and host proteins. The physiochemical overlap between exosome and viral particles may in part explain how retroviruses are able to seize host machinery within the endosomal compartments to facilitate spread.

It has been shown that exosomal proteins can be sorted on the basis of both higher-order oligomerization (the oligomerization of oligomers) and plasma membrane association. Orthoretroviridae Gag proteins are known to bind the plasma membrane and assemble into higher-order oligomeric complexes (Coffin et al. 1997). This higher-order oligomerization is sufficient to target plasma membrane proteins to HIV virus-like particles, suggesting that Gag proteins possess inherent exosomal-sorting information. One study demonstrated this concept using the HIV Gag protein. Due its plasma membrane anchor and oligomerization domains, the HIV Gag protein, targeted to sites of exosome budding on the PM, and co-localized with exosomal markers CD81 and CD63 at PM cap domains (Fang et al. 2007). Similar patterns have also been observed for Gag proteins other retroviruses including equine infectious anemia virus (EIAV), murine leukemia virus (MLV), HTLV-1, Rous sarcoma virus (RSV), Mason-Pfizer monkey virus (MPMV), and HERV-K (Fang et al. 2007). Retroviruses may also hijack the exosomes biogenesis pathway using other means. The generation of ILVs/exosomes results from the binding of the hepatocyte growth factor tyrosine kinase substrate (Hrs) to ubiquitinated cargo, which recruits Tsg101. HIV-1 Gag is known to mimic Hrs, thereby taking over Tsg101 and other components of the MVB machinery to facilitate viral budding (Pornillos et al. 2003).

Though viral spread through exosomes is thought to be a low-efficiency process, it remains a mechanistically important and previously overlooked mode of infection. The

Trojan exosome model has important implications for the host immune response. This process would allow the virus to access innate and adaptive immune cells, and may help to explain resistance to neutralizing antibodies, a phenomenon observed in HIV infection. The failure of protective HIV vaccines may also be attributed to this model. When viral particles are camouflaged within exosomes, retroviruses are able to bypass the host adaptive immune response. This may help to explain why retroviral antigen vaccines are unlikely to provide prophylactic protection. Given their endosomal origin, exosome-bearing retroviral particles should be sensitive to inhibitors of exosome biogenesis and fusion, allowing for better response to inhibitors of the classic Env-dependent infection (Nguyen et al. 2003).

Other aspects of HIV pathology may be induced by exosomes. Specifically, CNS inflammation observed in HIV associated neurodegenerative disorder (HAND) may also be mediated by exosomes. Previously, investigators have identified that SIV and HIV infection upregulates certain microRNAs (miRNAs) in macaque and human brains (Chaudhuri et al. 2013; Noorbakhsh et al. 2010). A recent study demonstrated that exosomes isolated from rhesus macaque SIVE brains contained miR-21 that could activate TLR7, leading to neurotoxicity (Yelamanchili et al. 2015).

Exosomes play a role in other viral infections. During Human T-lymphotropic virus type 1 (HTLV-1) infection, exosomes that contain the protein Tax cause phenotypic changes in unaffected cells, potentially contributing to pathogenesis of adult T-cell leukemia (Jaworski et al. 2014). Likewise, a correlation between exosome release and viral spread has also been observed for Hepatitis B, C, and E viruses (Bukong et al. 2014), Human Herpes Virus and Herpes simplex (Temme et al. 2010), and Epstein-Barr virus (Pegtel et al. 2010).

20.2.3 Exosomes and Neurodegeneration

Exosomes have become an increasingly popular topic in the field of neurodegeneration. Several studies have demonstrated that exosomes' capacity to transport pathogenic proteins such as alpha-synuclein and amyloid precursor protein. Recently key proteins involved in neurodegenerative diseases such as Alzheimer's (AD) and Parkinson's (PD) disease, and Amyotrophic lateral sclerosis (ALS) have demonstrated the potential for induced spreading of misfolded forms of these proteins in a manner similar to that of prions (Brundin et al. 2010; Goedert 2015; Prusiner 2013).

In addition to transmission of infectious proteins, exosomes may also contribute to pathobiology of neurodegenerative diseases via immune modulation. As previously discussed, exosomes mediate various innate and adaptive immune responses. Among neurodegenerative disorders, one commonality is the involvement of innate and adaptive

immune responses in the CNS. The interplay between peripheral and resident CNS immunity can affect neuroinflammatory responses and exacerbate neurodegeneration (Anderson et al. 2014). Thus, it is possible that inappropriate immune activation induced by exosomes contributes to the pathogenesis of a broad range of neuroinflammatory and neurodegenerative disorders including ALS, AD and PD.

Likewise, exosome cargo RNA may also play a role in neuroinflammation and neurodegeneration. A relationship between exosomes, miRNAs and TLR activation may exist in the nervous system. The interplay of exosomes and TLRs possibly contributes to the pathophysiology of AD, PD, and other related disorders. Several studies have shown that exosomes carry miRNAs associated with pathological alterations during the course of many neurological diseases. miRNAs entering the cells via exosomes may regulate the activation of TLRs, leading to outcomes such as inflammation or apoptosis (Paschon et al. 2016).

20.2.3.1 Parkinson's Disease

Alpha-synuclein (α -syn) aggregation plays a central role in Parkinson's disease pathology, and the transmission of alpha-synuclein from diseased to healthy neurons may be important in the spread of PD through the nervous system. Currently, exosome-based models of α -syn transmission are of particular interest. It has been reported that exosomes released from α -syn over-expressing cells contain α -syn and are capable of transferring α -syn to unaffected cells. The study also demonstrated that lysosomal dysfunction also led to an increase in α -syn production in exosomes and transmission to recipient cells (Alvarez-Erviti et al. 2011a). α -syn can affect neurons via exosomes. Treatment of microglia cells with alpha-synuclein increased exosomal secretion. Exosomes derived from alpha-synuclein treated mouse microglia cell line BV-2 cells were found to express a high level of MHC class II molecules and membrane TNF- α , and were observed to increase apoptosis of rat cortical neurons in vitro (Chang et al. 2013). In all, microglial exosomes produced in response to α -syn may be an important mediator of neurodegeneration in PD. Following the discovery of exosomal α -syn, it was recognized that α -syn might be produced through different pathways, and the mode of secretion may affect α -syn transmission and toxicity. One study concluded that exosomal α -syn oligomers not only are taken up more readily by recipient cells, but can also induce greater toxicity compared to free oligomers (Danzer et al. 2012).

In addition to the transmission of protein aggregates, exosomes may also contribute to PD pathology by propagating an improper immune response. In the inflammatory model of neurodegeneration, chronic activation of microglia is thought to result in loss of dopaminergic neurons (Lull and Block 2010). As previously discussed, exosomes have the ability to affect many aspects of immunity, including antigen presentation and

T-cell activation. Given this, exosomes may mediate the cross talk between that innate and adaptive immune response in the CNS. To date, the role of exosomes in neuroinflammation and Parkinson's has yet to be elucidated.

20.2.3.2 Alzheimer's Disease

Exosomes may contribute to neurodegeneration seen in AD. It has been shown that primary astrocytes secrete exosomes associated with ceramide and PAR-4 in response to A β exposure in vitro. This process is dependent upon ceramide generation by neutral sphingomyelinase 2 (nSMase2). The activation of nSMase2 and expression of PAR-4 is critical for the secretion of apoptotic exosomes and glial apoptosis. Thus, these exosomes may contribute to glial apoptosis, and therefore, neurodegeneration in AD (Wang et al. 2012).

Currently, the role of exosomes in AD is unclear in regards to A β plaque clearance. While some evidence suggests that exosomes interfere with A β clearance, while other studies imply that exosomes may enhance uptake of A β fibrils. The processing of amyloid precursor protein (APP) occurs in early endosomes. Given that exosomes generation also occurs at the endosome, small fractions of A β peptides can be secreted from the cells via exosomes (Rajendran et al. 2006). Pathogenic proteins, such as A β and tau are secreted from the exosomes into the extracellular space where they can interact with TLR2, 4 and 9, receptors overexpressed in AD animal models. Interaction of pathogenic proteins with the TLRs may activate the microglial inflammatory response, leading to clearance of AB plaques (Richard et al. 2008). Likewise, another study demonstrated that exosome secretion increases A β fibrils associated with exosomes, enhancing A β uptake by microglia and eventually resulting in the reduction of extracellular A β (Yuyama et al. 2012). It is thought that the neuronal exosomes capture A β through their enriched glycosphingolipids (Yuyama et al. 2015). Conversely, there is evidence to show that exosomes contribute to the propagation of aggregated proteins. Exosomes have been shown to interfere with uptake of A β by primary cultured astrocytes and microglia in vitro (Dinkins et al. 2014). More recently, Asai and colleagues demonstrated that microglia spread tau via exosomes, and inhibition of exosome biogenesis through pharmacologic blockade of sphingomyelinase-2 reduced tau transmission in vitro and in vivo (Asai et al. 2015).

20.2.3.3 Amyotrophic Lateral Sclerosis

Both mutant and misfolded wild-type SOD1 can traverse cell-to-cell either as protein aggregates that are released from dying cells and taken up by neighboring cells via the surface of exosomes (Grad et al. 2014). Propagation and transmission of misfolded wild-type SOD1 via exosomes is therefore a potential mechanism in the systematic progression of ALS pathology.

20.2.3.4 Chronic Mental Diseases

The study of aggregated proteins can contribute to our understanding of the chronic and progressive mental illness diseases. Dysbindin, a protein encoded by the schizophrenia susceptibility gene DTNBP1 has previously been reported to aggregate with DISC1 (Ottis et al. 2011). Exosomes have been shown to propagate transmission of these neurotoxic dysbindin-1B aggregates in mice (Zhu et al. 2015).

20.2.4 Cancer: T and B Cell Malignancies, Glioblastoma and Neuroblastoma

While exosomes are involved in a myriad of different cancers including melanoma (Hood et al. 2011), breast (Luga et al. 2012), and prostate (Corcoran et al. 2012), their participation in cancers of the CNS and immune system are of particular interest within the field of neuroimmune pharmacology.

Glioblastoma exosomes contain angiogenic proteins and stimulate tubule formation by endothelial cells, and mRNAs with the capacity to remodel the tumor stroma and encourage tumor growth (Skog et al. 2008). Glioblastoma exosomes have a network of nanofilaments on their surface, a structural feature absent in normal human astrocyte exosomes. It is thought that these nanofilaments may increase the probability of exosome binding to target cells (Sharma et al. 2014). If exosomes contain tumor-promoting proteins, and RNAs, this feature may increase their malignant effect. Malignant properties of neuroblastoma may also be modulated by exosomes. Proteomic studies have revealed that neuroblastoma-derived exosomes contain proteins such as prominin-1 (CD133), B7-H3 (CD276), basigin (CD147 or EMMPRIN), and GD2 ganglioside, which may promote tumor-supportive microenvironment and promote tumor progression (Marimpietri et al. 2013).

Exosomes derived from malignant T and B cells have similar properties to those of glioblastoma and neuroblastoma. For instance, Hypoxic leukemia cells secrete exosomes containing miRNAs including miR-210, which modulates tumor microenvironment in a way that promotes endothelial cell tube formation (Tadokoro et al. 2013). Additionally, exosomes from a chronic myeloid leukemia cell line (K562), induced angiogenic activity (Mineo et al. 2012). Both oxidative stress and thermal stress were shown to increase the release of exosomes bearing Natural Killer Group 2 member D (NKG2D) ligands such as MICA/B, ULBP1 and ULBP2 from human T cell leukemia Jurkat- and B cell leukemia/lymphoma Raji cells (Hedlund et al. 2011). These NKG2D ligands prevent NK cell activation, and are upregulated under stressed conditions, allowing immune evasion through the suppression of the NKG2D-dependent NK cell cytotoxicity (Raulet 2003). In B-cell lymphoma, exosomes may contribute to the cellular composition of the tumor, specifically the populations of clonogenic side

population cells and non- side population cells. Exosome-, mediated Wnt signaling enables transitions between clonogenic states, and thus tumor progression (Koch et al. 2014).

20.3 Applications in Nanomedicine

Recently, the diagnostic and therapeutic potential of exosomes has generated immense interest. The ubiquitous nature of exosomes, and their differential miRNA expression in disease states encourages their use as non-invasive biomarkers. Furthermore, their inherent ability to carry metabolically active cargo and travel in the body makes exosomes attractive as therapeutic delivery vehicles.

20.3.1 Biomarkers

As exosomes can be isolated from circulating fluids such as serum, urine, and cerebrospinal fluid (CSF), they provide a potential source of biomarkers for neurological conditions (Street et al. 2012). Analysis of exosomal RNA or protein content may be used to both diagnose disease and predict patient response to therapy. Exosomes appear attractive as biomarkers due to their prevalence in bodily fluids, non-invasive isolation from patients, and differential enrichment of RNAs in pathological conditions. Exosomes isolated from patient bio-fluids may have the potential to diagnose a plethora of diseases or predict patient outcomes. Phosphorylated tau associated with exosomes is present in CSF samples from human AD patients and age-matched controls. Significant and selective enrichment of exosomal CSF phospho-tau was observed in mild (Braak stage 3) stages of AD (Saman et al. 2012). In another example, glypican-1 (GPC1) positive circulating exosomes isolated from the serum of patients and mice with pancreatic cancer were able to distinguish healthy subjects, those with benign pancreatic disease, and those with early and late stage pancreatic cancers. Cohort data found that the levels of GPC1⁺ circulating exosomes correlated with both tumor burden and the survival of patients pre-/post-surgery. Additionally, mutant Kras mRNA was detected in GPC1⁺ exosomes isolated from mice and humans with spontaneous pancreatic cancer (Melo et al. 2015). As the previous study suggests, exosomes may be able to predict patient response to therapy. Response to chemotherapy in patients diagnosed with acute myeloid leukemia (AML) may be predicted through analysis of exosome cargo. One study demonstrated that changes in exosomal TGF- β 1 content are correlated with stage of treatment in AML patients. The investigators found that low exosomal TGF- β 1 levels might be predictive of long-term survival, because exosomal protein levels of patients who achieved long-term remission were not significantly elevated (Hong et al. 2014).

20.3.2 Cell-Free Therapeutic

Exosomes have generated immense interest as a cell-free therapeutic. They offer many advantages over current nanoscale delivery vectors. One such advantage is that exosomes are able access immunologically restricted tissues. While some exosomes actively participate in immune function, other exosomes are able to avoid immune-surveillance, perhaps due to the nature of self-tolerance. Their ability to circumvent immunological barriers and traffic to privileged sites, such as the CNS, is especially relevant in the field of neuroimmune pharmacology. Several studies have demonstrated the capacity of exosomes to mediate delivery of therapeutic bioactives to immune privileged sites. In a report, exosomes were used to encapsulate both curcumin and an activator of Stat3 inhibitor, JSI124. Intranasal administration of these exosome formulations led to rapid delivery drug to the brain, where microglial cells selectively took them up. Treated mice showed protection from LPS-induced brain inflammation (Zhuang et al. 2011). In another study, when exosomes loaded with catalase were administered intranasally in PD mouse model, exosomes were readily taken up by neuronal cells, and significant neuroprotective effects in *in vitro* were observed (Haney et al. 2015). In all, these studies suggest exosome based therapeutics may be a novel therapeutic approach for treating brain inflammatory-related diseases.

Exosome-based delivery systems also allow for targeted delivery. Several studies have also described various methods that allow targeted delivery of exosomal cargo. For instance, exosomes isolated from tolerized CD8⁺ suppressor T cells target effector T cells in an antigen-specific manner via surface coating of antibody light chains. Upon this finding, investigators used this antigen-specific system to deliver inhibitory miR-150 to contact sensitivity effector T cells (Bryniarski et al. 2013). The synthesis of second-generation “biomimetic” exosomes may also represent an efficient approach to develop antigen carriers for specific targeting (Li et al. 2015). Targeting molecules may also be synthetically introduced to exosomes. To achieve delivery of short interfering siRNA to the mouse brain, self-derived dendritic cell exosomes were engineered to express Lamp2b fused to the neuron-specific RVG peptide3. Following intravenous injection, the targeted exosomes delivered GAPDH or BACE1 siRNA to neurons, microglia, and oligodendrocytes in the brain, and resulted in a specific gene knockdown (Alvarez-Erviti et al. 2011b). This method shows great potential in exosome-targeting strategies, however such peptides are subject to proteolysis in circulation. To overcome this, chemical modifications of the peptide may be required. One study demonstrated that glycosylation of peptides on the exosome surface allows for enhanced delivery. This study not only suggests that glycosylation stabilizes targeting peptides, but

also that such modifications do not impede peptide interactions with the target receptor (Hung and Leonard 2015).

Exosomes can either have a stimulatory or inhibitory effect on the immune system; because of this attribute they are attractive as immunotherapy agents. This natural capacity can be utilized to modulate immune response for therapeutic purposes. Exosomes have been investigated for immunotherapeutic treatment of cancer, autoimmune diseases, and as a novel vaccination strategy. In regards to cancer therapy, one approach involves direct interaction between the cancer cells and exosomes. This idea was demonstrated using THP-1 macrophages, which were transfected with chemically modified miR-143 *ex vivo*. Following intravenous injection into in xenografted nude mice, exosome-like vesicles containing the modified miR-143 were secreted, and miR-143 was detected in the in the serum, tumor, and kidney of the host animals. These results study suggests the possible therapeutic use of exosomes in an RNA drug-delivery system (Akao et al. 2011). Apart from directly targeting exosomes to tumor cells, immune cells could also be primed by exosomes containing genetic material, enabling the immune system to recognize and destroy cancer cells. Several studies have utilized DC- exosome bearing functional MHC class I/ peptide complexes to stimulating a specific CTL anti-tumor response (Zitvogel et al. 1998; André et al. 2004). Tumor-derived exosomes have also been shown to act in a similar manner, promoting CD8⁺ T-cell-dependent antitumor effects *in vitro* and *in vivo* (Wolfers et al. 2001).

Immune cell priming via exosomes could also be applied for the development of retroviral vaccines. As discussed previously, failure of protective prophylactic retroviral vaccines, like HIV, may be attributed to the fact that HIV is internalized into CD81⁺ DC intracellular compartments, converging with the exosome biogenesis pathway and allowing for effective viral transmission to CD4⁺ T-cells (Izquierdo-Useros et al. 2010). In all, the proposed exosomal origin of retrovirus predicts that HIV poses an unsolvable paradox for adaptive immune responses (Nguyen et al. 2003). Exosomes-based vaccines may help to overcome this problem. One study demonstrated that DC exosomes bearing HIV_{Gag} were capable of stimulating Gag-specific effector CD8⁺ CTL responses, and resulted in some degree of protective immunity (Wang et al. 2014). Conversely, some exosome have demonstrated the capacity to inhibit CTL responses, which may prove beneficial for autoimmune diseases. Exosomes derived from CD8⁺25⁺ T regulatory (Treg) cell-secreted are capable of inhibiting *in vivo* DC-induced CTL responses (Xie et al. 2013). Because CD4⁺25⁺ and CD8⁺25⁺ regulatory Treg have been shown to inhibit autoimmune diseases (Zwar et al. 2006), CD4⁺25⁺ and CD8⁺25⁺ Treg derived exosomes may become an alternative for immunotherapy of autoimmune diseases. Overall, exosomes may represent a new approach in the development of immunotherapies.

Exosomes have potential use in the field of regenerative medicine. Stem cell transplantation has been thoroughly studied as a means of regenerative therapy. However, exosomes offer several advantages over stem cell transplantation namely; exosomes lack the ability to self-replicate. Due to this fact, exosome therapy would not lead to teratoma formation, a risk associated with stem cell transplantation. Additionally, exosomes can be readily isolated from patients, minimizing immunogenic reactions such as graft versus host disease associated with hematopoietic stem cell transplantations (Storek et al. 1997). Several studies have demonstrated the exosomes' regenerative capacity in neurological and demyelination disorders. One study found that nasal administration of young serum-derived exosomes increase myelin in aging rats through the delivery of miRNA 219 (Pusic and Kraig 2014). Another demonstrated that INF- γ stimulated DC exosomes also increased brain myelin (Pusic et al. 2014). Following traumatic brain injury, exosomes isolated from multipotent mesenchymal stromal cells facilitated functional recovery in rats by promoting angiogenesis and neurogenesis while reducing inflammation (Zhang et al. 2015). In all, exosomes have potential application as cell-free therapeutics for neurodegenerative diseases.

Exosomes have a natural capacity to carry and transmit functional RNAs and DNAs (Valadi et al. 2007; Kahlert et al. 2014). Thus, they have become attractive as gene therapy vectors. In vitro, exosomes can transfer miRNAs from T cell to APCs during immune synapsis, modulating gene expression in recipient cells (Mittelbrunn et al. 2011). Several studies investigating the potential of exosomes as gene-therapy mediators have capitalized on this inherent ability to traffic RNA. Plasma exosomes have been used to transport exogenous siRNA to human monocytes and lymphocytes, effectively delivering siRNA into the blood cells and causing selective gene silencing of mitogen-activated protein kinase (Wahlgren et al. 2012). Exosomal delivered miRNA has also been used to target tumor cells (Akao et al. 2011). These studies suggest that exosomes may be efficient gene delivery vectors, providing cells with therapeutic RNAs.

In addition to the transmission of therapeutic RNAs, exosomes may also allow new opportunities for enzyme therapeutics. Certainly, one could deliver mRNA of interest to the target for later translation into a functional protein. Another approach would involve the loading of functional proteins into exosomes, since the vesicles provide proteolytic protection. Genome editing tools, specifically the CRISPR Cas9 system, have demonstrated the ability to eradicate latent HIV infection (Hu et al. 2014). However, the use of such technology has limited translational applications due to its rapid degradation in vivo. Thus, exosomes might allow technologies such as the CRISPR-Cas9 system to be used therapeutically in humans, allowing for simultaneous delivery of both the enzyme and the RNA components of CRISPR.

20.3.3 Exosome as a Theranostic Tool

Exosomes are unique in their capacity to function as both biomarkers and therapeutic vehicles. The concept of a dual therapeutic and diagnostic agent is termed theranostics in the field of nanomedicine. Chemical modifications to the exosome surface may allow exosomes to be used both diagnostically and therapeutically. One study utilized click chemistry to functionalize the surface of exosomes with azide-fluor 545. Surface modification did not appear to alter uptake into cells, suggesting that the bioconjugation of the fluorescent molecule was functionally inert (Smyth et al. 2014). Reactions like the one described here could theoretically be used to decorate exosomes with a variety of compounds such as radionuclides, fluorescent moieties, or contrast agents. This would also allow for precise in vivo tracking of administered exosomes, potentially useful implication for pharmacokinetic studies of exosome therapeutics.

20.4 Concluding Remarks

Previously thought to be purely waste management in function, exosomes have recently generated intense interest based on their role as signaling mediators. Through the delivery of bioactive cargo such as RNA and protein, exosomes are involved in a wide range of normal and pathogenic processes including CNS function, immunity, inflammation, and cancer. Understanding the role of exosomes in both normal physiology and human disease is important for developing novel therapeutic strategies. Potentially, exosome biogenesis, release, and fusion pathways could become novel pharmacological targets. The ubiquitous nature of exosomes, and differential miRNA expression in disease states encourages their use as non-invasive biomarkers. Furthermore, their inherent ability to carry metabolically active cargo and travel in the body makes exosomes attractive as therapeutic delivery vehicles. The field of exosome biology is rapidly expanding, with exciting discoveries being made in areas of basic research, biomarker discovery, drug delivery and therapeutics.

20.5 Review Questions

1. How was the idea of exosomes first hypothesized?
2. Describe the differences between microvesicles, apoptotic blebs, and exosomes.
3. Describe the contents of the exosomal membrane.
4. What are the three different proposed models of exosome function?
5. Explain Gould's "Trojan exosome" hypothesis
6. How do Glioblastoma exosomes potentially increase the effects of cancer cells?
7. How can an exosome-based drug delivery system be used successfully?

20.6 Answers

1. The first notion for the existence of exosomes was based on an observed vesicular release from maturing reticulocyte endosomes into the extracellular environment (Harding et al. 1983; Pan and Johnstone 1983).
2. Microvesicles (100 nm–1 µm) directly bud from the plasma membrane; apoptotic blebs (50–500 nm) are released by cells undergoing apoptosis; exosomes (30–100 nm), released by exocytosis from MVBs of late endosomes (Urbanelli et al. 2013).
3. The exosomal membrane is enriched with lipid-rafts including cholesterol, sphingolipids, ceramide and glycerophospholipids containing long and saturated fatty-acyl chains.
4. (1) internalization by target cells, (2) binding to the cell surface and triggering second messenger pathways, and (3) releasing the components into the extracellular matrix.
5. Exosomes have the capacity to facilitate viral spread, a receptor-independent, and Env-independent mode of infection. Currently, this Trojan exosome model is also being evaluated in protein-misfolding neurodegenerative diseases as a possible mechanism for the spread of pathogenic proteins involved in neurodegeneration.
6. Glioblastoma exosomes contain angiogenic proteins and stimulate tubule formation by endothelial cells, and mRNAs with the capacity to remodel the tumor stroma and encourage tumor growth (Skog et al. 2008). Glioblastoma exosomes have a network of nanofilaments on their surface, a structural feature absent in normal human astrocyte exosomes. It is thought that these nanofilaments may increase the probability of exosome binding to target cells (Sharma et al. 2014). If exosomes contain tumor-promoting proteins, and RNAs, this feature may increase their malignant effect.
7. Exosomes isolated from tolerized CD8⁺ suppressor T cells target effector T cells in an antigen-specific manner via surface coating of antibody light chains. Upon this finding, investigators used this antigen-specific system to deliver inhibitory miR-150 to CS effector T cells (Bryniarski et al. 2013).

Abstract

The importance of non-coding RNAs that regulate cellular processes has become evident in the recent past. The most prominent among this class of RNAs are microRNAs (miRs) that are 20-22-nucleotide long single stranded RNAs. miRs are transcribed from the genome as longer transcripts called primary miRs that are processed sequentially by RNase III enzymes DROSHA and Dicer to generate the mature form. In the cytoplasm, miRs recruit a protein complex called the RNA-induced silencing complex (RISC) and mediates down-regulation of translation from target mRNAs. miRs are expressed in a tissue, cell-type and developmental stage specific manner. Aberrant expression of miRs therefore contributes to disease pathology as a consequence of dysregulation of target protein levels. In this chapter we review the discovery, biogenesis, mechanism of action of miRs and their role in neuronal function and dysfunction with emphasis on HIV-associated neurocognitive disorders.

Keywords

DICER • DROSHA • HIV • Inflammation • microRNA • Neurodegeneration • Non-coding RNAs • RISC

21.1 Background and Discovery

The central dogma of molecular biology assigned ribonucleic Acids (RNAs) with the sole function of deciphering the genetic code, stored in deoxyribonucleic acids (DNA). The three types of RNAs that had been identified at that point, namely, messenger RNAs (mRNAs), transfer RNAs and ribosomal RNAs, were all found to play a role in protein synthesis leading to the conclusion that the sole role of RNA was as the intermediate between transcription and translation. This set of assumptions left proteins responsible for all subsequent cellular functions.

However, shortly after the central dogma was proposed, a series of experiments by Howard Temin and David Baltimore led to the discovery that RNA can also serve as a template for DNA synthesis, and provided the first evidence for broader functional roles of RNAs (Temin and Mizutani 1970; Baltimore 1970). Subsequently, the characterization of ribonuclease (RNase) P as a ribozyme, that is, an RNA molecule with catalytic function (Stark et al. 1978), and the discovery of small nuclear RNAs (snRNAs) that function in mRNA splicing (Lerner et al. 1980; Rogers and Wall 1980) promoted RNA to share some of the role of proteins in carrying out cellular functions. The diversity and complexity of the RNA world became evident with the completion of the human genome project that showed that while only 1 % of the genome is translated into proteins, the vast majority of the genome is transcribed into RNA. Several new species of RNAs, for example, small nuclear RNAs, responsible for post-transcriptional modification of nucleotides in other RNA molecules, long non-coding RNAs that regulate chromatin structure and genomic imprinting and microRNAs (miRs) that regulate mRNA translation were soon discovered

added to this growing list of ‘non-classical’ RNAs (Eddy 2001). The first miRs were co-discovered by the laboratories of Gary Ruvkun and Victor Ambros. During the investigation of *lin-4*, a gene responsible for temporal regulation embryonic development in *Caenorhabditis elegans* (*C. elegans*), it was found that *lin-4* lacks traditional start or stop codons. Introducing mutations into the putative open reading frame for *lin-4* also failed to recapitulate the phenotype induced by its loss-of-function mutations. This led to the conclusion that *lin-4* cannot encode a protein (Wightman et al. 1993; Lee et al. 1993). Rather, the *lin-4* RNA appeared to be its functional form, as it was found to oppose the function of *lin-14* protein in embryogenesis of *C. elegans* (Lee et al. 2004b). Wightman et al. demonstrated that *lin-4* RNA binds to complementary sequences on the 3′-untranslated region (UTR) of its target mRNA *lin-14* resulting in reduction of *lin-14* protein levels (Wightman et al. 1993). Lee et al. showed that *lin-4* primary transcript is processed to generate two smaller RNAs: a 61-nucleotide long *lin-4L* and a 22-nucleotide long *lin-4s*. This 22-nucleotide long *lin-4s* is now recognized as the founding member of a new class of small non-coding RNAs known as miRs (Lee et al. 1993). For 7 years *lin-4* remained an exception, the only RNA of its kind, capable of binding to and down-regulating its target mRNA, until in 2000, it was discovered that *let-7* operates by the same mechanism (Reinhart et al. 2000). Unlike *lin-4*, the *let-7* sequence was conserved evolutionarily (Pasquinelli et al. 2000). This provided the impetus for a systematic search for similar small non-coding RNAs in other organisms culminating in the discovery of several such RNAs in *C. elegans*, *Drosophila melanogaster* (*D. melanogaster*) and HeLa cells. This new class of small regulatory RNAs was named by common consent of the three research groups as microRNA (miRs) (Lagos-Quintana et al. 2001; Lee and Ambros 2001; Lau et al. 2001).

21.2 Biogenesis of miRs

Genes encoding miRs are usually found in clusters. Based on their location, miRs genes can be classified as intergenic or intronic. Intergenic miR genes are located in between traditional protein-coding genes and independent promoters regulate their transcription. On the other hand, intronic miR genes are located within introns of protein-coding genes and are transcribed along with the host gene by the same promoter. The majority of the miRs are transcribed by RNA polymerase II, however certain miRs with *Alu* (*Arthrobacter luteus*) repeat sequences are transcribed by RNA polymerase III (17). The long primary transcript initially generated is called primary-miR (pri-miR). Similar to mRNAs, pri-miRs have 7-methyl guanosine caps and poly-A tails. The secondary structure of pri-miRs represents a stem-loop along with single-stranded RNA (ssRNA) tails at the 5′ and 3′ ends (Lee et al. 2004a).

Pri-miRs generated from intergenic miR genes are processed co-transcriptionally in the nucleus by the microprocessor complex which consists of the class 2 RNase III enzyme Drosha and along with its associated protein: the DiGeorge syndrome critical region 8 protein (DGCR8) in humans or Pasha in *D. melanogaster* and *C. elegans* (18, 19, 22, 23). Drosha contains two RNase III domains and a double-stranded RNA (dsRNA) binding domain. However, the dsRNA-binding domain is not sufficient for its interaction with the pri-miR. Loading of Drosha to the pri-miR is achieved with the assistance of DGCR8/Pasha. These proteins recognize the dsRNA-ssRNA junction in the pri-miR and anchor the microprocessor complex by interacting with it both the ssRNA tails, as well as the dsRNA stem. Once loaded, Drosha cleaves the pri-miR stem 11 base pairs from the ssRNA-dsRNA junction to generate a smaller stem-loop precursor-miR (pre-miR) (Zeng and Cullen 2005; Han et al. 2006). Pri-miRs that are generated from intronic sequences do not require this Drosha processing step (Kim and Kim 2007). Instead, these pri-miRs are spliced out of the host pre-mRNA with the help of spliceosomal proteins.

The pre-miR is next transported out of the nucleus into the cytoplasm by the exportin 5-RanGTP complex that not only facilitates cytoplasmic transport but also prevents nuclear degradation of pre-miRNA (Lund et al. 2004). In the cytoplasm, the pre-miR is cleaved by Dicer (Hutvagner et al. 2001), a class 3 RNase III containing two RNase III domains, one dsRNA binding domain, one PAZ domain, and a helicase domain. Dicer recognizes the 3′ overhang in the pre-miR with the help of its PAZ domain, and the dsRNA binding domain enables Dicer to bind to the pre-miR without the help of any of its associated proteins. The Dicer-associated proteins TAR-RNA binding protein (TRBP or loquacious in *D. melanogaster*) and protein activator of the interferon induced protein kinase (PACT) appear to help load the mature miR into the RNA-induced silencing complex (RISC) (Chendrimada et al. 2005; Lee et al. 2006). The distance between the PAZ domain and RNase III domain of Dicer fixes the cleavage site at exactly 22 nucleotides away from the Drosha cleavage site thereby generating a 22-nucleotide long mature miR (Hutvagner et al. 2001). Cleavage of pre-miR by Dicer is ATP-dependent and relies on ATP to undergo the necessary protein conformational changes for enzyme turnover and product release.

After the synthesis, the mature microRNA duplex is loaded onto the RISC complex by Dicer, TRBP, and one of the Argonaute (Ago) proteins, that together form the RISC loading complex (RLC) (MacRae et al. 2008). The exact mechanism of RISC loading by RLC is unknown. However, in *Drosophila*, another associated protein called R2D2 acts as a thermodynamic sensor (Tomari et al. 2004). Relative thermodynamic stability governs the orientation of miR duplex loading onto the RISC. The end of the duplex that is

thermodynamically more stable is bound to Dicer and/or TRBP, while the other end is bound to Ago. Additionally, thermodynamic stability also appears to determine which of the two strands of the duplex will be loaded into the RISC. The strand with less stable base-pairing at the 5' end is incorporated into the RISC. This is the functional strand of the mature miR and is known as the guide strand. The remaining strand, known as the passenger or star (*) strand, is degraded (Khvorova et al. 2003; Schwarz et al. 2003). Therefore, mature miR duplexes that have similar thermodynamic stability at both ends can generate two functional miR strands because both have equal probability of being incorporated into the RISC. It has been demonstrated that Ago2 has endonuclease activity and is responsible for the degradation of the passenger strand (Matranga et al. 2005; Rand et al. 2005). However, the mechanism of degradation of the passenger miR strands associated with the other three isoforms of human Ago (Ago1, 3 and 4) is yet to be determined.

21.3 Regulation of MIR Biogenesis

RNA polymerase-associated transcription factors regulate transcription of miR genes (Rao et al. 2006; Conaco et al. 2006). Expression of certain miR genes, such as miR-203, is regulated by differential DNA methylation (Bueno et al. 2008). Mature miR levels can be altered by factors that regulate the expression and/or activity of the miR generating enzymes, Drosha and Dicer, or the associated proteins, DGCR8 and TRBP. Drosha and DGCR8 form an autoregulatory loop. Interaction with DGCR8 stabilizes Drosha, while Drosha cleaves DGCR8 mRNA and decreases DGCR8 protein level. This autoregulatory loop helps maintain the microprocessor activity homeostasis. Additionally, post-translational modifications can affect both level of expression and localization of miR generating proteins. Glycogen synthase kinase 3 beta-mediated phosphorylation is required for nuclear localization of Drosha. Acetylation prevents degradation and stabilizes Drosha. Similarly, extracellular signal-related kinase (ERK)-mediated phosphorylation stabilizes DGCR8, while deacetylation increases its affinity for binding pre-miRs. Additionally, phosphorylated methyl-CpG-binding protein 2 (MECP2) binds to and sequesters DGCR8, thereby preventing miR processing. In contrast, the bone morphogenetic protein/transforming growth factor beta signaling pathway increases Drosha processing activity and may influence miR expression levels (Davis et al. 2008a). Similarly, post-translational modifications can also regulate pre-miR processing in the cytosol. Phosphorylation of TRBP by ERK leads to preferential upregulation of growth-promoting miRs by an unknown mechanism. Several RNA binding proteins, for example, KSRP and lin-28, also modulate Dicer activity by binding to the pre-miR.

miR stability is sometimes determined by 5' and 3' end variations. Such variations may arise as a result of non-template directed addition of nucleotides (in case of 3' end variations) or alternative processing by Drosha (in case of 5' end variations). The non-template directed addition of 14 uridine nucleotides to the 3' end of pre-let-7 has been shown to interfere with processing of this pre-miR by Dicer (Heo et al. 2008). The 5' end variations can arise from alternative processing by Drosha as shown with miR-142 (Wu et al. 2009). In addition to affecting miR stability, such variations can also alter the miR target repertoire. Further, RNA-editing enzymes, such as adenosine deaminase acting on RNAs (ADARs), alter the pri-miR sequence by converting adenosine to inosine thus making them poor substrates for Drosha (Yang et al. 2006).

21.4 Mechanism of Action of miRs

miRs regulate the expression of about 60% of all protein-coding genes (Friedman et al. 2009). They do so by binding to the target mRNA and typically decreasing the level of protein product. First the guide strand of the mature miR binds to the target mRNA, most commonly in the 3'UTR, although some miRs have been reported to bind to the 5'UTR and coding sequence (Forman and Collier 2010; Reczko et al. 2012; Grey et al. 2010). The nucleotides in the position two to seven base pairs from the 5' end of the miR are known as the seed sequence. The seed sequence of a miR is perfectly complementary to the miR recognition element (MRE) in the target 3'UTR (Lewis et al. 2003). The miR seed sequence-MRE interaction is often stabilized by base-pairing at the 3' end of the miR (Grimson et al. 2007), presence of an adenine residue at position 1 or an adenine/uridine residue at position 9 from the 5' end of the miR (Lewis et al. 2005). Additionally, presence of multiple MREs on the target 3'UTR increases the probability and extent of inhibition of the target by the miR (Filipowicz et al. 2008). Besides the traditional seed sequence described above, atypical seed sequences have also been reported that exhibit extensive base pairing of the 3' end of the miR to the target 3'UTR (Lewis et al. 2005; Bartel 2009).

Binding of miR to its target mRNA is followed by either inhibition of translation or degradation of the target. RISC-mediated inhibition of translation can occur at the initiation step or at the elongation step. Ago proteins are structurally similar to the translation initiation factor eIF4E and compete for binding to the 7-methylguanosine cap of the target mRNA to prevent initiation of translation (Humphreys et al. 2005; Kiriakidou et al. 2007). Further, RISC interacts with eIF6, blocking the association of the 60s and 40s ribosomal subunits to prevent elongation (Chendrimada et al. 2007). Additionally, miRs can stimulate the premature release of the targets from the ribosome during elongation or decrease the speed of elongation (Petersen et al. 2006). The miR-RISC can

also cause accelerated degradation of its target by recruitment of the CCR4-NOT complex followed by deadenylation of the mRNA poly-A tail and decapping (Wu et al. 2006). The net result of all such processes is a decrease in the cellular level of the protein product of the target mRNA. Although most miRs-mRNA interaction leads to decrease in levels of the target mRNA or its protein product or both, some miRs have also been reported to activate translation of their targets (Vasudevan and Steitz 2007).

21.5 Degradation of miRs

While most of the research thus far has focused on how miRs are generated and what downstream cellular pathways they regulate, our knowledge about the processed leading to their degradation is limited. Only a few miR degrading enzymes have been identified. In *Arabidopsis*, miRs are degraded by small RNA degrading nucleases (SDN1-4) (Ruegger and Grosshans 2012). However, it is not known whether SDN homologs in other eukaryotes also function as miR degrading enzymes. In *C. elegans*, XRN1 and XRN2 help in miR turnover by virtue of their 5'–3' exoribonuclease activity. The miR degrading function of XRN1 appears to be conserved in human cell lines. Polynucleotide phosphorylase (PNPT1) has also been reported to degrade certain mature miRs in humans. Additionally, several pre-miR degrading enzymes have been identified in humans. These include the following: MCPIP that cleaves and inactivates immune system related pre-miRs, IRE1 α that degrades miRs that regulate apoptosis, Dis3l2 that degrades poly-uridylated let-7 and translin/trax complex that competes with Dicer/TRBP leading to degradation certain pre-miRs (Asada et al. 2014). It appears that the miR degrading enzymes identified thus far act only on specific sets of miRs/pre-miRs. In the case of translin/trax, this specificity is conferred by pre-miR secondary structure, trax being a single-strand-specific endonuclease is able to degrade only those pre-miRs that have unpaired bulges in their stem. Our knowledge about regulation of miR turnover is still nascent and requires further investigation.

21.6 Methods in miR Research

Differential expression of miRs can be identified by performing miR microarrays and can then be confirmed by performing qRT-PCR or Northern blot. Localization of miR can be determined by performing in situ hybridization. Because most miRs act by downregulating expression of specific targets, putative miR targets can be identified *in silico* from expression data using various algorithms. The most commonly used tools for such analysis are TargetScan (Friedman et al. 2009), microRNA.org (miRanda) (Betel et al. 2008),

PicTar (Krek et al. 2005), and DianaMicroT (Maragkakis et al. 2009a, b). Most of these algorithms use the miR seed sequence (nucleotide 2–7 from the 5' end) to search for potential matches on the 3'UTR of mRNAs. However, such *in silico* analysis yields hundreds of potential targets for a single miR. To narrow down on physiologically relevant targets, it is necessary to perform further bioinformatic analysis and/or literature review. For example, gene ontology (GO) analysis can be performed to group the predicted targets according to the biological processes (BP) in which they are involved, cellular components (CC) in which they are expressed, or their molecular functions (MF). If GO analysis identifies an overrepresentation of certain BP, CC or MF, it is reasonable to hypothesize that the miR of interest regulates that particular pathway. Direct action of the miR of interest on the 3'UTR of the predicted targets in that group can then be tested experimentally. 3'UTR-luciferase reporter assays are commonly used for this purpose (Aldred et al. 2011). In this experimental paradigm, the 3'UTR of the target of interest is cloned into a luciferase reporter vector and co-transfected into a cell line along with the miR of interest. If this miR indeed binds to the 3'UTR, this should result in a decrease in expression of the luciferase as compared to co-transfection with a scrambled miR sequence. The decrease in luciferase expression is detected as a reduction in light signal (luminescence) in the assay. Downregulation of the target by the miR can again be confirmed by performing qRT-PCR or Western blot. However, a negative result in qRT-PCR should be interpreted with caution, as some miRs prevent translation without affecting mRNA levels.

21.7 miRs and Neuronal Physiology

Given the widespread influence of miRs on cellular protein levels, it is not surprising that they participate in regulation of development of the central nervous system (CNS), neuronal differentiation and function. The first indication of the importance of miRs in brain development came from studies that disrupted expression of proteins involved in miR biogenesis (Dicer, DGCR8) or function (Ago). Deletion of Dicer in zebrafish resulted in impaired miR biogenesis and led to abnormal neural tube development, neural positioning and touch-induced behavioral response (Giraldez et al. 2005). Surprisingly, overexpression of a single miR, miR-430, was sufficient to rescue most of the neural deficits of dicer deficiency. miR-430 belongs to a subset of miRs that are specifically enriched in the brain (Sempere et al. 2004). Expression levels of these brain-enriched miRs are regulated in a developmental stage and cell-type specific manner (Miska et al. 2004). Similar to the findings in zebrafish, deletion of Dicer in *D. melanogaster* and HeLa cells led to accumulation of abnormal protein aggregates characteristic of neurodegenera-

tive disorders (Bilen et al. 2006). Complete deletion of Dicer is embryonically lethal in mice (Murchison et al. 2005). To overcome this limitation, researchers have focused on conditional deletion of dicer in specific brain regions. Dicer deletion in the forebrain led to motor impairments and early post-natal death accompanied by multiple defects in brain development including microcephaly, enlarged lateral ventricles, increased neuronal apoptosis, altered dendritic spine length, abnormal dendritic morphology, and axonal pathfinding defects (Davis et al. 2008b). Similarly in the midbrain and hindbrain, dicer deletion resulted in reduction in cerebellum size, impaired development of dopaminergic neurons and increased apoptosis (Huang et al. 2010). Both of these studies demonstrated that dicer deletion was associated with reduced expression of brain-specific miRs.

Similar to the Dicer-knockout, it was found that complete deletion of DGCR8 also resulted in embryonic lethality, and caused DGR8-knockout mice to die around embryonic day 6.5. The DGCR8 heterozygous mice exhibited reduced dendritic spine width, reduced complexity of dendritic spines, and impaired working memory (Stark et al. 2008).

Knocking down or mutating genes that encode argonaute proteins offers a second mechanism of disrupting the cellular miR machinery. Loss-of-function mutations of Ago1 in *D. melanogaster* have been found to cause malformation of the nervous system with reduction in number of neurons and disruption of axons (Kataoka et al. 2001). Just as in the Dicer and DGCR8 knockouts, homozygous knockout of Ago2 in mice were found to cause embryonic lethality and heterozygous deletion of Ago2 were found to cause severe developmental defects, including failure of neural tube closure (Liu et al. 2004). These studies emphasized the importance of maintaining a normal global miR expression profile during CNS development and function.

Specific miRs that regulate neuronal development have also been identified. miR-124 appears to be the most abundantly expressed miR in adult brain (Lagos-Quintana et al. 2002). Transfection of miR-124 into HeLa cells alters the cellular gene expression such that it begins to resemble a neuronal profile (Lim et al. 2005). miR-124 functions in an inhibitory feedback loop with the repressor element 1-silencing factor (REST) to promote differentiation of neurons from neural progenitor cells (Conaco et al. 2006; Visvanathan et al. 2007). Another brain-enriched miR, miR-137 increases neuronal differentiation and regulates adult neurogenesis (Silber et al. 2008; Szulwach et al. 2010). miR-9, a brain-specific miR expressed in the neurogenic niche in both embryonic and adult brain, regulates neural stem cell proliferation and neural differentiation by controlling the expression level of several transcription factors (Zhao et al. 2009; Shi et al. 2010). The let-7 family of miRs, although not brain-specific, is highly expressed in the brain and also induces neuronal differentiation (Sempere et al. 2004). miR-184 on the other hand, promotes neural stem

cell proliferation and inhibits neuronal differentiation by downregulating its target mRNA, NUMBL (Liu et al. 2010). Other miRs that regulate neurogenesis include miR-125b and miR-128 (Lang and Shi 2012).

Differential sub-cellular localization of miRs in mature neurons provides an efficient method of regulating local mRNA translation. Besides the cell body, in mature neurons, miRs and RISC are found at dendritic spines and axon terminals as well (Hengst et al. 2006; Cougot et al. 2008). At the synapse miRs can regulate expression levels of key proteins in response to neuronal activity or neurotrophic and growth factors in a rapid and bidirectional manner without affecting the overall expression of these proteins. miR-134 was one of the first miRs found to be localized within dendrites where its expression increased with synaptic activity. miR-134 was found to regulate dendritic spine morphology (Schratt et al. 2006). In addition to its role in neuronal differentiation, miR-124 has also been detected in the presynaptic compartment (Rajasethupathy et al. 2009) and it regulates neurite outgrowth and serotonin induced long-term plasticity (Yu et al. 2008; Rajasethupathy et al. 2009). In *Drosophila*, neuronal activity relieves miR and RISC mediated inhibition of translation of Ca²⁺/Calmodulin dependent protein kinase II (CaMKII) mRNA thereby enhancing neuronal plasticity (Ashraf et al. 2006). A similar mechanism of activity-dependent relief of miR-138-mediated translational repression of CaMKII, LIM domain Kinase I, and lysophospholipase 1 mRNAs occurs in rats (Banerjee et al. 2009). Expression levels of certain miRs, e.g., miR-132, are increased in response in neuronal activity. Upregulation of miR-132 in turn increases dendritic spine formation and synaptic excitability (Magill et al. 2010). Other miRs that have been reported to regulate dendritic growth and synaptic function including miRs-34a, -375, -125b, and -188 (McNeill and Van Vactor 2012).

Finally, although most of the studies so far have concentrated on the expression and function of miRs in neurons in the CNS, miRs also play an important role in glial cell genesis and function. In this context, miRs-219 and -338 downregulate transcription factors Sox6 and Hes5 to promote differentiation of oligodendrocytes (Zhao et al. 2010). The miR-17-92 cluster promotes proliferation of oligodendrocyte precursors (Budde et al. 2010). Postnatal deletion of Dicer in astrocytes led to ataxia, cerebellar degeneration, seizures, and premature death. These Dicer-deficient astrocytes displayed a gene expression profile characteristic of immature and reactive astrocytes, and contributed to excitotoxic neuronal damage (Tao et al. 2011).

21.8 miRs in CNS Pathology

Differential miR expression has been reported in several neurodegenerative, neurodevelopmental, and neuropsychiatric disorders. This differential expression could either be a cause or

consequence of the observed pathological changes. miRs may target proteins that have been implicated in these disorders and contribute directly to disease pathogenesis. Alternatively, changes in miR expression downstream of changes in the disease-causing pathways may add on to the pathological manifestations by modulating neuronal survival or death pathways.

Accumulation of β -amyloid ($A\beta$) plaques is a hallmark of Alzheimer's disease (AD). This could be due to an increase in expression of the amyloid precursor protein (APP), increased processing of APP to $A\beta$ or decrease in $A\beta$ degradation. The miR-29 family can regulate expression of β -site APP cleaving enzyme 1 (BACE1), an enzyme required for $A\beta$ production. Decrease in expression of the miR-29 family may therefore lead to increased expression of BACE1 resulting in more $A\beta$ production and accumulation, as seen in AD (Hebert et al. 2008). Other studies have reported decrease in miR-107 expression in brain of AD patients in the early stages of the disease accompanied by increase in BACE1 protein levels (Nelson and Wang 2010; Wang et al. 2011). miR-107 can also bind to the 3'UTR of BACE1 and reduce its expression.

A point mutation in the 3'UTR of fibroblast growth factor 20 (FGF20) has been identified as a risk factor for Parkinson's disease (PD). FGF20 regulates expression of α -synuclein, a protein that accumulates in PD. The point mutation on the FGF20 3'UTR disrupts a miR-433 binding site (Wang et al. 2008). The loss of downregulation of FGF20 by miR-433 may therefore contribute to increase in α -synuclein levels. miR-133 is another miR that may be associated with PD. Expression of miR-133 is lower in post-mortem brain tissue of PD patients (Kim et al. 2007). miR-133b is highly enriched in midbrain dopaminergic neurons, and the degeneration of these neurons in PD may be the reason of the observed decrease in miR-133b levels. Decreased expression of miRs-34b and -34c has also been observed in PD in the frontal cortex, amygdala, substantia nigra, and cerebellum. In vitro, downregulation of miRs-34b and -34c in cell lines led to cell death, oxidative stress, and mitochondrial dysfunction—all characteristics of the neuronal dysfunction found in PD (Minones-Moyano et al. 2011). A number of miRs, including miR-7 and -153, downregulate expression of α -synuclein in vitro and in animal models of PD (Junn et al. 2009; Doxakis 2010). Reduced expression of these miRs may lead to increased synthesis and accumulation of α -synuclein characteristic of PD.

Amyotrophic lateral sclerosis (ALS) is associated with mutations in several RNA-binding proteins including Transactivating response element (TAR) DNA-binding protein 43 (TDP-43) and fused in sarcoma (FUS). Both TDP-43 and FUS regulate biogenesis of miRs. TDP-43 enhances miR biogenesis at the Drosha and Dicer processing steps (Kawahara and Mieda-Sato 2012). FUS interacts with Drosha to promote miR biogenesis (Morlando et al. 2012). Aberrant biogenesis of miRs may therefore contribute to pathogenesis of

ALS. Expression of miR-155 was found to be increased in animal models of ALS and inhibition of this miR increased survival in this model (Koval et al. 2013). miR-155 is an inflammatory miR, that increases secretion of pro-inflammatory cytokines by targeting suppressor of cytokine signaling 1 (SOCS1) mRNA (Wang et al. 2010) and prevents the immunosuppressive action of transforming growth factor β (TGF β) by targeting its downstream effectors Sma- and Mad-related protein (SMAD) 2 (Louafi et al. 2010) and SMAD5 (Rai et al. 2010). miR-206, a skeletal muscle-specific miR, inhibits translation of histone deacetylase 4 (HDAC4) thereby inducing secretion of fibroblast growth factor binding protein 1 (FGFBP1) from muscles (Williams et al. 2009). FGFBP1 promotes presynaptic differentiation at the neuromuscular junction. miR-206 may therefore be beneficial in ALS and knockdown of miR-206 has been shown to be detrimental in animal models of ALS (Williams et al. 2009).

In Huntington's disease (HD), decreasing levels of expression and miR-9 and miR-9* have been observed with disease progression (Packer et al. 2008). These miRs regulate the expression of transcription factors REST and its co-repressor. Upregulation of the REST repressor complex due to reduced levels of miR-9 and miR-9*, leads to a decrease in expression of pro-survival genes including brain derived neurotrophic factor (BDNF).

In fronto-temporal lobar dementia (FTLD), a single nucleotide polymorphism (SNP) in the 3'UTR of the granulin (GRN) gene was found to be associated with a familial form of the disease. This SNP introduces a miR-659 recognition element in the GRN 3'UTR. miR-659 that is normally expressed in the brain can bind to this MRE and reduce expression of the pro-survival and anti-apoptotic protein GRN (Rademakers et al. 2008).

Fragile X-syndrome (FXS) is an inherited neurodevelopmental disorder caused by triplet repeat expansion in the 5'UTR of the Fragile X mental retardation protein (FMRP) leading to hypermethylation and reduced expression of this gene. FMRP is a RNA-binding protein that has been found to associate with Dicer and Ago. In *Drosophila*, loss of function of FMRP led to defects in miR processing as evidenced by a decrease in mature miR-124a and accumulation of pre-miR-124a (Xu et al. 2008b). Expression of miR-124a appeared to be important for dendrite branching. Several miRs have now been shown to be associated with FMRP. Examples include miR-9, 124, -125a, -125b, -128, -132 and -219, which are localized in dendrites and control synaptic plasticity (Edbauer et al. 2010; Xu et al. 2008b). Interestingly, it was shown that FMRP acts a bidirectional switch controlling local RISC activity at the dendritic spine. Phosphorylated FMRP associates with miR-125a-RISC and enhances binding to and inhibition of translation of the target post-synaptic density 95 (PSD95) mRNA. In response to glutamate receptor signaling, FMRP was dephosphorylated and could no longer bind to miR-125a-RISC, which caused the

release the PSD95 mRNA from the inhibitory complex (Muddashetty et al. 2011). Loss of FMRP function could therefore impair synaptic activity dependent protein synthesis that is required for the formation of long-term memory.

Rhett syndrome is an X-linked neurodevelopmental disorder that has been associated with the mutation of the gene encoding methyl-CpG-binding protein 2 (MeCP2). In primary cortical neurons, expression of this protein is regulated by miR-132, a brain-enriched miR whose expression is induced by BDNF (Klein et al. 2007).

Genome-wide association studies have also indicated involvement of miRs in autism spectrum disorders (ASD). Two of the most significant copy number variations detected include microduplication of the 22q11.2 locus that includes the DGCR8 gene and imbalance at 15q13.2-15q13.3 that contains the miR-211 gene (Glessner et al. 2009; Marshall et al. 2008; Miller et al. 2009). The latter was associated with intellectual disability, epilepsy and electroencephalographic abnormalities of ASD.

In Down's syndrome (trisomy 21), five miRs, whose genes are located on chromosome 21, were found to be upregulated in the fetal brain. Of these, miRs-155 and -802 downregulate expression of MeCP2 and may partially contribute to the neurological manifestations of the disease (Kuhn et al. 2008).

The deletion of a part of human chromosome 22 (22q11.2 microdeletion) is one of the most important risk factors for schizophrenia. The deleted region includes the gene encoding the Drosha-associated protein DGCR8, indicating that miR biogenesis may be dysregulated in the disease. In a mouse model where the syntenic region harbored on mouse chromosome 16 was deleted, downregulation of a specific subset of miRs including miR-134 was observed and could be attributed to heterozygous loss of DGCR8 (Stark et al. 2008). Genome-wide association studies for SNPs in schizophrenia patients have identified duplication of a region encompassing the Dicer1 gene and association of the miR loci for miR-137, miR-206 and miR-198 (Schizophrenia Psychiatric Genome-Wide Association Study (GWAS) Consortium 2011; Hansen et al. 2007; Xu et al. 2008a). Additional evidence of altered miR expression in schizophrenia comes from miR expression analyses of post-mortem brain tissue from schizophrenia patients. These show evidence of dysregulation of miR-7, -24, -26b, -29b, -30a-5p, -30b, -30e, -92, -181b and -195 (Mellios et al. 2009; Beveridge et al. 2008; Perkins et al. 2007).

Major depression is associated with deficits in serotonergic neurotransmission and miRs that regulate synthesis, reuptake, or degradation of this neurotransmitter may be involved in pathogenesis of this disorder. miR-16, for example, targets the serotonin transporter, and overexpression of this miR can lead to antidepressant like effects (Baudry et al. 2010). Polymorphisms in genes encoding miRs-30e and -183 have also been associated with increased susceptibility to depression, although the downstream pathways regulated by these miRs are yet to be identified (Xu et al. 2010; Saus et al. 2010).

21.9 miRs and HIV-Associate Neurocognitive Disorders (HAND)

Expression profiling has provided some insight into the role of miRs in the pathogenesis of HIV-associated neurocognitive disorder (HAND). Noorbakhsh et al. compared the miR expression profile in the frontal cortex from autopsied brain of four individuals with HIV-encephalitis (HIVE) to four uninfected controls (Noorbakhsh et al. 2010). Using miR microarray and quantitative real-time PCR (qRT-PCR) they found expression levels of fourteen miRs were significantly altered greater than two-fold between HIVE and control sample. Of these, six were upregulated and eight were downregulated in HIVE samples. The authors then performed an *in silico* search for miR targets. Functional clustering of the predicted targets led to identification of caspase pathway as a common target for many of these miRs. Since most of the miRs targeting the caspase pathway were downregulated in HIVE samples, they concluded that derepression of the caspases may contribute to neuronal apoptosis.

In a second study, Yelamanchili et al. investigated the miR expression profile in the caudate nucleus of HIVE samples, as well as in the caudate nucleus and hippocampus of Simian immunodeficiency virus encephalitis (SIVE) samples using miR microarray (Yelamanchili et al. 2010). Six miRs were found to be upregulated in the caudate nucleus of SIVE samples compared to uninfected controls. Four of these miRs were also found to be upregulated in the caudate nucleus in HIVE and in the hippocampus of SIVE samples. Post-validation using qRT-PCR confirmed significant upregulation of three of these miRs (miRs-21, 142-3p and -5p). Interestingly, upregulation of miR-142-3p and -5p was confirmed by both groups of researchers. Of these, miR-21 was found to regulate the transcription factor Mef2c and alter potassium current in human neurons grown in vitro. miR-142, on the other hand, was found to target and downregulate SIRT1, which eventually led to decrease in the level of dopamine metabolizing enzyme monoamine oxidase A.

A third study by Tatro et al. utilized a PCR-based miR microarray platform to compare miR expression in the frontal cortex of uninfected control individuals, HIV infected individuals and those with HIV infection and major depression (Tatro et al. 2010). However, it was not indicated whether any neurocognitive impairment was present independent of depression, and as such no conclusions could be drawn about miR expression changes in HAND from this study.

How does HIV alter neuronal and glial miR levels? Studies in cell culture models have indicated that HIV proteins Tat and Vpr regulate miR expression in cultured human neurons and neuronal cell lines (Mukerjee et al. 2011; Chang et al. 2011). However, whether these viral proteins can regulate neuronal miR expression in vivo

remains to be determined. In microglial cells, HIV can subvert cellular defense mechanisms by increasing the expression of miR-146a, which in turn downregulates CCL8 (Rom et al. 2010), a chemokine that normally inhibits viral entry by binding to the receptor CCR5.

In addition to intracellular miRs, a large body of research has focused on miRs secreted in body fluids because these miRs can serve as potential biomarkers for diseases and drug treatments. One study compared the miR levels in the cerebrospinal fluid (CSF) of HIV infected patients with and without encephalitis to those of uninfected controls (Pacifi et al. 2013). Eleven miRs were found to be significantly differentially expressed across the three groups, out of which, six were also differentially expressed in the frontal cortex. The same study found a general trend of downregulation of miR expression in HIV infected group without encephalitis compared to uninfected controls. However this trend was reversed in the HIV infected group with encephalitis, in whom most of the miRs were upregulated compared to those without encephalitis. Comparison of the HIV encephalitis group to uninfected controls showed that most of the miRs were relatively unchanged in the CSF.

21.10 Future Directions

Since their discovery a just over a decade ago, numerous studies have established the importance of miR expression and function, both in normal physiological state, as well as in pathological conditions. However, several aspects of miR biology need further investigation. Each miR has several hundreds of potential target mRNAs. The principles that govern preferential target selection are largely unknown. One important criteria would be co-expression of the miR and its target mRNA in the same cell at the time frame being assessed. But, controlling for co-expression still leaves us with a large target pool for one miR. Other factors that could help determine target selection and efficiency of target downregulation need to be determined. Investigators are just beginning to study the stability and mechanisms of degradation of miRs. From initial reports it appears that miR degrading enzymes are specific for certain groups of miRs, the specificity being determined, at least in one case, by miR secondary structure (Asada et al. 2014). While most miRs bind to the 3'UTR of their target mRNA by complementary base pairing between the traditional miR seed sequence and MRE, several instances of miR binding to the coding sequence and 5'UTR have now been documented. We need to determine whether such binding is an exception to the general rule, or a common occurrence that has been overlooked.

21.11 Review Questions

1. Briefly describe the mechanism of biogenesis of miRs. What factor determines the strand selection for mature miRs while incorporation into the RISC?
2. How do miRs regulate level of the protein product of their target mRNAs?
3. List 5 miRs that are upregulated in the brain in HIV. Explain the probable mechanism through which any one of these miRs contributes to pathogenesis of the disease.
4. You suspect that 'disease X', a neurodegenerative disease, is associated with defects in miR biology. What method will you use to identify and thereafter validate miRs with altered expression in the disease?
5. You identify that miR-9999 is downregulated in 'disease X'. While performing qRT-PCR for validating the level of expression of miR-9999, by mistake, you add the primer for pre-miR-9999 instead of the mature form. However, your results show that there is no change in pre-miR-9999 expression. How can you explain your result?

21.12 Answers

1. Section 21.2 and Fig. 21.1 describes in detail the mechanism of miR biogenesis. Relative thermodynamic stability of the two ends of the miR duplex determines which of the two strands will be loaded into the RISC. The strand with less stable base-pairing at the 5' end is incorporated into the RISC. This is the functional strand of the mature miR and is known as the guide strand. The other strand, known as the * strand is degraded.
2. miRs decrease the level of protein product of the mRNAs that they target. They may do so by two mechanisms: inhibition of translation or degradation of the target mRNA. Section 21.4 describes the mechanism of action of miRs.
3. Table 21.1 lists the miRs that are upregulated in HIV. The probable mechanism of action of these miRs is described in Sect. 21.9.
4. Section 21.6 describes the methods used in miR research. Generally, miR microarrays can be used to identify global changes in miR expression. qRT-PCR is used to validate the level of expression of candidate miRs.
5. Expression of the mature form of miR-9999 is decreased while pre-miR-9999 expression level did not change in 'disease X'. This implies that there may be a defect in the miR biogenesis machinery. Particularly Dicer/TRBP processing step or at the export of pre-miR by exportin 5 may be defective.

Fig. 21.1 Biogenesis and mechanism of action of miRs. Pri-miRs are transcribed by RNA polymerase II and processed in the nucleus by DROSHA/DGCR8 complex to pre-miRs. Pre-miRs are exported to the cytoplasm by exportin-5-Ran-GTP. In the cytosol pre-miRs are cleaved

by Dicer/TRBP complex to generate mature miRs that are incorporated into RISC complex consisting of Argonaute proteins (Ago1-4). Mature miR-RISC binds to 3'UTR of target mRNA leading to inhibition of translation or degradation of target

Table 21.1 MicroRNAs in HIVE

miRs-135a, -128, 129-3p, -129*, -130a, -7, -218, -329	Downregulated in frontal cortex in HIVE compared in uninfected control
miRs-338-5p, -181a, -142-5p, -142-3p, -584, -219-3p	Upregulated in frontal cortex in HIVE compared to uninfected control
miRs-21, -142-3p, -142-5p	Upregulated in caudate nucleus in HIVE, caudate nucleus and hippocampus in SIVE compared to uninfected control
miRs-1203, -1224-3p, -182*, -19b-2*, -204, -362-5p, -720, -744, -934, -937	Upregulated in CSF in HIVE compare to HIV infection without encephalitis
miRs-484	Downregulated in CSF in HIVE compare to HIV infection without encephalitis
miRs-1224-3p, -204, -720, -934	Upregulated in frontal cortex in HIVE compare to HIV infection without encephalitis

Part II

Immunology of Neurodegenerative, Neuroinflammatory, Neuroinfectious and Neuropsychiatric Disorders

Serge Przedborski

Abstract

Neurodegeneration is any pathological condition in which the nervous system or nerve cell (i.e. neuron) loses its function, structure, or both. On a medical point of view however, the term neurodegeneration is used in a more restricted sense. Typically, it represents a large group of heterogeneous disorders in which affected neurons belong to specific subtypes, within specific anatomofunctional territories of the nervous system. Often, but not always neurodegenerative diseases arise for unknown reasons and progress in a relentless manner. Within the context of this definition diseases of the nervous system can be catalogued into three board categories: (i) pathologies which are restricted to the nervous system and which are *primary neuronal* diseases (i.e. neurodegenerative diseases *per se*); (ii) pathologies which are restricted to the nervous system but are not *primary neuronal* diseases, such as brain neoplasm or cerebral edema and hemorrhage; and, (iii) pathologies provoked by systemic causes which damage the nervous system, such cardiovascular arrest, carbon monoxide poison, or infections due to herpes simplex. Based on this simple categorization, hundreds of disorders of the nervous system including Alzheimer's disease, Parkinson's disease, Huntington's disease, and amyotrophic lateral sclerosis clearly fulfill the criteria of neurodegenerative disorder and are unanimously regarded as such.

22.1 Introduction

An examination of the literature indicates that since 1982 the term *neurodegeneration* appears in the title of over 4100 indexed publications. Neurodegeneration is a mentioned topic of virtually all neurological science textbooks. Thus, it is safe to assume that the meaning of the word *neurodegeneration* is universally understood. Most relevant textbooks however will not actually define neurodegeneration but will discuss the

issue in bits and pieces as part of the discussion of various diseases of the nervous system rather than as a single chapter. As discussed in Przedborski et al. (2003) and in the previous iteration of this chapter, neurodegeneration is composed of the prefix “neuro-,” which denotes relationship to a nerve or the nervous system (<http://tropmed.org/dictionary/coverpage9.htm>) and of “-degeneration,” which here is synonymous of devolution, meaning a process of declining from a higher to a lower level of effective power, vitality or essential quality (<http://www.wordreference.com>). Thus, neurodegeneration is any pathological condition in which the nervous system or nerve cell (i.e. neuron) loses its function, structure, or both. On a medical point of view however, the term neurodegeneration is used in a more restricted sense. Typically, it represents a large group of heterogeneous disorders in which affected neurons belong to specific subtypes, within specific anatomofunctional territories of the nervous system. Often, but not always neurodegenerative diseases arise for unknown reasons and progress in a relentless manner. Within the context of this definition diseases of the nervous system can be catalogued into three broad categories: (i) pathologies which are restricted to the nervous system and which are *primary neuronal* diseases (i.e. neurodegenerative diseases *per se*); (ii) pathologies which are restricted to the nervous system but are not *primary neuronal* diseases, such as brain neoplasm or cerebral edema and hemorrhage; and, (iii) pathologies provoked by systemic causes which damage the nervous system, such cardiovascular arrest, carbon monoxide poison, or infections due to herpes simplex. Based on this simple categorization, hundreds of disorders of the nervous system including Alzheimer’s disease (AD), Parkinson’s disease (PD), Huntington’s disease (HD), and amyotrophic lateral sclerosis (ALS) clearly fulfill the criteria of neurodegenerative disorder and are unanimously regarded as such. Aside from these unambiguous neurodegenerative diseases, others such as essential tremor, torsion dystonia, Tourette’s syndrome, or schizophrenia represent an interesting nosological challenge, as they do not show any distinct neuronal loss. Perhaps they have been traditionally included in this category because they are chronic diseases of the nervous system with an unknown cause. Finally, diseases such as multiple sclerosis (MS) also represent a perplexing situation. Conventionally, MS has been linked to pathology of the myelin that ensheath neuronal axons and not of the neuron *per se*. Several experts however have argued that MS is not only a demyelinating disease but also a disease where the neurons die due to a destruction of their axons. Worth noting, long-term disability in MS has a higher correlation with axonal damage than with the degree of demyelination (Bjartmar et al. 2003). For these reasons, several scientific authorities, as stressed in Trapp and Nave (2008), are now wondering whether inflammatory demyelination in MS might not be secondary in the disease process and that MS would be, in fact, a true neurodegenerative disease as defined above.

22.2 Frequency, Lifespan, and Co-morbidity

The two most prevalent neurodegenerative diseases are AD and PD, and according to a report from the World Health Organization published about a decade ago, AD (together with other forms of dementias) and PD made up more than 14 % of the global burden of neurological illnesses (2006). Scientists estimate that up to 4.5 million Americans suffer from AD and 1.2 million from PD. This represents roughly 2.5 % of the entire population in the United States. This estimate is likely valid for most, if not all countries of the world as epidemiological studies have found roughly comparable incidence and prevalence rates of AD and PD around the globe. Nevertheless, some geographic and temporal clusters of neurodegenerative conditions have been described. Two such examples include the marked increase in cases of parkinsonism in connection to the influenza pandemic of 1918 (Casals et al. 1998) and the high incidence of PD-ALS-dementia complex confined to the Chamorro Indians who live on the Western Pacific Island of Guam (Chen and Chase 1986). These clusters while quite enlightening must be regarded as the exceptions rather than the rules. The most consistent risk factor for developing a neurodegenerative disorder, especially in regards to AD and PD, is increasing age (Tanner 1992) and this fact may have far-reaching implications for the generations to come. As previously noted (Przedborski et al. 2003), over the past century, the growth rate of the population ages 65 and above in industrialized countries has far exceeded that of the population as a whole. Therefore, it can be anticipated that, over the next generations, the proportion of elderly citizens will double. Consequently, unless effective preventive strategies are soon found, the number of persons suffering from a neurodegenerative disorder will rise dramatically and the epidemiological numbers provided above may have to be amended to higher percentages.

It is also important to emphasize the fact that nearly all neurodegenerative disorders shorten the life expectancy of affected patients even if medications which alleviate the symptoms are available. This is well illustrated in the case of PD in which symptoms worsen over time. As discussed elsewhere (Dauer and Przedborski 2003), before the introduction of the potent symptomatic treatment levodopa, the mortality rate among PD patients was three times that of the normal age-matched subjects. Unexpectedly, population-based surveys suggest that PD patients continue to display a decreased longevity compared to the general population despite the fact that motor problems can be controlled by levodopa (Levy et al. 2002; Morgante et al. 2000; Hely et al. 1989). Yet, only a few neurodegenerative disorders are fatal *per se*. Indeed, only those diseases in which the affected neurological structures are implicated in controlling or driving vital physiological functions such as respiration or circulation are truly lethal.

Amongst these ALS is found, where the losses of lower motor neurons innervating the intercostal and diaphragm muscles lead to fatal respiratory paralysis. In Friedreich ataxia, the association of neurodegeneration with heart disease (Harding 1981) can also be a cause of death, although, in this case, death is not due to any neurodegenerative event but instead to cardiodegenerative problems such as congestive heart failure. In most other neurodegenerative disorders, death is attributed neither to the damage of the nervous system nor to any associated extra-nervous system degeneration but rather to medical problems including fatal falling, aspiration pneumonia, pressure skin ulcers, malnutrition, and dehydration, whose occurrence is favored by immobility, impaired balance, and cognitive decline. The leading causes of death in our industrial societies include cancers and cardiovascular problems. As a result it is worth mentioning that medical co-morbidity such as atrial fibrillation and cancer doubles the chances of death in nursing homes of demented patients (Van Dijk et al. 1996). Cardiovascular problems such as high blood pressure have also been suggested to stimulate the dementing process (Doraiswamy et al. 2002). Thus, medical co-morbidities appear to aggravate the long-term prognosis of patients inflicted with a neurodegenerative disease. However, whether or not patients suffering from a neurodegenerative disease are at greater (or lower) risk for cancer, stroke, or heart attack, remains to be demonstrated.

22.3 Classification

The estimated number of different neurodegenerative diseases is a few hundred and, among these, many appear to overlap with one another clinically and pathologically. Classification of neurodegenerative diseases, while useful, is quite a complicated task. In neurodegenerative diseases, it is typical that several areas of the brain are affected. Yet, the degrees in which these different brain areas are damaged often vary from one case to another, thus giving rise to different phenotypes. For example, in a disease such as multisystem atrophy where typically parkinsonism is a prominent feature, it may be accompanied with either severe ataxia, autonomic failure, or both depending on whether, in addition to the basal ganglia, the cerebellum and the intermediolateral column of the thoracic spinal cord also degenerate (Wenning et al. 2004). Even in the case of a defined genetic defect, a similar mutation may also produce varied phenotypes. For instance, in familial parkinsonism linked to mutations in the leucine-rich repeat kinase-2 (LRRK2) gene a striking pleomorphic pathology has been reported with some members of the affected family, developing a motor neuron disease superimposed to dementia and/or parkinsonism (Zimprich et al. 2004). Despite these difficulties, it remains that the most popular categorization of neurodegenerative disorders

is based on either the main clinical feature or the location of the predominant lesion, or often on a combination of the two. This proposed classification has been discussed previously (Przedborski et al. 2003) and will be repeated here for the sake of completeness of this chapter. We have proposed that neurodegenerative disorders may be grouped into diseases of the main anatomical division of the central nervous system: cerebral cortex, basal ganglia, brainstem/cerebellum, and spinal cord. Within each anatomical group, diseases may be sub-grouped based on their main clinical features.

Based on this clinico-anatomical classification, diseases of the cerebral cortex may be divided into cortical diseases associated with dementia (e.g., AD) and without dementia. In theory, circumscribed degeneration of the cerebral cortex can occur in absence of dementia as reported in some cases of progressive primary aphasia (Kirshner et al. 1987). However, because the cerebral cortex is so heavily involved in cognition, neurodegeneration, over time, often spreads beyond the initial locus of pathology and the majority of these patients end-up with dementia (Le Rhun et al. 2005). It is thus not surprising to find that neurodegenerative diseases of the cerebral cortex are usually equated to dementia. While AD in this group of diseases is by far the most frequent (Sulkava et al. 1983), about 50 other and less prominent dementing cortical diseases can be found (Tomlinson 1977).

Diseases of the basal ganglia are essentially characterized by abnormal motor activity. Based on the type of the motor problem, diseases of the basal ganglia can be classified into hypokinetic or hyperkinetic groups. Hypokinetic basal ganglia disorders include PD, in which the amplitude and velocity of voluntary movements are diminished or, in extreme cases, non-existent. Aside from PD, parkinsonism—which refers to an association of at least two of the following clinical signs: resting tremor, slowness of movements, stiffness, and postural instability—is also found in a variety of other diseases of the basal ganglia (Dauer and Przedborski 2003). In some, there is only parkinsonism (e.g., striatonigral degeneration) but in others, often called Parkinson-plus syndromes, there is parkinsonism plus signs of cerebellar ataxia (e.g., olivopontocerebellar atrophy), orthostatic hypotension (e.g., Shy-Drager syndrome) or paralysis of vertical eye movements (e.g., progressive supranuclear palsy). Because early on, Parkinsonism may be the only clinical expression of Parkinson-plus syndromes, it is difficult to formulate a definitive and accurate diagnosis before the patient reaches a more advanced stage of the disease. This problem is particularly well depicted by the fact that more than 77% of patients with parkinsonism are diagnosed in life as having PD (Stacy and Jankovic 1992), but as much as a quarter of the diagnosed patients are found at autopsy to have lesions incompatible with PD (Hughes et al. 1992). Of note, it is customary to classify the stiff-person syndrome among the hypokinetic diseases. However, available evidence would argue that the

stiff-person syndrome while being a hypokinetic condition is an autoimmune disease involving the nervous system and not a neurodegenerative disease.

Found at the other end of the spectrum are the hyperkinetic basal ganglia disorders, which are represented by HD and essential tremor. In these two conditions, excessive abnormal movements such as chorea or tremor are superimposed onto and interfere with normal voluntary movements. Although hyperkinetic basal ganglia disorders are probably as diverse as hypokinetic basal ganglia disorders, their specific disease markers such as gene mutations, which exist for several of the hyperkinetic syndromes, create accurate classifications, which classify this group as less problematic.

All neurodegenerative diseases of the cerebellum and its connections are clinically associated with ataxia, meaning that the main criteria of classification will rely not on the clinical presentation but on the loci of pathology. In order to utilize a meaningful and functional classification it is particularly a challenging task. Some diseases of the cerebellum and connections can easily be grouped into three main neuropathological types: cerebellar cortical atrophy (lesion confined to the Purkinje cells and the inferior olives); pontocerebellar atrophy (lesion affecting several cerebellar and brainstem structures); and Friedreich ataxia (lesion affecting the cerebellum and to a much greater extent the posterior column of the spinal cord, peripheral nerves, and the heart). However, several other diseases of the cerebellum and its connections fall somewhere in between these three well delineated categories such as, dentatorubral degeneration, in which the most conspicuous lesions are in the dentate and red nuclei, and Machado-Joseph disease, in which degeneration involves the lower and upper motor neurons, substantia nigra, and the dentate system.

Among the neurodegenerative disorders predominantly affecting the spinal cord are, ALS and spinal muscular atrophy, in which the most severe lesions are found in the anterior part of the spinal cord, and the already cited Friedreich ataxia, in which the most severe lesions are found in the posterior part of the spinal cord. Finally, there is one group of neurological diseases which are often, but not always, considered neurodegenerative because of their chronic course and unknown etiopathogenesis but, unlike those described above, these show no apparent structural abnormalities. These include torsion dystonia, Tourette syndrome, essential tremor, and schizophrenia. However, structural abnormalities are referred to here as a loss of neuronal cell bodies, but it is unknown whether or not structural damage restricted to synaptic connections occurs in torsion dystonia or schizophrenia, which could account for the disease phenotype. Moreover, in all of these singular neurodegenerative disorders, various brain imaging studies and electrophysiological investigations have revealed significant functional abnormalities. Thus, could it be that some neurological diseases

labeled as neurodegenerative disorders such as torsion dystonia may be caused by a loss of function of specific neural networks with minimal or no loss of neuronal viability?

Collectively, the above discussion was aimed at stressing some of the obtrusive shortcomings of the current classification of neurodegenerative diseases. To circumvent these problems researchers have tried over the recent years to reconstitute and complete the clinical/pathological-based classifications by using molecular information obtained from various neurodegenerative diseases. Based on this novel approach, some neurodegenerative diseases, which used to belong to very distinct categories, are now brought together because of a common molecular alteration. For example, HD, spinal-cerebellar atrophy, and myotonic dystrophy now fall under the category of the trinucleotide repeat disorders (Cummings and Zoghbi 2000); Creutzfeldt-Jakob disease, Gerstmann-Straussler-Scheinker syndrome, and fetal familial insomnia fall under the category of the prion diseases (Prusiner 1998); PD, progressive supranuclear palsy, and diffuse Lewy body dementia fall under the category of the synucleinopathies (Galvin et al. 2001); and AD, corticobasal degeneration, fronto-temporal dementia with parkinsonism linked to chromosome-17, and Pick's disease fall under the category of tauopathies (Goedert and Spillantini 2001). Although the jury is still out on whether or not this new type of classification will alleviate the problems previously encountered, we strongly believe that a recasting of the conventional neuropathological-based classification to a molecular-based classification holds the promise of a more practical and less ambiguous standing for neurodegeneration from a clinical and therapeutic point-of-view.

22.4 Etiology of Neurodegenerative Diseases

The word *etiology* refers to the initiating factor of a disease. In some cases a given clinical entity is linked to a single etiological factor such as in HD. Interestingly, however, several others can be caused by various and quite distinct factors. PD, for example, can be caused by overexpression of the small synaptic protein alpha-synuclein (Singleton et al. 2003), loss of parkin E3-ubiquitin ligase activity (Shimura et al. 2000), or by an increase in kinase activity of LRRK2 (West et al. 2005), to cite a few. These observations raise an important issue that plagues the field of neurodegeneration which is whether prominent disorders such as PD or AD are indeed diseases or rather syndromes, i.e. very different diseases lumped together under a same name because they merely share the same clinical expression.

Regardless of this problem, it should be known that the causes of neurodegenerative diseases or syndromes are in most instances unknown. Even in some rare cases when the

etiology has been identified, the mechanism by which the etiological factor leads to neuronal death remains, at best, speculative. For example, while the etiology of HD was identified more than 20 years ago (Group THsDCR 1993), we still do not know with certainty how mutant huntingtin kills striatal neurons. The same circumstances are also true for superoxide dismutase-1 (SOD1) whose mutations are linked to a familial form of ALS (Rosen et al. 1993).

Among the neurodegenerative disorders, only a few arise as a familial condition, supporting a genetic basis. Within the affected members of a family, these genetic diseases can run as an autosomal dominant condition, which is the case for HD and dentatorubral-pallidoluysian atrophy. Less frequently, the disease can run as an autosomal recessive (e.g., familial spastic paraparesis), an X-linked (e.g., spinal and bulbar muscular atrophy), or even a maternally inherited trait (e.g., mitochondrial Leber optic neuropathy). In addition to these genetic-neurodegenerative diseases, others, while primarily sporadic, can also show a small contingent of patients in whom the illness is inherited. This is the case for PD, AD and ALS where less than 10 % of all cases are generally familial.

For those in whom the disease is truly sporadic, which is the vast majority of patients; it appears that any genetic contribution to the neurodegenerative process would be minimal (Tanner et al. 1999). In these cases, environmental factors may be the prime suspects in initiating neurodegenerative processes. Relevant to this idea is the observation that some neurodegenerative conditions as mentioned above might arise in geographic or temporal clusters. For instance, in the case of the PD-ALS-dementia complex of Guam which was introduced previously, it is believed that the pathology is caused by a toxic compound contained in the *Cycas circinalis*, an indigenous plant commonly ingested as food or medicine by the Chamorros Indians (Kurtland 1988). Intoxication with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, a by-product of the synthesis of a meperidine compound, is also known to produce a severe and irreversible parkinsonian syndrome, which is almost identical to PD (Przedborski and Vila 2001). Several large-scale epidemiological studies have failed however, to link in a definitive manner the environmental factors to diseases such as PD (Tanner 1989). Furthermore, most of the toxic exposures known to cause neurological problems occur within a specific geographic, social, or professional context and in absence of any significant association with an increased incidence of PD, AD or other prominent neurodegenerative diseases. Collectively, the aforementioned findings argue that sporadic cases are neither clearly genetic nor clearly environmental. Alternatively, this does not exclude the possibility that neurodegenerative disorders can result from a combination of both. Along this line, the demonstration of a non-syndromic familial deafness linked to a mitochondrial point mutation (Prezant et al. 1993) provides compelling support for this

view. In this study, family members who harbor the mitochondrial mutation develop a hearing impairment only upon exposure to the antibiotic aminoglycoside, thus illustrating the significant pathogenic interactions between genetics and environment. Also striking is the demonstration that the gene encoding for Ataxin-2, which is a known cause of spinocerebellar ataxia when its polyQ expansions is >34 glutamines, can also increase the risk of developing ALS when its polyQ expansions between 27 and 33 (Elden et al. 2010). The latter work illustrates quite-well the notion that genetic variants could predispose to environment factors.

22.5 Pathogenesis of Neurodegenerative Diseases

Compared to *etiology*, *pathogenesis* does not refer to the initiation of the disease process but rather to the cascade of cellular and molecular mechanisms set into motion by the etiological factor(s) and which ultimately leads to the demise of the affected neurons. As mentioned above, only in a very small group of so-called neurodegenerative conditions comprise of diseases with no apparent neuropathological changes. Along this line, it is worth remembering that the loss of neuronal cell bodies is often the cardinal feature used to define the neuropathology of a given neurodegenerative disorders. Yet, it is increasingly recognized that in neurodegenerative disorders such as AD, PD and ALS show, especially early on, damages predominate, not at the level of the cell body, but at the level of the synapse (Overk and Masliah 2014). While synaptic lesions may be challenging to detect, it may be critical to develop specific methods to survey the state of the synaptic fields as this may help to not only refine the classification of neurodegenerative disorders, including those which are associated with no apparent neuropathological changes, but also to shed light into pathogenic mechanisms of neurodegeneration. In all others, overt neuropathology, mainly in the form of a focal loss of neurons with gliosis, is discernible. Residual neurons may exhibit varying morphologies ranging from an almost normal appearance to a severe distortion with a combination of abnormal features such as process attrition, shape and size alterations of the cell body and nucleus, organelle fragmentation, dispersion of Nissl bodies, cytoplasmic vacuolization, and chromatin condensation. In several neurodegenerative disorders, spared neurons can also present with various types of intracellular proteinaceous inclusions, which, in the absence of any definite known pathogenic role, are quite useful in differentiating neurodegenerative disorders. As for the glial response it is comprised of innate resident immune cells including astrocytes and microglia. To a lesser extent, adaptive immune cells such as T-lymphocytes can also be found in the diseased areas of the brain.

All neurodegenerative disorders associated to cell death have in common the fact that specific subpopulations of neurons at the level of specific structures of the nervous system degenerate. This means that autopsy areas of the brain that are damaged can be surrounded by healthy tissues and that within the affected regions, degenerating and healthy neurons are intermingled. In some neurodegenerative diseases, such as olivopontocerebellar atrophy, multiple brain structures within the nervous system are affected. In these so called *system neurodegenerative diseases*, the spatial pattern of the lesions often becomes better defined as the disease progresses (Przedborski et al. 2003). In regards to the spatial pattern of the lesions it is essentially unrelated to the distribution of blood vessels. Conversely, as emphasized by Oppenheimer and Esiri (1997) the different lesions appear, at least in some cases, functionally and anatomically interconnected. Such a linked degeneration is observed in ALS, where both the corticospinal track and spinal cord lower motor neurons are affected, or in progressive supranuclear palsy, where both the globus pallidus and the subthalamic nucleus are lesioned. Although such trans-neuronal degeneration is a well-recognized phenomenon (Saper et al. 1987), still very little is known about its molecular basis except for the fact that this trans-synaptic demise occurs by programmed cell death (DeGiorgio et al. 1998; Ginsberg and Martin 2002). Relevant to this enigma is the increased attention paid to the possible self-propagating and spread, in a prion-like manner, of several neurodegenerative disorder-related misfolded proteins such as synuclein or Tau (Goedert et al. 2010). According to this interesting speculation, synuclein, for example, is prompt to adopt deleterious conformations; hence, once entering neighboring cells, misconformed synuclein promotes, perhaps by an alteration of free energy, will trigger a harmful protein stress. Trans-neuronal degeneration is, however, unlikely to account for all of the combinations of lesions that are found in system neurodegenerative diseases. In Friedreich ataxia there is degeneration of the spinocerebellar tracts and the dentate nuclei, but not of the Purkinje cells, which would have been the link between these two lesions. It is thus more probable to consider that etiological factors are ubiquitous, but that the pathological threshold is attained by specific structures of the nervous system at different times. Perhaps, in some neurodegenerative diseases, some areas of the nervous system may never reach this threshold and will thus remain unaffected throughout the span of the disease. Also, not in all neurodegenerative disorders are large numbers of areas of the nervous system at risk. In some specific neurodegenerative diseases, the lesions appear restricted to one or only a few brain regions. This is particularly well illustrated in spinal muscular atrophy, in which the degenerative process is limited to a loss of lower motor neurons, or in ALS, which is characterized by damage to the upper and lower motor neurons which may represent

the sole neuropathological change. Nevertheless, almost all neurodegenerative disorders, which initially appeared *monosystemic*, will eventually become *multisystemic* over the progression of the degenerative process. In ALS for example it is typical to observe overt neuropathological changes mainly at the level of the spinal cord and motor cortex in patients who died after the short course of the disease, for unrelated causes (i.e. car accident or heart attack). However, in ALS patients with a more protracted course of degenerative changes can now also be detected in the substantia nigra (Sasaki et al. 1992) and the oculomotor and trochlear nuclei (Hayashi et al. 1991). Recognition of this temporal spreading of the neurodegenerative process has led some neuropathologists (Braak et al. 2003) to propose that the neurodegenerative process starts on a specific circumscribed area of the nervous system where it begins a domino-effect: the initial affected area is responsible for the disease occurring in the next region, whereby propagating the degenerative process. Although quite appealing, this model is speculative and would only be true if the different regions affected in the neurodegenerative conditions were anatomic neighbors which, as mentioned above, is often not the case.

In most if not all neurodegenerative disorders the locations of the principal lesions have been well established. However, it often remains difficult to determine the extent of degeneration affecting more than one group of neurons and, consequently, to define the exact neuropathological topography of certain diseases. This problem stems from at least three issues. First, lesions are often missed through incomplete examination of the brain and spinal cord. Second, quantitative morphology in post-mortem samples seldom use the rigorous counting methods necessary to generate reliable neuron numbers (Saper 1996). The third issue pertains to sick neurons, which will not necessarily die. These compromised neurons often lose their phenotypic markers which are used for identification purposes in order to count them (Clarke and Oppenheim 1995). Accordingly, the use of phenotypic markers in pathological conditions may lead to erroneous conclusions about the status of a given group of neurons. For these reasons, reported estimations regarding the distribution and magnitude of neuronal loss in neurodegenerative disorders may, perhaps with a few exceptions, have to be taken with caution.

22.6 Onset and Progression of the Disease

As indicated above, prominent neurodegenerative disorders are sporadic and with the absence of pre-symptomatic markers for virtually all of them, patients are seeking medical attention only when the first symptoms of the diseases emerge. Because there is significant cellular redundancy in neuronal pathways, the onset of symptoms does not equate

with the onset of the disease. Instead, the beginning of symptoms merely corresponds to a neurodegenerative stage at which the number of residual neurons in a given pathway drops below the number required to maintain its endowed function. It is thus clear that the onset of the disease occurs at some preceding time, which, depending on how fast the neurodegenerative process evolves, it can range from a few months to several years. Our ability to determine the actual onset of the disease is at this point unfortunately undermined by the lack of pre-symptomatic markers and the little knowledge about the true kinetics of cell demise.

Occasionally there is a sudden worsening of a patient's condition. Although a sudden acceleration of the neurodegenerative process cannot be excluded, especially under the effect of intercurrent deleterious factors such as infection, it is more probable that the rate of neuronal death remains about the same throughout the natural course of the disease. However, the relationship between the clinical expression of a disease and the number of residual neurons does not have to be either linear or even constant. For instance, a patient may clinically remain unchanged during a prolonged period of time despite a loss of many cells and then abruptly their condition may deteriorate as the number of neurons drop below a functional threshold. Another important aspect is that virtually all neurodegenerative disorders progress slowly over time, often taking several years to reach end-stage. It must be remembered that neuronal degeneration corresponds to an asynchronous death (Pittman et al. 1999) in that cells within a population die at very different times. The correlate of this fact is that at any given time, only a small number of cells are actually dying and among these, they are at various stages along the cell death pathway. However, standard clinical, radiological, and biochemical measurements, which are critical to assessing the disease, generate information about the entire population of cells. Therefore, the rate of change in any of the usual clinical parameters reflects the decay of the entire population of affected cells and provides very little, if any insight into the pace at which the death of an individual cell occurs. Still, if one looks at the large body of *in vitro* data, it appears that, once a cell gets sick, the entire process of death proceeds rapidly. Given these facts, it may be possible that the protracted clinical progression is the reflection of only a small number of neurons dying at any given time from a rapid demise.

22.7 Non Cell-Autonomous Nature of the Degenerative Process

As indicated above, neurodegeneration refers to pathology of neurons. It is thus not surprising to find from an examination of the literature that all theories about neurodegeneration pathogenesis revolve around neurons. This rather *neuronocentrist* view is increasingly at odds however with

the current concept of neurodegeneration pathogenesis. As stressed above, in most prominent familial neurodegenerative diseases, the mutant proteins are ubiquitously expressed. This is the case for example with mutant alpha-synuclein in familial PD and of mutant SOD1 in ALS. While the underlying gene mutations are unquestionably pathogenic, ALS-linked SOD1 mutations expressed selectively in astrocytes (Gong et al. 2000) or in neurons (Pramatarova et al. 2001; Lino et al. 2002) fail to provoke the death of motor neurons in transgenic mice. Conversely, the expression of ALS-linked SOD1 mutations in all cells does cause an adult-onset paralytic phenotype in both transgenic mice and rats (Gurney et al. 1994; Nagai et al. 2001). Of further support to the idea that many different cell types collaborate to achieve the demise of neurons in neurodegenerative diseases comes from the work of Clement and collaborators (2003). In the study, the authors produced chimeric animals made of mixtures of normal and SOD1 mutant-expressing cells. They found that motor neurons that chronically expressed mutant SOD1 did not degenerate if they were surrounded by a sufficient number of normal non-neuronal cells. In addition, normal motor neurons surrounded by mutant-expressing non-neuronal cells showed to acquire intraneuronal ubiquitinated deposits consistent with the concept that mutant-expressing cells could transfer the diseases phenotype to normal neighboring cells. These data provide a compelling argument in that death of neurons in neurodegenerative diseases such as ALS may not be as cell-autonomous as previously thought. Accordingly, the cellular environment surrounding neurons may play a critical role in determining the demise of specific neurons within these types of diseases of the nervous system. Among the prime candidates that mediate this non-cell autonomous mechanism of neurodegeneration are glial cells. Along this line, neuroinflammation has indeed emerged over the past decade as a key contributor to neurodegeneration in diseases such as AD, PD and ALS (Wyss-Coray and Mucke 2002; Przedborski and Goldman 2004; McGeer and McGeer 2002). Based on both epidemiological and pre-clinical studies in animal models of human diseases (Chen et al. 2003; Wyss-Coray and Mucke 2002; Przedborski and Goldman 2004; McGeer and McGeer 2002), it is now proposed that neuroinflammation could stimulate neurodegeneration. Furthermore, the contribution of non-cell autonomous mechanisms mediated by non-neuronal cells, such as astrocyte or oligodendrocytes, to the demise of neighboring neuronal cells are increasingly recognized (Garden and La Spada 2012). Likewise, alterations in the neurovascular unit—which is comprised of neurons and glial cells as well as brain endothelial, pericytes and vascular smooth muscle cells—has received growing attention from the perspective of neurobiology of disease. For instance, Zlokovic (2010) is reminding us that the state of the blood-brain barrier, and more specifically, its non-neuronal cellular

constituents, by regulating the exchange between the circulating blood and the brain extracellular fluid may be instrumental in driving the neurodegenerative process.

22.8 Review Questions

1. Define neurodegeneration.
2. What are the three broad categories of diseases of the nervous system?
3. Provide examples of diseases from the three categories.
4. What is expected to occur with the prevalence of neurodegenerative diseases in the forthcoming generations and why?
5. What is the effect of neurodegeneration on the life expectancy and for what reason(s) typically patients with neurodegenerative disease die?
6. What is the common method used in classifying neurodegenerative diseases and what are the difficulties inherent with this type of classification?
7. Describe the different forms of genetic contributions among the neurodegenerative diseases.
8. What does multisystemic neurodegeneration refer to?
9. Why are neurodegenerative diseases progressive and what does it mean at the level of the whole population of affected cells and a single affected cell.
10. Define the notion of non-cell autonomous neurodegeneration and provide an example.

22.9 Answers

1. Neurodegeneration is any pathological condition in which the nervous system or nerve cell (i.e. neuron) loses its function, structure, or both.
2. Pathologies which are restricted to the nervous system and which are *primary neuronal* diseases (i.e. neurodegenerative diseases *per se*);
 - (a) Pathologies which are restricted to the nervous system but are not *primary neuronal* diseases
 - (b) Pathologies provoked by systemic causes which damage the nervous system
3. Alzheimer's disease, Parkinson's disease, Huntington's disease
 - (a) Brain neoplasm or cerebral edema and hemorrhage
 - (b) Cardiovascular arrest, carbon monoxide poison, or infections due to herpes simplex
4. It can be anticipated that, over the next generations, the proportion of elderly citizens will double. Consequently, unless effective preventive strategies are soon found, the number of persons suffering from a neurodegenerative disorder will rise dramatically and the epidemiological numbers provided above may have to be amended to higher percentages.
5. Nearly all neurodegenerative disorders shorten the life expectancy of affected patients. Deaths are often attributed to medical problems including fatal falling, aspiration pneumonia, pressure skin ulcers, malnutrition, and dehydration, whose occurrence is favored by immobility, impaired balance, and cognitive decline.
6. The most popular categorization of neurodegenerative disorders is based on either the main clinical feature or the location of the predominant lesion, or often on a combination of the two. Classification of neurodegenerative diseases, while useful, is quite a complicated task. In neurodegenerative diseases, it is typical that several areas of the brain are affected. Yet, the degrees in which these different brain areas are damaged often vary from one case to another, thus giving rise to different phenotypes.
7. Among the neurodegenerative disorders, only a few arise as a familial condition, supporting a genetic basis. Within the affected members of a family, these genetic diseases can run as an autosomal dominant condition, which is the case for Huntington's disease and dentatorubral-pallidoluysian atrophy. Less frequently, the disease can run as an autosomal recessive (e.g., familial spastic paraparesis), an X-linked (e.g., spinal and bulbar muscular atrophy), or even a maternally inherited trait (e.g., mitochondrial Leber optic neuropathy). In addition to these genetic-neurodegenerative diseases, others, while primarily sporadic, can also show a small contingent of patients in whom the illness is inherited. This is the case for Parkinson's disease, Alzheimer's disease and Amyotrophic Lateral Sclerosis where less than 10% of all cases are generally familial.
8. The neurodegenerative disease may initially begin in one location, but will eventually cause degeneration to other parts of the system.
9. The neurodegenerative disease will progressively cause more damage to the patient as its influence spreads throughout the body. The disease actively corrupts a single cell at a time.
10. Accordingly, the cellular environment surrounding neurons may play a critical role in determining the demise of specific neurons within these types of diseases of the nervous system. Among the prime candidates that mediate this non-cell autonomous mechanism of neurodegeneration are glial cells.

Abstract

Demyelinating diseases encompass a range of acute and chronic diseases affecting both the central and peripheral nervous systems. Many of these diseases share elements of autoimmune etiology, such as the presence of autoreactive T cells and B cells producing autoantibodies, followed by cell- and complement-mediated tissue damage, often following viral infection. The most common chronic demyelinating disease is multiple sclerosis (MS), a neuroinflammatory disease affecting the central nervous system (CNS). Histologically, the disease is characterized by lymphocytic infiltration of the CNS with oligodendrocyte loss, but its etiology is complex and not fully understood. Epidemiological studies implicate both environmental and genetic factors in its pathogenesis. Approved pharmaceutical treatments are predominantly immunosuppressive agents targeting the inflammatory components of disease. This review will highlight the mechanisms by which these treatments are understood to interact with the complex cast of inflammatory mediators present in MS pathogenesis.

Acute disseminated encephalomyelitis • Central nervous system • Cerebrospinal fluid • Multiple sclerosis • Experimental allergic encephalomyelitis • Immune system • T-cell receptor • Lymphocyte • Virus

23.1 Introduction

Multiple sclerosis (MS) is a chronic inflammatory disease of the central nervous system (CNS), in which episodes of oligodendrocyte loss result in focal regions of axonal demyelination disseminated in time and space ('t Hart and Massacesi 2009). The formation of these sclerotic demyelinated plaques in the cerebral white matter is associated with focal neurological deficits and progressive disability. MS is the primary cause of non-traumatic disability in young adults (Noseworthy et al. 2000; Ramagopalan and Sadovnick 2011), affecting

approximately 250,000–350,000 people in the U.S. (Jacobson et al. 1997; Simpson et al. 2011). MS most commonly presents as a relapsing-remitting disease (RR-MS), but approximately 50–60 % of patients with RR-MS eventually enter a secondary progressive phase (SP-MS), in which a relapse occurs and symptoms progressively worsen without subsequent remissions (Antel et al. 2012). In 10 % of patients, the disease may present with a primary progressive course (PP-MS), in which disease onset is followed by immediate progression without remission (Compston and Coles 2008). While the etiology of MS is not fully understood, both genetic elements and environmental exposures, such as antecedent viral exposure, have been identified as risk factors for MS, and autoimmune processes are recognized to contribute to its pathogenesis. Like many diseases with autoimmune etiology, MS predominantly affects women, and approximately 70 % of MS patients are female (Alonso and Hernan 2008).

Primary progressive disease, however, lacks this female predominance and carries a worse prognosis in men (Antel et al. 2012). Geographically, MS prevalence increases with latitude and distance from the equator, with a frequency of 60 per 100,000 or more in the northern United States, northern Europe, New Zealand, and southeast Australia, as compared to 5–6 per 100,000 at tropical latitudes. An intermediate frequency of 30 per 100,000 is seen at intermediate latitudes in southern Europe and central Asia and Australia (Simpson et al. 2011).

23.2 Histopathology and Pathophysiology of MS

Histologically, MS is characterized by focal regions of demyelination known as plaques. These lesions show perivenular infiltrates of mononuclear cells, in particular, CD8+ T lymphocytes, macrophages and microglia, as well as B lymphocytes and plasma cells. These infiltrates are especially prominent in early lesions. In later lesions, inflammatory infiltrates are diminished and reactive gliosis becomes the more prominent histological feature (Popescu et al. 2013).

The demyelination seen in these lesions results from the separation of the outer lamellae of the oligodendrocyte processes surrounding the axon, which disrupts the integrity of the myelin sheath but does not necessarily indicate degeneration of the oligodendrocyte itself. Nonetheless, oligodendrocytes may still show variable levels of degeneration. Axons, however, are relatively spared (Popescu et al. 2013). Axonal loss may become more significant in irreversible phases of disease (Jadidi-Niaragh and Mirshafiey 2011).

This demyelination leads to loss of saltatory conduction, which results in slower conduction and longer conduction times. Sodium channels are upregulated and redistributed along the length of the demyelinated axonal membrane to compensate for the loss of saltatory conduction and maintain electrical transmission, but this also results in an increase in energy demand, which may cause the patient to experience fatigue, even when electrical transmission is fully compensated. As the disease progresses, increasing conduction capacity is no longer sufficient to compensate for lost saltatory conduction, and electrical transmission is compromised (Compston and Coles 2008). Conduction may be furthered compromised by heat, leading to conduction block at increased temperatures, a symptom known as Uhthoff's phenomenon (Humm et al. 2004).

23.3 Clinical Manifestations and Diagnostic Criteria

The optic nerve is the only cranial nerve to share an embryological origin with the CNS and, thus, is the only cranial nerve myelinated by oligodendrocytes rather than Schwann

cells (Wilson-Pauwels et al. 2010). Consequently, the optic nerve is preferentially affected in MS, and optic neuritis, or inflammation of the optic nerve, is both the most common lesion of MS patients, affecting approximately 50 % of patients over the course of a lifetime, and one of the most common presenting complaints, affecting 15–20 % of patients at presentation (Balcer 2006). The condition is typically unilateral and presents as a complete or partial loss of vision, sometime with pain on movement of the affected eye (Foroozan et al. 2002). Other clinical manifestations include focal sensory losses, such as numbness and paraesthesias, and motor deficits, such as weakness of the extremities (Compston and Coles 2008).

The loss of saltatory conduction may result in spontaneous electrical discharges producing the perception of flashing lights (Compston and Coles 2008). Lhermitte's sign is the sensation of an electrical shock descending through the spinal cord, typically upon flexion of the neck, and is described in a variety of pathologies of the cervical spinal cord but is most closely associated with MS (Kanchandani and Howe 1982). The previously described conduction block that occurs with increases in temperature following compromised saltatory conduction—Uhthoff's phenomenon—may result in a worsening of symptoms with exercise or after taking a bath (Humm et al. 2004).

Spinal cord involvement may result in sexual dysfunction and urinary symptoms, such as retention and frequency. In later stages of the disease, motor deficits progress from focal losses to full paresis and disability. Regardless of clinical course, the most common symptom of MS is fatigue, and many patients also experience depression and cognitive impairments (Compston and Coles 2008). Other diagnostic criteria include the increased synthesis of IgG in the intrathecal compartment and the detection of oligoclonal bands of IgG that are present in the CSF but absent from the sera ('t Hart et al. 2009).

23.4 Variants

Balo's concentric sclerosis is a demyelinating condition that presents radiologically with Balo lesions—large multilayered lesions consisting of multiple concentric rings of demyelination and remyelination. It is commonly thought to be a rare variant of MS but is sometimes observed in association with other neurological diseases, throwing its association with MS into question (Merkler et al. 2006).

Neuromyelitis Optica is a demyelinating disease that shares many features of MS but is distinguished serologically by its specific association with the presence of IgG autoantibodies against extracellular components of a water channel protein, aquaporin-4 (AQP4), found on the surfaces of astrocytes. These anti-AQP4 antibodies, also known as NMO-IgG, are thought to mediate the pathogenesis of NMO

by fixing complement. NMO-patient sera has been shown to effect the lysis of AQP4+ astrocytes in vitro in the presence of complement, sparing AQP4- cells (Saadoun et al. 2011). The success of plasma exchange therapy in treatment of NMO supports the centrality of NMO antibodies and associated complement activation in NMO pathogenesis (Compston and Coles 2008).

Clinically and radiologically, NMO shows preferential involvement of the optic nerves and spinal cord, with relative sparing of the brain. Histologically, lesions exhibit macrophage infiltration and perivascular granulocytes but little T cell involvement, in contrast to multiple sclerosis, in which lesions show significant CD8+ T cell infiltration (Saadoun et al. 2011).

NMO shows the highest prevalence in East Asian, African, and Aboriginal populations but more recently has been recognized in Northern European populations with the advent of serological testing for anti-AQP4 antibodies (Compston and Coles 2008).

Acute demyelinating encephalomyelitis (ADEM) is an acute inflammatory disease mediated by autoimmune attack of the central nervous system, most commonly in response to viral infection but rarely following vaccinations and bacterial infections. The condition manifests with disseminated lesions of the brain and spinal cord and associated focal neurological deficits. Symptoms arise typically 1–3 weeks following viral infection. Typically, patients are treated with high dose corticosteroids, such as methylprednisolone, to rapidly reduce inflammation. While the prognosis is typically good, with 57–81 % of patients making a full recovery, mortality may be as high as 10 %. Approximately 25 % of patients experiencing ADEM eventually develop MS (Dale and Branson 2005; Menge et al. 2007).

23.5 Radiological Manifestations

The gold standard imaging technique for the monitoring of neuroinflammatory disease is magnetic resonance imaging (MRI) (Politi et al. 2007). MS patients most typically exhibit significant involvement of the white matter of the CNS, particularly in the optic nerves, spinal cord, brain stem, and cerebellum (Popescu and Lucchinetti 2012). Gadolinium- and T2-hyperintense enhancing lesions of the cerebral hemispheres frequently exhibit a periventricular distribution clustering near the lateral ventricles and corpus callosum (Compston and Coles 2008). In patients with advanced disease, T1-weighted MRI may show “black holes,” formerly enhancing lesions that have become irreversibly demyelinated with subsequent axonal damage (Kamphorst and Ravid 1998; Laule et al. 2007; Paolillo et al. 2000; Zivadinov 2007).

Gray matter involvement may also be seen in the form of cortical demyelination, and is thought to be responsible for symptoms of fatigue and cognitive impairment (Compston and Coles 2008). Lesions predominantly affect the cortex

and cerebral nuclei (Brownell and Hughes 1962; Cifelli et al. 2002) and are characterized by apoptotic neurons (Peterson et al. 2001) and infiltration by ramified microglia (Peterson JW). Gray matter pathology is thought to relate to white matter pathology and the majority of gray matter lesions are classified as Type I lesions, which are contiguous with plaques of subcortical demyelination in the white matter (Pirko et al. 2007).

23.6 Pathogenesis

While the etiology of MS remains poorly understood, genetic, geographic, and demographic data suggest the synergistic interplay of environmental exposures and genetic susceptibility factors (’t Hart et al. 2004; Kawakami et al. 2012). Key features of pathogenesis include (1) the activation of self-reactive CD4+ Th1 and Th17 cells in the peripheral blood (Domingues et al. 2010), (2) the presentation of myelin antigen by dendritic cells in lymphoid tissues (Isaksson et al. 2009; ’t Hart and Massacesi 2009; Zozulya et al. 2009), and (3) the increased permeability of the blood brain barrier to infiltrating immune cells (’t Hart and Massacesi 2009) as contributing factors. However, the precise causal relationship between these events has yet to be fully understood.

T cell Immunity: Early theories have suggested that Th1 and Th17 cells initially sensitized to pathogenic antigens in the peripheral blood and lymphoid tissues subsequently cross-react with myelin antigens and cross the blood-brain barrier (BBB), initiating the cascade of inflammatory damage that leads to CNS damage (’t Hart et al. 2009; Domingues et al. 2010). While this response was initially believed to be purely Th1-driven, understanding of the disease has broadened to recognize the significant role that Th17 cells play in the permeabilization of the BBB. This disruption is mediated by the secretion of IL-17, a pro-inflammatory cytokine, which promotes the activation of matrix metalloproteinase-3 (MMP-3) as well as the recruitment of neutrophils. IL-17 levels are highly associated with active disease in MS, and IL-17 levels were found to be higher in the peripheral white cells of MS patients with active disease than healthy controls and patients with inactive disease (Jadidi-Niaragh and Mirshafiey 2011).

Other immunologic changes associated with MS include the functional impairment of T regulatory cells (T_{reg}) (Haas et al. 2005; Zozulya and Wiendl 2008). T_{regs} are CD4+, CD25+, and transcription factor forkhead box protein P3 (FoxP3+) cells, which play a role in the downregulation of autoreactive Th1 and Th17 cells (Zozulya and Wiendl 2008). Their dysregulation is implicated in a wide array of autoimmune diseases. The deletion of T_{regs} in mice has been found to produce spontaneous autoimmune disease, whereas the passive transfer of Treg cells has been shown to alleviate experimental models of autoimmunity, including animal

models of multiple sclerosis (Zozulya and Wiendl 2008). CD39 is another marker co-expressed by FOXP3+ Treg cells that is thought to play a role in tolerance induction, as CD39–Treg cells exhibit impaired ability to block allograft rejection (Fletcher et al. 2009). While MS patients have been found to have the same levels of CD4+, CD25+, and FoxP3+ Treg cells as healthy controls (Feger et al. 2007; Putheti et al. 2004), further studies have demonstrated reduced numbers of CD39+ Treg cells in MS patient sera (Borsellino et al. 2007) as well as functional impairment *in vitro* with diminished capacity to suppress T cell proliferation upon stimulation with anti-CD3 and anti-CD28 antibodies (Viglietta et al. 2004).

Environmental factors: Other theories of pathogenesis propose that the activation of Th1 and Th17 cells is not an initiating event but is instead an immune response to an intrinsic neurodegenerative process of unknown etiology ('t Hart et al. 2009). While no distinct triggering method has yet been identified, patient sera studies have shown the clonal expansion of T cells in reaction to common viruses such as cytomegalovirus (CMV) or Epstein-Barr virus (EBV), thus suggesting antecedent viral infections as an environmental factor ('t Hart et al. 2009). Other studies have identified vitamin D deficiency as a potential contributor (Holick 2004), which is supported by the increased prevalence of MS at latitudes where sun exposure is less direct and vitamin D deficiency more common. The strongest genetic association in MS is with the major histocompatibility complex type II (MHC-II) haplotypes HLA-DR15 and DQ6 ('t Hart et al. 2009). Closely associated genotypes include DRB1*1501, DRB5*0101, DQA1*0102, and DQB2*0602 (Compston and Coles 2008), with HLA-DRB1*1501 being the single most closely linked genotype ('t Hart et al. 2009). Because vitamin D is required for many immune cell functions and MHC-II is required for the presentation of endocytosed extracellular antigens by antigen presenting cells, both associations support the role of immune dysregulation in the pathogenesis of MS. However, risk has been observed to vary with migration, depending on the age of the subject. Subjects moving to high-risk areas prior to adolescence experience the increased risk associated with their destination. For subjects moving after the age of 15, risk remains unchanged (Compston and Coles 2008). This suggests MS susceptibility to depend on both environmental exposure and age at time of exposure.

B Cell Immunity: The inclusion of elevated IgG antibody levels and CSF-specific oligoclonal IgG bands as diagnostic criteria indicates B cell and plasma cell involvement as another crucial component of MS pathogenesis. Patient studies have revealed the expansion of clonally related B cells in the CSF (Harp et al. 2007; Qin et al. 1998; 't Hart and Massacesi 2009) but this change is not specifically associated with MS. Nonetheless, histological analysis has identified antibody-mediated complement deposition in the CNS

as a key pathological feature of disease progression ('t Hart et al. 2009). The binding of autoreactive antibodies to CNS tissues also can promote the recruitment of macrophages expressing the Fc receptor, triggering macrophage-mediated myelin breakdown and phagocytosis (Prineas and Graham 1981). Ultimately, the presence of B cell involvement further affirms suspicions of an infectious trigger in MS pathogenesis. Of particular interest are EBV-infected B-cells. Epstein Barr virus is a gamma-herpesvirus that demonstrates a tropism for B cells and subsequently establishes a latent infection in the memory B cells of infected individuals. These EBV-infected B cells have been implicated not only in lymphoproliferative disorders but also in the pathogenesis of MS. While EBV infection in early life is typically asymptomatic, approximately 40 % of EBV infections in adolescence and adulthood progress to infectious mononucleosis, an acute lymphoproliferative condition of several weeks duration that is associated with a several-fold increase in MS risk (Ascherio and Munger 2010; Levin et al. 2010). MS patients are almost universally seropositive for EBV, with >99 % of patients exhibiting seroconversion, as compared to only 90 % of healthy individuals of all ages and only 70 % of young, healthy individuals (Santón et al. 2011). While alternative theories suggest that the correlation of IM and MS may be explained by hygienic behaviors in early life delaying exposure to both EBV and other pathogenic triggers until adolescence, this theory is diminished by the low risk of MS in EBV-negative individuals. These individuals theoretically share the high hygiene practices that would delay their exposure to other potential infections leading to MS. Thus, they would be equally likely to develop MS if hygiene practices were truly a confounding factor (Ascherio and Munger 2010). Additionally, a 2003 study of military personnel performed showed that increased titres of antibodies against EBV nuclear antigen-1 (EBVNA-1) were associated with a 34-fold increase in risk of MS (Ascherio et al. 2005; Levin et al. 2003). While antibody titres showed no difference between cases and controls prior to age 20, significant differences were found between the ages of 25 and 29, where control titres remained unchanged but case titres increased, ultimately reaching a maximum (Ascherio et al. 2005). These associations have spurred interest in an EBV vaccine as a possible preventive strategy in the treatment of MS.

Regeneration: Additional theories of pathogenesis suggest the persistence of lesions in MS requires not only an initiating demyelinating event but also a deficit in the process of remyelination. In the healthy adult CNS, demyelination is normally followed by remyelination, but this capacity for remyelination normally declines with age and may be further compromised in patients with MS (Crawford et al. 2013). Studies of oligodendrocyte lineage attribute capacity for remyelination to a specific subpopulation of cells expressing nerve and glial antigen-2 (NG2) and platelet derived growth

factor- α (PDGFR- α) (Crawford et al. 2014; Franklin and Gallo 2014). These NG2-positive cells, termed oligodendrocyte precursor cells (OPC) or NG2-glia, are found to migrate in response to inflammatory injury and proliferate in sites of demyelination, where they subsequently differentiate. Studies in mouse models of focal demyelinating injury have identified distinct populations of dorsal and ventral OPC that migrate and proliferate in response to damage (Tripathi et al. 2014; Zhu et al. 2011). Their differentiation in particular is thought to play a crucial role in the repair process, as blocking differentiation with inhibitors of OPC differentiation such as HDAC inhibitors and semaphorins significantly impairs remyelination in vivo (Franklin and Gallo 2014).

The process of remyelination is also strongly linked to the surrounding milieu of immune cells. Inflammatory autoimmune diseases are associated with increases in the ratio of macrophages and microglia demonstrating an immunogenic M1 phenotype to those demonstrating a tolerogenic M2 phenotype. Similarly, in animal models of multiple sclerosis, peak clinical scores are associated with high M1:M2 ratios (Miron and Franklin 2014). A 2013 study by Miron et al. showed that M2 macrophage-conditioned media enhanced oligodendrocyte differentiation in vitro and that M2 cell density is increased in remyelinating MS lesions, suggesting that remyelination is favored by the conversion of macrophages and microglia from an M1 phenotype to an M2 phenotype (Miron and Franklin 2014; Miron et al. 2013).

23.7 Treatment

MS therapies generally adopt the strategy of (1) blocking the action of cellular and molecular mediators of inflammation to combat the progression of inflammatory damage or (2) promoting the repair of existing damage. Examples of the former include numerous immunosuppressive therapies, such as corticosteroid treatments and antibody-mediated therapies for the depletion of T cells and B cells (Constantinescu et al. 2011). Other pharmacologic strategies include immunomodulation via the induction of T regulatory cells that tolerize immune cells to myelin-derived self-antigens with glatiramer acetate (Zozulya and Wiendl 2008). Recognition of the potential role of EBV and B cells in MS pathogenesis, meanwhile, has spurred interest in EBV vaccination as a strategy of prevention (Ascherio and Munger 2010). Still other branches of research seek to promote oligodendrogenesis and myelin repair (Deshmukh et al. 2013; Kokaia et al. 2012). At the intersection of these preventive and reparative strategies stand cell-based treatments such as stem cell transplantation, which is hypothesized to play both a regenerative role in cell replacement and an immune regulatory role in the creation of a tolerogenic environment favoring repair.

23.7.1 Immunosuppressive Strategies

In this section, we will give a broad overview of the evolution of MS treatment, covering a range of therapeutic strategies, from early treatments and established mainstays to newer treatments, noting both successes and challenges.

23.7.2 Glucocorticoids

Glucocorticoids suppress inflammation both by inhibiting the synthesis of molecular mediators of inflammation and inhibiting lymphocyte proliferation. Glucocorticoid treatments such as intravenous prednisone and methylprednisolone are favored in the treatment of acute exacerbations, for which they have been shown to reduce recovery time. However, they have not been shown to improve the ultimate degree of recovery (Goodin 2014). These medications are also associated with significant side effects, including derangements in lipid and sugar metabolism, which may produce hyperglycemia, resulting in a condition known as “steroid diabetes.” The excess corticosteroid may produce Cushing’s syndrome, which is characterized by weight gain, fat redistribution, and skin changes. Other manifestations include osteoporosis, gastrointestinal disturbances, and psychosis. Patients are also at risk of adrenal insufficiency should they fail to recover adrenal function during steroid withdrawal (Shaikh et al. 2012).

23.7.3 Alemtuzumab (Campath)

Alemtuzumab is a human anti-CD52 monoclonal antibody used for the depletion of T-cells and monocytes. It is established clinically for the treatment of chronic lymphocytic leukemia (CLL) and, in 1994, was established for the prevention of relapse in RR-MS. More recently, alemtuzumab has been explored in the treatment of early multiple sclerosis and the prevention of secondary progression. A study by Coles et al. reported reduced accumulation of disability and reduced lesion burden on T2-weighted MRI in patients taking 24-mg doses of the drug. However, adverse effects associated with its use in this trial included the development of autoimmunity, with 23 % of patients developing autoimmune thyroid disease and 3 % developing immune thrombocytopenic purpura (Coles et al. 2008).

23.7.4 Rituximab

Rituximab is a chimeric anti-CD20 monoclonal antibody engineered for the depletion of CD20+ B cells. It has predominantly been used in the treatment of B-cell lymphoma but has

more recently been studied in the treatment of multiple sclerosis (Carson et al. 2014). A 2008 study demonstrate a significant decrease in disease relapse and reduced counts of gadolinium-enhancing lesions on T1-weighted MRI in patients treated with the antibody (Bourdette and Yadav 2008).

23.7.5 Natalizumab

The $\alpha 4, \beta 1$ -integrin, or very late antigen (VLA)-4 integrin, is a glycoprotein expressed by activated lymphocytes and monocytes that mediates their adhesion to the vascular endothelium of the blood-brain barrier and facilitates their transmigration into the CNS. This transmigration is mediated by the binding of VLA-4 to vascular cell adhesion molecule 1 (VCAM-1). Natalizumab is a human monoclonal antibody that binds the VLA-4 integrin and prevents its interaction with VCAM-1, thus blocking lymphocytic infiltration of the CNS. A placebo-controlled trial showed a reduction in both lesion load and frequency of clinical relapse over a 6-month period. Suppression of lymphocyte migration, however, may result in the re-activation of latent infections. The JC virus is a polyomavirus that typically persists latently in the bone marrow, kidneys, and spleens of immunocompetent individuals but may become active in the immunosuppressed (Constantinescu et al. 2011; Kleinschmidt-DeMasters and Tyler 2005; Langer-Gould et al. 2005). Historically, its reactivation in HIV and AIDS patients and, more recently, its reactivation in patients treated with natalizumab has been associated with the development of progressive multifocal leukoencephalopathy (PML), a diffuse demyelinating condition of the CNS resulting from spread of the virus to the CNS and infection of oligodendrocytes. The condition is named for its progressive course and the radiological observation of multifocal white matter lesions on MRI. Clinical manifestations include progressive weakness and sensory loss, loss of vision and speech, and eventual progression to disability and death (Kleinschmidt-DeMasters and Tyler 2005).

23.8 Immunomodulatory Strategies

Fingolimod (FTY720) is an oral medication derived from myriocin, a metabolite produced by *Isaria sinclairii*, a fungus (Schmitz et al. 2015). Once phosphorylated, fingolimod binds the sphingosine-1-receptor of lymphocytes and prevents lymphocyte migration from the lymph nodes to other compartments of the body, effectively blocking their infiltration of the CNS (Kappos and Radue 2010; Kappos et al. 2006). Fingolimod is thought to exert additional immunomodulatory effects through its action on the sphingosine-1-receptor and may also play a neuroprotective role by

promoting remyelination (Kappos et al. 2006; Schmitz et al. 2015). A 2010 placebo-controlled study on fingolimod for the treatment of RR-MS showed significant decreases in relapse, progression to disability and gadolinium-enhancing lesions on MRI for patients receiving the drug (Kappos and Radue 2010).

Dimethyl fumarate is a natural compound previously approved for the treatment of psoriasis that has shown moderate efficacy in the reduction of clinical scores in animal models of multiple sclerosis (Schmitz et al. 2015). In clinical trials, it has been associated with a significant reduction in active MRI lesions and relapse rate (Hutchinson et al. 2014).

Glatiramer acetate (GA) is an acetate salt of a polymer consisting of L-alanine, L-lysine, L-glutamic acid and L-tyrosine, an amino acid sequence found in myelin basic protein (MBP) (Aharoni et al. 2013). This synthetic polypeptide, formerly known as copolymer-1, has been found to induce T regulatory (Treg) cells promoting tolerance of MBP. Mechanistically, GA competes with MBP and is incorporated in its place at the MBP-binding site of the MHC-II molecule. The MHC-bound GA (MHC-GA) competes with MHC molecules presenting MBP (MHC-MBP) for binding to T-cell receptors (TCRs). Binding of MHC-GA to the TCR during antigen presentation induces a tolerogenic, regulatory Th2-like phenotype. In animal models of MS, GA has been shown to promote oligodendrogenesis and is suggested to play a role in neuroprotection and repair. However, while GA carries relatively little risk of significant side effects, its clinical efficacy has yet to be clearly determined. A recent multicenter, placebo-controlled trial of GA failed to show efficacy in slowing disease progression, but the lack of treatment effect in this study may be attributable to discontinuation of medication as well as low rates of disease progression in all study participants (Wolinsky et al. 2007).

Interferon- β -1a is a cytokine that is typically administered to patients intramuscularly or subcutaneously and decreases T cell infiltration of the CNS. It also increases nerve growth and repair via increases in nerve growth factor production. While a systematic review of clinical studies found a slight decrease in frequency of exacerbations in patients receiving interferon therapy (Filippini et al. 2003), a 2012 study reported no reduction in progression to disability with interferon administration (Shirani et al. 2014). Moreover, interferon therapy is associated with a number of adverse effects, which include flu-like symptoms and hyperthermia, likely due to cytokine release (Compston and Coles 2008).

23.9 Cell-Based Therapies

The transplantation of immune cells such as autologous tolerogenic dendritic cells (Zozulya et al. 2009) and attenuated anti-myelin T cells (Compston and Coles 2008) have been examined

as a means of targeting autoimmune processes in MS. Further attention has been paid to stem cell transplantation as a means of generating oligodendrocytes for remyelination and neurons for the replacement of cortical and axonal damage. Neural stem cell transplant therapies are currently of interest both as a means of direct cell replacement and a mediator of tolerogenicity, promoting an environment that downregulates the inflammatory response and favors remyelination and repair. Human neural progenitor cells (hNPCs) have been demonstrated to suppress the proliferation of MOG-specific T cells upon re-stimulation with MOG antigen as well as the proliferation of T cells and PBMC stimulated with anti-CD3 and anti-CD28 antibodies. Additionally, hNPCs were shown to impair the development of mature CD1a⁺ dendritic cells from monocytes in a dose-dependent manner under maturation conditions. These monocytes also exhibited dose-dependent decreases in the expression of MHC-II and the co-stimulatory molecules CD80 and CD86 with increasing concentrations of hNPCs (Pluchino et al. 2009). Adult NSCs (aNSCs), similarly, have been found to down regulate macrophage effector functions in vivo (Martino and Pluchino 2006). Mesenchymal stem cells have been shown to induce increased secretion of IL-10 and decreased secretion of TNF- α and IL-6 in co-cultured macrophages (Kim and Hematti 2009). Previously, Pluchino et al. have previously explored the transplantation of endogenous neural precursor cells (NPC) in the treatment of experimental autoimmune encephalomyelitis (EAE), the primary model of multiple sclerosis. Intravenously administered hNPC were found to significantly decrease mortality and EAE clinical scores (Pluchino et al. 2009).

The transplantation of endogenous neural precursor cells is limited however by its requirement for allogeneic fetal tissue sources, which provoke both ethical questions and practical concerns of tissue rejection (Takahashi and Yamanaka 2006). With the advent of iPS technologies, however, there has been particular interest in the generation of autologous patient specific stem cells for the regeneration of the CNS (Qiu and Farnsworth 2013). Induced pluripotent stem cells (iPSC) derived from somatic cells may be subsequently re-differentiated into neural precursor cells (Caiazzo et al. 2011; Pang et al. 2011). Alternatively, somatic cells may be directly transdifferentiated into cells of neural lineage (Caiazzo et al. 2011; Pang et al. 2011; Pfisterer et al. 2011; Thier et al. 2012; Vierbuchen et al. 2010). These lineage-restricted induced neural stem cells carry the advantage of reduced tumorigenicity relative to iPSC, which have also been found to form teratomas in vivo (Leten et al. 2014).

23.10 Concluding Remarks

MS is a complex inflammatory disease mediated by recognized autoimmune processes but potentially also by intrinsic neurodegenerative processes and endogenous defects in

immunoregulation and remyelination. Currently available treatments are predominantly immunosuppressive pharmaceuticals that target the autoimmune processes implicated in its pathogenesis through the depletion and downregulation of immune cells. These drugs are largely used for the treatment of RR-MS, in which the prevention of new inflammatory episodes is sufficient to maintain the disease in remission and damage is not yet extensive enough to produce lasting deficits in the absence of active inflammation. Many of these pharmaceuticals are also hypothesized to favor repair by promoting endogenous processes of remyelination while maintaining a tolerogenic environment that inhibits further inflammatory damage. However, there are currently no accepted drugs to show efficacy in the treatment of secondary progression, in which demyelination is extensive and irreversible and may be associated with significant neurodegeneration. Cell-based treatments such as the transplantation of autologous DC tolerized to myelin antigen or attenuated T cells are of interest in the quest for antigen-specific tolerance. Stem cell transplantation has attracted both scientific and public interest for its potential role as an immunoregulatory treatment and a source of cell replacement for CNS repair.

23.11 Review Questions

- Which of the following statements is true about gender differences in MS?
 - Men are more likely than women to develop MS.
 - Women are likely to have a later age of disease onset.
 - Women have a more rapid disease progression
 - Men with MS have a worse prognosis.*
- The geographic distribution of MS:
 - Follows an east-west gradient
 - Increases at higher altitudes
 - Increases with distance from the equator*
 - Is skewed toward northern latitudes in both hemispheres
- An environmental component in the etiology of MS is supported by:
 - The geographic distribution of MS
 - Migration studies
 - Relatively low concordance (25–30%) in identical twins
 - Reports of MS epidemics
 - All of the above*
- Oligoclonal bands represent:
 - Immunoglobulins directed against recently identified myelin epitopes in MS
 - Immunoglobulins directed against unknown CNS epitopes in MS
 - Immunoglobulins that have been shown to deposit around demyelinated plaques in MS*

- (d) Immunoglobulins often detected in the serum of individuals with MS
- (e) b & e
- 5. Optic neuritis is the presenting symptom in what percentage of MS patients?
 - (a) 10 %
 - (b) 20 %
 - (c) 30 %
 - (d) 40 %
 - (e) 50 %
- 6. The diagnostic criteria for MS:
 - (a) Depend upon the demonstration of white matter abnormalities in the brain or spinal cord by MRI.
 - (b) Require evidence for the presence of neurological dysfunction for the diagnosis in all cases.
 - (c) Require that there is no better explanation (other than MS) for the clinical presentation.
 - (d) None of the above
 - (e) a, b & c
 - (f) a & c
 - (g) b & c
- 7. MS plaques have been histologically demonstrated to include:
 - (a) Infiltration of CD8+ T-cells
 - (b) Infiltration of CD4+ T-cells
 - (c) Infiltration of B-cells
 - (d) IgG deposition
 - (e) Complement deposition
 - (f) *All of the above*
 - (g) a & b
 - (h) a, b & c
 - (i) a, b, c & d

Guillain-Barré Syndrome, Chronic Inflammatory Demyelinating Polyradiculoneuropathy, and Axonal Degeneration and Regeneration

24

Ralf Gold and Klaus V. Toyka

Abstract

Current knowledge of the pathogenic mechanisms involved in Guillain-Barré syndrome (GBS) and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) supports an autoimmune etiology. Some of the cellular and humoral immune responses that contribute to the development of GS and CIDP resemble those implicated in multiple sclerosis (MS). Also, the role of persistent axonal damage in these diseases has recently been revisited, similar to the situation in MS. Currently axonal damage is best understood in GBS associated with preceding infections. In all other subtypes, histopathological studies speak to the heterogeneity of disease mechanisms in GBS and CIDP. Several immunotherapies are available to treat GBS or CIDP. Intravenous immunoglobulin and plasma exchange are of comparable therapeutic efficacy for the acute phase of both diseases, whereas prednisone (or analogues) and immunosuppressive drugs are effective only to treat CIDP, which usually requires long-term therapy. Although some approaches have been made to support axonal regeneration in the model of experimental autoimmune neuritis, currently no promising specific therapeutic concept is available which can be transferred to treat the human disease.

24.1 Introduction

Guillain-Barré syndrome (GBS) and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) are acquired demyelinating diseases of the peripheral nervous system (PNS), characterized by progressive or relapsing proximal and distal muscle weakness with possible sensory loss

(Saperstein et al. 2001; Hughes and Cornblath 2005). Historically GBS was described in 1916 in two French soldiers as an acute, postinfectious paralysis with elevated cerebrospinal fluid (CSF) protein but without cells. At that time also epidemics of poliomyelitis have occurred producing “Landry paralysis”, as a direct consequence of enterovirus infection, and in contrast to GBS is usually asymmetrical and associated with CSF pleocytosis. In the following decades, with the availability of electrodiagnosis the clinical hallmarks of GBS have been described more precisely. Estimated annual disease incidence in industrialized countries is up to 2/100,000. In contrast to CIDP, about 50 % of GBS cases are linked with preceding infections, typically diarrhea caused by *C. jejuni* (Enders et al. 1993) or infections of the respiratory tract (Hadden et al. 2001). In GBS acute respiratory failure or cardiac arrhythmias due to

dysfunction of the autonomic nervous system cause at least 3 % mortality even in specialized centers, especially in elderly patients with rapid disease progression and those suffering from multimorbidity (Hughes and Cornblath 2005). In addition, both in GBS and CIDP, residual symptoms and chronic fatigue may lead to long-lasting disability in about half (Merkies et al. 1999).

The last years have seen remarkable progress in understanding cellular and molecular pathways that cause autoimmune damage in these disorders of the PNS (see reviews in (Gold et al. 2003; Kieseier et al. 2004; Gold et al. 2005; Mathey et al. 2015)). Based on the observations that a significant proportion of patients with CIDP are responsive to immunotherapy and that an inflammatory response is observed at sites of active disease (Schmidt et al. 1996; Sommer et al. 2005), it is generally accepted that GBS and CIDP are autoimmune disorder with myelin as the likely target for the immune response. There is increasing evidence that GBS and CIDP have heterogeneous pathomechanisms. The dominant subtype of GBS is the acute inflammatory demyelinating form (AIDP), a classical demyelinating disease, but an increasing number of axonal variants has been described after the first series linked to preceding infections in China with acute motor axonal neuropathy (AMAN) (McKhann et al. 1991). Whilst first data seemed to associate axonal damage to preceding *C. jejuni* infection, especially with Penner 19 strain (Ho et al. 1995), these regional specificities could not be confirmed in the largest multicenter GBS-study performed to date (Hadden et al. 1998, 2001). Acute motor-sensory axonal neuropathy (AMSAN) is clinically and electrophysiologically similar to AMAN, but has a detectable sensory involvement. Thus, there is probably no single or unique mechanism that leads to axonal damage, but several immunological components will be discussed which may contribute to neuronal dysfunction and degeneration. This heterogeneity of the disease is further underscored by the variant of GBS, the Miller Fisher syndrome (MFS), where cranial nerves and caudal spinal roots are involved, and the disorder is strongly linked with anti-ganglioside GQ1b immunoreactivity.

Chronic inflammatory demyelinating polyneuropathy (chronic polyneuritis, CIDP) characteristically presents as symmetrical weakness, with some impairment of distal sensation. Yet to our experience only about 50 % of CIDP patients display the classical phenotype. Variants include the sensory predominant CIDP, the progressive sensory ataxic CIDP, and motor dominant CIDP with often acute onset (Mathey et al. 2015). By electrophysiology both motor and sensory nerves are affected with slowing of nerve conduction velocity, especially in proximal nerve segments as reflected by abnormal F-wave examination. Cranial nerves may be involved, but less frequently than in GBS. The disease course may either be relapsing-remitting or stepwise progressive. If

the initial attack of CIDP is subacute, disease progression up to reaching a plateau level is longer than 8 weeks. The diagnosis is supported by an elevated CSF protein, and inflammatory demyelination in sural nerve biopsy.

24.2 Experimental Models

For many aspects of both diseases, the various models of experimental of autoimmune neuropathies (EAN) have helped us to better understand the immunological mechanisms (see review in (Gold et al. 2005)). The monophasic EAN of the Lewis rat has its greatest advantage for defining pathogenetic hallmarks and establishing innovative therapeutic principles, similar to the chronic EAN in dark agouti rats. Upon immunization with increasing doses of the neurotogen or when antigen-specific T cell lines are used for adoptive transfer (AT-EAN), many clinical and electrophysiological signs of the human diseases could be reproduced (Heininger et al. 1986; Hartung et al. 1988). In particular, a profound and rapidly evolving nerve dysfunction occurred dose-dependently which correlated with increased axonal damage due to Wallerian degeneration. In the high-dose adoptive transfer model, most likely endoneurial ischemia resulting from severe inflammation and edema was an admixed and critical pathogenic mechanism. In all these experimental autoimmune encephalomyelitis (EAE) models, the pathology was mediated by CD4+ T cells specific for myelin antigens. In contrast to these models induced by immunisation, a spontaneous EAN model in the non-obese diabetic (NOD) mouse developed when the costimulatory molecule B7-2 was knocked out (Salomon et al. 2001). Further analysis of pathogenic T cell populations showed that CD4+ T cells recognizing myelin protein P0 were crucial in mediating disease (Louvet et al. 2009).

Progress in molecular biology has allowed generation of an increasing number of transgenic mice, which are typically on the genetic background of C57BL/6. For these mouse strains defined peptides of the myelin protein P0 have been described as neuritogenic (Miletic et al. 2005; Visan et al. 2004). Besides the acute and chronic autoimmune models induced by immunization or adoptive transfer of T cells, the immune system has been shown to contribute to disease progression and expression in inherited myelinopathies, which was elucidated by Martini and colleagues (see review in (Martini and Toyka 2004)). When the immune system was paralyzed by backcrossing the P0 deficient mice on C57BL/6 background with recombination-activating gene (RAG) deficient knockout mice, a remarkable delay of myelin pathology was observed within 6 months. This was not limited to demyelination, but also axonal damage was reduced which may reflect trophic aspects of the axon-Schwann cell unit and possibly also immune responses to Schwann cell nodal

antigens. Recent *in vitro* studies have confirmed that indeed dorsal root ganglia cultures from a rat model for Charcot Marie Tooth disease undergo axonal atrophy over a period of time (Nobbio et al. 2006). This model may be utilized to study the molecular changes underlying demyelination and secondary axonal impairment, in particular in the chronic disorders such as CIDP. As axonal damage may occur after just 3 months and tissue cultures represent a strictly controlled environment, this model may also be ideal for testing neuroprotective therapies.

24.3 Pathogenesis of Axonal Damage in GBS and CIDP

The presence of prominent demyelination, with “onion bulb” formations in chronic disease, and of perivascular inflammatory infiltrates are both hallmarks of CIDP pathology (Bosboom et al. 2001b; Sommer et al. 2005), although they may not always be found on small nerve samples from human biopsies. The “onion bulb” formation is a manifestation of excessive Schwann cell processes and is often produced by segmental repetitive demyelination and remyelination (Krendel et al. 1989; Bosboom et al. 2001a). As the disease progresses, secondary axonal degeneration becomes more established, but it also may occur early in the disease course (Dalakas 1999). This is very similar to the situation in multiple sclerosis (MS), where the work of Trapp’s group (Trapp et al. 1998) quantified progressive axonal damage in late disease stages, complemented by the findings of axonal damage in early biopsied MS lesions (Kuhlmann et al. 2002). The precise mechanisms that lead to demyelination and (early) axonal damage in the CNS and PNS are not known, but are thought to be mediated by both cellular and humoral immune factors. In MS, axonal damage has been associated with cytotoxic CD8 T cells (Neumann et al. 2002), nitric oxide (NO) (Smith et al. 2001) and free oxygen radicals. Similar observations relate to the detrimental role of focal nitric oxide in the PNS (Kapoor et al. 2003) although in the whole animal, the opposite effect has also been described (Kahl et al. 2003).

Importantly, nodal and paranodal antigens in the non-compacted myelin have received increased importance as mediators of humoral immune destruction. In CIDP, these regions are often disrupted (Devaux et al. 2012) have described that up to 30% of patients’ sera bind to cellular adhesion molecules such as neurofascin (NF), gliomedin, and contactin. In another study 4% of serum samples from GBS and CIDP showed antibodies to human recombinant NF 155 and NF 186. The majority of identified autoantibodies were reactive against the glial neurofascin isoform NF155. These were IgG3 or IgG4 subtypes, and the patients with this high-titre immunopattern responded well to plasma exchange therapy (Ng et al. 2012).

A novel mechanism has been described for antiganglioside antibodies in the axonal subtype of the GBS namely AMAN: uptake of these antibodies in nerve terminals and its endocytic processing may have an impact on axonal pathogenicity (Fewou et al. 2012; Buchwald et al. 1998). Similar mechanisms may also apply to the more chronic inflammatory neuropathies.

24.3.1 Neurotrophic Factors and Survival in the Inflamed Nervous System

Experimental models have revealed that the immune system is not the only denominator for the extent of damage in the inflamed nervous system. In EAE the neurotrophic cytokine CNTF (ciliary neurotrophic factor) has clear neuroprotective role on survival of oligodendrocyte progenitor cells and mature oligodendrocytes (Linker et al. 2002). This in turn leads to enhanced demyelination in mice where CNTF was lacking, and ultimately was associated with axonal damage. In contrast to other neurotrophins CNTF does not have an effect on immune cells, so that these findings could be attributed only to neuroprotection. A retrospective study in MS patients gave additional evidence that CNTF is also relevant in the human disease MS: those MS patients which have a genetic deficiency of CNTF appeared to exhibit earlier motor symptoms and a more severe disease course (Giess et al. 2002).

Since CNTF has also been described as lesion factor in the PNS (Sendtner et al. 1992), it seemed attractive to substitute neurotrophic factors by exogenous administration. This is a major problem with CNTF, which is mostly absorbed in the liver upon *s.c.* injection (Dittrich et al. 1994), and did not show protective effects on regeneration of the inflamed nerve in the Lewis rat EAN model (Gold et al. 1996). In contrast LIF (leucemia inhibitory factor), another family member of this IL6-cytokine group turned out to augment survival of oligodendrocytes during EAE (Butzkueven et al. 2002) as confirmed by signalling studies and molecular histology. The administration of LIF had positive effects on the disease course both in a preventive and in a therapeutic setting. Yet LIF also interferes with the immune system and affects T cell priming thus contributing to a different quality of cellular inflammation with fewer macrophages in the inflamed neural structure. In addition, the chemokine pattern was changed with an increase of CXCL1 early and a decrease of CCL2, CCL3, and CXCL10 later in the disease (Linker et al. 2008).

Studies with *s.c.* administration of the neurotrophin BDNF have been performed in Lewis rat EAN (Felts et al. 2002). Treatment of Lewis rats with BDNF (10 mg/kg day) did not significantly affect the neurological deficit, nor significantly improve survival, motor function or motor innervation. The weight of the urinary bladder was significantly increased in control animals with EAN, but remained

similar to normal in animals treated with BDNF. These results speak for a very limited effect of exogenous administration of BDNF. For thorough interpretation it would be required that pharmacological tracking studies are performed to verify the effect of BDNF on the target organ. With the use of conditional knockout mice for BDNF and inducing EAE, its role has become much clearer in central demyelination. C57BL/6 mice lacking BDNF in CD4⁺ T lymphocytes and monocytes developed more severe chronic EAE, coinciding with more pronounced demyelination and axonal damage. A partial rescue could be performed with BDNF-transfected T lymphocytes carrying a transgenic T cell receptor (Linker et al. 2010). These findings underline the idea that immune cell-associated BDNF may imply a putative neurotrophic survival effect.

It is currently not clear how local factors in the target tissue modulate recovery from an immune attack in the PNS. As yet unknown genetic susceptibility factors may modulate the inflammatory process itself and the response of axons and of myelinating Schwann cells to the inflammatory assault. As an example, axonal degeneration occurring in autoimmune neuropathies clearly affects prognosis (Dalakas 1999). Indeed, parallel expression of neurotrophic factors and their receptors in CIDP may reflect such survival mechanisms in the PNS (Yamamoto et al. 2002).

Besides neurotrophic factors also small molecules mediating survival in the inflamed PNS have been described recently. Pitarokoili used laquinimod, a derivative of linoimide, to treat EAN in the Lewis rat and observed maintained integrity of axonal function (Pitarokoili et al. 2014). Furthermore, when she treated EAN with dimethyl fumarate she detected a reduction of early signs of axonal degeneration through a reduction of amyloid precursor protein expressed in axons of the peripheral nerves (Pitarokoili et al. 2015). This correlated with an increase of nuclear factor (erythroid derived 2)-related factor 2 positive axons, supporting a direct neuroprotective potential of dimethyl fumarate. Furthermore, nuclear factor (erythroid derived 2)-related factor 2 expression in Schwann cells was only rarely detected and there was no increase of Schwann cells death during EAN. This supported the notion that this did not result from increased trophic support from Schwann cell contact.

24.3.2 Cellular Immune Factors

Inflammatory infiltrates as seen in nerve biopsies, consisting primarily of macrophages (Sommer et al. 2005) and T cells (Schmidt et al. 1996), suggesting that a T-cell-mediated delayed hypersensitivity reaction directed toward myelin antigens is a probable cause of inflammatory tissue damage in GBS and CIDP. Inflammatory immune reactions are coordinated by a number of soluble chemical mediators and selective adhesion molecules, including the following: direct

differentiation and migration of T cells; translocation of T cells across the vascular endothelium; stimulation of protease release; and recruitment of macrophages and additional T cells to sites of inflammation (reviewed in (Gold et al. 2003)). In both CIDP and its CNS counterpart multiple sclerosis, dysregulation of these chemical mediators (i.e., cytokines, chemokines, and adhesion molecules) is postulated to play a role in the breakdown of the blood-nerve and blood-brain barriers, respectively. Furthermore, dysregulation of chemical mediators may be responsible for aberrant trafficking of T cells into the PNS and perpetuation of inflammatory responses that lead to demyelination. In both the PNS and CNS, inflammatory T cells are eliminated by apoptosis, occurring either during the natural disease course or after treatment with glucocorticosteroids (Zettl et al. 1995).

24.3.3 Humoral Immune Factors

In the last decades, postinfectious molecular mimicry has been postulated as the foremost putative mechanism underlying GBS. This implies that antigenic determinants are shared between an infectious agent and the peripheral nervous system. Thus the initial antigenic stimulation by the infectious agent results in a secondary immune response directed against the nervous system. Several microbial organisms share antigens with the nervous system: *C. jejuni* serotypes O19 or Lior 11 have lipopolysaccharides (LPS) or lipo-oligosaccharides with ganglioside-like structures (causing anti-GM1 or anti-GQ1b immunoreactivity). In addition, *Haemophilus influenzae* has homologies with GM1 and GT1a, *Mycoplasma pneumoniae* with galactocerebroside, and cytomegalovirus has crossreactivity with GM2 gangliosides.

Antibody binding to major glycolipid or myelin protein antigens has been shown in both GBS-CIDP and MS. Antibodies may bind to macrophages via their Fc portion, activating phagocytosis and release of inflammatory mediators toward the myelin sheath. An alternative mechanism is through neuromuscular blocking antibodies. An early study of the functional activity of serum IgG antibodies demonstrated a slowing of nerve conduction in marmoset monkeys upon passive transfer of purified IgG from CIDP patients (Heininger et al. 1984). Recently, IgG antibodies that are capable of blocking neuromuscular transmission were identified in CIDP patient serum (Buchwald, Ahangari and Toyka, unpublished observations). This neuromuscular blockade by IgG antibodies has first been observed in GBS and its variant Miller Fisher syndrome (Buchwald et al. 1998, 2002). In the latter study a new mode of action has been defined for polyvalent immunoglobulin G from healthy donors namely neutralizing the pathogenic effects of autoantibodies. These findings were detailed using monoclonal antibodies to various gangliosides (Buchwald et al. 2007).

As described above, amongst these immune targets the antigens of the nodal and paranodal region in non-compacted myelin may also be of critical importance.
