decreased proportion of circulating CD16+ monocytes, a reduction in monocyte HIV DNA content and reduced soluble CD163. These changes were associated with significant improvement in neuropsychological performance in six subjects who entered the study with mild to moderate cognitive impairment, thereby suggesting that maraviroc intensification may have efficacy against HAND (Ndhlovu et al. 2014). In another study, neurocognitive performance was evaluated in conjunction with CSF HIV VL and inflammatory markers in HIV+ individuals as they were transitioned from a traditional ART regimen (tenofovir/emtricitabine/efavirenz) to a maraviroc-containing regimen with better CNS penetration (abacavir/lamivudine/maraviroc). Eight subjects completed the protocol and assessment at 24–36 weeks after treatment switch. Compared to baseline, abacavir/lamivudine/maraviroc treatment resulted in a trend, albeit non-significant, towards improvement in neurocognitive status and reduced TNF- α concentrations in the CSF (Tiraboschi et al. 2015). Because maraviroc is highly CNS-penetrating, these early results for maraviroc are promising and emphasize the potential importance of accessing primary immune cell reservoirs in the CNS (T lymphocytes, monocyte/macrophages) as critical therapeutic targets in HAND.

Cenicriviroc acts as a CCR5 and CCR2 chemokine co-receptor antagonist and is thereby hypothesized to block virus entry, inflammation and monocyte migration. A current clinical trial is investigating if dual CCR5 and CCR2 blockade will allow for reduced monocyte activation and entry into the CNS and thereby prevent cognitive decline. The trial is actively recruiting patients with a study design of a single arm, 24-week trial of cenicriviroc in HIV-1 suppressed patients on ART for 1 year or more with mild to moderate cognitive impairment. This clinical study is currently recruiting subjects (NCT02128828).

44.5.3 Potential Targeting of Immune Activation and Oxidative Stress

Neurocognitive impairment results from dendritic damage and neuronal loss, especially in the cortex, hippocampus, and basal ganglia (Ho et al. 1989; McArthur et al. 2003; Everall et al. 2009). HIV-induced neuronal injury in vitro is associated with the release of various toxins from HIV-infected macrophages, and NMDA receptor-mediated excitotoxicity may be the common injury pathway (Lipton 2004; Kaul et al. 2005). Monocyte and macrophage activation, either due to viral infection or inflammation, results in the production and release of known neurotoxins including glutamate, nitric oxide, carbon monoxide and TNF- α into the CNS compartment. HAND patients have elevated levels of multiple pro-inflammatory cytokines, including IL-1 β , TNF- α and IL-6 in the CNS and/or CSF (Oster et al. 1987;

Perrella et al. 1992; Achim et al. 1993; Foli et al. 1997). Immune activation of astrocytes could similarly amplify these potentially neurotoxic pathways. Inflammatory mediators modulate the permissibility of the blood brain barrier and the entry of infected monocytes into the CNS. Additionally, TNF- α contributes to inflammatory processes in the periphery, such as gut permeability and bacterial translocation, which has been linked to neurological complications of HIV (Ancuta et al. 2008; Brenchley et al. 2006a, b; Brenchley and Douek 2008). Therefore, reducing inflammation in the periphery as well as within the CNS could be expected to improve neurocognitive impairment in HIV-infected patients.

Systemic oxidative stress in HIV infection is driven by chronic immune activation and through direct effects of HIV proteins (Elbim et al. 1999; Repetto et al. 1996; Allard et al. 1998). Evidence of oxidative stress was first suggested after diminished levels of reduced glutathione were found in plasma, lymphocytes, PBMCs, and monocytes isolated from HIV+ individuals (Eck et al. 1989; Malvy et al. 1994; de Quay et al. 1992). Additionally, in vivo markers of oxidative stress correlate with systemic disease progression in HIV-infected individuals (Suresh et al. 2009; Wanchu et al. 2009). Suppression of HIV replication with ART significantly reduces immune activation and oxidative stress, however this suppression is incomplete (Roc et al. 2007; Bandaru et al. 2007; Eden et al. 2007). This persistence suggests that the pathways driving production of neurotoxins remain active and that neuronal damage is accumulating even during virologic suppression.

Specific work examining the role of the antioxidant response in modulating neurotoxicity and neurocognitive dysfunction led to the identification of heme oxygenase-1 (HO-1) as a key marker and potential regulator of HAND (Cross et al. 2011; Gill et al. 2014). HO-1 is an inducible, detoxifying enzyme that is critical for limiting oxidative stress, inflammation, and cellular injury within the CNS and other tissues. Prefrontal cortex HO-1 deficiency correlated with higher brain and CSF viral load, markers of immune activation, and a clinical diagnosis of HAND (Gill et al. 2014). Using an in vitro model, it was demonstrated that HIV infection reduces levels of HO-1 in macrophages and that this deficiency is linked to increased production of the excitatory neurotoxin, glutamate (Cross et al. 2011; Gill et al. 2014). And, as restoration of HO-1 reduced the production of glutamate by HIV-infected macrophages, therapeutics that can induce HO-1 expression in the CNS may have efficacy in preventing the progression of HAND in HIV+ individuals. Tecfidera (dimethyl fumarate) is a recently FDA approved therapeutic for multiple sclerosis. Dimethyl fumarate, and its primary in vivo metabolite monomethyl fumarate, has been demonstrated to effectively induce HO-1 expression, inhibit HIV replication and attenuate

macrophage-mediated neurotoxicity in an in vitro model of HAND (Cross et al. 2011). Future studies may continue to target components of the immune response and oxidative stress pathways in order to directly modulate the production of neurotoxins and limit HAND.

44.5.4 Anti-inflammatory Properties of Statins

The neuropathogenesis of HAND is attributed to chronic inflammation and the production of excitatory neurotoxins from activated monocytes, which are recruited to the CNS during HIV infection. Persistent monocyte/macrophage activation has been proposed as a critical target for adjunctive therapy to prevent HAND. Atorvastatin has been demonstrated to have anti-inflammatory properties on monocyte activation status in vitro and in ART treated HIV+ individuals (Ganesan et al. 2011). A clinical trial to determine if atorvastatin will reduce the inflammatory and activated phenotype of monocytes in HIV+ individuals on ART is currently recruiting subjects (NCT01600170). Ongoing research is also examining the role of other statins on monocyte-mediated inflammation and activation, especially in regards to reducing neurovascular risk factors in HIV+ individuals (Subramanian et al. 2012; Funderburg et al. 2014).

Outside of a novel therapeutic in HAND, statins have been prescribed in the treatment of hyperlipidemia, which, particularly in mid-life, appears to be associated with an increased risk of dementia (Anstey et al. 2008). Statins also promote cardiovascular and, presumably, cerebrovascular health through antioxidant and anti-inflammatory effects and improved endothelial function (Miida et al. 2007; Jain and Ridker 2005). A recently published systematic review of the role of statins in preventing cognitive decline and dementia reviewed randomized controlled trials and observational studies of various study designs. The conclusion of the analysis was that initiation of statins in late life does not prevent cognitive decline or dementia over the next few years (3–5 years) (Power et al. 2015). It could not be determined if mid-life or long-term statin use has beneficial effects on cognition in later years, however, the authors state that these findings have no bearing on existing recommendations regarding statin use for primary and secondary prevention of cardiovascular disease.

44.6 The Effect of Common Comorbidities in HAND

While HAND can develop at almost any stage of HIV infection, it is more common as immunosuppression and disease burden progresses. Some demographic risk factors have been identified however, including anemia, low body mass index,

increasing age, injection drug use and female sex (McArthur and Brew 2010). In the era of ART, HIV+ individuals are living longer and accumulating additional risk factors for neurocognitive impairment including those associated with aging, Alzheimer's disease and neurovascular events.

44.6.1 Hepatitis C Co-infection and HAND

Hepatitis C virus (HCV) infection is a worldwide problem that is often linked to HIV infection, with an estimated 30% of HIV+ patients having co-infection with HCV (Armstrong et al. 2006). HCV has been suspected to be an independent risk factor for neurocognitive impairment (Forton et al. 2005), however, studies attempting to determine the contribution of HCV to HAND in HIV co-infected cohorts have been limited. In a recently published study, the effect of HCV on neurocognitive performance in chronically HIV-infected patients enrolled in the CHARTER study demonstrated that HCV co-infection does not contribute to neurocognitive impairment (Clifford et al. 2015). Specifically, global deficit scores, the proportion of impaired individuals and the domains of neurocognitive functioning did not differ with HCV status. Among those with HCV, there was no association between neurocognitive performance and serum HCV RNA levels (Clifford et al. 2015). Notably, this CHARTER study excluded those HCV+ individuals with substantial HCV-associated liver damage. However, new treatments for HCV that are both more tolerable and effective are becoming available (Liang and Ghany 2013) with Sofosbuvir (Sovaldi) gaining FDA approval for treatment of HCV in HIV+ individuals.

44.6.2 Aging, APOE and Neurovascular Risk Factors and HAND

The number of older people living with HIV is growing due to the increased life expectancy of people with HIV undergoing ART but also due to the increasing number of people seroconverting at an older age. In 2013, an estimated 4.2 million people aged 50 years and older were living with HIV (Mahy et al. 2014). Those living with HIV have an increased risk of age-associated comorbidities including peripheral arterial disease, cardiovascular disease, and impaired renal function (Schouten et al. 2014; Canizares et al. 2014). Metabolic and systemic effects of ART can compound these risk factors (Samaras et al. 2007) and the risk for an ischemic stroke is higher in those with HIV+ (Sico et al. 2015). In addition to neurovascular events affecting cognition, genetic risk factors such as the *Apolipoprotein E* (APOE) $\epsilon 4$ allele may predispose to developing HIV-associated dementia, although this association remains controversial (Morgan et al. 2013; Valcour et al. 2004). Additionally, clinical

depression may present or be caused by cognitive impairment (Woods et al. 2009). Recognizing the numerous other factors contributing to neurocognitive function and decline in HIV+ individuals has already led to the examination of several potential therapeutics (see Sect. 44.4) and will undoubtedly lead to more therapeutic targets in the future.

44.6.3 Genetic Variation as Risk Factors in HAND

HAND is a complex phenotype and many studies to date have focused on the frontal cortex, (rather than white matter, hippocampus and basal ganglia) and investigated the most severe forms of HAND (HAD and HIV encephalitis). Host genetic variation is expected influence the neuropathogenesis of HAND, just as host genetics have been demonstrated to impact an individual's susceptibility to infection and rate of disease progression (Rappaport and Berger 2010; Naicker et al. 2012; Guernon et al. 2012). Genomic, transcriptomic, and epigenomic studies have highlighted the role of inflammation, immune regulation, metabolism and oxidative stress in the development of HAND (reviewed in Kallianpur and Levine (2014)). An important distinction between identifying genetic risk factors for HIV encephalitis (HIVE) and identifying risk factors for HAND, which is the more relevant goal in the era of ART. An autopsy study conducted through the National NeuroAIDS Tissue Consortium (Gelman et al. 2013), distinguished transcriptome patterns in individuals with HAND with HIVE from those with HAND without HIVE. Notably, HAND without HIVE is associated with low brain viral load, increased expression of endothelial-type transcripts, and absence of HIVE-specific transcriptomic features. A broad range of functions/pathways identified by grouping of genes identified by weighted-gene coexpression network analysis (WGCNA) includes genes involved in cancer and oligodendrocyte function were implicated in HAND pathogenesis (without HIVE).

Thus, although candidate genes have been suggested as either risk or protective factors in HAND, variations in study design and methodology and changing epidemiology (pre-ART vs. post-ART) have resulted in a lack of identification and validation of individual genes and associated variants as predictive markers for increased risk for HAND. As such, the quest for identifying genetic risk factors for HAND is somewhat similar to the quest for identifying risk factors for multiple sclerosis: no single gene/variant can fully account for heritable risk, but perhaps multi-genic influences on immune function, inflammatory responses, synaptic plasticity and neuronal function, and oxidative stress and mitochondrial function represent the driving forces for HAND that defy further identification of a signature genetic risk.

Future studies are necessary to explore the interplay of genes in different brain regions and they will have to tackle the more subtle changes associated with today's predominant forms of HAND, ANI and MND. These future studies may be able to identify additional therapeutic targets and improve our understanding of the complex neuropathology mediating HIV-associated cognitive impairment.

44.7 Review Questions

1. List 3 major disorders that fall under HAND that are discussed within this chapter.
2. Why can HAND not be mediated simply by uncontrolled HIV replication in the CNS compartment and the neuro-pathogenesis of this syndrome?
3. How is Functional MRI (fMRI) used to examine the symptoms of HAND?
4. How has ART been used for the treatment of HAND?
5. How is systemic oxidative stress created in patients with HIV infection?

44.8 Answers

1. Asymptomatic neurocognitive impairment (ANI), mild neurocognitive disorder (MND), and HIV-associated dementia (HAD)
2. Initiation of neuronal damage and clinically evident HAND can occur before AIDS criteria are met, as is evident by a prospective study that identified HAND in 8–34 % of aviremic patients who had no comorbidities and with a CD4 nadir of greater than 200 cells/ μ L (Cysique et al. 2006).
3. It can examine the hemodynamic response related to neural activity, and impairment of normal recruitment of brain regions that suggest brain dysfunction. Using this technique, it has been shown that HIV+ individuals have greater parietal activation for a simple attention task and greater frontal and parietal activation during more complex tasks (Chang et al. 2001).
4. With ART treatment, many patients have shown durable and complete suppression of HIV replication as determined by plasma viral RNA quantification, although a surprisingly high overall rate of HIV 'blipping' (defined as spontaneous expression of viral RNA copies (plasma, CSF)) in individuals on ART with sustained antecedent undetectable VLs with return to undetectable levels (Grennan et al. 2012) of up to 25 % has been reported.
5. Systemic oxidative stress in HIV infection is driven by chronic immune activation and through direct effects of HIV proteins (Elbim et al. 1999; Repetto et al. 1996; Allard et al. 1998).

Abstract

Alzheimer's disease (AD) is a progressive neurodegenerative disorder in which memory and cognitive dysfunctions are the earliest symptoms. Pathologically, the disorder is characterized by neuron loss in hippocampus and multiple cortical regions, along with the formation of extracellular amyloid plaques and intracellular neurofibrillary tangles. The amyloid in this disorder is comprised largely of a peptide called A β , which is a degradation product of a protein with unknown function referred to as the amyloid precursor protein. The genetics of dominant inherited forms of Alzheimer's disease implicate increased production of the long form of the A β peptide as the critical feature leading to unavoidable development of the disease. This recognition has led many to consider anti-amyloid therapeutics as a means of slowing or arresting the disease. One approach that may become the first to test the so-called "amyloid hypothesis" is immunotherapy. Both vaccination and monoclonal antibody therapies have been tested with considerable success in mouse models of amyloid deposition. These approaches can prevent the formation of amyloid deposits, remove already existing deposits, and reverse the memory deficits associated with amyloid deposition in these mice. A human clinical trial was cut short due to an apparent autoimmune reaction in a fraction of the patients, but the results from this truncated trial still suggest that there may be therapeutic benefits of the approach. Current research is focusing on trying to understand the mechanisms by which antibodies directed against A β aid in clearing the amyloid deposits, how the vaccines might be constructed to overcome self-tolerance without evoking autoimmune reactions, and testing various monoclonal antibody preparations for efficacy in clinical trials. Even partial success in slowing the progression of this disease can have considerable societal and economic impact. Furthermore, verification of the amyloid hypothesis will encourage development of a number of other anti-amyloid therapies that may synergize with the immunotherapeutic approach.

45.1 Introduction

Historically, the condition of dementia first described by Alzheimer in 1907 was called generically "presenile dementia." This nomenclature distinguished Alzheimer's as a disease, and not the dementia that occurred typically as humans

reached advanced years, known commonly as “senility”. It was believed that all of us would develop senility after living long enough, and that this was a normal part of the aging process.

One of the defining characteristics of Alzheimer’s was its pathology, consisting of senile or neuritic plaques and intracellular inclusions termed neurofibrillary tangles (see below). In the last quarter of the last century it became increasingly clear that many cases of “senile dementia” also had these same plaques and tangles common to the presenile form described by Alzheimer. This led to terminology referring to “senile dementia of the Alzheimer-type” to describe these late-onset cases. Ultimately, it became recognized that the pathologies Alzheimer reported were associated with dementias at any age, and the term “Alzheimer’s disease” was used to describe any severe cognitive deterioration that was associated with plaque and tangle pathology. This nomenclature has held for roughly the last two decades.

Over this same period, the numbers of individuals diagnosed with Alzheimer’s disease increased dramatically. In part, this was due to increased public awareness that severe cognitive deterioration was not normal human aging (senility) but a disease with specific pathological determinants. A second reason was the increasing number of humans living to the age of risk for developing Alzheimer’s disease. Although his original patient was quite young (50s), the vast majority of Alzheimer victims are in their 70s and 80s when they begin to show symptoms. The average age of death of an Alzheimer patient is greater than the age of death in the general population. In the past, these were survivors whose physiology protected them from cardiovascular disease and cancers (the leading causes of death for the last 50 years). Today, the remarkable medical success in retarding the age-adjusted incidence of cardiovascular disease has expanded the population reaching these later years, leading to increased numbers of demented patients (currently reaching four million in the United States, or slightly more than 1 out of every 100 Americans). Medical care costs for Alzheimer patients, who average 10 years survival with the disease, total \$100 billion, or 7% of all medical costs in the US. The major reason this disease is so costly is that most are institutionalized for some period preceding their demise. It is estimated that if the onset of dementia could be delayed by as little as 5 years, this would save \$50 billion in medical costs (essentially the same as the new Medicare drug benefit). Clearly, effective therapeutic or preventative approaches to this disorder would provide clear benefits not only to the patients and their families, but the nation as a whole.

The pathology of Alzheimer’s disease was initially described using silver stains of histological sections. This resulted from the success of the emerging photographic industry in the early part of the last century, where silver chemistry was being worked out with great precision. The plaques and

Fig. 45.1 Compacted parenchymal amyloid plaque in APP transgenic mouse hippocampus. Section was stained with Congo red and viewed with cross-polarized light. Total magnification $\times 400$

tangles described by Alzheimer were by definition, “argyrophilic,” meaning they bound silver molecules, which could then be reduced chemically to reveal stained regions.

The neuritic or senile plaques, also now called compact plaques, are comprised of fibrils of a short peptide called the A β peptide. This 40–42 amino acid peptide aggregates in a beta-pleated sheet structure to form fibrils, which are themselves aggregated into these dense plaques. These fibrils are referred to as “amyloid” because they stain with a dye called Congo red. There are many types of amyloids in the body, all of which share the properties of beta-pleated sheet structures, fibril formation and binding of Congo red dye. One feature of the Congo red dye is that it will shift the plane of polarized light when bound to beta sheet structures, leading to a characteristic red–green birefringence when viewed through crossed polarizing filters (Fig. 45.1). Surrounding these amyloid plaques is a zone of degenerating neuronal processes called neurites. These neurites are swollen, apparently drawn towards the amyloid plaques, and contain proteins or modifications of proteins (such as phosphorylation) not normally found in the larger processes of neurons. In addition to the compacted amyloid plaques, this amyloid material could often be found in association with blood vessels, where it was called cerebral amyloid angiopathy.

In the mid-1980s, George Glenner and his team (Glenner and Wong 1984) tried to determine the amino acid sequence of the amyloid deposits in Alzheimer’s disease. He had already found that other forms of amyloid in the body consisted of small fragments of much larger proteins that aggregated in this beta-pleated sheet secondary structure. When he tried to sequence the amyloid from the compacted plaques, he found variable results because much of the material had been truncated at the N terminal used to initiate the sequencing. However, the vascular deposits were more uniform, and he sequenced a 40 amino acid peptide called A β . This led within a year to the identification of a previously uncharacterized

parent molecule containing the A β peptide sequence called the amyloid precursor protein (APP). This molecule has a single transmembrane spanning domain and the bulk of the 1000 amino acid peptide is oriented towards the outside of the cell. A more detailed description of amyloid synthesis and its different form of aggregation is available in a separate chapter for "Alzheimer's disease."

Neurofibrillary tangles proved more difficult to identify at the molecular level. They also were fibrillar aggregates of a protein, and they also had a great deal of beta-pleated sheet structure, including staining by Congo red. However, their location within cells precluded them from being referred to as an amyloid. It is now widely accepted that these neurofibrillary tangles are comprised of abnormally and excessively phosphorylated forms of the microtubule associated protein tau. These tau filaments are largely insoluble by most known solvents, which slowed the identification of their major components.

A more detailed description of tau biology and neuroinflammation associated with AD pathology can be found in a separate chapter for "Alzheimer's disease."

A detailed account of the genetics of Alzheimer's disease is beyond the scope of this chapter. Others have detailed this quite thoroughly (Hardy 1997). However, there are at least three genetically identifiable categories of Alzheimer's disease. The first are those rare cases in which Alzheimer's is caused by a dominant genetic mutation (Table 45.1). While accounting for at most 1–2% of all cases, these have been very informative. Three genes are known to carry these mutations. One is the APP itself (Goate et al. 1991). Mutations in APP which modify its cleavage to favor either more A β or longer forms of A β (A β ending at amino acid 42 instead of amino acid 40) can cause an early onset form of Alzheimer's, with symptoms beginning in the 40s to 50s. A second gene that can carry a large number of different mutations and cause Alzheimer's disease is referred to as presenilin-1 (Sherrington et al. 1995). All tested mutations in this gene that cause Alzheimer's disease increase production

of the long form of A β . Presenilin-1 is a component of the complex that cleaves the variable C terminal of A β . It is also relevant that an extra gene dosage of APP can cause plaque and tangle pathology. Most Down's syndrome carriers have an extra copy of the APP gene located on human chromosome 21. By age 40, most will have plaque and tangle pathology upon autopsy, and many will develop a dementia condition in their late 40s and 50s.

A second genetic category includes normally occurring polymorphisms that increase the risk of developing the disease. While many polymorphisms have been mentioned, one that is consistently linked to increased risk is the Apolipoprotein E4 allele. Individuals carrying this allele have a threefold greater risk of developing the disorder (Corder et al. 1993; Poirier et al. 1993). One effect of this allele is to lower the age of onset, so these cases are often found in the 60s. The third category is comprised of those cases for which genetic linkage cannot be identified. It is important to note that the extreme age of onset complicates genetic analyses, as the likelihood of forebears reaching the typical age of onset is quite low. Thus, the size of the idiopathic group is not well defined. As more gene polymorphisms become consistently linked to increased risk, the size of this population may decline.

The recognition that the final common path for all known genetic causes of Alzheimer's disease, including Down's syndrome, is increased amounts of the longer A β variants led to the development of transgenic mice over-expressing mutated forms of human APP. While many unsuccessful mice were generated in the early 1990s, the first to demonstrate compacted amyloid plaques was the PDAPP mouse expressing a platelet-derived growth factor gene promoter-driven human APP (isoforms 695, 751, and 770) with the V717F (Indiana) mutation (Games et al. 1995). Shortly thereafter, a second APP mouse, the Tg2576, was found to have remarkably similar pathology (Hsiao et al. 1996). In the same month, a presenilin transgenic mouse developed was described (Duff et al. 1996). Although the presenilin transgenic mice alone had little pathology, our group found that the presenilin mutation greatly accelerated the accumulation of plaque pathology when crossed with the Tg2576 mouse (Holcomb et al. 1998).

There are now a variety of different APP transgenic mice that develop plaque pathology. The similarities are, in the opinion of these writers, more striking than their differences. All develop compacted plaques in the cerebral cortex and hippocampus. These plaques are associated with dystrophic neurites and the activation of astrocytes and microglial cells. All mice develop a memory dysfunction that is usually correlated with A β levels in mice of a given age (Morgan et al. 2000; Lewis et al. 2001). In none of the mice is there extensive neuron loss, as found in AD. Moreover, none of these mice develop tau pathologies, such as neurofibrillary tangles.

Table 45.1 The genetics of Alzheimer's disease

Type of Alzheimer's	Age of onset	Inheritance	Comments
Familial (<2 %)	40s–50s	Autosomal dominant	Mutations in amyloid precursor protein, presenilin-1 or presenilin-2 account for most cases
Inherited Risk (30–50 %)	60s–70s	Not dominant	Apolipoprotein E4 allele increases risk (earlier age of onset). Pathology more severe
Sporadic (50–70 %)	70s–80s	None identified	Increased risk; head trauma, decreased risk; education

Thus, these mice should be characterized as being models of amyloid deposition, not models of Alzheimer's disease.

When A β is added to tau transgenic mice, the results suggest that amyloid pathology may precipitate tau pathology. Either when APP mice are crossed with tau mice (Lewis et al. 2001) or exogenous A β is applied to tau transgenic mouse brain (Gotz et al. 2001), there is acceleration of the tau pathology. Later, a triple transgenic mouse has been generated that harbors APP, presenilin and tau mutations (Oddo et al. 2003), although neuron loss has not been reported to date. These transgenic models of select aspects of Alzheimer pathology have proven useful for preclinical evaluation of experimental therapies, which might be able to slow or halt the progression of Alzheimer's disease, including immunotherapy.

45.2 Early Studies

The first suggestions that anti-A β antibodies may be useful in ameliorating amyloid pathology came from work by Beka Solomon and colleagues in Israel. They published that anti-A β antibodies could block the formation of A β fibrils from monomeric forms in vitro (Solomon et al. 1996). They then proceeded to show that these antibodies could disaggregate preformed amyloid fibrils, and that the antibodies could achieve disaggregation at stoichiometries less than 1:1 (Solomon et al. 1997). This suggested that the antibodies were catalytically dissolving the fibrils, presumably by favoring the formation of non-beta sheet conformations. Inclusion of antibodies could block the in vitro neurotoxicity of A β . Subsequently, they identified a 4 amino acid sequence in the N terminal domain of A β they felt was the essential epitope for this mode of action (Frenkel et al. 1998). The catalytic disaggregation hypothesis remains one of the major proposed mechanisms for the action of anti-A β antibodies (Table 45.2).

The first observation that vaccination against A β might effectively lower A β deposition in vivo came from Schenk's

study (Schenk et al. 1999). These authors demonstrated that immunization of young PDAPP transgenic mice resulted in dramatic reduction in amyloid deposition as the mice aged. Even when started at midlife, the immunization protocol eliminated formation of amyloid deposits. Importantly, they observed the presence of activated microglia in the vicinity of the few remaining deposits. This led them to speculate that opsonization of the amyloid deposits led the microglia to phagocytose this material.

The same group subsequently demonstrated antibody-stimulated phagocytosis could occur in vitro (Bard et al. 2000). They placed microglia on sections of Alzheimer disease brain tissue, with and without anti-A β antibody present. Only in the cases where the antibody was present did they observe clearance of the amyloid deposits by the microglia. Although cultured primary microglia and cell lines phagocytose fibrillar A β added to cultures, antibody addition accelerates this process (Webster et al. 2001). Thus, a second mechanism by which anti-A β antibodies may clear amyloid deposits is by microglial activation and stimulation of phagocytosis (Table 45.2).

A third mechanism by which antibodies might reduce brain A β levels was suggested by DeMattos et al. (DeMattos et al. 2001). These authors noted that passive administration of a monoclonal antibody generated against A β resulted in large increases in circulating A β , analyzed by ELISA (enzyme-linked immunosorbent assay, a measurement that may be complicated by circulating antibody under some circumstances). They suggested that the circulating antibodies would sequester A β in the periphery, thereby increasing the brain to blood concentration gradient leading to a greater net efflux of A β from the brain to the periphery. It is important to recognize that the deposition of A β in mouse brain requires considerable over-expression of the APP transgene, always with a mutation that further increases the production of longer forms of A β . Thus it is conceivable that even minor shifts in the production and clearance of A β may have profound impacts on whether deposits accumulate or not.

For the most part, early studies of A β vaccination focused upon amyloid deposition. However, some of the APP mice were also being characterized behaviorally, and were found to have deficits in memory function that correlated with the extent of amyloid deposition. Thus, shortly after the publication that amyloid vaccination effectively reduced amyloid loads, our group and that of St-George-Hyslop et al. began immunizing APP transgenic mice to observe the impact on memory formation. To be honest, our group was concerned that the vaccine might provoke excessive inflammation in the brains of the transgenic mice (by over-activating microglia), and cause premature memory deficits. This was based on a widely-held belief that inflammation associated with amyloid deposits may be a pathogenic mechanism in Alzheimer's disease (Akiyama et al. 2000). However, our

Table 45.2 Mechanisms of Anti-A β Action

Catalytic Dissolution	Antibody binding converts A β secondary structure to form incapable of β -sheet fibril formation	Solomon et al. (1996) Solomon et al. (1997)
Microglial Activation	Opsonization of amyloid deposits activates microglia via effector molecules to clear deposits by phagocytosis or other mechanisms	Schenk et al. (1999a) Bard et al. (2000)
Peripheral Sink	Circulating anti-A β antibodies bind A β and reduce the free concentration in blood. This leads to increased net efflux from the brain	DeMattos et al. (2001)

testing specifically failed to identify premature memory loss with the immunization, and instead found protection from the development of memory deficits as the mice aged. Similar protection was found by the St-George-Hyslop group in the CRND8 APP transgenic mouse, and we arranged for tandem publication of these results (Morgan et al. 2000; Janus et al. 2000). Subsequent work found that some types of memory deficits could be reversed quite rapidly using passive immunization (Dodart et al. 2002; Kotilinek et al. 2002). This has led to the hypothesis that some pool of A β other than fibrillar deposits is responsible for some of the memory deficits observed in transgenic mice, and that this pool can be rapidly depleted by some anti-A β antibodies. Recent studies suggest that it is an oligomeric pool that is responsible for disruption of synaptic plasticity (Walsh et al. 2002; Cleary et al. 2005). Anti-A β antibodies appear capable of neutralizing the plasticity-disrupting influence of these oligomers (Klyubin et al. 2005).

It is not certain which of the proposed mechanisms of anti-A β immunotherapy is most correct. It is important to recognize that they are not mutually exclusive, and that all three may be working. In fact, the balance among these three mechanisms may vary for different types of immunotherapy.

45.3 Clinical Trial Experience with Active A β Vaccination

Based on the success of the A β vaccination approach in mouse models of amyloid deposition, Elan and Wyeth teamed to perform phase 1 and phase 2A trials in humans. Phase 1 trials resulted in no overt adverse events in human volunteers. Thus a phase 2 trial was initiated with 300 patients receiving a vaccine against A β (AN1792; using QS-21 as an adjuvant) and 60 patients receiving placebo inoculations. The original goal of the trial was to repeatedly vaccinate patients until a predetermined anti-A β antibody titer was reached. It was noted in the phase 1 trial that only a portion of the patients developed measurable antibody titers against A β (Schenk 2002). Even in the mouse studies, repeated inoculation was necessary to achieve high antibody titers (Dickey et al. 2001). This was further complicated by the advanced age of the patient population, which is known to cause increased variation in the response to vaccines.

Within several months of initiating the trial, the trial was interrupted due to the occurrence of multiple instances of adverse reactions in the patient population. This was characterized as aseptic meningoencephalitis, essentially swelling in the brain that was a form of autoimmune reaction presumably elicited by the vaccine (Orgogozo et al. 2003). Examination of tissue from two patients who ultimately came to autopsy revealed substantial T cell infiltration into the brain (Nicoll et al. 2003; Ferrer et al. 2004). In all, roughly

6% of the patients in the trial developed these symptoms, with the majority recovering after treatment with steroidal anti-inflammatory agents.

Although the inoculations with the A β vaccines were discontinued, the patients in the trial continued to be monitored both medically and cognitively. One cohort of patients in the trial, those in Zurich, appeared to have benefited from the vaccine. Hock et al. (Hock et al. 2003) found that those patients with the highest antibody titers appeared to remain stable cognitively. This stabilization appeared to extend 2 years after the last immunization. Importantly, it was the titers of antibodies that reacted with the amyloid deposits on brain sections that were associated with cognitive benefits (Hock et al. 2002). ELISA assayable titers did not associate with improved behavioral outcomes. When the entire study was analyzed, the linkage between antibody titers and cognitive benefit was less substantial (Gilman et al. 2005). It is unclear whether measurement of brain reactive antibody titers would improve this association as found for the Zurich cohort. Important caveats regarding the implications of this study stem from its truncation. Any results have to be considered within the context that the trial was not completed as planned and the potential benefits or failures must be considered in this context.

The histopathology of the patients in this trial is limited to three published reports. Two from patients that had a meningoencephalitic reaction (Nicoll et al. 2003; Ferrer et al. 2004) and one from a patient lacking any adverse reaction to the vaccine (Masliah et al. 2005). Although control cases were archival and the number of cases is very small, all three reports suggest there was less amyloid deposition than would be expected for an AD patient at each patient's stage of the disease. The reductions did not appear uniform throughout the brain. Moreover, the reductions appeared to be primarily in the neuritic plaque and diffuse A β deposits, but not in the amyloid deposits associated with the blood vessels.

A curious observation in the trial was the magnetic resonance imaging (MRI) findings of increased hippocampal shrinkage in those patients with the highest antibody titers (Fox et al. 2005). This occurred over the first year of the trial, and was also accompanied by ventricular enlargement. A similar observation was made within the Zurich cohort, however in this case, by the end of the second year, the hippocampal volumes were greater in those patients with the highest brain reactive antibody titers (Nitsch 2004). Nitsch has speculated that the initial loss of brain volume is secondary to two major changes; elimination of the bulk of the accumulated A β peptide and reduction of the inflammation and edema associated with the glial reaction to the amyloid deposits.

A 4.6-year follow-up study reports that there was no difference in percentage decrease in whole brain or hippocampal volume, or percentage increase in ventricular volume between antibody responders and placebo-treated patients,

either from the last visit in the phase 2a study or from the baseline MRI in the phase 2a study (Vellas et al. 2009). The samples size was limited to 7–8 per group in this follow-up study. The antibody responders maintained a low but detectable antibody titer and less cognitive decline as determined by the Disability Assessment for Dementia scale. Thus, this study supports the hypothesis that A β immunotherapy may have long-term functional benefits.

Table 45.3 depicts the A β —targeted clinical trials after the AN17982 trial. Second-generation vaccines were designed using a shorter peptide fragment, such as A β (1–6) or A β (1–7), in an attempt to prevent non-specific immune responses seen with the full-length A β vaccine. Using the second-generation vaccine, CAD106 was the first that reached the clinical phases of development (Wiessner et al. 2011). A recently completed phase II clinical trial has shown an A β -specific antibody response in 75 % of treated patients, without causing adverse inflammatory reactions. Vanutide cridifcar, developed by Janssen, has recently completed phase II trials with an additional phase II trial still ongoing (Ryan and Grundman 2009). However, the pharmaceutical company has abandoned the plans for further development of this vaccine. Affitope AD02 is another second-generation vaccine which completed a phase 2 trial (Schneeberger et al. 2010), but could not reach either primary or secondary outcome measures.

45.4 Other Forms of Active Immunization in Pipeline

Certainly, the AN1792 vaccine developed by Elan was relatively simple. It consisted of full length A β peptide, incubated in a physiological salt solution to promote fibril formation injected with a QS-21 adjuvant. One of the major issues in developing an effective A β vaccine is the recognition that A β is a self-protein to some extent. A β may be present in normal cells, albeit as a minor and short-lived product of APP processing. Thus vaccines may need to break self-tolerance (Monson et al. 2001). A second consideration is that an autoimmune reaction may have undesirable effects, such as that observed in those patients developing meningoencephalitis in the AN1792 trial. Presumably, these adverse reactions were due to development of a T cell response against A β , a self-antigen. A third consideration is that the relatively short A β peptide is not by itself a very potent immunogen. Thus, since the original publication by Schenk et al. (Schenk et al. 1999), there have been a number of alternative vaccine formulations investigated to produce anti-A β antibodies.

One of the first was an attempt to use mucosal vaccination as an alternative to injections (Weiner et al. 2000; Lemere et al. 2002). This was found to be an effective approach with

both production of high titer antibodies and clearance of amyloid deposits in transgenic mice. Another approach was to use a liposome-based therapy with the A β 1–16 peptide rather than full-length molecules (Nicolau et al. 2002). This palmitoylated vaccine construct was effective in breaking down self-tolerance to the vaccine in A β -overproducing mice. A different rationale was developed by a group at New York University (Sigurdsson et al. 2002). They were concerned that injecting full-length A β , a known neurotoxin, could produce adverse reactions by forming fibrils. This group has explored use of a truncated and modified A β peptide, which retains immunogenicity but not the capacity to form fibrils. Importantly, this vaccine can also reverse memory deficits in transgenic mice (Sigurdsson et al. 2004).

Another series of vaccines have used genetic engineering to produce a B-cell epitope towards A β and a T-cell response towards a non-self antigen. Agadjanyan et al. (Agadjanyan et al. 2005) used the first 15 amino acids of A β (where the vast majority of vaccine-generated antibodies bind; Dickey et al. 2001; McLaurin et al. 2002) coupled to a synthetic universal T cell epitope (PADRE). This succeeded in producing an immune response with high anti-A β antibody titers, but with no splenic T cell activation against the A β peptide. Presumably, a vaccine with these properties would not result in the autoimmune T cell reaction and would avoid the meningoencephalitic reaction found in some patients in the AN1792 trial. Importantly, these same authors found that the adjuvant chosen for the AN1792 trial, QS-21, biased the immune response toward a Th1 type of reaction (Cribbs et al. 2003). Given that Th1 responses are associated with autoimmune reactions, while Th2 responses suppress autoimmune responses, the choice of adjuvant may have contributed to the adverse events that were found with the active vaccine trial.

Another approach has been the development of DNA-based vaccines, where A β or a component is encoded genetically. Several of these have used viral vectors to deliver the vaccine. (Hara et al. 2004) administered adeno-associated virus encoding the A β peptide orally to mice. This resulted in epithelial cell expression of A β and prolonged elevation of anti-A β antibody titers, without eliciting T cell responses against A β (Hara et al. 2004). Kim et al. used an adenovirus vector encoding A β plus an adenovirus vector encoding GM-CSF to produce an immune response after intranasal administration (Kim et al. 2004). This response was found to have a Th2 bias, and was effective in reducing A β content in the brains of APP transgenic mice. Lavie et al. used a filamentous phage vector displaying only 4 amino acids from A β (EFRH; aa3–6) (Lavie et al. 2004). This vaccine produced a humoral response against A β , reduced brain amyloid loads and protected APP mice from cognitive deficits. Interestingly, another approach using an herpes simplex virus (HSV) amplicon to drive A β expression with a tetanus toxin fragment

produced in the central nervous system (CNS) inflammation, and may serve as a model for the autoimmune reaction apparently found in the AN1792 trial (Bowers et al. 2005).

Thus, there have been a number of clever alternative approaches to developing active immunization protocols for the possible treatment of Alzheimer's disease. Most either enhance the immunogenicity of the vaccination regimen, reduce the possible autoimmunity or both. Nonetheless, there are still potential problems with all of the vaccines. For example, the response will be variable in an aged population, as was clearly found for the AN1792 trial (Bayer et al. 2005; Vellas et al. 2009). A second consideration is the epitope specificity of the humoral response. Antibodies directed against one epitope may be more effective than others (for example, the apparently greater effectiveness of antibodies reacting with brain amyloid deposits (Hock et al. 2003)). A final consideration is that it is still not certain why the patients developed the meningoencephalitic reaction in the first place. Certainly, the argument that T cell activation against a self-antigen elicited an autoimmune reaction appears logical, but this is not at all proven. There is no good mouse model of the type of reaction found in the two human cases that have come to autopsy (the report by (Furlan et al. 2003) has been difficult to replicate). Active immunization reactions can be difficult to control; one cannot unvaccinate someone after the plunger has gone down. Still, if anti-A β immunotherapy does prove effective in halting or even slowing the progression of Alzheimer's dementia, it is likely that active immunization regimens will become a critical component to therapy for this disease, if only because of their reduced costs compared to passive immunization approaches.

45.5 Passive Immunization

The use of monoclonal antibodies as therapeutics has become commonplace. Antibodies or chimeric proteins against tumor necrosis-factor (TNF)- α are very effective in quelling certain inflammatory diseases. Trastuzumab (against HER2) is effective in reversing the growth of some breast tumors. As of 2015, there were 43 antibody therapeutics approved for use in the US (2 in 2015, 6 in 2014).

Monoclonal antibodies against A β appear equally effective in reducing brain amyloid deposits as active immunization against A β . Bard et al. (2000) were the first to demonstrate that systemic administration of anti-A β antibodies can lower amyloid loads (Bard et al. 2000). Importantly, they found that not all antibodies were equally effective in reducing brain A β content (Bard et al. 2003). In a striking demonstration that amyloid plaques are rapidly reversible structures in transgenic mouse brain, Bacskai et al. found that amyloid deposits imaged through a craniotomy window with multiphoton microscopy could be removed within 3 days after

topical administration of an anti-A β antibody (Bacskai et al. 2001). Injections of anti-A β antibodies directly into the brain parenchyma caused a time dependent clearance of A β deposits over a period of a week (Wilcock et al. 2003). Similar effects of monoclonal antibodies were found after intraventricular administration (Chauhan and Siegel 2002, 2003). In the triple transgenic mouse model, Oddo et al. found that anti-A β antibody injections into the hippocampus not only cleared amyloid deposits, but also reduced the hyperphosphorylation of tau at some sites (Oddo et al. 2004). Intriguingly, after 45 days, the amyloid deposits returned as did the tau hyperphosphorylation.

Within the passive immunization field, there have been discussions of antibody superiority based upon the epitope domain of the antibody (usually divided into N terminal, mid domain or C terminal) or the antibody subtype (IgG1, IgG2a, IgG2b etc.), with the conclusion that one type of epitope specificity or subtype is better than another. A third consideration is antibody affinity for A β . Unfortunately, none of these features has been manipulated independent of the others. Each individual antibody will vary in all of these properties, and, particularly for epitope specificity, it is very difficult to assume equivalence. Thus far, in the opinion of this author, each antibody needs to be considered a separate entity. Each antibody's ability to clear amyloid *in vivo*, inactivate oligomers, activate microglia, bind A β , increase circulating A β and activate effector molecules (such as Fc γ -receptors) must be measured directly. It is plausible that some antibodies may have superior profiles in clinical trials because of one or more of these properties. However, assuming that it is one of these properties, which confer superiority without measuring them, all will likely be misleading.

45.6 Clinical Trials of Passive Immunization

As of 2015, six monoclonal antibodies reached either phase 2 or 3 clinical trials: BAN2401 (phase 2, active), bapineuzumab (phase 2, completed), crenezumab (phase 2, active), ganetenerumab (phase 2, active), ponezumab (phase 2, completed), and solanezumab (phase 2/3, active) (Table 45.3). The other active A β -related clinical trials are for BACE inhibitors: E2609 (phase 2) and verubecestat (phase 2/3) (Table 45.3). No other A β -related clinical trials, such as active immunization, gamma-secretase inhibitors (GSIs), gamma-secretase modulators (GSMs), non-steroidal anti-inflammatory drugs (NSAIDs), or intravenous immunoglobulin (IVIG), are active.

Bapineuzumab and solanezumab are the first two monoclonal antibodies reached phase 3 clinical trials (Salloway et al. 2014; Doody et al. 2014). Both of them are humanized monoclonal antibodies targeting A β (1–6) or A β (1–28). Bapineuzumab was tested on two double-blind, randomized, placebo-controlled, phase 3 trials involving patients with

mild-to-moderate AD; one involving 1121 carriers of the apolipoprotein E (APOE) $\epsilon 4$ allele and the other involving 1331 noncarriers for 6.5 months. The monoclonal antibody treatment did not significantly improve cognitive functions as determined by the change from baseline in the ADAS-cog11 and DAD scores (Salloway et al. 2014). They rather observed significant edema as determined by brain MRI in antibody dose and APOE $\epsilon 4$ allele dose-dependent manner.

Solanezumab was tested on two double-blind trials (EXPEDITION 1 and EXPEDITION 2) involving patients with mild-to-moderate AD; one involving 1012 and the other involving 1040 patients for 18 months. Neither study showed significant improvement in the primary outcomes as determined by the change from baseline ADAS-cog11 score or ADCS-ADL scores (Panza et al. 2014b). Solanezumab is still active in phase 3 trials of AD patients (NCT01127633, EXPEDITION EXIT, and NCT01900665, EXPEDITION 3), but not recruiting patients.

BAN2401 is currently active on double-blind, randomized, placebo-controlled, phase 2 trials and recruiting up to 800 MCI and mild AD patients (NCT01767311). BAN2401 is also humanized antibody against A β .

Crenezumab recognizes multiple forms of aggregated A β , including oligomeric and fibrillar species and amyloid plaques with high affinity, and monomeric A β with low affinity. Crenezumab was tested on two phase 2 trials (ABBY and BLAZE), none of the study met the primary endpoints of change on ADAS-cog and CDR-SOB or PET amyloid imaging, but did report a separation on the secondary endpoint of cerebrospinal fluid (CSF) A β (Watt et al. 2014; Jindal et al. 2014). Crenezumab is also being tested in a prevention paradigm. In a landmark, adaptive, 5-year study that started in 2013, crenezumab is the first immunotherapy to be evaluated as part of the study (Garber 2012; Corbyn 2013).

Gantenerumab is a fully human monoclonal IgG1 antibody designed to bind with subnanomolar affinity to a conformational epitope on A β fibrils. The epitope encompasses both N-terminal and central amino acids of A β . One phase 2 trial was started on 2010, which was extended to a phase 3 trial enrolling 799 people (SCarlet RoAD). The study was discontinued by the end of 2014, followed by a report of no efficacy on primary or secondary endpoints in this trial (Jindal et al. 2014; Panza et al. 2014c). In March 2014, Roche started a new phase 3 trials of gantenerumab on 1000 patients with a clinical diagnosis of mild AD. Gantenerumab, together with solanezumab, is also being investigated by the Dominantly Inherited Alzheimer Network (DIAN) in a Phase 2/3 trial aimed at preventing dementia in 210 people who are on the path to AD due to an inherited autosomal-dominant mutation in APP, PS1, or PS2 (Corbyn 2013; Panza et al. 2014a, c; Mills et al. 2013).

Finally, ponezumab is a humanized IgG2 δ A monoclonal antibody that binds the free carboxy terminal amino acids 33–40 of the A β 1–40 peptide. Ponezumab was tested on a phase 2 trial (NCT00722046). Development of ponezumab

was discontinued due to no effect on the primary endpoints of change in brain or CSF A β burden.

45.7 Circulating Antibodies

Several groups have found that some individuals have titers of antibodies against the A β peptide. Unfortunately, consensus regarding a relationship to Alzheimer's disease has not yet emerged as there are reports of increased titers with disease (Nath et al. 2003), decreased titers with disease (Weksler et al. 2002) or no effect of disease (Hyman et al. 2001). It should be noted that the antibody titers observed are extremely low compared to those observed after immunization. Moreover, it is not clear the degree to which endogenous A β may interfere with the detection of anti-A β antibodies by ELISA (Li et al. 2004).

Still, this has led to a short, open label trial of human intravenous immunoglobulin (IVIG), an FDA approved product that has benefit in several types of disorders, including multiple sclerosis. Dodel et al. reported that monthly administration of intravenous immunoglobulin to 5 Alzheimer patients reduced A β in cerebrospinal fluid, increased A β in serum and improved cognition (Dodel et al. 2004).

Three phase 2/3 trials were conducted on IVIG therapy: gammagard, gamunex and octagam[®] 10% (Table 45.3). Gammagard was tested on two pivotal phase 3 trials. One was Alzheimer's Disease Cooperative Study, enrolling 390 patients with mild to moderate Alzheimer's disease for 18 months. The study did not show significant changes in primary endpoints: cognitive and global function as assessed by the Alzheimer's Disease Assessment Scale-Cognitive Subscale and the Alzheimer's Disease Cooperative Study Activities of Daily Living, CSF measurements, cerebral metabolism by fluorodeoxyglucose-positron enhanced tomography (FDG-PET), and brain amyloid load by PET (Loeffler 2013). The second phase 3 trial was subsequently terminated.

Gamunex is also one of several IVIG products and is currently actively tested on phase 2/3 trial by enrolling in 350 mild to moderate AD patients (NCT01561053).

Finally, octagam[®] 10% has been tested on two phase 2 trials. One was a multicenter, placebo-controlled phase 2 trial at seven sites in the USA and five in Germany (Dodel et al. 2013). This trial missed its primary endpoint of change in plasma A β levels, and was negative for most of its secondary biomarker outcomes. A second, single-center phase 2 study reports possible effects on the Clinical Dementia Rating Sum of Boxes and brain atrophy as seen on MRI (Kile et al. 2015). The study is still active but not recruiting new patients.

Overall, one feature of immunoglobulin therapy is that the circulating levels of IgG increase dramatically. This results in feedback regulation of a number of immune pro-

cesses, as the levels gradually return towards normal. This may also explain the rather curious finding that administration of a proteasome adjuvant with glatiramer acetate alone is adequate to reduce amyloid deposits in transgenic mice (Frenkel et al. 2005). This does not require the presence of antibodies, and appears related to the activation of resident microglial cells near the amyloid deposits. Thus, it is conceivable that immunomodulation may be just as important as a specific immune reaction in the benefits of immunotherapy in APP transgenic mice. Clearly it will be critical to identify if the same holds in human trials.

45.8 Future Directions

In addition to anti-A β immunotherapy, tau has been a target for the future immunotherapy (Pedersen and Sigurdsson 2015). For example, AADvac1 was the first anti-tau vaccine to enter phase 2 clinical trials (NCT02579252) (Godyn et al. 2016). AADvac1 composed of a tau peptide fragment linked to keyhole limpet hemocyanin (Kontseikova et al. 2014). More pre-clinical and clinical trials on the immunotherapy of tau protein are on the horizon for a future direction.

45.9 Review Questions

1. What are the 2 main neuropathological hallmarks of Alzheimer's disease? Compare and contrast their anatomical location and protein composition.
2. Describe the major types of genetic mutations that are associated with Alzheimer's disease.
3. What is the "Amyloid Hypothesis" of Alzheimer's disease?
4. Review 3 proposed mechanisms of action for how anti- β -amyloid antibodies might remove amyloid deposits.
5. What is the difference between active and passive vaccination?
6. List 3 barriers to the use of active vaccination clinically.
7. List 2 advantages of passive immunotherapy over active immunotherapy?
8. List 2 disadvantages of passive immunotherapy over active immunotherapy?

45.10 Answers

1. The two main neuropathological hallmarks of Alzheimer's disease are amyloid plaques and neurofibrillary tangles. Amyloid plaques are extracellular, and are composed of the β -amyloid peptide, while neurofibrillary tangles are

intracellular in neurons, and are composed of abnormally phosphorylated tau protein.

2. Mutations in the amyloid precursor protein, presenilin-1 or presenilin-2 can be inherited in some families. These genes are dominant, so inheritance of one gene copy causes the symptoms of Alzheimer's disease. The gene apolipoprotein-E has been identified as a risk factor. Inheritance of the apolipoprotein-E4 allele is associated with an increased probability of developing Alzheimer's disease.
3. The "Amyloid Hypothesis" posits that the symptoms of Alzheimer's disease result from the accumulation of extracellular amyloid in the brain of affected individuals.
4. The 3 proposed mechanisms include (1) catalytic dissociation of amyloid fibrils by the antibodies directly, (2) activation of brain microglial cells causing phagocytosis of β -amyloid and (3) efflux of β -amyloid from the brain to the circulation as antibodies in the circulation bind β -amyloid, which reduces free β -amyloid concentrations in the blood and causes a change in the equilibrium between brain and blood β -amyloid concentrations.
5. In active vaccination, a protein is injected together with an adjuvant (a molecule that enhances immunity), leading to the activation of the host immune system and the production of antibodies against the injected protein. In passive vaccination, the antibodies are injected directly.
6. (1) The production of antibodies is variable, resulting in different numbers and types of antibodies in different individuals. (2) There may be side effects due to activation of undesired components of the immune system. (3) Once the protein is injected into the host, the immune response cannot be stopped if adverse events ensue.
7. (1) Because a therapeutic agent is administered directly in passive vaccination, its pharmacokinetics can be measured, controlled and standardized. (2) If adverse events ensue, injections of the therapeutic antibody may be stopped. Neither is true of active vaccination.
8. (1) Production and storage of the therapeutic antibody for passive immuno-therapy is more complicated and expensive than active vaccination. (2) Administration of passive immunotherapy must be repeated over long durations as symptoms continue. In contrast, active vaccination is administered once, or in as a short series of boosters.

Acknowledgments I would like to thank Drs. Dave Morgan and Marcia N. Gordon at University of South Florida for contributing the original version of the chapter.

Abstract

Although patterns of neuronal degeneration are unique in PD and ALS, both disorders share common pathways and processes that support and possibly initiate neurodegeneration. Most of these processes are associated with induction, propagation, or consequences of neuroinflammation. Increased numbers of microglia that express reactive phenotypes and proximate dying neurons reflect the neuroinflammatory cellular response. Neuroinflammation amplifies oxidative stresses via reactive oxygen, nitrogen, and carbon species that react with biomolecules and increase molecular modifications of lipids, proteins, and nucleic acids. These reactive modifications eventually become deleterious to biochemical and cellular processes resulting in dysregulation of cellular functions and further neuronal injury and death. Whether neuroinflammatory responses are causal or consequential remains to be determined. Nevertheless, the importance of inflammatory responses to neurodegeneration is underscored in animal models, whereby attenuation of neuroinflammation by genetic manipulation or pharmacological agents mitigates neurodegeneration and increases neuronal survival. As such, immunological strategies that target neuroinflammatory processes represent promising candidates for therapeutic intervention in neurodegenerative disorders. These strategies embrace the capacity of regulatory T cells to protect neurons either directly via neurotrophic factors, or indirectly by modulation of microglial function to attenuate neuroinflammatory responses and by induction of astrocyte-derived neurotrophic factors.

46.1 Introduction

Parkinson's disease (PD) and amyotrophic lateral sclerosis (ALS) are progressive neurodegenerative disorders ranking 2nd and 5th in disease prevalence within the United States

(Relja 2004). PD is characterized by progressive loss of dopaminergic neurons in the substantia nigra pars compacta (SNpc) and reductions in their terminals within the dorsal striatum (see Przedborski, Sect. 22.2.4.2). These lead to profound and irreversible striatal dopamine loss. Neurological signs and symptoms consist of tremor, disturbances in gait, balance and coordination that commonly progress to cognitive and autonomic impairments. Cell loss modeling indicates that 100–200 SNpc neurons degenerate/day in PD (Orr et al. 2002). For ALS (known also as Lou Gehrig's disease) motor dysfunctions are characterized by gradual degeneration of spinal cord motor neurons eventually leading to progressive

weakness, paralysis of muscle, and death (see Simpson et al., Sect. 32.2.4.3). The mechanisms for neurodegeneration in both disorders relate, in part, to the abnormal accumulation, oligomer formation and misfolding of α -synuclein (α -syn) in PD and superoxide dismutase 1 (SOD1) or TAR DNA-binding protein 43 (TDP-43) in ALS. These protein aggregates form at synapses and axons leading to signaling abnormalities and neuronal dysfunction. Neuroinflammatory responses, mitochondrial function, glutamate transport toxicity, and free radical formulation are linked to protein toxicities and lead to neuronal destruction in both. It is hypothesized, that changes in the balance between factors promoting aggregation, clearance and synthesis of α -syn and SOD1 or TDP-43 underlies disease pathogenesis.

Microglial activation and alterations in lysosomal function are linked to oligomer accumulation in the membrane and extracellular and can be recognized by antibodies that often promote their clearance (Masliah et al. 2005). Anti- α -syn antibody-mediated clearance leads to decreased accumulation of aggregated α -syn in neuronal cell bodies and synapses with reduced neurodegeneration. Antibodies may also recognize abnormal α -syn associated with the neuronal membrane and promote α -syn degradation through lysosomal-autophagy pathways. Thus, the generation of humoral and cellular responses against aggregated proteins by vaccination may be effective in reducing the neuronal accumulation of α -syn aggregates. This approach, if administered appropriately, could improve disease outcomes (Miller and Messer 2005). Indeed, vaccination strategies with α -syn or SOD1 have been developed for treatments that highlight anti-amyloidogenic responses. To such ends, antibodies specific for peptides or conformations of misfolding neurodegenerative disease proteins can be engineered for affinity and stability then delivered intracellularly as intrabodies. For SOD1-linked familial ALS, or TDP-43 in sporadic disease, aberrant oligomerization of mutant proteins affects disease. Moreover, the formation of soluble oligomers suggests a general, unifying picture for SOD1 or TDP-43 aggregation in neuronal destruction. In the case of ALS, vaccination with recombinant SOD1 or passive immunization with antibodies against SOD1 was successful in animal models for ALS and PD (Urushitani et al. 2007; Gros-Louis et al. 2010; Masliah et al. 2005, 2011). The approach is based on reductions of toxic mutant proteins, but could also elicit secondary tissue destructive effects. Work from our own laboratory has shown that vaccine induction of the adaptive immune system can have both destruction and protective disease outcomes for PD and ALS (Benner et al. 2004; Reynolds et al. 2007, 2009; Kosloski et al. 2013; Olson et al. 2015). Immunoregulatory treatments (e.g. glatiramer acetate (GA), vasoactive intestinal peptide (VIP), granulocyte macrophage-colony stimulating factor (GM-CSF), and 1,25-dihydroxyvitamin D3) that modulate protective T cell

responses can be part of successful immunotherapeutic strategies. However, those treatments that elicit destructive immune responses can lead to opposite outcomes. In this chapter, we review the roles of the innate and adaptive immune system in the pathogenesis of PD and ALS and the recently developed means to harness both for therapeutic benefit (Fig. 46.1). To these ends, we provide a balanced review for the role of immunity in the pathogenesis of PD and ALS and the means to modulate it for therapeutic benefit. The strengths and concerns for each of these approaches are outlined and discussed.

46.2 Protein Misfolding and Modifications

46.2.1 α -Syn, SOD1 and TDP-43 Biology and Biochemistry

α -Syn is a major constituent protein in Lewy bodies, protein aggregates found in brains of Parkinson's disease patients (Spillantini et al. 1997). The expression of several mutations, including duplication or triplication of genes encoding for α -syn induce early-onset PD (Polymeropoulos et al. 1997; Kruger et al. 1998; Singleton et al. 2003; Farrer et al. 2004; Chartier-Harlin et al. 2004; Ibanez et al. 2004). Misfolding of this protein and lack of clearance are thought to play a major role in progression of PD. Two major cellular mechanisms of clearance include degradation by the ubiquitin-proteasome and the autophagic-lysosomal pathways. The former is supported by mutations in PD patients for parkin (*PARK2*) (Waters and Miller 1994) and UCH-L1 (*PARK5*) (Liu et al. 2002), proteins with ubiquitin E3 ligase and ubiquitin C-terminal hydrolase activities, respectively. In addition, blocking proteasome activity mitigates the degradation of α -syn (Webb et al. 2003; Machiya et al. 2010). The latter mechanism is supported in α -syn overexpressing cells by the presence of α -syn in organelles with morphological features of autophagic vesicles, increased clearance of α -syn with rapamycin, an autophagy stimulator, and increased accumulation of aggregated α -syn when autophagy is blocked (Webb et al. 2003; Lee et al. 2004). Moreover, α -syn clearance seemingly occurs in an aggregation stage-specific manner where the more toxic oligomeric intermediates are susceptible to clearance, but mature fibrillar inclusion bodies are not. Preformed α -syn fibrils are able to resist clearance by both the proteasome and autophagy in HEK cells expressing α -syn (Tanik et al. 2013). In this system, α -syn fibrils impair autophagy at the level of autophagosome clearance. Neutralization of the acidic compartments leads to the accumulation of α -syn aggregates and exacerbates α -syn-mediated toxicity and cell death (Lee et al. 2004). Wild type and A53T mutant α -syn increase numbers of LC3-II puncta associated with mitochondria and decrease

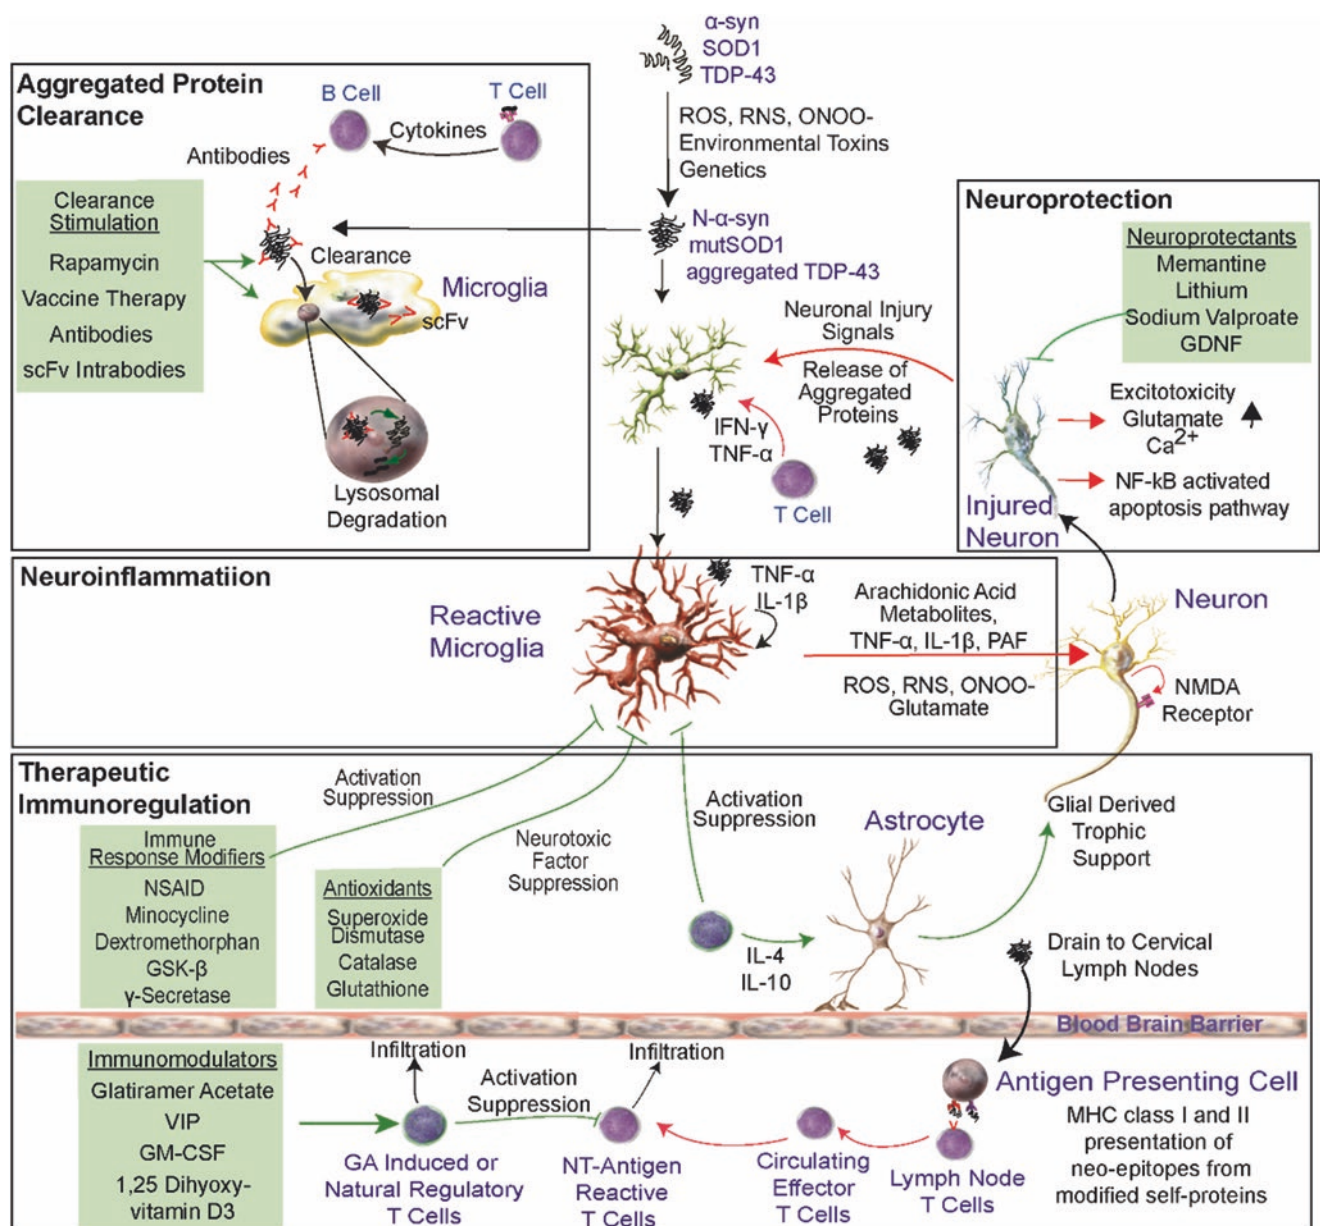

Fig. 46.1 Immunotherapeutic strategies for PD and ALS. There are several different targeted approaches currently available, or that can be imagined for the treatment of PD or ALS. The first of these is targeting the aggregated or misfolded proteins themselves to prevent oligomer-induced microglial activation. Vaccine-induced antibodies or intracellular-produced single chain antibodies (scFv, intrabodies) directed against misfolded/aggregated proteins, or drugs (e.g., rapamycin) that stimulate microglial/macrophage phagocytosis and lysosomal degradation may prove of therapeutic benefit by clearance of extracellular or intracellular misfolded/aggregated proteins. Another approach may use drugs that directly inhibit neurotoxicity (e.g., by inhibiting excitotoxicity or apoptosis) or promote neuroprotection (e.g., glial cell line-derived neurotrophic factor, GDNF), thus slowing disease progression. Finally, significant efforts are being made towards modulation of the immune response to misfolded/aggregated proteins. This may be accomplished by use of immune response modifiers and antioxidants that attenuate microglial activation. With the realization that disease can

either be exacerbated by effector T cells specific for neo-epitopes from modified self-CNS proteins (e.g. NT-modified proteins) or be ameliorated by regulatory T cells (natural or antigen-induced), therapeutic immunoregulation by immunomodulators or adjuvants to induce or upregulate regulatory T cell responses can inhibit exacerbated adaptive and innate immune responses and interdict further neurodegeneration. *α-syn* α-synuclein, *GA* glatiramer acetate, *GM-CSF* granulocyte macrophage colony stimulating factor, *GSK3-β* glycogen synthase kinase 3-β, *IFN-γ* interferon-γ, *MHC* major histocompatibility complex molecule, *mutSOD1* mutant superoxide dismutase-1, *N-α-syn* nitrated α-synuclein, *NMDA* N-methyl-D-aspartic acid, *NSAID* nonsteroidal anti-inflammatory drugs, *NT* nitrotyrosine, *ONOO-* peroxynitrite, *PAF* platelet-activating factor, *RNS* reactive nitrogen species, *ROS* reactive oxygen species, *SOD1* superoxide dismutase-1, *TDP-43* TAR DNA-binding protein 43, *TNF-α* tumor necrosis factor-α, *VIP* vasoactive intestinal peptide

numbers of mitochondria which are associated with decreased neuronal culture viability (Choubey et al. 2011). Dysregulation of protein degradation via autophagy and proteasomal functions may not be entirely distinct processes, but rather may be linked. Beclin-1, a protein involved in autophagy regulation, interacts with the E3 ubiquitin ligase parkin (*PARK2*) (Lonskaya et al. 2013). This interaction is decreased in both sporadic PD and the A53T PD model. The use of tyrosine kinase inhibitors increases the interaction of beclin-1 and parkin, and protects tyrosine hydroxylase positive neurons in the substantia nigra. In addition, PC12 cells transfected with human α -syn treated with the autophagy inhibitor 3-MA have decreased proteasome function as well (Yang et al. 2013).

In ALS, SOD1-positive aggregates are observed in the spinal cords from autopsied familial ALS (FALS) patients as well as from mutant SOD1 transgenic mice and are thought to play a critical role in toxicity and neuronal cell death (Kabashi and Durham 2006; Bruijn et al. 1997b; Watanabe et al. 2001; Shibata et al. 1996; Puttaparthi et al. 2003). Clearance of SOD1 aggregates involves proteasome activity, as inhibition of proteasome-mediated proteolysis promotes SOD1 aggregation in tissues from mutant SOD1-G93A mice, whereas restoration of activity reverses aggregate formation (Puttaparthi et al. 2003). In spinal cords of ALS patients, proteasome activity is decreased compared to healthy controls (Kabashi et al. 2012). Of interest, cytoplasmic, but not nuclear, proteasome activity is impaired from motor neurons of mutant SOD1 mice. Impairment of the 26S proteasome by conditional knockout of Rpt3 leads to ALS-like symptoms of decreased motor function, decreased body weight and decreased forelimb and hind limb strength (Tashiro et al. 2012). Basophilic inclusions are also increased with accumulations of TDP-43, FUS, optineurin and ubiquitin-2 in neurons. Additionally, clearance of mutant SOD1 by autophagy is comparable to that of the proteasome pathway as shown under conditions where mutant SOD1 is not toxic, the inhibition of macroautophagy induces mutant SOD1-mediated aggregation and cell death (Kabuta et al. 2006). Thus enhancing proteasomal or lysosomal function may be potential therapeutic strategies to halt disease progression in those afflictions associated with aggregation of misfolded proteins (Fig. 46.1).

More recently, sporadic and familial ALS patients without SOD1 mutations exhibit neuronal aggregates of the DNA binding protein, TDP-43 (Neumann et al. 2006; Mackenzie et al. 2007). Normally TDP-43 is found in the nucleus, however in ALS patients, TDP-43 aggregates accumulate in the cytoplasm. TDP-43 is also degraded by both the proteasome and autophagy (Wang et al. 2010). Pharmacological blockage of the proteasome leads to TDP-43 translocation to the cytoplasm. Monomeric and nuclear TDP-43 are primarily degraded by the proteasome, but aggregates and cytoplasmic

TDP-43 are cleared by autophagy (Urushitani et al. 2010; Scotter et al. 2014). The data show the importance of proper protein clearance by both the proteasome and autophagy/lysosome in the neuropathology of PD and ALS. New directives in genomics, proteomics and bioimaging have allowed monitoring of the effects of misfolded proteins in disease and provide new future therapeutic directives.

46.2.2 Protein Nitration and Oxidation

Postmortem analyses of PD patients consistently demonstrate the increased presence of nitrated residues as biomarkers for oxidative stress. Levels of serum nitric oxide and peroxynitrite are increased in PD patients compared to controls (Kouti et al. 2013). Protein modifications are among the many biomarkers detected in the brains of PD patients. Compared to brains and CSF from control donors, levels of nitrated proteins are elevated in PD patients (Aoyama et al. 2000). Most notable are 3-nitrotyrosine (NT) modifications of proteins that comprise Lewy bodies (LB); neuronal inclusions that are considered hallmarks of PD and consist primarily of α -syn, ubiquitin, and lipids (Giasson et al. 2000; Duda et al. 2000). These modifications suggest increased participation of inflammatory responses and reactive molecular species in PD; however, whether those modifications occur before or after inclusion into LB remain unclear. Also S-nitrosylated forms of parkin (*PARK2*) have been isolated from the temporal cortex from PD patients (Yao et al. 2004). S-nitrosylation of parkin can regulate its E3 ubiquitin ligase activity as well as mitochondrial quality control (Ozawa et al. 2013). Other oxidative post-translation modifications are also detected in tissues from PD patients. For example, carbonyl modifications, which are reflective of protein oxidation, are increased in SN, basal ganglia, globus pallidus, substantia innominata, cerebellum and frontal pole compared to controls and patients with incidental LB disease (ILBD), a putatively pre-symptomatic PD disorder (Alam et al. 1997). Whether the involvement of the latter two regions reflects a consequence of L-DOPA treatment or a more global consequence of the inflammatory spread of oxidative stress in PD is unclear. There are also increased oxidized forms of the PD-related proteins UCH-L1 (*PARK5*) and DJ-1 (*PARK7*) in the brains of PD patients (Choi et al. 2004, 2006). In addition, increased expression of neural heme oxygenase-1 by nigral astrocytes provides additional evidence for oxidative damage to proteins in PD (Schipper et al. 1998).

In ALS, abundant evidence points to the effects associated with peroxynitrite in affected tissues. Significant increases in levels of NT moieties are detected on CSF proteins from ALS patients (Shaw and Williams 2000; Aoyama et al. 2000), including Mn superoxide dismutase (Mn-SOD),

which are only slightly increased in patients with AD and PD (Chou et al. 1996; Aoyama et al. 2000). Moreover, NT immunoreactivity is associated with motor neurons of the spinal cord and axons (Calingasan et al. 2005), and co-localizes to axonal conglomerates and spheroid neurofilament accumulations of upper and lower motor neurons (Chou et al. 1996) and with A β 40 depositions within abnormal neurons (Calingasan et al. 2005). Oxidized SOD1 has been isolated from human central nervous system tissue (Auclair et al. 2013) and from immortalized lymphocytes. SOD1 appears to be oxidized by hydrogen peroxide at cysteine 111 (Bosco et al. 2010; Auclair et al. 2013). Oxidized SOD1, much like mutant SOD1, alters the conformation of Bcl2 by exposing the BH3 domain which can damage the mitochondria (Guareschi et al. 2012) and can inhibit proteasome activity (Le Pecheur et al. 2005). Whether TDP-43 is modified by nitration or oxidation in ALS patients remains unreported.

46.3 Microglial Inflammatory Responses

46.3.1 Innate Immunity and Disease

PD is characterized by activation of microglial cells found in and around degenerating neurons. Reactive microglia are commonly seen within the SNpc of PD brains investigated at autopsy (Croisier et al. 2005). A sixfold increase in the numbers of reactive microglia phagocytosing dopaminergic neurons has been shown (McGeer et al. 1988a) and correlates with the deposition of α -syn (Croisier et al. 2005). These reactive microglia over-express HLA-DR of the human MHC II complex, complement receptor type 3 (CR3, CD11b/CD18, Mac-1, Mo 1), CD23 (Fc ϵ RII, Fc receptor II for IgE), CD11a (lymphocyte function-associated antigen-1, LFA-1), CD54 (ICAM-1) and CD163 (scavenger receptor) (Hunot et al. 1999; Imamura et al. 2003; Pey et al. 2014). They also secrete a plethora of proinflammatory cytokines such as interferon- γ (IFN- γ) tumor necrosis factor- α (TNF- α), interleukin 1- β (IL-1 β), and upregulate proinflammatory enzymes such as inducible nitric oxide synthase (iNOS), lipocortin-1 and cyclooxygenase (COX) 1 and 2 (Hunot et al. 1999; Knott et al. 2000). MHC class II positive microglia also are significantly increased in the substantia nigra, putamen, hippocampus, transentorhinal cortex, cingulate cortex and temporal cortex of the PD brain (McGeer et al. 1988a; Imamura et al. 2003). Reactive microglia serve as *in vivo* indicators of neuroinflammatory responses and contribute significantly to progressive degenerative processes. In early-stage PD imaging, PK11195 ligand binding to peripheral benzodiazepine receptors, which are upregulated on reactive midbrain microglia and also serve as markers of neuroinflammation, inversely correlates with binding of 2- β -carbomethoxy-3 β -

(4-fluorophenyl) tropane (CFT) to the dopamine transporter (DAT) in the putamen as a measure of surviving dopaminergic termini, and also with the severity of motor impairment (Croisier et al. 2005). While the ability of nonsteroidal anti-inflammatory drugs (NSAIDs) to mitigate the severity of PD is in question (Ton et al. 2006; Bornebroek et al. 2007; Samii et al. 2009; Driver et al. 2011; Manthripragada et al. 2011), the fact that some studies suggest these drugs decrease the risk of developing PD point to a putative role for neuroinflammation in PD (Chen et al. 2003, 2005; Hernán et al. 2006; Wahner et al. 2007; Gagne and Power 2010; Gao et al. 2011). Also supporting the importance of inflammation in PD are biochemical and histological evidence in PD brains showing increased levels of carbonyl and nitrotyrosine protein modifications, lipid peroxidation, DNA damage, and reduction of glutathione and ferritin, the end results of inflammatory processes (Hald and Lotharius 2005). Postmortem samples of SNpc from sporadic PD patients also show elevated levels of the protein gp91^{phox}, the main transmembrane component of NADPH-oxidase, which co-localizes with microglia and is associated with the production of ROS. Likewise, in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated mice (see Przedborski, Sect. 22.2.4.2), large increases in gp91^{phox} immunoreactivity also co-localize in the SNpc with activated (Mac-1 immunoreactive positive) microglia, but not with astrocytes or neurons. Studies of post-mortem brains from three human subjects who, after 3–16 years previously had injected MPTP and developed parkinsonian syndromes, exhibited accumulations of activated microglial cells around dopaminergic neurons (Langston et al. 1999); however, histories of other self-administrative events remain unknown. Thus, an initial acute insult to dopaminergic neurons is thought to lead to a secondary and perpetuated neuroinflammatory response. This neuroinflammatory reaction, serves to alter homeostatic neural mechanisms or exacerbate disease processes by production of proinflammatory factors (Fig. 46.1).

In ALS patients, an abundance of data indicates the active involvement of the immune system in disease processes. Activated macrophages and perivascular microglia (mononuclear phagocytes, MPs) are found in affected tissues in ALS patients (Henkel et al. 2004; Graves et al. 2004). Several postmortem studies of tissues from ALS patients exhibiting neuronal loss compared to those of controls, demonstrate the increased presence of activated microglia in the ventral horn of the spinal cord, corticospinal tract, motor cortex, and brainstem (Henkel et al. 2004), and are thought to be involved in phagocytosis of degenerating neurons since they are found in close proximity in tissues showing early signs of degeneration. Macrophages and amoeboid microglia within those affected tissues from ALS patients exhibit upregulated HLA-A, -B, -C, -DR, -DP and -DQ molecules, CR3 (CD11b/CD18), CR4 (CD11c/CD18),

macrophage-colony stimulating factor (M-CSF) receptor (CSF-1R), β 2 integrins, CD68, MCP-1 and COX-2, which strongly suggest those microglia are in a reactive state (Kawamata et al. 1992; McGeer et al. 1993; Akiyama et al. 1994; Maihofner et al. 2003; Henkel et al. 2004). Furthermore, in vivo PET imaging using PK11195 to visualize upregulated peripheral benzodiazepine receptors by activated microglia show increased levels in the motor cortex, dorsolateral prefrontal cortex, thalamus, and pons of ALS patients. Recent works in mutant SOD1 (mSOD1) transgenic mice (see Simpson et al. Sect. 32.2.4.3) suggest a promising therapeutic strategy targeting the innate immune system. In the transgenic SOD1-G93A mice, the COX-2 inhibitor sulindac extended survival (Kiaei et al. 2005b). However, mixed and conflicting results are reported concerning the use of NSAIDs and the risk of developing ALS (Fondell et al. 2012; Tsai et al. 2015). The presence of wild type cells in the wild type/SOD1 Tg mouse chimeras enhances survival, whereas mutant SOD1 acting within non-neurons was toxic, no matter whether chimeric construction used was delivered via embryonic cells or bone marrow transplantation to irradiated recipients (Clement et al. 2003; Corti et al. 2004). To assess the role of SOD1 expression in MP cells on survival, mice transgenic for mutant SOD1 and flanking LoxP sequences (LoxSOD1) were crossed with mice expressing Cre under control of the CD11b promoter, an integrin exclusively expressed by myeloid cells (Boillee et al. 2006). Those crosses exhibited diminished SOD1 expression in microglia and macrophages, but not other cells, and extended survival compared to LoxSOD1 controls. Although no discernible differences in the activation phenotype of microglia or macrophages could be demonstrated, SOD1 expression was significantly diminished. Finally, reconstitution of SOD1-G93A/PU.1^{-/-} mice with wild-type bone marrow cells, established donor-derived microglia within the CNS, slowed motor neuron loss, prolonged disease duration and survival compared to mice treated with bone marrow cells from SOD1 transgenic animals (Beers et al. 2006). Taken together, these data suggest that targeting innate immunity and expression of SOD1 in the CNS of ALS represent a plausible therapeutic modality for ALS (Fig. 46.1).

46.3.2 Oxidative Stress

Once activated, microglia can produce noxious factors including pro-inflammatory cytokines, chemokines, quinolinic acid, and excitatory amino acids among others (Espey et al. 1997; Brown and Bal-Price 2003; Lee et al. 2002). In addition to these factors, activated microglia produce free radicals and reactive molecular species which are potentially toxic to invading organisms. NADPH oxidase (expressed by

microglia, macrophages and neutrophils) and myeloperoxidase (expressed predominately by neutrophils) are the enzymatic complexes, in their respective myeloid lineage cells, which produce radicals and reactive molecules. Among the cells in the CNS, microglia are responsible for generating a major portion of free radicals (Fig. 46.2) (Klegeris and McGeer 2000).

Reactive species of oxygen, nitrogen, and carbon are thought to play an active role in PD and ALS, wherein the very utilization and production of neurotransmitters produces harmful reactive species. The metabolism of dopamine produces H₂O₂ which can lead to inflammation and tissue damage by feeding into the ROS cycle and/or by dopamine-quinone modification of protein sulfhydryl groups via nucleophilic additions (Stokes et al. 1999). This is particularly important in PD where the ability to clear reactive oxygen species is reduced (see Sect. 46.3.2.3 Glutathione). Glutamate signaling through the NMDA receptor involves the generation of hydroxyl radicals in a NOS-dependent manner (Culcasi et al. 1994; Ayata et al. 1997). The excess of hydroxyl radicals can lead to neuronal death, which can be attenuated by antagonists of NMDA receptors (Mailly et al. 1999). In the MPTP model, NMDA antagonists alleviate parkinsonian symptoms (Steece-Collier et al. 2000), but this has not translated to PD patients (Addy et al. 2009). However, production of the majority of reactive oxygen species is mediated through the superoxide radical produced by NADPH-oxidase; the inhibition of which mitigates neurodegeneration in numerous model systems including MPTP (Wu et al. 2003). Increased nitro-tyrosine levels are detected in the SOD1-G37R model of ALS, but not hydroxyl radical markers 2,5 DHBA and MDA (Bruijn et al. 1997a). In addition, knockout of NADPH oxidase protects neurons in transgenic mice expressing mutant human SOD1-G93A (Wu et al. 2006). Lastly, the NMDA receptor antagonist [³H] MK-801 has higher binding in ALS patient brains compared to controls, suggesting that NMDA receptor expression or affinity is altered (Gredal et al. 1996). Combined, these data show that reactive molecules play substantial roles in the pathogenesis of PD and ALS.

Nitric oxide (NO) is a biological messenger molecule that has numerous physiological roles in the CNS and is associated with the protective killing function of macrophages and microglia. In contrast to the physiological roles of normal NO levels, excessive NO produced under pathological settings can act as a potent neurotoxin in a number of neurodegenerative models (Dawson and Dawson 1998). Excess NO reacts with super oxide species to form peroxynitrite, which readily crosses cell membranes and contributes to nitrotyrosine formation on proteins such as α -syn and SOD1 (see Sect. 46.2.2. Protein Nitration). In sporadic PD and some animal models, neuronal NOS (nNOS) and iNOS are both upregulated, while genetic ablation or pharmacological

Fig. 46.2 Neuroinflammatory and oxidative stress pathways in PD and ALS pathogenesis. Free radicals can arise several diverse ways, such as glial cell activation, mitochondrial dysfunction, and protein aggregation. Increased microglia activation is attributable to increased neuronal cell death and cell debris including aggregated proteins. In ALS and related-animal models, mutated SOD1 (mutSOD1) expression or aggregated TDP-43 increases aggregated proteins, neuronal death and microglial activation. Microglial derived NO and superoxide (O_2^-) species react in extracellular spaces to form peroxynitrite (ONOO^-). Peroxynitrite readily crosses cell membranes where it contributes to lipid peroxidation, DNA damage and nitrotyrosine formation in α -synuclein and other cellular proteins. Damaged proteins are targeted

to cellular proteasomes for degradation via the ubiquitination pathway. Excess NO produced by activated microglia can lead to nitration or S-nitrosylation of cellular proteins, including parkin. Such modifications may diminish E3 ubiquitin ligase activity necessary for efficient protein turnover by proteasomes. Excessive protein damage caused by oxidants and disruptions in the ubiquitin pathways may overload or inhibit protein degradation quality control measures leading to the accumulation of damaged proteins in cells. When reactive species exceed anti-oxidant defenses, oxidative stress is generated; destroying molecular structures, such as proteins, lipids and DNA, causing irreversible and detrimental damage, neuronal cell injury and death. Adapted from Gao et al. (2003)

inhibition of excess NO production is neuroprotective in the MPTP model (Przedborski et al. 1996; Liberatore et al. 1999; Hancock et al. 2008). Patients with higher UPDRS scores are associated with decreased *NOS2* (the gene for iNOS) methylation, which is suggestive of increased expression (Searles Nielsen et al. 2015). In ALS patients, expression of nNOS and endothelial NOS (eNOS) as determined by immunohistochemistry is significantly higher than that found in controls (Kashiwado et al. 2002), and iNOS expression among spinal cord infiltrates is noted in both ALS patients and the SOD1-G93A transgenic mouse model of ALS (Wong and Strong 1998; Almer et al. 1999).

46.3.2.1 DNA Modifications

Modification of nucleic acids by free radicals and reactive species can induce chromosomal aberrations with high efficiency, suggesting that chromosomal damage exhibited in neurons of PD patients might be related to an abnormally high oxidative stress. Among the most promising biomarkers of oxidative damage to nucleic acids is nucleoside 8-hydroxyguanosine (8-OHG) for RNA or 8-hydroxy-2'-deoxyguanosine (8-OHdG) for DNA. 8-OHG is an oxidized base produced by free radical attack on DNA by C-8 hydroxylation of guanine and is one of the most frequent nucleic acid modifications observed under conditions of oxidative

stress. In PD patients, levels of 8-OHG nucleic acid modifications are commonly increased in the caudate and SN compared to age-matched controls (Zhang et al. 1999). Immunohistochemical characterization of these modifications indicates that the highest levels of 8-OHG modifications are found in neurons of the SN and to a lesser extent in neurons of the nucleus raphe dorsalis and oculomotor nucleus, and occasionally in glial cells. Given that 8-OHG nucleic acid modifications are rarely detected in the nuclear area, mostly restricted to the cytoplasm, and that immunoreactivity is significantly diminished by RNase or DNase and ablated with both enzymes (Zhang et al. 1999), suggests that targets of oxidative attack include both cytoplasmic RNA and mitochondrial DNA. Of particular interest are the findings that concentrations of 8-OHG in CSF of PD patients are higher than in age-matched controls; however, serum concentrations of 8-OHG appear highly variable (Abe et al. 2003). Similarly, 8-OHdG levels are increased in CSF of PD patients compared to age matched controls (Isobe et al. 2010). Further evidence for the role of oxidized nucleic acids in PD comes from the upregulation of the enzymes that repair oxidized bases. 7,8-Dihydro-8-oxoguanine triphosphatase (MutT homolog 1 (MTH1) or nudix (nucleoside diphosphate linked moiety X)-type motif 1) hydroxylase 1) cleaves oxidized dNTPs to dNMPs to monophosphates preventing their incorporation). 8-Oxoguanine DNA glycosylase (OGG1) performs base excision repair on 8-OHdG. The mutY Homolog (MUTYH) glycosylase excises oxidized adenosine pair with guanine bases in DNA. All three enzymes are upregulated in PD compared to age matched controls (Shimura-Miura et al. 1999; Fukae et al. 2005; Arai et al. 2006). Additionally, in the MPTP model, striatal neurodegeneration is more severe in MTH1 null mice compared to WT (Yamaguchi et al. 2006). Together, these data suggest that 8-OHG or 8-OHdG are markers of oxidative damage in PD.

In ALS, 8-OHdG modified DNA is detected in spinal cord tissues (Calingasan et al. 2005) and CSF (Ihara et al. 2005) from sporadic ALS (SALS) and familial ALS (FALS) patients, while the level of nuclear 8-OHdG increased in motor cortex of SALS patients, but not FALS patients (Shibata et al. 2000). This is also recapitulated in the SOD1-G93A transgenic mouse model of ALS where 8-OHdG is increased in the spinal cord, frontal cortex and striatum (Aguirre et al. 2005).

46.3.2.2 Lipid Peroxidation

4-Hydroxy-2-nonenal (HNE) is a reactive α,β unsaturated aldehyde that is a major product during the oxidation of lipid membrane polyunsaturated fatty acids, which form stable adducts with nucleophilic groups, such as thiols and amines, on proteins. HNE modification of membrane proteins forms stable adducts that can be used as biomarkers of cellular damage due to oxidative stress. Compared to post-

mortem tissues from control subjects, immunochemical staining on surviving dopaminergic nigral neurons from PD patients show the presence of HNE-modified proteins on 58 % of the neurons compared to only 9 % from controls. Weak or no staining was detected on oculomotor neurons in the same midbrain sections from PD patients (Yoritaka et al. 1996), and the presence of HNE-modified proteins was confirmed on LB from PD and diffuse LB disease patients, but not controls (Castellani et al. 2002). HNE is increased in the caudate nucleus, but not in the putamen or the frontal cortex (Mythri et al. 2011), suggesting that lipid oxidation occurs in specific regions in patients with synucleinopathies. HNE species are typically more stable than reactive oxygen species, thus they easily spread from the site of production to modify targets at a distant site. HNE modifications of DNA, RNA, and proteins have various adverse biological effects such as interference with enzymatic reactions, induction of heat shock proteins, and are considered to be largely responsible for cytotoxic effects under conditions of oxidative stress (Toyokuni et al. 1994). The cytotoxic effects of HNE modifications may be in part due to inhibition of complexes I and II of the mitochondrial respiratory chain; induction of caspase-8, -9, and -3, cleavage of poly(ADP-ribose) polymerase (PARP) with subsequent DNA fragmentation; inhibition of NF- κ B mediated signaling pathways; or diminution of glutathione levels. Consistent with an abundance of data showing the dysregulation of proteasomal function in PD, direct binding of HNE to the proteasome also inhibits the processing of ubiquitinated proteins. Concentrations that induce no acute change in cell viability in vitro initially cause a decrease in the proteasomal catalytic activity to the extent that it induces accumulation of ubiquitinated and nitrated proteins, reductions in glutathione levels and mitochondrial activity, and increased oxidative damage to DNA, RNA, proteins, and lipids (Hyun et al. 2003). In addition to disruption of the proteasome, dopamine catabolism is impaired in the presence of HNE and malondialdehyde (MDA) (Rees et al. 2007). This leads to the accumulation of the reactive dopamine intermediates.

In SALS patients, HNE levels are significantly elevated in the sera, CSF, the ventral motor neurons and surrounding glia (Shibata et al. 2000; Simpson et al. 2004). HNE levels in serum and CSF are directly correlated with the extent of the disease, but not with the rate of disease progression. One HNE-modified protein was the astrocytic glutamate transporter EAAT2 (GLT-1) (Pedersen et al. 1998), suggesting a role for HNE-mediated impairment of glutamate transport, increased glutamate levels and excitotoxic-induced neurodegeneration in ALS. In the SOD1-G93A mouse model of ALS, three HNE-modified proteins were identified in the spinal cord, dystrophin related protein 2 (DRP-2), Hsp70 and α -enolase, proteins involved in axonal outgrowth, proper protein folding and glycolysis respectively (Perluigi et al. 2005).

46.3.2.3 Glutathione

Production of ROS and NO in neurons is buffered primarily by the glutathione (GSH) system. GSH content in the SNpc of PD patients is decreased by 40–50 %, but not in other regions of the brain, not in age-matched controls, and not in patients with other diseases affecting dopaminergic neurons (Sian et al. 1994a). This diminution continues with progression and severity of disease, suggesting a correlation with concomitant increases in reactive species (Pearce et al. 1997). GSH depletion has been suggested as the first indicator of oxidative stress during PD progression, possibly occurring prior to other hallmarks of PD including the decreased activity of mitochondrial complex I (Andersen 2004). Also, elevated GSSG/GSH ratios in PD patients (Sian et al. 1994a) argue strongly for a role of oxidative stress in this disease (Dringen 2000). An increase in glutathione peroxidase immunoreactivity, exclusive to glial cells surrounding surviving dopaminergic neurons, is observed in PD brains (Damier et al. 1993). Interestingly and possibly more important, the SN and striatum have lower levels of GSH relative to other regions of the brain, which include, in increasing order: SN, striatum, hippocampus, cerebellum, and cortex (Kang et al. 1999). Although varying in different regions of the brain, all GSH levels diminish by about 30 % in the elderly, suggesting a possible link with the age-associated risk factor for PD. GSH depletion cannot be explained by increased oxidation of GSH to GSSG as levels of both are diminished in the nigra of PD patients (Chen et al. 1989; Sian et al. 1994a). Diminished GSH levels do not appear to be caused from failure of GSH synthesis as γ -glutamylcysteine synthetase is unaltered, as are glutathione peroxidase and glutathione transferase activities (Sian et al. 1994b). Glutathione peroxidase is found near or co-localized with Lewy bodies in PD patients' brains (Power and Blumbergs 2009). In addition, *in vitro* glutathione peroxidase can accelerate the formation of and become entangled in α -syn fibrils (Koo et al. 2013). This suggests that glutathione peroxidase may interact directly with α -syn as part of PD pathogenesis. Glutathione transferase is increased in the synaptosomal fractions in PD patients compared to controls (Shi et al. 2009). Glutathione transferase also increases over the progression of PD, suggesting an attempt by neurons to detoxify oxidized proteins. Other possible mechanisms for diminished levels include increased removal of GSH from cells by γ -glutamyltranspeptidase (Sian et al. 1994b) and the formation of adducts of glutamyl and cysteinyl peptides of GSH with dopamine. Nevertheless, depletion of GSH may render cells more sensitive to toxic effects of oxidative stress and potentiate the toxic effects of reactive microglia (Chen et al. 2001). This is born out in rats where selective depletion of GSH leads to neurodegeneration of nigral neurons (Garrido et al. 2011). Inhalation of GSH by PD patients

decreases UPDRS scores showing that increasing GSH has a clinical benefit (Mischley et al. 2015) and suggesting that strategies that increase GSH may prove to be a valuable target.

Direct evidence for perturbations of the glutathione system in ALS is more limited compared to PD. One report demonstrated increased levels of oxidized NO products, higher GSH levels, and lower GSSH levels, thus lower GSSH/GSH ratios in the CSF of SALS patients (Tohgi et al. 1999). Through MRI imaging, GSH levels were determined to be lower in the motor cortex of ALS patients compared to healthy controls (Weiduschat et al. 2014). However, no change in total, oxidized or reduced GSH were detected in the erythrocytes of ALS patients compared to controls (Baillet et al. 2010), but glutathione peroxidase levels were decreased in erythrocytes of ALS patients compared to controls (Cova et al. 2010). In addition, reports of increased GSH-binding sites in the spinal cord of ALS patients could reflect an upregulation of glutathione receptors (Bains and Shaw 1997). These data suggest a decrease in GSH function in ALS, though more work is needed to test GSH expression and activity in the spinal cord and motor neurons of ALS patients. This could be especially important in familial ALS caused by mutant SOD, since this mutant protein is also part of the antioxidant system of the cell.

46.3.3 Modulation of Innate Immunity

46.3.3.1 PPAR- γ

Immune suppression through receptor modulation has been another approach attempting to alleviate or reverse PD progression. The peroxisome proliferator-activated receptor- γ (PPAR- γ), a nuclear receptor involved in carbohydrate and lipid metabolism, is upregulated in the ipsilateral substantia nigra of MPTP-treated hemiparkinsonian Rhesus monkeys compared to control and the contralateral substantia nigra (Swanson and Emborg 2014). Agonists of peroxisome PPAR- γ inhibit inflammatory responses in a variety of cell lines, including monocyte/macrophages and microglial cells (Breidert et al. 2002). *In vivo* administration of PPAR- γ agonists modulates inflammatory responses in the brain. Pioglitazone, a PPAR- γ agonist used currently as an anti-diabetic agent, has anti-inflammatory effects in animal models of autoimmune disease, attenuates glial activation, and inhibits dopaminergic cell loss in the SN of MPTP-treated mice (Breidert et al. 2002). Pioglitazone also rescued diminution of rearing events and increases in freeze time and duration for MPTP-intoxicated mice to traverse a beam (Laloux et al. 2012; Quinn et al. 2008), suggesting that this PPAR- γ agonist can also reverse some motor dysfunction. Pioglitazone also improves the clinical score,

decreases CD68⁺ cell number, and protects neurons in the striatum and the substantia nigra of MPTP-treated monkeys (Swanson et al. 2011). In addition, another full PPAR- γ agonist, rosiglitazone, has been shown to protect nigral neurons and decrease TNF- α and COX-2 expression in the striatum (Lee et al. 2012). LSN862 and GW855266X, partial agonists of PPAR- γ , protect nigral neurons and mitigate microgliosis in the MPTP mouse and 6-hydroxy dopamine (6-OHDA) rat models, respectively (Swanson et al. 2013; Sadeghian et al. 2012). Treatment with pioglitazone and GW855266X after 6-OHDA, also protects neurons in the substantia nigra as well as decreases microgliosis (Sadeghian et al. 2012). In addition, the PPAR- γ antagonist GW9662 decreases the viability of nigral neurons and further decreases neurons in the substantia nigra following MPTP intoxication (Martin et al. 2012). In cynomolgus macaques, pioglitazone reduces dyskinesia caused by L-DOPA treatment (Huot et al. 2015). Diabetic patients who were prescribed glitazone drugs had decreased incidence of PD when controlling for smoking, head injury, disease severity and other medications (Brauer et al. 2015). However a phase 2 clinical trial testing the efficacy of pioglitazone in treating PD failed to decrease UPDRS scores (Investigators. 2015) or serum IL-6, serum 8-OHdG, or PGC-1 α (Simon et al. 2015). This data suggests that PPAR- γ receptor agonists can decrease neuroinflammation and neurodegeneration in PD models, however, this has yet to be translated into a PD therapy.

Pioglitazone has not been studied to the same extent in ALS as PD, but data suggests that PPAR- γ agonists are protective in ALS models. Pioglitazone mitigates the loss of neurons in the lumbar spinal cord and the increase in microglia and astrocytes in the SOD1-G93A transgenic mouse model (Kiaei et al. 2005a; Shibata et al. 2008; Schutz et al. 2005). Pioglitazone increases survival time, improves motor performance, mitigates increased NF- κ B, iNOS, nitrotyrosine residues, phosphorylated p38, and I κ B α in the lumbar spinal cord of those mouse models of ALS. A clinical trial using pioglitazone to treat ALS was unable to increase survival time in riluzole and pioglitazone-treated group compared to those treated with riluzole alone. In fact, pioglitazone treatment increased the hazard for death by 21 %, however, this was not significant (Dupuis et al. 2012) and may be due to pioglitazone-induced metabolic dysregulation (Jawaid et al. 2014).

46.3.3.2 Minocycline and Modulators of Microglial Activation

Minocycline, a semisynthetic second generation tetracycline, easily penetrates the blood–brain barrier and has been shown recently to effectively protect from neurodegeneration in several disease models including ALS, PD, cerebral ischemia, Huntington's disease, multiple sclerosis, and spinal

cord injury (Domercq and Matute 2004), all of which involve microglial activation as the principle effector of secondary neurotoxicity. Tetracyclines prevent cell death in models of neurodegeneration by both attenuation of innate and adaptive immunity and blockage of apoptotic cascades (Domercq and Matute 2004). Minocycline specifically inhibits microglial activation and proliferation, the induction of caspase-1 and -3, iNOS, and COX-2 (Chen et al. 2000; Domercq and Matute 2004; Wang et al. 2004). Minocycline also attenuates adaptive immunity by reducing the expression and activity of matrix metalloproteinases, which alter blood–brain barrier permeability (Brundula et al. 2002; Popovich et al. 2003; Zhu et al. 2002; Domercq and Matute 2004). Minocycline can also alter the blood–brain barrier by inhibiting the function of the p-glycoprotein transporter (Milane et al. 2007). In the MPTP mouse model of PD, oral administration of minocycline attenuates microglial activation, protects dopaminergic neurons in the SNpc, and restores motor function (Peng et al. 2006). Administration of minocycline was also effective in ALS transgenic mice, which delayed onset of disease, increased motor performance, and extended survival by 2–3 weeks compared to non-treated mice (Zhu et al. 2002; Kriz et al. 2002). Minocycline decreases M1-type responses (decreased number of CD11b⁺ cells and decreased expression of CD86, CD62 TNF- α , IFN γ , and IL-1 β) and increased M2 responses (increased CD206, arginase-1, IL-4, IL-10, and Ym1) in the SOD1-G93A transgenic model of ALS (Kobayashi et al. 2013). Based on these results, and early human trials showing minocycline is safe in humans (Pontieri et al. 2005), a phase III clinical trial was initiated to treat ALS patients. However, patients given minocycline had a trend toward more rapidly progressing and severe disease compared to placebo control (Gordon et al. 2007). Other modalities that have been used successfully to attenuate microglia activation in models of neurodegeneration include non-steroidal anti-inflammatory agents (Dairam et al. 2006), COX-2 inhibitors such as rofecoxib (Hewett et al. 2006) and parecoxib (Reksidler et al. 2007), and dextromethorphan (Zhang et al. 2006) among others (Fig. 46.1).

Free radical production by activated microglia accompanied by dysregulation of antioxidants (e.g., SOD1, glutathione and catalase) diminish the protective potential by establishing a pro-oxidative stress environment. In turn, these antioxidants may be used therapeutically to modulate the microglial response. While SOD-1 and GSH levels decline in PD patients (Poirier et al. 1994; Kunikowska and Jenner 2003), gastrodin (Wang et al. 2014), melatonin (Zaitone et al. 2013), and exercise (Tsou et al. 2015) protect nigral neurons, as well as increase GSH and SOD expression in the MPTP model. Despite this success in animal model, these strategies to reduce inflammation in PD patients have met with limited success to date.

46.4 Adaptive Immunity

46.4.1 Cell-Mediated Immunity

While naïve T cells are typically precluded from CNS entry, neuroinflammation aggressively recruits activated components of the adaptive immune system to sites of active neurodegeneration by increasing expression of cellular adhesion molecules and inducing chemokine gradients. Moreover, glial cells secrete toxic factors that disrupt blood brain barrier function. Nonetheless, evidence indicates a far more complex relationship between the CNS and immunological system than previously realized. Further challenging this view of the “immune privileged” status of the CNS are severe combined immunodeficiency (SCID), RAG2 knockout and CD4⁺ depleted mice which have exacerbated neuronal loss following facial neuron axotomy (Serpe et al. 1999, 2003). However, reconstitution of these mice with splenocytes and more specifically CD4⁺ T cells help protect damaged facial nerves. Rodents and humans that have sustained CNS injuries also have expanded T cell repertoires against myelin-associated antigens, yet do not appear to be at increased risk for the development of CNS autoimmunity (Jones et al. 2002, 2005; Popovich et al. 1996). Any functional consequence of such T cell responses against CNS antigens following injury remains to be determined.

Evidence exists for associations between HLA type and PD. Early reports identified significant association of PD with expression of HLA-Aw24, -B14, -B16, -B17, -B18, -A2, and -A28 (Hoffman et al. 1977; Elizan et al. 1980), whereas later works failed to detect significant deviations of HLA haplotypes among PD patients compared to unaffected controls (Marttila et al. 1981; Lees et al. 1982). Interestingly, a study analyzing HLA class I and II alleles among 45 German PD patients demonstrated a significant increase in the representation of the DQB1*06 allele suggesting an association between idiopathic PD and the immune system (Lampe et al. 2003). The association of HLA-DQB1 alleles in PD patients was verified by genome-wide association studies (Nalls et al. 2014). Meta-analysis of genome-wide association databases has also indicated that HLA-DRB1*04 and HLA-DRB1*08 are also associated with increased incidence of PD (Ahmed et al. 2012).

The association of any one HLA type with ALS is controversial. While some studies found no statistical association with ALS (Bartfeld et al. 1982; Norris et al. 1986; Woo et al. 1986), others found increased incidences of ALS patients that express HLA-A3, -A12, -Bw40, -Bw35 (Antel et al. 1976; Jokelainen et al. 1977; Hoffman et al. 1978; Kott et al. 1979). Additionally, milder disease progression may be associated with HLA-Bw40 (Jokelainen et al. 1977), whereas more aggressive disease is associated with HLA-Bw35 (Hoffman et al. 1978). The discrepancies between these studies may be

explained by different populations examined and/or the relatively small numbers of patients in these studies.

In PD patients, increased numbers of CD8⁺ T cells are found in close proximity to activated microglia and degenerating neurons within the SN; however, those numbers are consistently low (McGeer et al. 1988b). In the MPTP mouse model, numbers of CD8⁺ and CD4⁺ T cells are significantly increased as late as day 21 post-intoxication with mean CD4/CD8 ratios of 0.33 ± 0.07 (range 0.19–0.64) (Kurkowska-Jastrzebska et al. 1999), lower than CD4/CD8 ratios typically found in the peripheral circulation. Whether these infiltrating T cells are activated, antigen-specific, or migrating in response to microglial inflammation has yet to be determined, but the presence of major T cell subsets at levels exceeding those typically found in the CNS and in lower ratios found in the periphery suggests a more substantial role in PD than that associated with surveillance. In that vein, numerous aberrations in peripheral lymphocyte subsets are detectable in PD patients. Compared to age-matched controls, numbers of total lymphocytes, CD19⁺ B cells and CD3⁺ T cells were diminished in both drug-naïve and -treated PD cohorts (Bas et al. 2001). Among CD3⁺ T cells, numbers of CD4⁺ T cells were diminished; whereas, numbers of CD8⁺ T cells were not significantly changed. The frequencies of cells within CD4⁺ T cell subsets are differentially diminished, with a greater loss of naïve helper T cells (CD45RA⁺) and either unchanged or increased effector/memory helper T cell subset (CD29⁺ or CD45RO⁺) (Bas et al. 2001). The decrease in CD4⁺ cells correlates with more severe PD disease symptoms (Stevens et al. 2012). Increased frequencies of T cells with effector-type phenotype were noted in PD patients compared to age- and environment-matched controls (Saunders et al. 2012). Moreover, increasing frequencies of CD4⁺ T cells that expressed CD45RO⁺ or FAS⁺ were correlated with diminishing motor dysfunction as determined by increased UPDRS part III scores, whereas those that expressed CD31 or $\alpha 4\beta 7$ integrin diminished with increased UPDRS scores. The relative balance of the different CD4⁺ subsets is also changed with increased levels of Th1 and Th17 cells and decreased frequencies of Th2 and Tregs (Chen et al. 2015). Not only is T cell number altered during PD, but function may also be changed. Regulatory T cells (Tregs) from PD patients have less suppressive ability than Tregs from age- and environment-matched controls (Saunders et al. 2012). Experiments in the MPTP model demonstrated a detrimental role for CD4⁺ cells. SCID mice (Benner et al. 2008) and mice deficient in CD4⁺, but not CD8⁺ cells (Brochard et al. 2009) show no significant loss of dopaminergic neurons in the SN of MPTP-treated mice. These data from PD patients and mouse models suggest that alterations of T cell frequencies and function play a determinative role in the development and progression of PD.

The increased mutual co-expression of CD4 and CD8 by CD45RO⁺ T cells, as well as upregulation of CD25 (α -chain of the IL-2 receptor), TNF- α receptors, and significant down-regulation of IFN- γ receptors suggests that at least some T cell subsets are activated in PD patients. However, evaluation of these parameters to assess whether activated T cell phenotypes are derived from any one T cell subset or many subsets have yet to be incorporated into one study. Interestingly, a significantly greater number of micronuclei and unrepaired single strand DNA breaks, shown to result from exposure to higher levels of oxidative stress and inflammation (Cerutti 1985), are detected in lymphocytes and activated T cells from PD patients compared to age-matched controls (Petrozzi et al. 2002; Migliore et al. 2002). Moreover, 8-OHG is increased in peripheral leukocytes as well as decreased levels of glutathione peroxidase and vitamin E in PD patients compared to controls (Chen et al. 2009). Lymphocytes from PD patients also have increased total basal and mitochondrial ROS compared to controls (Prigione et al. 2009).

In ALS patients, lymphocytes, as well as myeloid cells, are consistently found within or around affected tissues (Graves et al. 2004). Tissues with lymphocytic infiltrates include spinal cords, brain, muscles, and associated vessels (Graves et al. 2004). Most reports have identified the infiltrating lymphocytes as T cells, with a minor presence of B cells. Most indicate that both CD4⁺ and CD8⁺ T cells are present within affected tissues. One report indicated the presence of CD8⁺ T cells, with rare CD4⁺ cells in the anterior and lateral corticospinal tracts and anterior horns (Troost et al. 1990), while another reported the presence of primarily CD4⁺ T cells with rare CD8⁺ cells in muscle (Troost et al. 1992). Although not rigorously examined, a consensus suggests that these T cells are in an activated state by the presence of upregulated surface markers such as MHC I and II molecules (Troost et al. 1992) and CD40 ligand (CD40L) (Graves et al. 2004). Of particular interest is the finding that PCR amplification of the third complementarity-determining region (CDR3) to examine the T cell receptor (TCR) repertoire of infiltrating T cells in cerebral spinal fluid (CSF), spinal cords and brains of ALS patients showed increased utilization of TCRBV2 (variable region 2 of the T cell receptor β -chain) transcripts, which was independent of HLA haplotype (Panzara et al. 1999). This result suggests there is specific expansion of T cells with a T cell receptor containing variable region 2 in ALS patients.

Early studies of ALS patient peripheral blood revealed a general loss of T cells as demonstrated by reduced numbers of E-rosetting T cells (a function mediated by CD2), and later confirmed by flow cytometric analysis showing significant losses of total CD2⁺ T cells with concomitant increase with increased numbers of surface Ig⁺ B cells (Provinciali et al. 1988). Other studies have failed to show significant differences in T or B cell frequency or function (Appel et al.

1986). Analyses of T cell subsets in ALS patients relative to normal controls show variable results, and include diminished or increased frequencies of CD4⁺ cells, diminished or unchanged CD8⁺ T cell frequencies (Mantovani et al. 2009; Chen et al. 2014). Of interest, ALS patients exhibit increased frequencies of both CD4⁺ and CD8⁺ T cells that co-express IL-13, a phenotype functionally associated with immunoregulatory functions (Shi et al. 2007). Increased frequencies of CD4⁺IL-13⁺ T cells are inversely correlated with clinical score, while the CD8⁺IL-13⁺ T cells directly correlate with the rate of disease progression (Shi et al. 2007). Additionally, numbers of CD4⁺ T cells that express IL-9, IL-17, IL-21 and IL-22 are increased in ALS (Saresella et al. 2013). ALS patients with more severe disease progression have diminished Treg numbers (Mantovani et al. 2009; Henkel et al. 2013). Of interest, in a minor subset of ALS patients with persistent motor conductance blockage, but not those without blockage, frequencies of CD3⁺, CD4⁺, and CD8⁺ T cells, as well as CD16⁺ mononuclear cells are increased, suggesting a relationship between peripheral blood abnormalities and pathogenic processes associated with conduction blockage in ALS patients (Tanaka et al. 1993). However, unlike the MPTP model of PD, depletion of CD4⁺ T cells in the SOD1 transgenic model of ALS leads to faster disease onset (Beers et al. 2008).

46.4.2 Humoral Immunity

The possibility that humoral immunity may play a role in either the initiation or regulation of PD has arisen from experimental studies triggering dopaminergic neuron degeneration, including the observation of C1q⁺ microglia (Depboylu et al. 2011), and neurons that stain with anti-IC3b and anti-C9 in the SN of PD patients (Loeffler et al. 2006). In both idiopathic and genetic cases of PD, pigmented dopaminergic neurons and Lewy bodies showed significant increased immunolabeling with IgG, but not IgM, and were associated with increased numbers of activated microglia expressing the high affinity IgG receptor Fc γ RI (Orr et al. 2005). One of the curiosities in PD is the presence of naturally occurring autoantibodies reactive to α -syn. Depending on the study, PD patients either have increased (Papachroni et al. 2007), decreased (Besong-Agbo et al. 2013) or no significant change (Heinzel et al. 2014) in the concentration of these antibodies in the serum compared to healthy controls. These autoantibodies are possibly associated with clearance processes for extracellular Lewy bodies, and as such may reflect a protective mechanism. It is also possible that these autoantibodies are reacting with α -syn on the surface of neurons which could mediate neuronal death. In addition, increased levels of autoantibodies to myelin oligodendrocytic glycoprotein (MOG), myelin basic

protein (MBP), myelin-associated glycoprotein (MAG), and proteolipoprotein (PLP) are detected in PD patients compared to healthy controls (Papuc et al. 2014). As with α -syn, the role these autoantibodies play in PD symptomology or disease progression remains unclear.

Perhaps the most studied of immune-associated aspects in ALS patients are those of humoral immunity. Global alterations of humoral immunity include increased IgG, IgA and immune complexes in the serum (Hoffman et al. 1981; Saleh et al. 2009); and the presence of immune complexes have been detected within kidney, spinal cord and motor cortex of ALS patients (Oldstone et al. 1976; Palo et al. 1978; Donnenfeld et al. 1984). Circulating immune complexes and complement component C3 are increased in ALS patients (Chen et al. 2014). The same is true of SOD1-G93A transgenic mice, wherein IgM and complement C3 are detected on motor neurons (Chiu et al. 2009). These humoral aberrations and depositions of humoral products provoked an increased impetus for an autoimmune approach to ALS etiology. Thus, many studies have assessed the possible antigenic reactivities of those antibodies. Those reactivities from ALS patients' sera and CSF comprise epitopes associated with nervous and non-nervous tissues as well. Nervous system specificities in ALS encompass those directed against moieties from spinal cord, motor neurons (Engelhardt and Appel 1990), neurofilaments (Niebroj-Dobosz et al. 2006) myelin (Edgington and Dalessio 1970), and Ca^{2+} channels (Smith et al. 1992; Kimura et al. 1994). The plethora of data showing antibody reactivities to gangliosides especially among IgM antibodies (Pestronk et al. 1989; Li and Pestronk 1991; Ben Younes-Chennoufi et al. 1992) is thought to reflect a possible pathogenic role in motor neuron diseases; however the mechanism by which those antibodies exact their toll has not been ascertained. ALS patients have increased IgG levels that bind oxidized SOD1 (van Blitterswijk et al. 2011). Interestingly, high levels of IgM that are reactive to oxidized SOD1 are associated with longer survival, whereas higher concentrations of IgG reactive to SOD1 are associated with shorter survival. Co-culture with neuronal tissues and passive transfer of sera or immunoglobulin from patients and immunized animals to rodent recipients has revealed functional consequences of these reactivities relative to ALS clinical signs. Passive transfer yields increased presence of human IgG in spinal cord motor neurons and neuromuscular junctions with increased miniature end-plate potential (MEPP) frequency (Appel et al. 1991), increases in the rate of spontaneous neurotransmitter release, and axonal degeneration and denervation in most muscles (Uchitel et al. 1992). Within 12–24 h of IgG transfer, increases are found in the densities of synaptic vesicles, CSF glutamate concentrations, Ca^{2+} levels in axon terminals of neuromuscular junctions and synaptic boutons on spinal motor neurons (Engelhardt et al. 1995, 1997; La Bella et al. 1997; Pullen

et al. 2004). Antibodies are internalized with increased phosphorylation of neurofilament H (Engelhardt et al. 1995) while Golgi system and rough endoplasmic reticulum dilate with concomitant increased Ca^{2+} levels that are precipitously depleted after 24 h (Engelhardt et al. 1997; Pullen et al. 2004). By 72 h after transfer, CSF glutamate and aspartate levels increase, without appreciable change in glutamine and glutathione levels (La Bella et al. 1997). By 8 days post-transfer, areas of neuronal cell necrosis are evident (Pullen et al. 2004) and sensitivity to L-type Ca^{2+} channel blockers is retained for up to 4 weeks post transfer (Fratantoni et al. 2000). Thus, passive transfer of immunoglobulin from ALS patients appears to lead to long-lasting effects of motor neurons at the neuromuscular junction and may reflect early stage events in immune-mediated pathogenesis of ALS.

46.5 Therapeutic Immunoregulation

46.5.1 Cell-Mediated Immunomodulation

Another potential therapeutic avenue for PD involves T cell-mediated immune responses (Fig. 46.1). Activation of T cells directed against antigens expressed at the injured areas of the CNS can be neuroprotective under acute and chronic neurodegenerative conditions (Kipnis et al. 2002). However, immunization with such antigens typically leads to development of autoimmune disease. Immunization with copolymer-1 (Cop-1, glatiramer acetate, Copaxone) or passive transfer of Cop-1 specific T cells is beneficial for protecting neurons from secondary degeneration after injurious conditions (Kipnis et al. 2000; Benner et al. 2004). Cop-1 reactive T cells have partial cross-reactivity with myelin basic protein (MBP) and other self-antigens expressed in the brain (Arnon and Sela 2003). Therefore, immunization with Cop-1 leads to increased accumulation of T lymphocytes in areas of injury within the brain and spinal cord and is neuroprotective without causing any adverse effects; however, the molecular mechanism of this response is not fully understood. T cells reactive to Cop-1 could be a source of brain-derived neurotrophic factor (BDNF) and other neurotrophic factors (Kipnis et al. 2000) or can induce production of neurotrophins by microglia or astroglia. Moreover, Cop-1 is a strong inducer of Th2 cells that secrete anti-inflammatory cytokines (Wang et al. 2011; Ibarra et al. 2007; Sela and Mozes 2004; Aharoni et al. 1997, 2000; Arnon and Sela 2003). In the MPTP model of PD, adoptive transfer of T cells from donors immunized with Cop-1, but not those from ovalbumin immunized donors, are neuroprotective for dopaminergic neurons within the substantia nigra as well as the striatal termini, and attenuates reactive microglial neuroinflammation (Benner et al. 2004). Additionally, adoptive transfer of those T cells prevents the loss of nigral N-acetylaspartate (NAA) levels

Fig. 46.3 T cell-mediated neuroprotection in a PD model. In MPTP-intoxicated mice, regulatory T cells infiltrate the inflamed nigrostriatal pathway where they encounter cross-reactive CNS antigens (such as myelin basic protein or reactive species-modified proteins) presented in the context of MHC by resident microglial cells. In response, activated T cells secrete anti-inflammatory cytokines such as IL-4, IL-10, and TGF- β that suppress toxic microglial activities. Neurotrophin expression may occur directly from T cells or T cell-derived IL-4, and IL-10 may induce neurotrophin production in neighboring glia. These activities lead to neuroprotection indirectly by suppression of microglial responses and directly through the local delivery of neurotrophins

associated with MPTP-induced neurodegeneration as determined by quantitative proton magnetic resonance spectroscopic imaging (^1H -MRSI) (Boska et al. 2005). Suppression of microglial-associated inflammation was associated with T cell accumulation within the SNpc, induction of a type 2 helper T cell (Th2) response with production of anti-inflammatory cytokines (IL-4, IL-10), and increased expression of glial cell-derived neurotrophic factor (GDNF) by astrocytes, but not by infiltrating T cells or microglia (Benner et al. 2004). CD4 $^+$ T cells, rather than CD8 $^+$ T cells, are primarily responsible for the bulk of the neuroprotective capacity, while passive transfer of anti-Cop-1 antibodies provide no apparent neuroprotection (Laurie et al. 2007). In addition, adoptive transfer of anti-CD3 activated CD4 $^+$ CD25 $^+$ regulatory T cells (Tregs), but not activated effector T cells, ameliorates MPTP-induced neuroinflammation and dopaminergic neurodegeneration with as few as 3.5×10^6 Tregs mediating virtual complete neuroprotection (Reynolds et al. 2007). Moreover, Tregs attenuate reactive microglia responses in vivo

and responses to inflammatory stimuli including nitrated α -syn as well as enhancing GDNF and BDNF gene expression and production by astrocytes.

Immunization with Cop-1 extends survival by 25 % in the SOD1-G93A transgenic mouse model of ALS (Angelov et al. 2003), however, the extended survival was not verified by others (Habisch et al. 2007; Banerjee et al. 2008), though onset of motor symptoms was delayed (Habisch et al. 2007). Much like PD, Cop-1 is thought to have a therapeutic effect in ALS by inducing regulatory T cells (Th2, Th3, or Tregs) in an epitope specific or non-specific manner. These activated Tregs extravasate in response to neuroinflammation from neurodegenerative processes; secrete anti-inflammatory cytokines in response to cross-reactive self-epitopes (e.g. myelin basic protein) to attenuate reactive microglia; suppress the inflammatory response; and induce neurotrophic responses by T cells and/or other glia (Fig. 46.3). This notion is supported by Cop-1-treated ALS patients that exhibit increased IgA, IgG and IgM reactivities to Cop-1 and

increased Th2/Th1 cytokine ratios in treated patients' serum (Mosley et al. 2007). In addition, the adoptive transfer of wild type Tregs into SOD1-G93A transgenic mice improved survival and delayed onset of motor dysfunction (Banerjee et al. 2008), suggesting the protective capability of increasing Treg numbers or function this ALS model. Treatment with Cop-1 is well-tolerated by ALS patients who exhibited both humoral and T cell-mediated immune responses (Gordon et al. 2006). However, Cop-1 was unable to delay the decline of motor function or the time to death, tracheostomy, or positive pressure ventilation compared to controls (Meininger et al. 2009). Despite the lack of success with Cop-1, induction of Tregs may prove to be a possible target for the treatment of ALS and other neuroinflammatory diseases.

The recent development of novel immune-mediated therapeutic vaccine strategies for disease intervention and attenuating neuroinflammation are predicated on the ability of Tregs, either induced or naturally occurring, to modulate both innate and adaptive immune responses and suppress inflammation both in autoimmune disease and in models of neurodegeneration. Treatment with vasoactive intestinal peptide (VIP) is emerging as a therapeutic tool to generate Tregs both *in vitro* and *in vivo*. VIP originates as a neuropeptide that functions as both a neurotransmitter and neuromodulator in many organ systems, including the central and peripheral nervous systems (Said 1976). VIP-containing neurons are present in the CNS in areas that influence the immune system as well as in lymphoid organs, and are thought to be involved in the recruitment of immune cells, many of which express receptors for VIP (Kaltreider et al. 1997; Reubi et al. 1998, 2000). VIP is also produced by lymphocytes, preferentially Th2 T cells, in response to different mitogenic or inflammatory stimuli (Delgado et al. 2005; Gomariz et al. 1990, 1992; Leceta et al. 1996). Th2-derived VIP also acts as an autocrine regulator by promoting Th2 responses *in vivo* (Delgado et al. 1999, 2000, 2002; Goetzl et al. 2001; Vassiliou et al. 2001; Voice et al. 2003). Additionally, VIP treatment was efficacious for the induction of Tregs in a variety of inflammatory disorders including arthritis, graft versus host disease, and experimental allergic encephalitis (EAE) (Delgado et al. 2005; Fernandez-Martin et al. 2006). VIP has also been used to expand regulatory T cells *ex vivo* and elicit conversion of CD4⁺CD25⁻ T cells to Tr1 regulatory T cells. Thus, VIP can be utilized to generate Tregs specific for self-antigens that can in turn promote antigen-specific tolerance and suppress development of autoimmune disorders in a variety of animal model systems (Fig. 46.1) (Delgado et al. 2005; Fernandez-Martin et al. 2006; Gonzalez-Rey et al. 2006). Splenocytes and Tregs from VIP-treated mice protect tyrosine hydroxylase-expressing neurons in the substantia nigra and striatum of MPTP-intoxicated mice as well as decrease the numbers of

activated microglia and degenerating neurons (Reynolds et al. 2010). Direct intra-nigral injection, and to a lesser extent intraperitoneal injection of VIP also led to neuroprotection, decreased microgliosis, and decreased levels of TNF- α , IL-1 β and iNOS expression in the MPTP mouse model (Delgado and Ganea 2003). In the 6-OHDA rat model of PD, intraperitoneal administration of VIP decreased lipid peroxidation, DNA fragmentation, SOD and catalase activity and NO levels (Tuncel et al. 2012). In the 6-OHDA rat model, VIP administration also increased synaptic density in the striatum compared to rats treated with 6-OHDA alone, suggesting that VIP plays a role in repairing or forming new synapses (Korkmaz et al. 2012). VIP's neuroprotective effect is mostly mediated by binding VIP receptor 2 (VIPR2, VPAC2). This was determined by creating agonists specific for each of the 2 VIP receptors and testing the neuroprotective and anti-inflammatory effects in the MPTP model of PD (Olson et al. 2015). VIP is also effective in the SOD1-G93A transgenic mouse model. Intraperitoneal injections of the lipophilic VIP-derivative stearyl-norleucine-VIP extended survival, increased the time until weight loss, and delayed onset of motor dysfunction compared to controls (Goursaud et al. 2015). Moreover, astrogliosis and microgliosis were diminished and proinflammatory mediators such as IL-1 β , NO, and TNF- α were diminished, while the expression in the spinal cord of IL-10, BDNF, and GDNF were promoted suggesting that VIP decreased inflammation.

Selective activation of particular subsets of dendritic cells (DCs) with 1,25-dihydroxyvitamin D3 (the active metabolite of vitamin D3) or GM-CSF (Fig. 46.1) can not only activate lymphocytes, but also induce T cell tolerance to self-antigens or to specific antigens tandemly administered as immunization or tolerization regimens. DCs also can affect B cell function, antibody synthesis, and isotype switching. DCs stimulated with GM-CSF or 1,25-dihydroxyvitamin D3 may exert tolerogenic functions through arresting type 1 helper T cells (Th1), skewing the Th1/Th2 balance, and generating Tregs (Gangi et al. 2005; Gregori et al. 2002; Vasu et al. 2003). In addition to its effects on DCs, 1,25-dihydroxyvitamin D3 can also increase autophagy (Li et al. 2015) and increase the number of cells expressing GDNF (Sanchez et al. 2009), both of which may be neuroprotective. The neuroprotective ability of vitamin D3 in PD was tested in a clinical trial that showed no worsening of clinical signs as determined by Hoehn and Yahr, and UPDRS II scores, whereas the placebo-treated group showed significant worse scores (Suzuki et al. 2013). Moreover, total Parkinson's disease questionnaire 39 (PDQ39) and PDQ39 bodily support scores improved or did not diminish in patients treated with vitamin D3, however, significantly declined in the placebo controls. This suggests that vitamin D3 may slow the decline in PD for the short term. In the SOD1-G93A transgenic mouse model of ALS,

a 10-fold increase in dietary vitamin D3 increased movement ability, motor performance, and paw grip endurance (Gianforcaro and Hamadeh 2012). Together, these data suggest that vitamin D3 plays a role in symptom alleviation in animal models as well as PD and ALS.

In addition to the effects on DCs, GM-CSF is protective in the MPTP and paraquat models of PD. Pretreatment with GM-CSF prior to MPTP intoxication or adoptive transfer of GM-CSF-induced Tregs protected dopaminergic neurons in the SN, diminished microgliosis, and restored spontaneous movement (Kim et al. 2009; Kosloski et al. 2013). Administration of GM-CSF into the SN leads to neuroprotection and decreased microgliosis following paraquat treatment (Mangano et al. 2011). Due to the neuroprotective capacity in the MPTP model, a Phase I clinical trial (NCT01882010) is underway to determine the safety of GM-CSF in PD patients and the effect on PD patient immune profiles.

46.5.1.1 Modulation of Humoral Immunity

Using another vaccine strategy to elicit humoral immune responses directed at cephalic epitopes, immunization of human α -syn transgenic mice with mutant human α -syn produced high affinity anti- α -syn antibodies with concomitant diminution of human α -syn inclusions in neurons and synapses, and diminished neurodegeneration (Masliah et al. 2005). Moreover, anti- α -syn antibodies recognized abnormal human α -syn and supported degradation of α -syn aggregates. In addition, in the MPTP model of PD, Fc γ receptor and RAG2 knockout mice are more resistant to loss of dopaminergic neurons than wild type mice suggesting an important role for humoral responses in neuroprotection (Lira et al. 2011). However, as stated in Sect. 46.4.2, not all PD patients have increased anti- α -syn antibodies (Heinzel et al. 2014; Besong-Agbo et al. 2013). In PD mouse models, the addition of exogenous anti- α -syn antibodies decreases α -syn fibrils (Games et al. 2013, 2014; Lindstrom et al. 2014). In addition, human intravenous immunoglobulin that contain an unknown mix of antibodies from thousands of donors, can bind monomeric and oligomeric α -syn. However, these antibodies were not able to significantly decrease α -syn fibril formation in vitro (Patrias et al. 2010; Smith et al. 2012). Several ongoing clinical trials using humanized anti- α -syn antibodies to clear truncated and aggregated α -syn (NCT02157714 and NCT02095171). Along those same lines, mimetopes for α -syn have been used in vaccine strategies for clearing extraneuronal α -syn deposits (Schneeberger et al. 2012; Mandler et al. 2014). Several clinical trials using these strategies (NCT01568099, NCT01885494, NCT02618941, and NCT02216188) are actively ongoing or have been completed, but not yet published.

Similarly, immunization of SOD1-G37R transgenic mice with recombinant mutant SOD1 reduced the amount of

mutant SOD1 in spinal cords of immunized mice, increased numbers of surviving motor neurons, and extended life span by greater than 4 weeks, which significantly correlated with increasing anti-SOD1 antibody titers (Urushitani et al. 2007). In contrast, this strategy failed to protect SOD1-G93A mice, which exhibit a more severe and aggressive phenotype than SOD1-G37R mice, however ventricular infusion of purified anti-human SOD1 antibody alleviated clinical signs and significantly extended life span by 4 %. These data provide support for immunotherapeutic strategies that target extracellular burdens of aggregated or misfolded toxic proteins such as α -syn and SOD1 in neurodegenerative disorders (Fig. 46.1).

46.5.1.2 Other Vaccine Strategies

One quasi-immunotherapeutic strategy targets intracellular accumulation of toxic proteins in neurons by using single chain antibodies (scFv) or intrabodies (Chen et al. 1994) (Fig. 46.1). This strategy is accomplished intracellularly by preventing misfolding of proteins to toxic forms, interfering with misfolded protein interactions, or enhancing degradation of the toxic form. Clearly, keys to this strategy are the production of scFv with affinities that retain epitope specificities in vivo and efficacious delivery to vulnerable or affected neurons. For delivery, genes encoding the scFv must be transfected into target cells and successfully expressed as a functional intrabodies. Several scFv to α -syn have been prepared (Emadi et al. 2004, 2007; Maguire-Zeiss et al. 2006; Barkhordarian et al. 2006; Miller et al. 2005). Several of those scFv recognize different conformations of α -syn, and upon co-incubation with monomeric α -syn in vitro, decrease the rate of α -syn aggregation, inhibit formation of oligomers and protofibrils, and inhibit toxicity. In transfected cells, scFv are stably expressed for greater than 3 months with minimal toxicity, bind intracellular α -syn, increase the amount of detergent soluble α -syn species, while decreasing the amount of insoluble species, and counter the reduced cell adhesion which characterizes cells that overexpress α -syn (Messer and McLearn 2006). When scFv reactive to α -syn are expressed in neurons, total, oligomeric and phosphorylated α -syn is diminished in transgenic mice expressing human α -syn (Spencer et al. 2014). Thus, anti- α -syn scFv have the potential to provide a therapeutic modality to control intracellular accumulation of toxic protofibrillar forms of α -syn, and possibly diminish or delay disease progression (Fig. 46.1). Similar findings were found in ALS mouse models. The expression of scFv against SOD1 decreases the number of SOD1 aggregates and increased cell survival (Ghadge et al. 2013). In addition, the expression of scFv in SOD1-G93A transgenic mice increases survival and time until disease onset (Patel et al. 2014). Thus, this data indicates that in PD and ALS models, scFv reduce the effects of protein misfolding in neurons and suggests a potential beneficial role as a therapeutic strategy in PD and ALS.

Therapeutic vaccine approaches using neuronal antigens represent a potential efficacious interdictory modality for slowing or halting the progression of neuroinflammation and secondary neurodegeneration and removing neurotoxic aggregates (Fig. 46.1). These approaches should be considered in strategies with other anti-inflammatory or antioxidant therapies for a combinatorial modality to protect against neuroinflammation and consequent neurodegeneration in PD and ALS. Since these interventions have failed to produce results individually and elements of innate and adaptive immunity contribute to inflammation, perhaps a combination would be more effective at ameliorating detrimental immune responses.

46.6 Neuroprotective Strategies

46.6.1 Growth Factors

The role of neurotrophins in reducing neurodegeneration and promoting neuroregenerative processes presents an exciting possibility for therapy in PD (Fig. 46.1). A study of lentiviral delivery of GDNF showed trophic effects on degenerating nigrostriatal neurons in a primate model of PD (Kordower et al. 2000). Results indicated the augmentation of dopaminergic functions in aged monkeys and reversal of functional deficits with complete prevention of nigrostriatal degeneration in MPTP-treated monkeys. These data indicate that GDNF delivery using a lentiviral vector system can prevent nigrostriatal degeneration and potentially induce regeneration in primate models of PD, showing the potential for a viable therapeutic strategy for PD patients. However, clinical trials of intraputamenally infused GDNF in PD patients are controversial with one 2-year phase I trial showing improved UPDRS scores and increased ^{18}F -dopa uptake in the putamen and no untoward effects in a limited cohort (Patel et al. 2005), while phase II trials were halted after 6 months due to lack of efficacy and adverse effects in patients (Nutt et al. 2003; Lang et al. 2006). Of note, several parameters that affect delivery of GDNF were changed between the trials. Several different strategies to deliver GDNF have been developed including delivery by installation of GDNF genes, GDNF-engineered mesenchymal stem cells, nanoformulated GDNF, AAV-GDNF gene constructs, continuous intracerebral administration of methionylated GDNF (Aly and Waszczak 2015; Hoban et al. 2015; Agbay et al. 2014; Peng et al. 2014; Wakeman et al. 2014); the latter two strategies are in clinical trials (NCT01621581 and NCT00006488).

Growth factors have also been used in the treatment of ALS. Intrathecal administration of BDNF has been used in different clinical trials of ALS patients; however, no significant beneficial effects were demonstrated (Kalra et al. 2003;

Beck et al. 2005). More recently, human progenitor cells over-expressing human GDNF were injected into the cisterna magna of SOD1-G93A transgenic mice, and differentiated into astrocytes, released GDNF, and protected motor neurons from degeneration; however microgliosis, loss of limb function, or survival were not affected (Suzuki et al. 2007; Park et al. 2009). Thus, strategies for treatment of PD and ALS with neurotrophic factors provide promising potential for neuroprotective benefit, however, to date, these strategies have yet to be proven efficacious in neurodegenerative diseases.

46.6.2 Neuroprotectants

Many diverse mechanisms, factors, and pathways are involved in neurodegenerative disorders, thus several different therapeutic methods have been developed to target a specific factor or an entire intricate pathway with the intent of ameliorating, preventing, or reversing neuronal cell damage. Inflammation and oxidative stress form a commonality between many neurodegenerative diseases; therefore most therapeutic modalities currently under investigation target MP activation to decrease the magnitude of the inflammatory responses. The targets of these therapies include, but are not restricted to, enhancement of neurotrophic factors such as GDNF, upregulation of anti-inflammatory cytokines (IL-4, IL-10, and TGF- β 1), inhibition of enzymatic activities that encourage neurotoxicity (GSK-3 β , γ -secretase), Ca^{2+} and glutamate excitotoxicity blockers that inhibit NMDA receptor function, antagonism of A2A receptors that stimulate release of GABA in the globus pallidus and suppress neuronal cytotoxicity (memantine, lithium, sodium valproate), and attenuation of inflammation by anti-inflammatory drugs (NSAID, minocycline) or β 2 adrenergic receptor agonists (norepinephrine, salmeterol). Anti-inflammatory and/or anti-oxidative therapies could be used in conjunction to form combinational therapies targeting multiple sites of oxidative stress that contribute to inflammatory responses and progressive degenerating disease (Fig. 46.1).

It should be noted that these therapies have shown promise in animal models, but have yet to be translated into patients. The exact reasons for this discrepancy between models and patients are unknown (Athauda and Foltynie 2015), but could be related to translating effects from an acute model to the progressive disease in patients. It should also be noted that patients receiving treatments may need more than palliative therapy to recover motor function. Perhaps neuroregeneration, as well as neuroprotective therapy is required for full recovery of motor function.

46.7 Genetics and Immunity

Recent evidence has shown that genetics may contribute to the onset of neurodegenerative disorders (Li et al. 2002). Familial PD is associated with several mutations in proteins such as α -syn, parkin, DJ-1 and others (Hardy et al. 2003). Genome-wide association studies (GWAS) of PD patients implicate several genes, including *STK39*, *BST1*, *SNCA*, *LRK2*, *CCDC62* and *MAPT* as being associated with PD (International Parkinson Disease Genomics Consortium et al. 2011; Lill et al. 2012; Nalls et al. 2014). Further analysis revealed some immune-related genes are associated with increased risk of PD. Besides the HLA alleles discussed above (4.1 Cell-Mediated Immunity) and *BST1* which promotes pre-B cell growth, linkages to the age at onset (AAO) for PD have been identified on chromosomes 1 and 10. The latter is significantly associated with glutathione s-transferase omega-1 (*GSTO1*) (Li et al. 2003); a provocative finding since *GSTO1* is thought to be involved in the post-translation modification of IL-1, a major component in the regulation of inflammatory responses (Laliberte et al. 2003). One factor associated with the chromosome 1p peak is the embryonic lethal abnormal vision 4 (*ELAVL4*) gene (Noureddine et al. 2005), a human homologue of the *Drosophila* ELAV (Good 1995) and essential for temporal and spatial gene expression during CNS development. Additionally, *ELAVL* gene products are known to bind to AU-rich response elements (ARE) in the 3'-untranslated region (3'UTR) of inflammation-associated factors (Good 1995). Interestingly, PD patients homozygotic for allele 1 at position -511 of the IL-1 β gene have an earlier onset of the disease than those homozygotic for allele 2, which produces higher amounts of IL-1 β . Thus, higher production of IL-1 β may provide some neuroprotective effect for dopaminergic neurons (Nishimura et al. 2000; Mizuta et al. 2001).

In ALS, one of the genes associated with the familial form of the disease is *SOD1* (Rosen et al. 1993), which has an important role in eliminating toxic levels of superoxide radicals. Gene expression analyses of post-mortem specimens showed differentially expressed genes associated with the immune response in ALS, most notably IL-1 receptor accessory protein (IL-1rap), MHC class II, thromboxane synthase, Fc ϵ R γ -chain, and the cytokine regulated upon activation, normal T-cell expressed and secreted (RANTES) (Malaspina and de Bellerche 2004; Wang et al. 2006). Of interest, as most of these analyses are performed with tissues from end-stage patients, only approximately 10 % of the differentially expressed genes from ALS patients are associated with inflammation/immune function, whereas the majority of genes pertain to stress-activated pathways (Malaspina and de Bellerche 2004). This is in contrast to mice that express the G93A mutation of human *SOD1*, wherein the majority of early changes are associated with inflammation/immune function genes (Malaspina and de Bellerche 2004). At this

time, the exact role of genetics in ALS is unclear. Approximately 17 gene regions are thought to be associated with ALS, but the genes in these regions which are responsible for this association are not known (Keller et al. 2014). To address this, ICSNPathway (Identify candidate Causal SNPs and Pathways) analysis of an ALS genome-wide association study revealed several pathways which may be affected in ALS including chromatin remodeling, interphase, nucleosome assembly, and classical complement activation (Lee and Song 2015).

46.8 Review Questions

- The cellular target for immunotherapy that would be most beneficial to inhibit secondary neurodegeneration is the
 - astrocyte
 - neuron
 - microglia
 - oligodendrocyte
- The primary producer of reactive oxygen species by microglia is
 - dopamine synthesis
 - NADPH oxidase*
 - myeloperoxidase
 - superoxide dismutase
- In PD, postmortem samples show increased
 - reactive microglia.
 - loss of striatal dopaminergic termini
 - loss of dopaminergic neuronal bodies within the substantia nigra pars compacta
 - reactive oxygen species modified proteins
 - all of the above
- CD45RO+ T cells that mutually express CD4 and CD8 more likely indicate those cells are
 - dead
 - recent thymic emigrants.
 - anergic
 - activated
- An example of free radical modification of RNA
 - 8-hydroxyguanosine (8-OHG)
 - 4-Hydroxy-2-nonenal (HNE)
 - 3-nitrotyrosine (NT)
 - 8-hydroxy-2'-deoxyguanosine (8-OHdG)
- Free radical modification of DNA is best exemplified by
 - 8-hydroxyguanosine (8-OHG)
 - 4-hydroxy-2-nonenal (HNE)
 - 3-nitrotyrosine (NT)
 - 8-hydroxy-2'-deoxyguanosine (8-OHdG)
- One molecular marker of nitric oxide modification of proteins is
 - 8-hydroxyguanosine (8-OHG)
 - 4-hydroxy-2-nonenal (HNE)

- (c) 3-nitrotyrosine (NT)
 (d) 8-hydroxy-2'-deoxyguanosine (8-OHdG)
8. A protein marker resulting from modifications due to lipid peroxidation is
 (a) 8-hydroxyguanosine (8-OHG)
 (b) 4-hydroxy-2-nonenal (HNE)
 (c) 3-nitrotyrosine (NT)
 (d) 8-hydroxy-2'-deoxyguanosine (8-OHdG)
9. Immunotherapeutic strategies using scFv directed against α -synuclein targets are designed to
 (a) prevent misfolding to the toxic form of the protein
 (b) interfere with misfolded protein interactions
 (c) enhance degradation of the toxic protein form
 (d) *all of the above*
10. Passive transfer of sera or immunoglobulin from ALS patients to rodent recipients results in increases in the following sequelae with the exception of
 (a) *denervation of striatum*
 (b) denervation of muscles
 (c) human immunoglobulins in spinal cord motor neurons
 (d) human immunoglobulins in neuromuscular junctions
 (e) miniature end-plate potential (MEPP)
11. A ligand utilized for in vivo imaging of reactive microglia via upregulated peripheral benzodiazepine receptors is
 (a) CFT
 (b) DA
 (c) GT1b
 (d) MPTP
 (e) *PK1195*
12. The ultimate effect of reactive species on cellular function include
 (a) ligand misrecognition
 (b) enzyme dysfunction
 (c) membrane damage
 (d) mutation
 (e) *all of above*
13. Glatiramer acetate is an immunomodulatory drug that is FDA approved and clinically indicated for
 (a) amyotrophic lateral sclerosis
 (b) *remitting/relapsing multiple sclerosis*
 (c) Parkinson's disease
 (d) Alzheimer's disease
 (e) Huntington's disease
14. Regulatory T cells capable of attenuating microglial responses are more likely to produce and secrete
 (a) *IL-10*
 (b) IL-2
 (c) IFN- γ
 (d) TNF- α
15. A first indicator of oxidative stress during progressive disease in PD, occurring prior to other hallmarks including loss of mitochondrial complex I activity, has been suggested to be
 (a) reactive microglia
 (b) diminished dopamine
 (c) increased astrocytosis
 (d) *depletion of glutathione*
 (e) all of the above
16. IL-2/IL-2R interactions are found localized to
 (a) T cell-T cell interactions
 (b) striatum
 (c) frontal cortex
 (d) cerebellum
 (e) *all of the above*
17. The possible mechanism by which glatiramer acetate functions is
 (a) competition with myelin-basic protein (MBP) for binding to major histocompatibility complex (MHC) molecules
 (b) competition of GA/MHC with MBP/MHC for binding to the T-cell receptor
 (c) partial activation and tolerance induction of MBP-specific T cells
 (d) induction of GA-reactive T-helper 2- (TH2)-like regulatory cells
 (e) *all of the above*
18. Levels of glutathione least concentrated in
 (a) *substantia nigra*
 (b) striatum
 (c) hippocampus
 (d) cerebellum
 (e) cortex

Acknowledgments Support for this research was provided by the National Institutes for Health grants P01 DA028555, R01 NS036126, P01 NS031492 2R01 NS034239, P01 MH064570, P01 NS043985, P30 MH062261 and R01 AG043540 to H.E.G.; R21 NS049264, R01 NS070190 to R.L.M.; DOD Grant 421-20-09A to H.E.G.; separate grants from the Michael J. Fox Foundation to H.E.G. and to R.L.M.; and in part by the University of Nebraska Foundation which includes individual donations from Carol Swarts, Frances and Louie Blumkin, and the Vice Chancellor's office of the University of Nebraska Medical Center for Core Facility Developments. We gratefully acknowledge the work of Ashley Reynolds, MD, PhD, and David K. Stone MD, PhD for their authoritative input and work as authors of the first edition version of this chapter.

Donald S. Sakaguchi

Abstract

This chapter has presented a number of approaches that may be effective in augmenting the limited repair capacity of the mammalian central nervous system (CNS). In comparison to the CNS, the regenerative capacity of the peripheral nervous system can be quite robust and a number of investigators have sought to identify differences in the hope of identifying molecular targets that may be exploited to enhance CNS regeneration. Another promising approach has been cell transplantation in order to replace lost cells within the damaged or diseased CNS. The choice of cell type will be critical in developing cell-based regeneration and repair strategies. For example, if stem cells (pluripotent or multipotent) are selected, the cells must be competent to generate specific cell types targeted for each disease. Furthermore, if pluripotent cells are selected, this increases the risk of teratoma formation. Cellular reprogramming or direct conversion of somatic cells into functional “induced” neuronal cell types may also be a feasible approach. However, there may be limitations on the number of cells that can be effectively generated using this methodology.

3-D scaffolds • Adipose stem cells • Astrocyte • Bioengineering • Biomaterials • Cellular reprogramming • Embryonic stem cells • Genetic engineering • Glia • Glial cell • Induced pluripotent stem cells • Mesenchymal stem cells • Microglia • Multipotent stem cells • Neuron • Neuroprotection • Neuroregeneration • Neurotrophic factors • Oligodendrocyte • Regeneration • Schwann cell • Tissue engineering

47.1 Introduction

The field of regenerative medicine in the context of the central nervous system (CNS) is focused on the ability to repair, replace and regenerate neural tissues, affected due to some disease condition, injury, or due to the aging process. The

underlying goals are to develop therapies capable of restoring function of the CNS.

The nervous system is composed of two major parts, the central nervous system (CNS) and the peripheral nervous system (PNS). The major components of the vertebrate CNS include the brain, spinal cord, and retinas (and optic nerves). The CNS integrates sensory information from the environment as well as internally and is responsible for coordinating the organism’s activities and behaviors. The PNS consists of the ganglia and nerves outside of the CNS and a principal function is to connect the CNS with limbs and organs, serving as the communication relay. Disease or damage to the nervous system can lead to severe functional and behavioral deficits. The neuroregenerative capacity of the PNS and the CNS are quite different and can vary widely across species

(Horner and Gage 2000). While regeneration of cut or damaged axons readily occurs in the mammalian PNS, as well as in the CNS of lower vertebrates such as frogs, newts and some fish, the adult mammalian CNS has limited capacity for regeneration.

A prominent difference in the regenerative capacity of the mammalian PNS versus the CNS is associated with the glial cells that form the myelin sheath on the axons, the Schwann cells and oligodendrocytes, respectively. The myelin sheath formed by these two glial cell types serves as an electrical insulator and facilitates the propagation of action potentials along the length of many axons throughout the nervous system. While there are a number of similarities between these two glial cell types, significant differences are clearly evident with respect to their role in neural regeneration (Martini et al. 2010). The Schwann cells of the PNS are derived from the neural crest and following peripheral nerve injury provide a conducive environment for axonal regeneration for peripheral neurons, as well as CNS neurons projecting through the PNS. Following peripheral nerve injury, proliferating Schwann cells produce and secrete a number of trophic factors with growth promoting activities including, nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and glial cell line-derived neurotrophic factor (GDNF) (Bunge 1994; Johnson et al. 1988). These neurotrophic factors promote the survival of the injured neurons and are also involved in regulating gene expression programs involved in axon regeneration and formation of the growth cone (Reichardt 2006; Kwok et al. 2014). In addition, they produce extracellular matrix molecules (ECM) such as laminin and fibronectin that promote neurite outgrowth and also express integrin ECM receptors and numerous cell adhesion molecules including, neural cell adhesion molecules (NCAMs) and N-Cadherin (Thornton et al. 2005).

A principal reason for the absence of a prominent regenerative capacity in the adult CNS resides within the glial environment. The myelin producing cells of the CNS, the oligodendrocytes are derived from oligodendrocyte progenitor cells (OPCs) generated from neuroepithelial cells lining the ventricles and central canal of the brain and spinal cord, respectively. The limited regenerative capacity of the adult mammalian CNS is in large part due to the oligodendrocytes, along with astrocytes (another major glial cell component of the CNS), that produce a number of inhibitory molecules at the site of injury that suppress regeneration and the reestablishment of function. Lesions in the CNS result in the formation of a glial scar and the production of myelin-associated molecules that inhibit axon regrowth including chondroitin sulfate proteoglycans (CSPGs), Nogo-A, myelin-associated glycoprotein (MAG), oligodendrocyte-myelin glycoprotein (OMgp), ephrins (B3 and A3), semaphorins (4D, 5A, and 3F), and myelin glycolipid sulfatide (Giger et al. 2010; Silver et al. 2015). Identification of corresponding receptor systems

for many of these molecules have demonstrated that the functional receptors mediate growth cone collapse and growth inhibition.

Advances in the fundamental understanding of neurodevelopment can provide insight in development of strategies for rescue and repair of the damaged and diseased nervous system. Experimental studies during early neural development as well as clinical observations suggest that when compared to the adult mammalian CNS, the immature CNS provides a more permissive environment such as that can support regeneration. For example, axonal regeneration across a lesion site can occur in fetal mouse and rat spinal cord. Results for successful spinal cord regeneration across a crush or transection in the neonatal opossum spinal cord (before 12 days postnatal) have led to reestablishment of synaptic connections and behavioral recovery (Saunders et al. 1998). During this permissive period of CNS regeneration there is a notable lack of myelin. Furthermore, the end of this “critical period” for CNS regeneration is marked by the appearance of neurite growth inhibiting molecules associated with the appearance of the oligodendrocytes (Varga et al. 1995). As such, a number of strategies to stimulate CNS regeneration have focused on neutralizing these inhibitory myelin oligodendrocyte-associate factors.

An additional limiting factor for successful axon regeneration appears to be a relatively poor intrinsic regenerative capacity within adult mammalian CNS neurons (Lu et al. 2014). Indeed, there is a difference in physiological neurite outgrowth during development compared to axon regeneration in mature neurons. One might surmise that axonal regeneration recapitulates axonogenesis during development since both processes require the formation of a growth cone for process extension. However, although intrinsic mechanisms play a significant role in axon outgrowth during development, extrinsic environmental cues are also essential in regulating this process and in determining target recognition (Kolodkin and Tessier-Lavigne 2011). Understanding how intrinsic and extrinsic cues regulate regeneration in the mature CNS has been a focus for regenerative medicine for many years (Fawcett et al. 2012; Harel and Strittmatter 2006). The earlier work of Aguayo and colleagues demonstrated that providing a permissive environment that of a peripheral nerve graft, supported the regeneration of some adult CNS axons (David and Aguayo 1981; Keirstead et al. 1989). Additional studies have demonstrated that, following lesions in the CNS, undamaged axons can sprout new neurites and form functional synaptic connections with considerable specificity within relatively localized regions. Furthermore, under the appropriate circumstances some severed CNS axons can regrow considerable distances (several centimeters) and form synaptic connections, however the majority of severed axons fail to regenerate. A number of recent studies have elucidated several molecular signaling

pathways that are involved in regulating the ability for adult axonal CNS regeneration (Lu et al. 2014). The PTEN/mTOR pathway appears to be a general signaling pathway regulating axon regeneration (Park et al. 2009). The JAK/STAT and DLK/JNK pathways may also be involved in providing signals from the damaged or lesioned axon to the neuronal soma in order to initiate an injury response leading to regeneration. Identification of these as well as other molecular pathways may provide insight into mechanisms for promoting regeneration of adult CNS axons following injury or disease.

47.2 Development of Experimental Strategies to Regenerate and Repair the CNS

The lack of a robust regenerative capacity in the CNS, along with limited treatment options for patients with CNS injury or other neurodegenerative conditions has in part led to the development of the fields of regenerative medicine and CNS tissue engineering. A number of different strategies are actively being pursued to enhance CNS regeneration.

One approach takes into consideration the regenerative capacity of the PNS by grafting a segment of peripheral nerve into the CNS. Earlier studies by Aguayo and colleagues were among the first to demonstrate that CNS axons, those of the retinal ganglion cells (RGCs), were able to regenerate effectively through an autologous peripheral nerve graft (Keirstead et al. 1989). In these studies a segment of the optic nerve was removed and replaced by a peripheral nerve graft taken from the sciatic nerve. The other end of the sciatic nerve was then sutured into the normal visual target, the superior colliculus. Following regeneration of at least some RGC axons, electrophysiological recordings revealed light evoked activity in the superior colliculus. However, behavioral recovery was not demonstrated after regeneration of host projections. These early studies provided compelling evidence for the regenerative capacity of adult mammalian CNS axons, under the appropriate conditions. Thus, providing a regenerative conducive environment (in this case a grafted peripheral nerve containing Schwann cells) is an important consideration for development of CNS regenerative therapies.

47.2.1 CNS Regenerative Failure and the Glial Environment

Studies using animal models of CNS injury have provided excitement in the field of CNS regenerative medicine by modulating and boosting the intracellular signaling pathways involved in axon outgrowth as well as manipulating the extracellular barriers associated with the glial scar. A number of

approaches have been employed to neutralize myelin-associated inhibitory factors that suppress CNS axon regeneration following injury. Approaches have included development of function-blocking antibodies, Nogo-receptor-blocking peptides and fusion proteins, as well as extensive *in vivo* studies generating knockout mice to regulate levels of expression of the myelin-associated inhibitory molecules. These strategies have been used in a number of experimental models including spinal cord injury, stroke, and autoimmune diseases. Studies conducted in adult non-human primates subjected to a unilateral spinal cord cervical lesion showed functional and behavioral recovery of some motor skills following intrathecal administration of a function blocking anti-Nogo A antibody (Freund et al. 2009). These strategies have been implemented in clinical trials for acute spinal cord injury (Abel et al. 2011) and ozanezumab, a humanized monoclonal antibody against Nogo-A has been used in amyotrophic lateral sclerosis (ALS) patients (Meininger et al. 2014).

47.2.2 Inflammation and CNS Regeneration

Most neurodegenerative diseases and CNS injury are accompanied by a local inflammatory response. Characteristics of the neuroinflammatory response include invasion of circulating immune cells (macrophages and lymphocytes) and induction of inflammatory mediators including a variety of cytokines and other reactive molecules. Since many of these molecular entities are produced locally around the site of injury or inflammation, they have become targets for possible therapeutic intervention. Neurons and glial cells (oligodendrocytes, astrocytes and microglia) can produce inflammatory mediators, as well as their respective cytokine receptors throughout the CNS. Their low levels of expression in the healthy brain suggest they may contribute to normal homeostatic functions within the CNS. Under pathological conditions, microglia and macrophages are recruited to the site of injury. Damaged cells and their associated debris serves to stimulate the resting microglia to transition into migratory macrophages that produce cytokines and trophic factors that can exert both damaging as well as protective effects on cells within the local environment. Differentiation of macrophages towards “classically” (M1) activated state can be neurotoxic and induce extensive retraction of damaged axons (Horn et al. 2008; Kigerl et al. 2009). As such, depletion of M1 macrophages appears to have neuroprotective effects in models of spinal cord injury. Interestingly, macrophages can also mediate sprouting of injured CNS axons likely through release of neurotrophic and growth factors and/or by indirectly activating glial cells within the scar region (Benowitz and Popovich 2011). Provision of neurotrophic factors by transplanted microglia and macrophages may help to explain their activity in promoting axon

outgrowth in different models of spinal cord injury (Rapalino et al. 1998). Differentiation of macrophages towards the “alternatively” (M2) activated state has been associated with neuroprotection and enhancement of neurite outgrowth from damaged CNS neurons. Compared with the M1 phenotype, the M2 macrophages appear more proficient at CNS repair (Silver et al. 2015). Therapeutic applications using autologous macrophage transplantation appears promising in clinical trials (Jones et al. 2010). Methods that modify the local injury environment to favor the conversion of macrophages towards the M2 phenotype are likely to have benefits in CNS regeneration and offer additional interesting therapeutic targets.

47.2.3 Adult Neural Stem Cells and Endogenous Repair of the CNS

Many neurodegenerative diseases result in significant neuronal loss. Neuronal cell death is also frequently associated with severe neural insults, such as traumatic brain injury (TBI), chronic traumatic encephalopathy (CTE), stroke, and spinal cord injuries. Development of strategies to replace dead or dying neurons is likely to rely, in part, on important advances in understanding the fundamental mechanisms of endogenous neurogenesis. As such, a fundamental concept of regenerative medicine in the CNS is to develop strategies to improve neuronal survival and replace cells lost as a result of neurological disease or injury.

The discovery of neural stem cells within the adult mammalian brain has focused considerable interest into harnessing the endogenous capacity of these cells for CNS regeneration and repair. The original concept of adult neurogenesis in the mammalian CNS was quite controversial and was met with considerable skepticism. However, it is now well established that new neurons are generated throughout life in specific neurogenic regions of the dentate gyrus (DG) of the hippocampus and the subventricular zone (SVZ) (Altman and Das 1965; Gage et al. 1998; Lois and Alvarez-Buylla 1993; Reynolds and Weiss 1992; Aimone et al. 2014). Since the original reports a number of studies have demonstrated that adult neurogenesis in the DG plays a role in hippocampal-dependent learning and memory (Aimone et al. 2014), while adult neurogenesis in the SVZ results in production of new olfactory interneurons necessary for the normal function of the olfactory bulb and associated behaviors (Sakamoto et al. 2014). Considerable research efforts have elucidated mechanisms regulating proliferation and the differentiation of these adult stem cells into specific neural cell types. Furthermore, studies have also investigated adult neurogenesis in the context of neurodegenerative conditions such TBI and experimentally induced focal lesions (Perederiy et al. 2013; Sun 2016). Studies have demonstrated that different

models of TBI significantly increased cell proliferation in the DG and SVZ of rodents (Sun 2016). However, due to a number of challenges including, difficulties in obtaining human brain tissue and cell birth dating studies, evidence of TBI-induced neurogenesis in the human brain is lacking. Nevertheless, mobilizing and augmenting endogenous adult neurogenesis is an attractive strategy towards repopulating the damaged or diseased CNS. Since the natural regenerative capacity of the adult CNS is quite limited, exogenous methods must be employed. With this type of strategy in mind, a number of studies have shown that different growth factors can enhance adult neurogenesis in vitro and in vivo in animal studies. Factors that have a demonstrated enhancement of neurogenesis and synaptic plasticity include, BDNF, basic fibroblast growth factor-2 (FGF-2), epidermal growth factor (EGF), NGF, vascular endothelial growth factor (VEGF) and insulin-like growth factor (IGF) (Vivar et al. 2013). In addition to neurotrophic and growth factors, a number of drugs currently in clinical trials for treating neurological conditions, including TBI, enhance neurogenesis in animal studies. These include, erythropoietin, statins, and imipramine (Sun 2016; Xiong et al. 2013). However, it should be noted that in addition to an enhancement of neurogenesis, these exogenous agents in many cases also exert neuroprotection which may also contribute to enhanced recovery in behavioral and functional studies. Nevertheless, these findings should prove valuable in designing clinical strategies to improve the prospects of endogenous adult neural stem cell-based therapies.

47.3 Stem Cells for CNS Repair Strategies

The successful isolation of human embryonic stem cells and the development of induced pluripotent stem cell technologies is making it possible to recapitulate developmental processes, as well as modeling neurodegenerative conditions. Furthermore, the advent of cellular reprogramming technologies has made it possible to implement rational strategies to generate specific cell types with a goal of developing cell-based therapies for CNS disorders. Additionally, advances in biomaterials and in 3-D scaffold fabrication techniques is making it feasible to mimic the neural stem cell niche. In this section I provide an overview of approaches merging stem cells, scaffolds, drug delivery systems, gene therapy, cellular engineering and biomaterials to develop experimental regenerative strategies for the CNS (Mallapragada et al. 2015; Sandquist et al. 2016).

Current therapies targeted for CNS-related disorders often rely on the use of pharmacological-based methods, which in many cases are not without serious side effects. As such, the implementation of cell-based therapies has gained considerable interest. In recent decades the field of stem cell biology and cell transplantation has come to the

Fig. 47.1 Central nervous system regeneration and repair strategies. Injections and administration of therapeutic agents to enhance regeneration (neuroprotection, stimulating axon growth, neutralizing inhibitory factors). Stimulating endogenous neurogenesis. Cell-based therapies using stem cells (ESCs, iPSCs), neural stem cells, neurons and glial cell types. A variety of other somatic stem cells, as well as other cell types may be used for cellular therapies. Coupling of engineering approaches with cell-based therapies is another strategy for CNS regeneration

forefront of biomedical research with aspirations of development of cures for various neurological disorders.

One approach is for transplanting cells that can replace the lost populations of neurons or glia (Fig. 47.1). Alternatively, transplanted cells may also provide trophic support via autocrine and paracrine signaling related to their cellular secretomes. An alternative approach involves harnessing the natural abilities for adult neurogenesis in order to generate new neurons. While another route takes advantage of bioengineering approaches, where cell-based approaches are combined with biomaterials, scaffolds and nanoneuro-medicine concepts, in order to develop novel therapies that target neurological conditions.

47.3.1 Pluripotent Stem Cells

Stem cells are defined by their potentially unlimited capacity for self-renew and ability to differentiate into multiple cell types. These properties are attractive to the field of regenerative medicine, which seeks to replace cells lost to neurodegenerative conditions, injury, or due to the natural aging process. Stem cells from a number of different sources are being used in neuroscience research in search of therapeutic treatment strategies targeting neurodegenerative diseases including Alzheimer's, Parkinson's, ALS and damage such as that from stroke as well as CTE. In general, stem cells are broadly categorized by their differentiation potential, from pluripotent cells, which are able to generate cells from all three primary germ layers (endoderm, mesoderm and ectoderm), to multipotent cells, which differentiate into a limited number of tissue specific cell types (Fig. 47.2).

47.3.1.1 Embryonic Stem Cells

Thomson and colleagues (Thomson et al. 1998) were the first to report the isolation and characterization of pluripotent human embryonic stem cells (ESCs) isolated from the inner cell mass of the blastocyst. Considerable interest has focused on the potential of ESCs to differentiate into various neural cell fates and thus, they have become useful as a source of cells for CNS transplantation and tissue engineering. However, derivation of specific cell types in some cases requires complicated and expensive schemes to generate a relatively small proportion of the desired cells and hence considerable effort is being devoted to overcome these obstacles.

Differentiation conditions to drive ESCs into a number of different neural cell types have been elucidated and these cells tested for possible therapeutic benefits in a number of neurodegenerative conditions; including Alzheimer's, Parkinson's, and Huntington's disease, spinal cord injury, TBI, stroke, as well as blinding ocular disease with varying success.

Generation of mesencephalic precursor cells and dopaminergic neurons derived from ESCs has been effective in recovering some motor function in models of Parkinson's disease (Bjorklund et al. 2002; Kim et al. 2002; Kriks et al. 2011; Yang et al. 2008). Implantation of ESC-derived neural precursors has also improved behavioral deficits in models of Huntington's disease (Song et al. 2007). In addition, transplantation of ESC-derived neural stem cells into the cortex of rodent models of Alzheimer's disease has resulted in some improvements in cognitive function (Wang et al. 2006). Embryonic stem cell-derived neural stem cells and neurons have also provided functional improvements in models of stroke (Daadi et al. 2008; Yanagisawa et al. 2006) and epilepsy (Cunningham et al. 2014). Preclinical studies using

Fig. 47.2 Stem cell hierarchy and multipotency of neural and retinal stem cells. Pluripotent embryonic stem cells (ESC) are derived from the inner cell mass of a blastocyst (in humans the blastocyst stage is about 4–5 days post fertilization). Under appropriate culture conditions the ESCs can produce multipotent tissue specific stem cells from all three germ layers (ectoderm, mesoderm and endoderm). This illustration depicts the generation of differentiated cell types from multipotent neural and retinal stem cells. Multipotent neural stem cells generate the three major neural cell types present

within the central nervous system (CNS): neurons, oligodendrocytes and astrocytes. Multipotent retinal stem cells produce the seven major cell types found within the vertebrate retina which include: ganglion cells, horizontal cells, cone and rod photoreceptors, amacrine cells, bipolar cells and Müller glial cells. Arrows curling back onto the same cell represent the ability for self renewal, while reversed arrows represent possible reprogramming events (*Source*: Reprinted from Sandquist et al.(2016), Copyright 2016, with permission from Springer)

human ESC-derived OPC transplants in a rat model of spinal cord injury demonstrated significant improvement in locomotor activity and histological examination of the injured spinal cords showed improved axon survival and extensive remyelination around the axons (Okamura et al. 2007). Clinical trials are underway utilizing human ESC-derived OPC transplants for acute spinal cord injury. Promising clinical trials for wet age-related macular degeneration and Stargardt's macular dystrophy (Schwartz et al. 2012) are employing transplantation of retinal pigmented epithelial (RPE) cells derived from human ESCs. In this paradigm, the human ESCs are directed along an in vitro differentiation paradigm taking into consideration the normal developmental profile to generate RPE cells.

The stem cell debate: While ESCs offer hope for development of new therapies, their use in biomedical research is

still hotly debated and raises considerable ethical and political concerns. Many believe that ESC research may lead to discoveries of new medical treatments for a number of debilitating neurological conditions that would potentially alleviate the suffering of thousands of patients. However, it still necessitates the destruction of a human embryo. This debate as to whether the potential benefits of human ES research outweigh ethical objections still remains a critical moral dilemma. The recent discovery of reprogramming somatic cells to pluripotent stem cells (see below) may serve as an alternative method of deriving stem cells with minimal ethical concerns. Nevertheless, many biomedical researchers strongly support the continued study of all stem cell types to determine similarities and differences and it still remains unclear which cell source will be the most useful for cell replacement therapies in the future.

Fig. 47.3 Stem cell research. Recent advances in stem cell biology have revolutionized research opportunities in drug discovery. The ability to isolate and generate stem cell and somatic cell lines associated with specific diseases is providing effective in vitro models for pre-clinical testing. Stem cell research is also providing powerful tools to help decipher the molecular mechanisms of gene regulation and

development. Another important goal of stem cell research is to elucidate the pathways for generating specific cell types that can be used for cell transplantation to treat a variety of degenerative diseases and injuries (Source: Reprinted from Sandquist et al.(2016), Copyright 2016, with permission from Springer)

47.3.1.2 Induced Pluripotent Stem Cells

The development of induced pluripotent stem cell (iPSC) technology was pioneered by S. Yamanaka and colleagues (Takahashi et al. 2007; Takahashi and Yamanaka 2006) who demonstrated that adult cells can be converted to pluripotent stem cells, thus removing many of the ethical barriers associated with ESC research. Induced pluripotent stem cells are created by genetically reprogramming adult cells into an “embryonic-like” pluripotent state by forced expression of genes and factors involved in maintaining pluripotency. Induced pluripotent stem cells hold significant promise in the field of regenerative medicine as they have become useful tools for drug development, for modeling diseases and have considerable appeal to generate patient specific-pluripotent stem cells (Fig. 47.3). Furthermore, since iPSCs have the ability of self-renewal, they can propagate indefinitely, as well as differentiate into a variety of cell types in the body (including, neurons, glia, heart, pancreatic, liver cells, etc.), thus representing a single source of cells that could potentially be used to replace cells lost to disease or damage.

These unlimited supplies of patient-specific cells could be used to generate autologous transplants, thus reducing graft-host immune rejection. The iPSC technology has recently advanced to the stage of clinical trials for retinal degenerative conditions.

The field of stem cell biology has taken advantage of the normal developmental process of neural pattern formation of the CNS. Understanding and elucidating normal development has provided a rational strategy to differentiate pluripotent stem cells into specific neural cell types. Neuronal differentiation from iPSCs (as well as ESCs) is commonly achieved through a developmental profile that combines embryoid body cultures, retinoic acid stimulation and activation, and Sonic Hedgehog pathway agonists. Using specific factors that establish morphogenic gradients for patterning neural tissue, transcriptional regulation of modular patterns of CNS development has been key to differentiating pluripotent stem cells into neural precursors (Zhou et al. 2010), OPCs (Wang et al. 2013), and subsequently differentiating these progenitors and precursors into dopaminergic neurons

(Kriks et al. 2011), cortical neurons (Shi et al. 2012), motor neurons (Chambers et al. 2009; Karumbayaram et al. 2009) as well as retinal cells (Hirami et al. 2009). In addition, identification of synthetic small molecules has also been useful for neural differentiation by activating signaling pathways that promote differentiation into specific cell lineages (Skalova et al. 2015).

A number of studies have successfully directed differentiation of iPSCs into specific neuronal cell types for therapeutic applications (Lindvall 2012; Lindvall et al. 2012). Transplant of iPSC-derived dopaminergic neurons into animal models used for the study of Parkinson's disease have shown functional benefits (Kriks et al. 2011; Wernig et al. 2008). Re-myelination provided by OPCs derived from iPSCs has provided functional improvement in congenital hypomyelination disorder (Wang et al. 2013). Additionally, iPSC-derived neural progenitors transplanted into animal models of multiple sclerosis have ameliorated clinical features (Laterza et al. 2013). In animal models used to study ALS, iPSC-derived neural stem cell transplants has resulted

in improved neuromuscular function and significantly increased life span (Nizzardo et al. 2014). Neural stem cells from iPSCs have also shown benefits for stroke (Yuan et al. 2013). A number of studies employing iPSC-derived neural precursor transplants in models of spinal cord injury have resulted in functional improvements as well (Romanyuk et al. 2014).

The development and differentiation of iPSCs and ESCs into specific neural cell types is often a very complicated, time consuming and expensive process. Furthermore, an inherent attribute of pluripotent stem cells is their ability for teratoma formation. To avoid this complication, a number of studies have used strategies to predifferentiate the stem cells and also selectively remove any remaining pluripotent cells prior to transplantation (Brederlau et al. 2006; Dihne et al. 2006; Doi et al. 2012; Erdo et al. 2003; Wernig et al. 2008).

Another approach is to avoid these developmental complications by direct induction of somatic cells to neural cells, skipping a pluripotent state (Fig. 47.4). Direct conversion has been achieved by forced expression of genes for

Fig. 47.4 Stem cell sources for CNS transplantation. *Left side of illustration:* Pluripotent hESCs isolated from the inner cell mass of a blastocyst are differentiated towards neural stem cells. Isolation of fetal CNS derived neural stem cells. iPSCs generated by reprogramming of somatic cells isolated from the patient. Direct conversion of somatic cells into neurons and/or glial cells. *Right side of illustration:* Different sources of MSCs for transplantation (BM-MSCs, UC-MSCs, and Adipose stem cells). Examples of other cell sources include OECs and OPCs. Arrows directed away from the patient

indicate potential autologous cell sources. Arrows directed toward the patient indicate cell sources for transplantation to the CNS. *Abbreviations:* hESCs human embryonic stem cells, iPSCs induced pluripotent stem cells, OECs olfactory ensheathing cells, MSCs mesenchymal stem cells, BM-MSCs bone marrow-derived mesenchymal stem cells, hESCs human embryonic stem cells, iPSCs, induced pluripotent stem cells, OECs olfactory ensheathing cells, UC-MSC umbilical cord mesenchymal stem cells, OPCs oligodendrocyte progenitor cells

differentiated neurons and by reprogramming somatic cells to a partially pluripotent state followed by culture with appropriate growth factors associated with neuronal differentiation (Matsui et al. 2014). A number of neuronal subtypes have been generated using these methods and have included, cholinergic neurons (Liu et al. 2013), dopaminergic neurons (Caiazzo et al. 2011; Pfisterer et al. 2011), and motor neurons (Son et al. 2011).

Human iPSCs have been praised as potential replacements for human ESCs. Although ESCs and iPSCs possess many similarities in differentiation potential, some studies suggest there are differences in gene expression and thus questions the equivalence of these two cell types (Ghosh et al. 2010; Narsinh et al. 2011). Comparison between different iPSC lines, as well as between different ESC lines has revealed differences in gene expression profiles, implicating differences in regulatory control (Chin et al. 2009; Wilson et al. 2009).

47.4 Multipotent Stem Cells for CNS Repair Strategies

Multipotent stem cells have the ability of self-renewal and can give rise to other cell types, but with more limited differentiation capacity when compared to pluripotent stem cells. Also referred to as somatic stem cells, multipotent stem cells tend to be tissue specific and are essentially committed to produce a particular set of cell types under normal conditions. Multipotent stem cells have been isolated and characterized from many organs and tissues, and are found in juvenile as well as in adult animals. In general, they appear to function to replenish cells in the various tissues throughout the life of the organism. Because of this cell replacement capacity, adult stem cells are of considerable interest in the field of regenerative medicine. Multipotent stem cells isolated from a number of different tissues have been used for CNS regeneration and repair strategies and include cells isolated from: brain, retina, bone marrow, adipose tissue, teeth, and skin (Fig. 47.4).

An important challenge has been to identify conditions or “factors” that trigger multipotent stem cells to generate specific cell types from that of their original tissue. Furthermore, it appears that at least some multipotent stem cells possess greater “plasticity” than originally thought, as they can be coaxed to go beyond original lineage boundaries for producing other cell types. However, the ability to isolate large quantities of somatic stem cells and to maintain them in a laboratory setting in order to generate therapeutic quantities of cells remains a significant issue. Although a number of challenges must be overcome before multipotent stem cells can be considered for routine use in the CNS, their potential benefits are numerous and they hold promise for treating neurodegenerative diseases and CNS injury (Fig. 47.4).

47.4.1 Neural Stem Cells

Neural stem cells are self-renewing multipotent stem cells that can differentiate into neurons, astrocytes and oligodendrocytes (Fig. 47.2). They have been isolated from the developing and adult CNS and have been produced in vitro through the differentiation of pluripotent stem cells (ESCs and iPSCs). Although significant progress has been made in understanding the biology of neural stem cells, much remains to be elucidated regarding identification of factors and conditions that regulate their fate.

Neural stem cells possess a number of characteristics that make them ideal vectors for CNS rescue and repair. Once isolated, they can be maintained long-term in vitro. In some cases neural stem cells isolated from the neonatal and adult mammalian brain have been maintained in culture as free-floating neurospheres in the presence of EGF and/or FGF-2 (Reynolds and Weiss 1992). Neural stem cells have also been isolated from the adult hippocampus and maintained in monolayer cultures grown on laminin or other ECM substrates in the presence of growth factors (Gage et al. 1998; Palmer et al. 1995). In addition, neural stem cells have also been isolated from the adult spinal cord (Weiss et al. 1996) and adult retinal stem cells from the pigmented ciliary margin (Tropepe et al. 2000).

Novel therapeutic applications are being developed that call for replacement of specific cell types, such as dopaminergic neurons for Parkinson’s disease, oligodendrocytes to treat spinal cord injury, and generating photoreceptors and RPE for blinding ocular disorders. One approach to manipulate neural stem cell fate has been through addition of neurotrophic and growth factors in vitro as well as in vivo. A number of different trophic factors, have been identified that can influence gene expression and ultimately neural stem cell differentiation potential. For example, as mentioned earlier, the mitogenic growth factors EGF and FGF-2 are important for maintenance and proliferation of neural stem cells. In addition, EGF converts transit-amplifying neurogenic precursors in the adult brain into multipotent stem cells (Doetsch 2003). Leukemia Inhibitory Factor (LIF) has been shown to support neural stem cell self-renewal in the adult brain (Bauer 2009; Bauer and Patterson 2006). A number of other studies have also demonstrated that multiple classes of trophic factors and growth factors, individually and especially in combinations, are also required for cell survival, avoidance of programmed cell death and for differentiation of neural stem cells and glial progenitors (Gallo and Deneen 2014; Urban and Guillemot 2014). Epigenetic regulation of transcription as a means of manipulating stem cell fate is a very active area of biomedical research (Fan et al. 2005). Micro-RNAs are an additional means to regulate transcription/translation and to influence neural stem cell fate (Hsieh et al. 2004; Kuwabara et al. 2004). The discovery of neural stem cells in the adult brain as

well as retina has encouraged research into their role during neurogenesis in the normal mature nervous system and following traumatic injury. Gaining a more thorough understanding of adult neurogenesis can contribute greatly to our knowledge of neurodegenerative diseases and to development of novel treatment platforms.

47.4.2 Non-neural Adult Stem Cells

It is well established that endogenous CNS stem cells, as well as those derived through differentiation of ESCs or iPSCs, can generate neurons, astrocytes, and oligodendrocytes. However, since neural stem cells are difficult to harvest from the adult brain, other stem cell sources are being evaluated as alternatives for cell-based therapies for neurological disorders. A number of somatic stem cell sources have been investigated for potential therapeutic applications in the CNS, including mesenchymal stem cells (MSCs), umbilical cord (blood) stem cells, adipose stem cells, and dental pulp stem cells, all sources that normally do not generate neural cell types (Fig. 47.4). In most cases, these non-neural adult stem cells appear to be capable of inducing endogenous neurogenesis. In addition to their neurogenic influence, these cell types may also have trophic effects that exert neuroprotective benefits when used to treat neurodegenerative conditions. However, evidence that they in fact differentiate into specific neural phenotypes is limited (Abraham and Verfaillie 2012; Stewart and Przyborski 2002).

This section will focus on MSCs as they have been isolated from a number of different tissue sources, including bone marrow, adipose tissue, liver, umbilical cord, and dental pulp tissues (Ding et al. 2011). They have the ability to differentiate into osteocytes, chondrocytes, myoblasts and adipocytes (Prockop 1997). Mesenchymal stem cells are emerging as particularly strong candidates for CNS cellular therapies (Fig. 47.4) due to a number of advantages. First, they are readily isolated from a number of tissue sources using well-established procedures. Second, they are easily maintained and expanded in culture and can be engineered to produce neurotrophic growth factors for long-term delivery of neuroprotective substances to the injured CNS (Harper et al. 2011; Levkovitch-Verbin et al. 2010; Sasaki et al. 2009). Third, MSCs can be isolated from the patient and therefore potentially serve as an autologous cell source. In addition, because MSCs express intermediate to low or negligible levels of MHC Class I or MHC Class II antigens, respectively, they are potentially suitable for use in allogeneic transplantation procedures and may thus avoid or minimize the need for aggressive immunosuppressive therapy (Aggarwal and Pittenger 2005; Le Blanc et al. 2003). Fourth, unlike pluripotent stem cells, MSCs have not been reported to form teratomas following transplantation. Another impor-

tant advantage is that there are few if any moral objections associated with the isolation and use of this adult stem cell population.

Mesenchymal stem cells have been used to treat CNS diseases in a number of preclinical models used to study Parkinson's disease, cerebral ischemia, TBI, retinal degeneration, and spinal cord injury. Benefits that have been reported include reduced lesion size, enhanced neuronal survival, axonal regeneration, and improved functional outcomes (Harper et al. 2011; Johnson et al. 2011; Kocsis 2009; Kurozumi et al. 2005; Abraham et al. 2009; Sasaki et al. 2009; Zhao et al. 2002; Lin et al. 2011). Although considerable optimism is associated with the use of MSCs for treatment of CNS neurological conditions, many challenges remain that must be overcome before their widespread clinical application.

In this section we have presented some examples of adult, non-neural stem cells that have been, or are currently, being evaluated for possible neural plasticity and neuroregenerative properties. While it is clear that true neural stem cells have the capacity to generate CNS neurons and glia, there is only limited evidence that non-neural stem cells generate CNS neural progeny. Nevertheless, many sources of non-neural adult stem cells, including bone marrow, adipose tissue, dental pulp and skin, appear to possess unique qualities that make them useful for consideration in cell-based therapies for CNS repair and regeneration. In some cases these cells appear to stimulate endogenous neurogenesis and in many cases can also provide neuroprotection when transplanted into the diseased or damaged brain, spinal cord, or retina.

47.4.3 Cellular Reprogramming Strategies

The biotechnological advancement of the ability to generate iPSCs has brought tremendous excitement to the field of regenerative medicine (Takahashi et al. 2007; Takahashi and Yamanaka 2006). However, the methodology is not without limitations and the reprogramming technology is sometimes inefficient, variable, time intensive and expensive. Furthermore, the pluripotent nature of the iPSCs can result in genetic instability, and when transplanted into animal models, the iPSCs may be tumorigenic. Therefore, it is important to develop alternative (or complementary) approaches for cellular reprogramming.

47.4.3.1 Directed Differentiation Towards Specific Cell Types

Cellular reprogramming is a strategy used to convert fully differentiated somatic cell types with defined functions, into another cell type. As a result, these reprogrammed cells display different characteristics and functions not normally associated with their original phenotype. In developing

reprogramming strategies clues are often collected from normal embryonic or early developmental processes. For example, normal embryonic cellular development is guided by an assortment of specific extracellular soluble factors, gradients of chemical cues and cell-to-cell interactions that ultimately lead to induction and activation of specific combinations of lineage-determining transcription factor pathways. By focusing on key developmental pathways and cell differentiation factors it has been possible to directly convert somatic cells from one fate/lineage to another using a small molecules approach (Zhang et al. 2012). This approach has identified a number of small molecules that serve to maintain self-renewal and to induce and/or facilitate cellular reprogramming (Zhang et al. 2012). Recently, epigenetic reprogramming of skin-derived fibroblasts into neural cells was achieved using a small molecules approach (Thoma et al. 2014). In this approach fibroblasts were initially subjected to conditions that enhance reversion towards a more “primitive” state. Under these conditions the cells were more susceptible to cell-fate changes, a process often referred to as transdifferentiation (Tursun et al. 2011). Potent neural inducing factors were then used to drive the cells towards proliferating neural progenitor cells, and finally the cells were induced towards specific neural cell fates. In this study the selection of small molecules was guided by developmental signaling molecules known to be involved in generation of the particular cell types. This gene-free approach for cellular reprogramming is likely to have applicability beyond generation of peripheral glial cells and may become an important strategy to generate CNS cell types as well (Thoma et al. 2014).

The direct conversion of somatic cells into neural stem/progenitor cells, as well as neurons has been demonstrated using viral delivery of transcription factors. Vierbuchen and colleagues (Vierbuchen et al. 2010; Vierbuchen and Wernig 2012) demonstrated that fibroblasts can be reprogrammed into functioning neurons using combinatorial expression of neural-lineage-specific transcription factors. They identified a combination of three factors, *Ascl1*, *Brn2* (also called *Pou3f2*) and *Myt1l*, which were sufficient to convert mouse embryonic and postnatal fibroblasts into functional neurons in vitro. Recently, the direct conversion of mouse fibroblasts into induced dopaminergic precursors was achieved by ectopic expression of a set of transcription factors that directly reprogram somatic cells into neuronal lineage-restricted progenitors (Tian et al. 2015). Following transplantation into a mouse Parkinson’s disease model (MPTP-lesioned mice), the induced precursors differentiated into dopaminergic neurons and were found to alleviate some motor deficits. Using direct reprogramming strategies to convert somatic cells into neurons or neuronal precursors has important applications for studies of neural development, patient-specific neurological disease modeling and CNS regenerative medicine.

47.4.3.2 Ex Vivo Gene Therapy Approaches for CNS Neuroprotection

Regeneration and repair strategies for the CNS should comprise a multi-factorial approach addressing a number of relevant issues, including optimization of survival and function of remaining CNS elements and modulation of trophic influences to promote neuroregeneration. Neurotrophic/growth factors are important candidates to augment neurorepair. Neurotrophic factors, including NGF, BDNF, and GDNF are essential during neuronal development and plasticity, and also can prevent apoptosis, enhance neuronal survival and facilitate axon regeneration. A number of approaches have been used for delivery of trophic factors to the damaged CNS. These have included direct bolus injections of the factors, incorporation into biodegradable polymer microparticles that slowly release the trophic factors, and gene therapy approaches. While each of these methodologies has advantages, a number of disadvantages necessitate the need to develop alternative strategies. Transplantation of genetically engineered cells can deliver therapeutic factors to the target site in the CNS and produce therapeutic effects at lower doses than are required with other means of delivery. In addition, a cell-based delivery system provides a potentially long-term delivery source.

Ex vivo gene transfer to a variety of different somatic cell types, including neural stem cells, MSCs, Schwann cells, and fibroblasts, prior to transplantation holds promise as cellular platforms for delivery of therapeutic factors. A number of viral vectors are available for *ex vivo* gene delivery, including, adeno-associated viral, adenoviral, retroviral and lentiviral vectors, each with their own advantages and disadvantages (Hendriks et al. 2004). A number of *in vitro* studies have demonstrated proof of concept for use of genetically engineered cells for delivery of trophic factors for neuroprotective strategies. Fibroblasts and MSCs engineered to secrete BDNF (Frim et al. 1994) enhanced the survival of retinal ganglion cells (RGCs) (Castillo et al. 1994) and also provided neuroprotection in a retinal cell line (RGC-5) when exposed to toxic cellular stressors such as glutamate or hydrogen peroxide (Harper et al. 2009), respectively. Mesenchymal stem cells engineered for delivery of BDNF have been transplanted into the striatum of a mouse model of Huntington’s disease and resulted in a decrease in behavioral symptoms typically associated with the disease (Dey et al. 2010). In addition, Harper and colleagues transplanted neurotrophic factor-engineered MSCs to deliver a constant, low level of BDNF and demonstrated that this approach had potential for functional and structural neuroprotection in an experimental rat model used to study glaucoma (Harper et al. 2011). Olfactory ensheathing cells (OECs) genetically modified to secrete GDNF were effective in promoting spinal cord repair. Another study demonstrated that human neural progenitor cells (hNPC) can be genetically modified to release

GDNF using an inducible promoter system (Behrstock et al. 2006). When transplanted into the striatum of mice the engineered cells migrated within the striatum, released physiologically relevant levels of GDNF, and enhanced host dopamine neuron survival and fiber outgrowth. Furthermore, these cells were found to survive and release GDNF for up to 3 months following transplantation into the aged monkey brain. These studies demonstrated the genetically modified hNPCs may be considered a safe and powerful cellular platform for delivering therapeutic factors to specific targets within the CNS for diseases such as Parkinson's.

Stem cells can be used to obtain a more thorough understanding of the complex events occurring during animal and human development. Gaining a more complete understanding of the genetic and molecular controls regulating developmental processes will likely yield information about how neurological diseases arise, and may provide novel strategies and targets for therapy (Fig. 47.3). Furthermore, stem cells (pluripotent and multipotent) and their derivatives are proving to be useful as model cellular systems for drug discovery and for toxicological bioassays (Fig. 47.3). This is particularly important for preclinical testing and verification of drug efficacy. Perhaps an especially significant application is for development and implementation of cell-based transplantation therapies (Fig. 47.3). Stem cells have the ability to generate specific cell types, providing a potentially renewable source of replacement cells that may be used to treat a variety of neurodegenerative conditions. Coupling stem cell biology with biocompatible materials provides a powerful toolbox for development and implementation of experimental strategies for CNS regenerative medicine.

47.5 Stem Cells and Bioengineering for CNS Repair Strategies

Materials fabricated from natural and synthetic polymers have been successfully used for fabrication of biomimetic 3-D scaffolding environments. A central goal of biomimetics in the context of CNS regenerative medicine is to imitate and model the extracellular matrix (ECM) and cellular microenvironment that support the growth and differentiation of native and transplanted cells. When developing materials and constructs for 3-D-scaffolds there are a number of important considerations regarding material selection, including biocompatibility, biodegradability, biological activity, mechanical properties, surface chemistry, cytotoxicity and trophic/growth factor binding capabilities (Dhandayuthapani et al. 2011; Sell et al. 2010; Zhu and Marchant 2011; Marti et al. 2012). Materials that are biodegradable, with chemistries permitting tunable degradation rates, and displaying mechanical and structural properties favoring cell adhesion, growth and proliferation will be important to neural regeneration

applications. This section provides a brief survey of potential stem cell-based biomaterial applications for CNS repair and regeneration. Recent review articles provide greater detail about specific biomaterials and applications in tissue engineering and CNS regeneration (Tam et al. 2014; Mallapragada et al. 2015; Sandquist et al. 2016).

A number of bioactive molecules have been used to enhance plasticity, stimulate neurogenesis, provide neuroprotection and promote CNS regeneration following neurological insults. Neurotrophins are a family of bioactive molecules that play a role in growth and survival of developing as well as maintenance of mature neurons. The neurotrophin family of trophic factors includes NGF, BDNF and Neurotrophin-3 and 4 (NT-3, NT-4). Other neurotrophic factors include CNTF, the GDNF family of ligands (GDNF, Nurturin, artemin and persephin), transforming growth factor β family, interleukin-6-related cytokines, FGF family members, as well as a number of other inductive signaling molecules involved in neural patterning (Reichardt 2006). Development of nano/microparticle systems capable of delivering and releasing such therapeutic molecules has revolutionized the field of drug delivery. Natural and synthetic polymers have been used to fabricate particulate systems for drug release due to their advantages, including improved drug stability, optimal encapsulation capacity, lower toxicity, fewer administration time points, ability to incorporate hydrophobic as well as hydrophilic drugs, sustained drug release capabilities, cellular uptake potential and ability to cross the blood-brain barrier (BBB) (Gelperina et al. 2005; De Jong and Borm 2008; Singh and Lillard 2009). The encapsulation of biologically active agents within biodegradable particulate systems has provided an effective means of overcoming numerous challenges encountered when developing strategies for drug and gene delivery, stem cell differentiation, imaging of live cells and encapsulated cell delivery systems for therapeutic proteins (Mudshinge et al. 2011; Norizadeh-Abbariki et al. 2014; Brustle et al. 2015; Ilie et al. 2012; Lee et al. 2012; Wang et al. 2010).

A number of studies have investigated delivery of neurotrophic growth factors including NGF, BDNF, CNTF and GDNF-encapsulated in poly-lactic co-glycolic acid (PLGA) microparticles as a therapeutic approach in animal models used for study of neurodegenerative conditions, including Alzheimer's, Parkinson's disease and retinal degeneration (Garbayo et al. 2009; Andrieu-Soler et al. 2005; Jollivet et al. 2004a, b; Péan et al. 2000; Grozdanic et al. 2010; Kyhn et al. 2009). Delivery of these trophic factors resulted in functional improvements and tissue regeneration, likely resulting from neuroprotective qualities associated with these factors. As a combination strategy, microparticles have also been incorporated into polymer or hydrogel scaffolds for better localization, sustained release and better clearance when implanted in vivo (Burdick et al. 2006). Other studies have encapsulated cells

along with growth factors within biofunctionalized polymer scaffolds as a promising strategy for neural regeneration (Wang et al. 2012).

A number of synthetic and natural polymers have been used to develop scaffolding platforms for organizing and delivering cells to the CNS. Nano and microfiber systems [such as poly(L-lactic acid) (PLLA), poly(D,L-lactide-co-glycolide) (PLGA), poly(ϵ -caprolactone) (PCL) etc.] have been extensively used to direct neural regeneration. Yang and colleagues produced aligned fibrous scaffolds using an electrospinning technique and found that the aligned nanofibers improved neurite outgrowth and enhanced differentiation of neural stem cells (Yang et al. 2005). Others have also used nano/microfiber systems to direct neurite growth and cellular alignment (Subramanian et al. 2011). In addition to providing physical alignment cues for cell growth, these types of scaffolds have also been functionalized and loaded with neurotrophic factors to promote neural regeneration (Chew et al. 2005).

Different types of scaffolds including films, nanotubes, gels, and porous materials have been used in developing neural regeneration strategies (Spivey et al. 2012; McCreedy and Sakiyama-Elbert 2012). Polymer-based porous films loaded with neurotrophic factors have been used to create gradients and surface modification used to create nano/micropatterns as conduits for neural regeneration (Tang et al. 2013; Kim et al. 2015). Scaffold systems bearing surface patterning have been used to provide topographic guidance cues to create regenerative platforms for a variety of cells, including astrocytes, neural stem cells, MSCs and Schwann cells (Roberts et al. 2014; Ho et al. 2015; McMurtrey 2014; Houchin-Ray et al. 2007; Rutkowski et al. 2004; Recknor et al. 2006; Sharma et al. 2016). Coupling stem cells and cellular reprogramming, along with 3-D scaffolds (i.e., nerve regeneration conduits) is a significant strategy to facilitate nerve regeneration. In many cases these bioengineering approaches have been effective in promoting peripheral nerve regeneration. However, with appropriate modifications these approaches will likely have significant benefits when applied to CNS regeneration as well.

47.6 Summary

The complexity and accessibility of the CNS has been a limitation in development of effective therapeutic interventions promoting neural regeneration. In addition, the environment of the damaged or diseased CNS is generally somewhat hostile and does not support extensive regeneration. The use of stem cells and/or neuroprotective factors coupled with biomaterials may provide a powerful approach to overcome many of these limitations.

This chapter has presented a number of approaches that may be effective in augmenting the limited repair capacity of

the mammalian CNS. In comparison to the CNS, the regenerative capacity of the PNS can be quite robust and a number of investigators have sought to identify differences in the hope of identifying molecular targets that may be exploited to enhance CNS regeneration. Another promising approach has been cell transplantation in order to replace lost cells within the damaged or diseased CNS. The choice of cell type will be critical in developing cell-based regeneration and repair strategies. For example, if stem cells (pluripotent or multipotent) are selected, the cells must be competent to generate specific cell types targeted for each disease. Furthermore, if pluripotent cells are selected, this increases the risk of teratoma formation. Cellular reprogramming or direct conversion of somatic cells into functional “induced” neuronal cell types may also be a feasible approach. However, there may be limitations on the number of cells that can be effectively generated using this methodology.

Once cells have been carefully and rigorously characterized *in vitro* they must be tested *in vivo* in preclinical animal models that best model the disease/condition. *In vivo* the transplanted cells must survive long-term at multiple CNS regions, integrate into existing host circuitry (for neurons), receive appropriate and specific regulatory inputs and elaborating axons that grow and form specific and functional synaptic contacts. Moreover, the transplanted cells must induce a clear long-term functional benefit. While established models may continue to prove beneficial, the generation of new genetic models, toxin-induced lesion models, or surgically induced lesion models should also be considered.

For cell transplantation, not only is choice of cell type important, but also the dose (number of cells) and location of cell transplants will need to be carefully considered. In addition to possible cell replacement, cell transplantation may also mediate repair and recovery through neuroprotection via release of neurotrophic growth factors, as well as the modification of the inflammatory environment. The successful outcome of cell transplants will also depend critically on the timing of the transplant in relation to the optimal stage of the disease at which the patient is likely to benefit the most from the therapy. It is important that preclinical studies also demonstrate protection of remaining neural elements using strategies that might be employed in future patients. Although histological evidence for cellular protection will be important, this must be accompanied with significant functional and behavioral improvements. To be clinically viable as a treatment option for CNS neurological conditions, the therapy must induce substantial amelioration of the neurological deficits without inducing significant deleterious side effects.

The combination of cellular-based therapies along with bioengineering approaches is an extremely powerful approach for regenerative medicine. Stem cell bioengineering provides a means of manipulating the molecular, physical and cellular environment in order to enhance regeneration

and repair of the CNS. Understanding and mimicking the complexity of the local environment, composed of a multitude of soluble and surface-associated signaling molecules, cell-to-cell contacts, cell-to-ECM, and local mechanical/physical cues will be important in regulating not only cell fate, but also cell behavior.

As the field of regenerative medicine in the CNS moves toward the future, it is apparent that systems-level approaches will help guide the field of stem cell bioengineering and the development of effective therapeutics. Understanding regulatory networks as well as the continued elucidation of neural connectomes will be essential for development of novel and effective neurotherapeutics for CNS regeneration and repair.

47.7 Review Questions

1. A prominent difference in the regenerative capacity of the mammalian PNS versus the CNS is associated with the:
 - (a) Neurons
 - (b) *Glial cell types*
 - (c) Stem cells
2. Stem cells are characterized by which of the following features?
 - (a) unlimited capacity for self-renew
 - (b) ability to differentiate into multiple cell types
 - (c) ability to differentiate into neurons only
 - (d) *a and b only*
 - (e) a and c only
3. A CNS neural stem cell can differentiate into which of the following cell types?
 - (a) neurons, muscle, and skin cells
 - (b) *neurons, astrocytes and oligodendrocytes*
 - (c) astrocytes, oligodendrocytes, and Schwann cells
 - (d) Schwann cells, motor neurons and microglia
4. What group of proteins plays a key role in controlling the program of developmental changes?
 - (a) motor proteins
 - (b) transporter proteins
 - (c) *transcription factors*
 - (d) synaptic proteins
 - (e) restriction endonucleases
5. A pluripotent stem cell is capable of:
 - (a) generating skin cells, but not nerve cells
 - (b) generating epidermal cells, but not mesoderm or endodermal cells
 - (c) generating cell types from skin and brain, but not muscle
 - (d) generating muscle and intestinal cells, but not neurons
 - (e) *generating neurons, skin, muscle and lung cells.*
6. Adult neural stem cells have been isolated from:
 - (a) muscle tissue and pancreatic tissue
 - (b) *the hippocampus and the subventricular zone*
 - (c) the pons and the superchiasmatic nucleus of the thalamus
 - (d) lewy bodies and neurofibrillary tangles
7. Which cell type produces factors that actively inhibit CNS regeneration?
 - (a) dorsal root ganglion neurons
 - (b) Schwann cells
 - (c) spinal reticular neurons
 - (d) *oligodendrocytes*
8. Myelin producing cells of the CNS are the:
 - (a) dorsal root ganglion neurons
 - (b) Schwann cells
 - (c) spinal reticular neurons
 - (d) *oligodendrocytes*
9. Myelin producing cells of the PNS are the:
 - (a) dorsal root ganglion neurons
 - (b) *Schwann cells*
 - (c) spinal reticular neurons
 - (d) oligodendrocytes
10. Which of the following are members of the neurotrophin family?
 - (a) CNS, PNS and ESC
 - (b) NCAM, N-cadherin, and laminin
 - (c) *NGF, BDNF and NT-3*
 - (d) IL-6, CNTF and FGF-2
11. Which of the following can be involved in cell-cell or cell-ECM interactions?
 - (a) PLLA, PLGA and PCL
 - (b) *NCAM, N-cadherin, and laminin*
 - (c) NGF, BDNF and NT-3
 - (d) IL-6, CNTF and FGF-2
12. Which of the following are myelin-associated molecules that inhibit axon regrowth?
 - (a) integrin receptors, neural cell adhesion molecule, and N-Cadherin
 - (b) PTEN/mTOR, JAK/STAT, and DLK/JNK
 - (c) fibroblast growth factor-2 and epidermal growth factor
 - (d) *chondroitin sulfate proteoglycans, Nogo-A, myelin-associated glycoprotein, and oligodendrocyte-myelin glycoprotein*
13. Generating dopaminergic neurons would likely be a very important consideration when developing stem cell-based therapies to treat which disease?
 - (a) glaucoma
 - (b) spinal muscular atrophy
 - (c) *Parkinson's disease*
 - (d) macular degeneration

14. Bone marrow-derived mesenchymal stem cells normally differentiate into which of the following cell types?
 - (a) islet cells, Schwann cells, and macrophages
 - (b) *osteocytes, chondrocytes, and adipocytes*
 - (c) neurons, astrocytes, and oligodendrocytes
 - (d) pigment cells, skin cells, and dorsal root ganglion cells
15. In designing an *in vitro* system to isolate and characterize neural stem cells which factors might you select to promote cell proliferation?
 - (a) NGF and/or BDNF
 - (b) CNTF and/or GDNF
 - (c) CSPG and/or LIF
 - (d) *EGF and/or FGF-2*
16. Integrin receptors typically bind ...
 - (a) neurotrophins
 - (b) *ECM molecules*
 - (c) myelin glycoproteins
 - (d) Nogo-A, but not Nogo-B
17. Characteristics of the neuroinflammatory response include invasion of circulating ...
 - (a) immune cells (oligos and astrocytes)
 - (b) MSCs
 - (c) *immune cells (macrophages and lymphocytes)*
 - (d) iPSCs
18. Adult neurogenesis in the SVZ results in production of new ...
 - (a) granule cells
 - (b) photoreceptor cells
 - (c) retinal pigment epithelial cells
 - (d) *olfactory interneurons*
19. Formation of teratomas is a potential risk associated with transplantation of ...
 - (a) MSCs
 - (b) *ESCs*
 - (c) neurons
 - (d) astrocytes
20. In theory, pluripotent cells are able to generate cells from which primary germ layers?
 - (a) *endoderm, mesoderm and ectoderm*
 - (b) periderm, endoderm and meristem
 - (c) mesencephalon, diencephalon and metencephalon

New Generation of Adjuvants for Protection Against Disease and to Combat Bioterrorism

48

Sam D. Sanderson, Joseph A. Vetro,
and Bala Vamsi Krishna Karuturi

Abstract

This chapter highlights the characteristics of traditional and non-traditional adjuvants, the advantages and disadvantages of their use in vaccines. It has so served to introduce the concept of molecular and host-derived adjuvants to improve immune outcomes while minimizing toxicities. A particular emphasis was placed on the generation of conformationally-restricted, response-selective agonists of the complement component C5a. These all appear to have therapeutic, manufacturing, and commercial potential. However, the development and use of such molecular adjuvants for vaccines represent only one approach put forward to meet the modern-day threats posed by antibiotic-resistant strains of bacteria and bioterrorism. It is clear that a well-organized and concerted worldwide effort that utilizes multiple approaches to develop novel adjuvant and vaccine designs will be required to overcome these growing threats to human and animal populations.

Antigen presenting cells • C5a • Complement • EP67 • Molecular adjuvant • Vaccines

48.1 Introduction

Vaccines remain one of the greatest advances of medical history having led to the eradication of smallpox and the near-eradication of polio. Vaccination is principally a prophylactic approach with the objective of generating long-lived humoral and cellular immune responses that provide protection against invading pathogens. Traditionally, vaccines rely on the use of live-attenuated, killed, or inactivated forms of a whole pathogen as the target antigen (Ag); i.e., that entity against which an immune response is sought. Such whole-pathogen vaccines are effective in generating protective immune responses primarily due to their close resemblance to natural infections. However, these vaccines pose certain

issues including undesirable host reactions, difficulties associated with generating the target Ag in culture, the risk of pathogen reversion to virulence, and logistical challenges in maintaining a cold supply chain for vaccine distribution. These vaccines also pose significant safety issues in immunocompromised and neonate patients.

In contrast to whole-pathogen vaccines that make use of a whole attenuated pathogen as the target Ag, subunit vaccines are short, specific fragments of pathogen-associated proteins, which are safer, noninfectious, and immunologically more defined than traditional, whole pathogen vaccine approaches. Advances in Ag discovery technologies using reverse engineering of protective immune responses from pathogen-infected subjects (disease non-progressors) have heralded a new era in vaccine development for prevention of global diseases.

A prominent feature that underscores the current era of modern vaccinology is the ability to generate a huge variety of Ags by various synthetic chemistry and genetic engineering techniques. As a result, Ags now can be produced rapidly

and in large quantities with well-defined structures and in highly purified forms—desirable attributes for their use in vaccines intended to generate Ag-specific immune responses in a diverse population. Unfortunately, the routine use of these Ags as integral components of vaccines is encumbered by their inherent lack of immunogenicity. Such vaccines, therefore, require the use of adjuvants in order to potentiate and focus the immune response to the Ag so that optimal immune outcome can be achieved. Thus, the discovery and development of new adjuvants is of growing importance to the design of vaccines capable of meeting the modern threats posed to human and animal populations by new or resurgent infectious and non-infectious diseases.

This chapter highlights recent trends in the development of adjuvants and, their current proposed mechanisms of action with an emphasis on adjuvants derived from components of the host (i.e., host-derived adjuvants) rather than the more commonly-used adjuvants derived from components of pathogens (i.e., pathogen-derived adjuvants).

48.2 Adjuvants: Vehicles and Immunomodulators

An adjuvant is any substance or any formulation of substances that enhances an immune response specific to an Ag. Adjuvants increase the magnitude, longevity and quality of Ag-specific immune responses. Apart from increasing vaccine effectiveness, adjuvants also reduce the amount and number of vaccine doses required to generate protective immune responses and thus contribute to increased patient compliance. As a general rule, adjuvants can be broadly classified into either vaccine delivery vehicles or immunomodulators. Often, both of these can be combined to further increase vaccine effectiveness. The use of adjuvants in vaccines to improve their effectiveness has traditionally been empirical. The necessity for new vaccine adjuvants arises from the shortcomings of currently approved adjuvants, which are incapable of eliciting immune responses that correlate with protection against different target pathogens. Rational design of vaccine adjuvants is essential for polarization of immune responses that correlate with protection against different pathogens and tumors.

48.2.1 Vehicles

Vaccine delivery vehicles are those adjuvants that help carry Ags to and retain them in proximity to lymphocytes and other auxiliary immune cells, particularly antigen presenting cells (APC), within various lymphoid tissues. Indeed, it is

this “depot” effect that is the defining mechanism of vehicle adjuvants. Classic examples of vehicles include liposomes, emulsions, proteosomes, and immunostimulating complexes (ISCOM) (Crouch et al. 2005). Typically, the final vaccine formulation is the Ag contained within the vehicle. Other examples of vaccines that utilize vehicles include formulations in which the Ag is covalently linked to biocompatible and biodegradable microparticles such as poly(D,L-lactide-coglycolide) (PLGA) (Diwan et al. 2004), nanoparticles, or adsorbed on the surface of carriers such as calcium and aluminum salts (phosphate or hydroxide), particularly alum, which is the only adjuvant currently approved for human use (Olive et al. 2001).

48.2.2 Immunomodulators

Immunomodulators are adjuvants defined by their ability to activate APCs and/or lymphocytes. Typically, this activation is characterized by the adjuvant-induced release of cytokines from lymphocytes and other auxiliary immune cells. Examples of immunomodulators include muramyl-dipeptide (MDP), monophosphoryl lipid A (MPL) (Ulrich and Myers 1995), lipopolysaccharide (LPS) (Johnson et al. 1956), bacterial cell membranes (Muhlradt et al. 1998), certain components of the complement system (Dempsey et al. 1996; Jacquier-Sarlin et al. 1995), cytokines (Afonso et al. 1994; Kurzawa et al. 1998), and oligonucleotide mimics of bacterial DNA. The typical vaccine formulation is one in which the Ag is admixed with the immunomodulator. Variations on this theme include those in which the Ag is covalently linked to the immunomodulator with the rationale that elements of the generalized immune response invoked by the adjuvant might be more directed to the Ag. Some examples of this approach include the incorporation of lipids, lipopolysaccharides, and lipoamino acids into peptide Ags by synthetic methods (Defoort et al. 1992; Martinon et al. 1992; Metzger et al. 1991; Olive et al. 2001; Wiesmuller et al. 1992) and the genetic fusion of chemokines/cytokines to protein Ags (Biragyn et al. 1999).

It should be pointed out that this classification of adjuvants is based more on historical observations than on strict mechanisms of action. In fact, there are several examples of adjuvants belonging to the vehicle family that act as immunomodulators. A noteworthy example of this is the saponins, which are extracted from the plant *Quillaja saponaria* and are used to create emulsions into which Ags are added. Over the years, a variety of chemical modifications of saponins have been used as adjuvants and all appear to stimulate the release of various T helper 1 (Th1) and T helper 2 (Th2) cytokines in addition to their vehicle-like mode of action (Shi et al. 2005).

Finally, there are many examples of vaccine formulations in which individual adjuvants are used in combination with others as a way of optimizing immune efficiency (efficacy) and outcome. Despite the current emphasis placed on evaluating the wide variety of adjuvants in experimental use today and the myriad of possible combinations and formulations, no particular adjuvant or adjuvant system has emerged as an ideal product. Also, given the variation within a data set in which adjuvants are employed, it appears that the effectiveness of an adjuvant or adjuvant system is best evaluated on a case-by-case basis.

48.3 Adjuvant Development: General Concepts

As stated above, the principal objective for the use of an adjuvant in a vaccine is to potentiate immune response to an Ag of minimal immunogenicity. How this potentiation is achieved varies from adjuvant-to-adjuvant and in many cases, the precise mechanism of action is unknown. However, as a rule, immune potentiation is accomplished by the ability of the adjuvant to induce a variety of non-specific activities within the innate arm of the immune system. Once activated, the innate branch of immunity, particularly the complement system, orchestrates the various humoral and cell-mediated responses that operate within and between the innate and acquired arms. The result is a generalized activation and potentiation of the immune system in response to the adjuvant with the hope that this generalized immune priming will allow for a more effective processing and recognition of the Ag contained within the vaccine.

48.3.1 Pathogen-Derived Adjuvants

The manner by which an adjuvant induces this immune priming emanates from the exquisite sensitivity of the mammalian immune system to detect the presence of bacteria and bacterial components and respond accordingly in a rapid and vigorous manner. The initial response to these bacterial signals is largely a function of the innate branch of the immune system, which has evolved under continual selective pressure from pathogenic bacteria and other disease-causing microorganisms. It is not surprising, therefore, that the majority of adjuvants in use today are composed of various molecules, components, and structures derived from bacteria. The use of these adjuvants in vaccines, therefore, provides the bacterial signals to which the innate arm of the immune system vigorously reacts, which results in the priming/potentiation of the immune system.

However, this rapid and vigorous innate response to the bacteria-like signals induced by such adjuvants can result in an overly aggressive and misdirected immune response that is accompanied by undesirable side-effects such as anaphylaxis, fever, injection site granulomas or rashes, and local or systemic inflammation. Another drawback is that the adjuvant tends to induce a generalized immune response with little immune specificity directed to the Ag of interest. Also, immunity that might be directed to the Ag can be masked due to the magnitude of the innate response to the adjuvant. In an attempt to overcome these drawbacks, there is a vigorous and concerted research effort to develop modifications of bacterial-derived adjuvants such that they retain their ability to induce innate responses to bacterial signals, but minimize or eliminate the deleterious inflammatory side-effects that can accompany such signals. Notable examples of such efforts include the many chemical and structural modifications developed and tested on MPL (Ulrich and Myers 1995) the saponins (Shi et al. 2005), and cholera toxin (Lycke 2005).

48.3.2 Host-Derived Adjuvants

Against the backdrop of the various issues that accompany the use of adjuvants derived from bacterial components, a new area of adjuvant discovery focuses on the development of adjuvants derived from naturally-occurring components of host innate immunity. Such host-derived adjuvants would provide the required signaling necessary for engagement of the various cellular components of innate immunity, but with a degree of immunologic control, focus, and tolerance that may not be achieved with pathogen-derived components. In this regard, the use of cytokines as immuno-stimulatory adjuvants would qualify as host-derived adjuvants. However, the mode of action of cytokines encompasses a wide range of cellular effects within the innate and acquired arms of immunity and their use is effectively limited by issues of immunologic focus, control, and tolerance. Nonetheless, the idea of developing an adjuvant from a natural component involved in induction of host innate/acquired immunity is of keen interest. As mentioned above, the major issue will be in engineering an element of specificity such that the host-derived adjuvant induces/activates a single (or limited) pathway of immune activation and/or engages a single (or limited) population of immune cells.

48.3.3 Mucosal Adjuvants

Most of the currently approved vaccine adjuvants are intended for use in systemic immunizations. Mucosal sur-

faces, however, are the major portal for the entry of a variety of pathogens and mucosal immunization generates humoral and cellular immune responses at the mucosal surface, which restricts the entry of invading pathogens. Furthermore, generating immune response at one mucosal site is capable of generating similar immune responses at distinct mucosal sites. This phenomenon, known as the “common mucosal immune system”, can be exploited to induce mucosal immune responses at inaccessible mucosal sites like the vagina and rectum, by immunizing through accessible mucosal routes such as the oral and intranasal cavity (Courtney 2010). Mucosal immunization is also the most feasible, non-invasive, and risk-free route for mass-immunization regimens.

In contrast to systemic immunization, which operates in a sterile milieu, mucosal immunization is confronted with the challenge of generating immune responses after being administered at a non-sterile site, which is constantly exposed to large quantities of harmless food and environmental antigens (Tsuji and Kosaka 2008). Mucosal immunizations also need to overcome the immune tolerance mechanisms at the mucosal site, which prevent unnecessary detrimental immune responses against non-pathogens and food antigens. While induction of immune tolerance is essential for preventing immune responses against food and environmental antigens, it necessitates the need for strong immunostimulatory components in the mucosal vaccines to generate immune responses.

Many adjuvant systems used for systemic vaccine applications such as oil-in-water emulsions and mineral salt adjuvants may not be suitable for mucosal applications. Adjuvants delivered at mucosal surfaces need to overcome the inherent tolerogenicity associated with mucosal tissues. The effective mucosal adjuvants currently being used in animal models include CpG, bacterial toxins such as cholera toxin (CT), heat-labile enterotoxins, cytokines/chemokines and VLPs (Courtney 2010; Huang et al. 2008; Lycke 2012; Vajdy and Lycke 1992; van Ginkel et al. 2005). Most of these compounds function as potent adjuvants through activation of antigen-presenting dendritic cells (DCs). Of the existing mucosal adjuvants, bacterial toxin adjuvants are most potent in generating humoral and cellular immune responses, but are very toxic and not fit for human use. CpG and other toll like receptor agonists have shown promise as mucosal adjuvants but are generally associated with inflammation. Whether pathogen-derived or host-derived, safe yet potent adjuvants that overcome mucosal tolerance and generate long-lived protective immune responses in mucosal and systemic immune responses are necessary for vaccination approaches that target pathogens, which infect through mucosal surfaces.

48.3.4 Molecular Adjuvants

The need for an adjuvant capable of inducing a robust *and* Ag-specific immune response accompanied with minimal inflammatory side-effects has given rise to a new class of adjuvants, which have come to be known as molecular adjuvants (Dempsey et al. 1996). The rationale for a molecular adjuvant is based on the notion that a single, well-defined and well-characterized molecular entity might be better in inducing an immune response more directed to the Ag with fewer non-specific side effects, particularly when the Ag is attached directly to the molecular adjuvant. Thus, a molecular adjuvant can be defined as a single molecular entity that targets an Ag to the cells of the immune system responsible for Ag processing and presentation (APCs) and/or activates specific pathways of Ag processing and presentation within these cells.

48.4 Development a Host-Derived, Molecular, and Humoral Adjuvant

As described above, “traditional” adjuvants typically are derived from bacterial components in order to provide the bacteria signals necessary for the activation and potentiation of the innate arm of the immune system. One of the first biological systems of that which becomes activated in response to these bacterial signals is the complement system. Consequently, complement and the various components that comprise the complement system provide a rich source from which a variety of host-derived adjuvants could be developed. This section describes the development of a host-derived adjuvant that was developed from a natural component of human complement known as C5a. This host-derived adjuvant embodies the attributes of a molecular adjuvant as well as a humoral adjuvant, examples of which are discussed below.

48.4.1 Complement

Complement is a plasma system comprised of interrelated proteases arranged in a cascade fashion that becomes activated in response to bacterial signals and Ags associated with bacteria. The role of complement is twofold: (1) to serve as an initial, first line of defense to invading microorganisms and (2) to enhance systemic host defense by activating and orchestrating the various humoral and cell-mediated responses within the acquired and innate arms of the immune system necessary for the effective elimination of the microorganism.

The “first line of defense” is accomplished through the generation of the membrane attack complex (MAC), which is assembled at the end of the complement cascade from the components generated by the proteolytic steps along the cascade. The MAC is directly involved in lysing the membranes of foreign microorganisms.

Secondly, the various humoral and cell-mediated responses operating at the interface of the innate and acquired arms of the immune system are activated and coordinated by pharmacologically active components that are released at certain steps along the complement cascade. These proteolytic byproducts induce the various humoral and cell-mediated aspects of the innate and acquired arms of immunity, all of which are necessary for the concerted elimination of the microorganism.

Principally because of this latter reason, these pharmacologically active components of complement are attractive as molecular adjuvants. This is because their use has the potential of enhancing specific pathways of the innate and acquired immune processing and subsequent recognition of an Ag as opposed to the broader and less Ag-focused activation of the innate system in response to bacterial signals that come from adjuvants derived from bacterial components.

48.4.2 Adjuvants Derived from Complement Components: Host-Derived Adjuvants

Components of complement have been used as molecular adjuvants to enhance Ag-specific immune responses to model Ags, specifically C3b, C4b (Arvieux et al. 1988; Jacquier-Sarlin et al. 1995), and C3d (Dempsey et al. 1996). These components were chosen primarily for their opsonic properties; i.e., their ability to bind to and coat the surface of a microorganism rendering it more susceptible to immune cell uptake via phagocytosis. The rationale, therefore, was that an Ag covalently attached to these complement fragments similarly would be rendered more susceptible for uptake by APCs and, consequently, would be more effectively processed and presented by the APC. In all cases, the immunogenicity of the model Ag in the Ag-complement vaccine complex was markedly enhanced relative to the Ag alone, suggesting that the complement fragment acted as a molecular adjuvant by enhancing Ag uptake by APCs and, in turn, the ability of the APC to process and present the Ag. These studies clearly demonstrate the immunologic potential of using complement components as molecular adjuvants in the design of vaccines.

48.4.3 The Anaphylatoxins

An important group of pharmacologically active byproducts of complement activation are the anaphylatoxins C3a, C4a, and C5a, which are small (74–76 residue) fragments cleaved from the larger, parent complement components C3, C4, and C5, respectively. The principal roles of the anaphylatoxins are to recruit inflammatory cells and lymphocytes to sites of tissue injury and infection and to then activate these cells’ various effector responses once recruited (Hugli 1981). However, the anaphylatoxins play important roles in the activation and regulation of humoral and cell-mediated responses to Ags due to their ability to modulate various humoral and cell-mediated activities between the innate and acquired arms of the immune system (Dempsey et al. 1996; Mastellos et al. 2005; Morgan 1986). Consequently, the anaphylatoxins are attractive as molecular adjuvants, which may be capable of invoking Ag-specific humoral and/or cell-mediated immune responses.

Unfortunately, the anaphylatoxins are also potent inflammatory mediators and their use as molecular adjuvants would surely be accompanied by local and/or systemic inflammatory side effects. Also, under certain conditions, the anaphylatoxins appear to downregulate immune function (Kawamoto et al. 2004; Morgan 1986). Thus, while the anaphylatoxins have desirable immune stimulatory activities that make them attractive for use as molecular adjuvants, they carry with them the potential for adverse inflammatory side effects and immune downregulation. Therefore, immune stimulatory activities must be enhanced at the expense of its inflammatory activities and any tendency to downregulate immune response.

48.4.4 Immunostimulatory and Inflammatory Properties of C5a

C5a is a 74-residue polypeptide with pleiotropic biological functions (Fig. 48.1) including smooth muscle contraction, vascular permeability, mast cell degranulation, and chemotaxis. C5a potentiates antibody and Ag-induced T cell proliferative responses in vitro possibly through activation of T helper cells (Morgan et al. 1983). Direct stimulation of mouse and human dendritic cells with C5a enhances the expression of MHC class II, co-stimulatory molecules CD80, CD86, CD40 and CD54, and induces secretion of cytokines of Th1 phenotype (Zaal et al. 2013; Rudilla et al. 2012; Li et al. 2012). Also, C5a induces the release of a variety of immunoregulatory cytokines from APCs including IL-1, IL-6, IL-8, IL-12, TNF α , and IFN γ (Buchner et al. 1995;

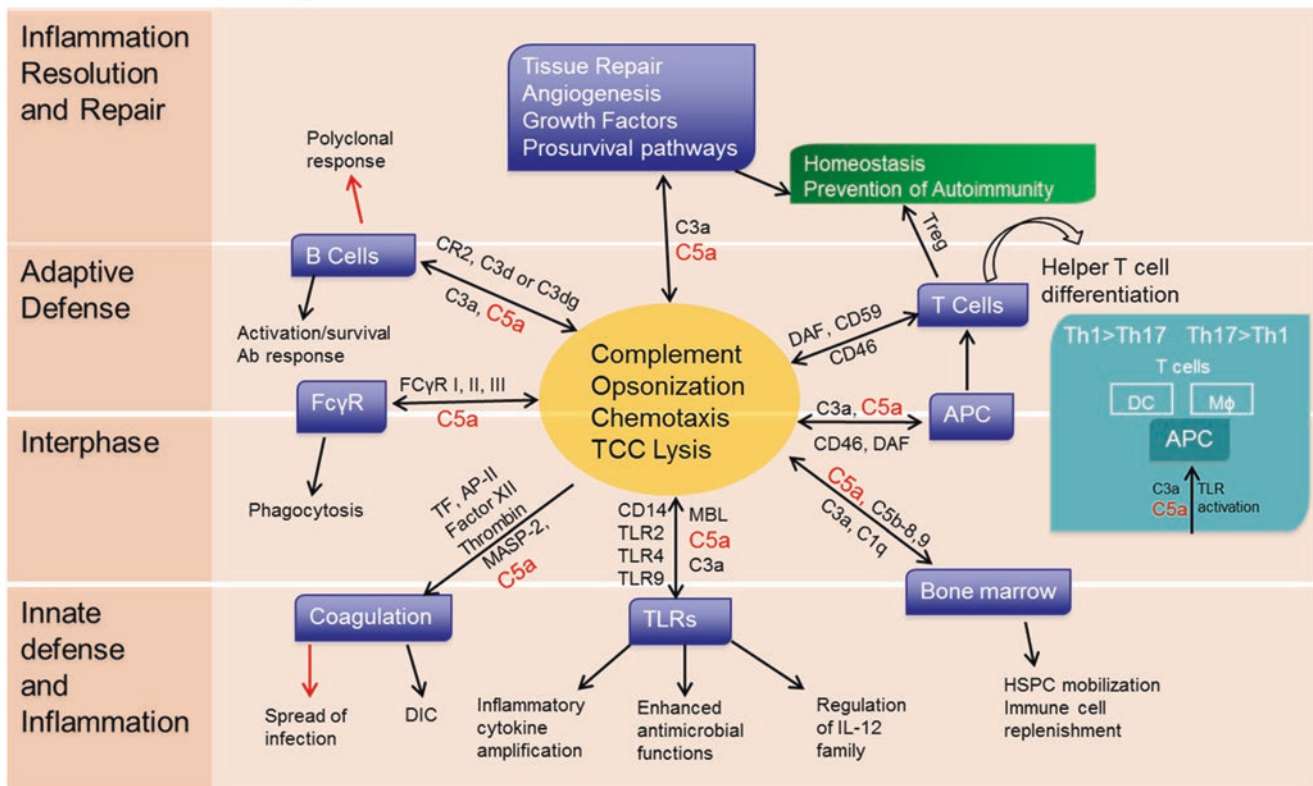

Fig. 48.1 Role of complement C5a in host defense and homeostasis. Adapted from Ricklin et al. (2010)

Goodman et al. 1982; Okusawa et al. 1987; Wetsel 1995b) (Gasque et al. 1995; Scholz et al. 1990); (Ember et al. 1994); (Floreni et al. 2007). C5a-mediated stimulation of DCs also decreased intracellular production of cAMP, which is a negative regulator of DC activation and function (Li et al. 2012). Furthermore, C5a interaction with C5aR activates PI3K, ERK1/2, NF-κB signaling pathways, which positively regulates Ag uptake, presentation, and secretion of proinflammatory cytokines by DCs (Li et al. 2012; Zaal et al. 2013). C5a was also shown to exhibit both synergistic as well as antagonistic crosstalk with toll like receptors (TLRs) in functional modulation of DCs (Li et al. 2012; Zaal et al. 2013). C5a decreased TLR4-mediated IL-12 secretion by DCs, but significantly increased secretion of other Th1 cytokines and CXCL16 involved in NK cell activation. C5aR ligation with C5a was shown to be essential for generation of protective anti-viral CD8⁺ T cells (Kim et al. 2004). In contrast, genetic ablation or pharmacologic blocking of C5aR signaling predominantly generated Th2 and regulatory T cell responses (Kim et al. 2004). Furthermore, previous studies found that blockade of the C5aR impaired the ability of immune system to generate memory CD4⁺ T cells (Moulton et al. 2007). Also, DCs stimulated with C5a showed increased expression of multiple co-stimulatory molecules, migration to the drain-

ing lymph nodes, and strong interaction with antigen-specific naïve T cells (Li et al. 2012).

Besides immunostimulatory properties that promote Ag presentation and functional immune responses, C5a also possesses highly proinflammatory properties. These include its potent chemotactic activities for the recruitment of inflammatory cells to sites of tissue injury and infection, its ability to induce smooth muscle contraction (Hugli et al. 1987; Shin et al. 1968), increase vascular permeability (Hugli 1990; Hugli et al. 1981; Hugli and Muller-Eberhard 1978), and induce the release of a variety of secondary inflammatory mediators such as histamine, lysosomal enzymes, and vasoactive eicosanoids from responsive cells such as mast cells, neutrophils, eosinophils, and macrophages (Drapeau et al. 1993; Goldstein et al. 1974; Johnson et al. 1975; Lundberg et al. 1987; Schorlemmer et al. 1976).

These biologic responses (inflammation and immunomodulation) are induced by the ligation of C5a to its specific, high affinity receptor (C5aR/CD88) that is expressed on the surface of the C5a-responsive cell(s). Traditionally, C5aR expression has been viewed as being limited to cells of myeloid origin such as neutrophils, monocytes, mast cells, and eosinophils (Wetsel 1995a). However, it is now known that a variety of cells of non-

myeloid origin express C5aRs. These include hepatocytes (Buchner et al. 1995), astrocytes (Gasque et al. 1995), bronchial epithelial cells (Floreani et al. 1998), epithelial cells of the gut and kidney (Wetsel 1995a), and osteoblasts (Pobanz et al. 2000).

As the inflammatory properties of C5a have been the motivation behind the development of C5a antagonists, so the immunostimulatory properties of C5a been the motivating factor for the development of agonists of C5a that can be used as surrogates of the natural factor for enhancing humoral and cell-mediated immune responses; i.e., as a molecular adjuvant. Using such agonists of C5a as a molecular adjuvant, however, requires developing response-selective agonists that are capable of invoking C5a-like immunostimulatory properties at the expense of C5a-like inflammatory properties.

48.4.5 C5a: Structure-Function Considerations

Human C5a is a 74-residue glycopolypeptide that is comprised of two important structural and functional domains. The first is the well-ordered N-terminal core domain comprised of residues 1–63, which is primarily involved in the recognition and binding of C5aRs (Mollison et al. 1989; Zuiderweg et al. 1989). The second is the C-terminal domain, residues 64–74, which extends from the N-terminal core as a finger-like projection. C5a_{65–74} (ISHKDMQLGR) is a region of considerable backbone flexibility and poorly-defined structure, yet the inflammatory *and* immunostimulatory activities characteristic of natural C5a reside in this small C-terminal stretch (Ember et al. 1992, 1994; Morgan et al. 1992).

Flexibility in the C-terminal region of C5a (C5a_{65–74} or ISHKDMQLGR) is a dominant feature of natural C5a. It may be that this flexibility allows the C5aR the ability to induce a unique conformation in this region of the C5a ligand that is conducive to the expression of biologic activity characteristic of that particular C5aR-bearing cell. It may be, in fact, that a biologically active conformation in this effector region of C5a responsible for activity in one type of C5aR-bearing cell may not be the ideal conformation for the expression of activity in another. This suggests that by employing a synthetic strategy in which the flexibility in this effector region of C5a is restricted, one might bias certain conformational features that are important for the expression of certain types of C5aR-mediated activities; i.e., a response-selective agonist. Such a specific and stabilized conformation, when presented to the C5aR, would be more likely to interact with those C5aRs that are capable of accommodating this particular conformation.

48.4.6 Conformationally Restricted Analogues of C5a_{65–74}

Over the years, our laboratory has generated a library of analogues of C5a_{65–74} in which backbone flexibility was restricted by specific amino acid substitutions. This was done with the goal of biasing certain conformational features that might be helpful in the search for biologically relevant conformations responsible for the induction of C5a-like immunostimulatory activities versus those responsible for C5a-like inflammation.

Backbone flexibility was restricted by introducing three principal types of residue substitutions within C5a_{65–74}: (1) Pro substitutions to restrict ϕ angle flexibility and to narrow the range of sterically allowed backbone conformations in the pre-proline residue (Misicka et al. 1991), (2) Ala substitutions to evaluate the biological importance of the side-chains in the peptide, and (3) D-residue substitutions to assess the contribution of stereoisomeric arrangements. The use of such peptide modifications has an additional advantage in that Pro, Ala, and D-residues occupy well-defined regions of sterically-allowed Ramachandran space (Hruby et al. 1991). Thus, an evaluation of the changes made in the biological activity of these conformationally restricted analogues of C5a_{65–74} can provide information about the specific types of backbone conformation features that are important to specific types of biological activity.

Using this approach, we showed that one peptide from this library, C5a_{65–74} Y65,F67,P69,P71,D-Ala73 or YSFKPMPLaR (EP54) exhibited about 10 % of the potency of natural C5a for its ability to induce the release of spasmogenic eicosanoids from human macrophages, but only about 0.1 % of C5a activity in its ability to induce the release of β -glucuronidase from human neutrophils (Finch et al. 1997) and was reflected by a corresponding difference in binding affinity to the C5aRs expressed on these cells (Finch et al. 1997; Vogen et al. 1999).

Structural analysis of YSFKPMPLaR indicated the presence of unique conformational features that appear to be responsible for the selective accommodation by C5aRs expressed on antigen presenting cells (APC) relative to C5aRs expressed on inflammatory neutrophils (Vogen et al. 1999). These backbone conformational features identified in EP54 were then used to guide the generation of other analogues designed to enhance their biologic importance. Prominent among these new analogues is EP67 (YSFKDMP(MeL)aR), which contains an N-methylated Leu residue to enhance backbone elongation in a crucial region of the peptide, which was deemed biologically important from the NMR structure of EP54. Indeed, EP67 was shown to exhibit more potency and macrophage/dendritic cell selectivity than EP54 (Vogen et al. 2001; Taylor et al. 2001).

48.4.7 Use of EP54 and EP67 as Host-Derived, Molecular and Humoral Adjuvants

48.4.7.1 Generation of Ag-Specific Humoral Immune Responses

In one study (Tempero et al. 1997), EP54 was used to induce Ag-specific antibody (Ab) responses to a B cell epitope derived from the human mucin type 1 glycoprotein (MUC1). A vaccine was generated by covalently attaching the MUC1 epitope (YKQGGFLGL) to the N-terminus of EP54 (YKQGGFLGLYSFKPMPLaR) and mice immunized with this vaccine generated high Ab titers specific for the MUC1 epitope. These anti-epitope Abs cross-reacted with MUC1 protein expressed on the surface of a transfected pancreatic cell line, indicating that the anti-YKQGGFLGL Abs recognized the epitope within intact whole MUC1 protein. Also, Ab isotypes generated by this EP54-containing vaccine were IgM, IgG2a, and IgG2b, contrasted with those generated by an analogous KLH construct, which were IgM and IgG1. This suggests that the EP54-containing vaccine induced an Ab class switch characteristic of a Th1-like response and, consequently, generated Ab with isotypes distinct from the traditional KLH construct. Over the years, we have used epitope-EP54 vaccine constructs to immunize rats, hamsters, rabbits, and cattle to a wide variety of epitopes of various lengths (8–35 residues) and small molecules such as nicotine (Sanderson et al. 2003) and methamphetamine (Duryee et al. 2009).

In similar fashion, EP67-containing vaccines have been used to generate Ab responses to peptide epitopes and proteins in mouse models. Mice immunized with these EP67-containing vaccines generated significant levels of Ag-specific IgM, IgG2a, and IgG2b responses (Morgan et al. 2009). Also, mice immunized with intact fungal spores from an attenuated strain of *Coccidioides posadasii* conjugated to EP67 increased the protective efficacy by a corresponding increase in Ag-specific IgG1 and IgG2a Ab responses (Hung et al. 2012).

48.4.7.2 Generation of Ag-Specific Cell-Mediated Immune Responses

Cytotoxic T cell responses (CTL) (CD4⁺ and CD8⁺) in murine models have been generated with EP54- and EP67-containing vaccines designed by their covalent attachment to peptide epitopes from the hepatitis B surface antigen (Ulrich et al. 2000), a tandem repeat region of MUC1 expressed on pancreatic cancer cells (Pisarev et al. 2005), and the gp70 glycoprotein from RAW 117-H10 lymphoma cells (Kollessery et al. 2011). Also, EP67-containing vaccines have been generated in which the target Ag is an entire protein using straightforward conjugation methods (Phillips et al. 2009). Using this approach, we have shown protective Th1 and Th17 CTL responses to *Coccidioides posadasii* in mice immunized with vaccines in which EP67 was conju-

gated to intact fungal spores from an attenuated strain of *C. posadasii* (Hung et al. 2012).

48.4.7.3 Generation of Ag-Specific Mucosal Immune Responses

Simple vaccines were made by the covalent conjugation of CD8⁺ T cell epitopes from proteins expressed on murine cytomegalovirus (MCMV) to EP67. Intranasal immunization generated functional mucosal and systemic epitope-specific CD8⁺ T cells that increased protection against primary mucosal infection with MCMV. Moreover, a large proportion of these CD8⁺ T cells formed a pool of long-lived memory CD8⁺ T cells that respond strongly upon reinfection even in the absence of CD4⁺ Th1 help. This is supported by findings that EP67-based CTL peptides generated a higher proportion of epitope-specific mucosal (lungs) and systemic (spleen) CD8a⁺/CD44⁺ cells with cell surface phenotype (CD127⁺/KLRG1[−]) associated long-lived memory (Karuturi 2014). In addition to CD127 and KLRG1, we found that EP67-based CTL peptides generated epitope-specific CD8⁺ T cells with an increased expression of CD27, which is a strong predictor of proliferative recall responses upon Ag encounter (Ochsenbein et al. 2004; Xiao et al. 2008).

The immunization results in mice demonstrate the unique ability of complement C5a-derived/host-derived adjuvants for use in systemic as well as mucosal vaccine applications. In particular, EP67 because of its significantly reduced inflammatory properties may be acceptable as a universal adjuvant for various vaccine applications. More recent studies have shown the ability of EP67 in protecting against influenza and MRSA infections via induction of innate immunity from its selective engagement of C5aR-bearing APCs (Sanderson et al. 2012; Hanke et al. 2013). Taken together, these studies indicate that EP67 has significant immunostimulatory properties that are conducive to desirable innate and acquired immune outcomes (Table 48.1).

48.5 Mechanism of Action

The immune outcomes obtained from EP54- and EP67-induced humoral and cell-mediated responses suggest that these adjuvants deliver both Ag and stimulatory signals to C5aR-bearing APCs—events that are consistent with the mechanism shown in Fig. 48.2.

This proposed mechanism is supported by confocal microscopy where fluorescent-labeled EP54 and fluorescent-labeled B and T cell epitopes attached to EP54 were rapidly internalized by human DCs (Hegde et al. 2008). Twenty-four hours later, the internalized epitopes were presented in the context of HLA-I and HLA-II determinants on the DC surface. Thus, EP54 (and EP67) both targets and activates APCs suggesting properties of both a vehicle and an immunomodulatory adjuvant.

Table 48.1 Vaccine adjuvant properties of EP54 and EP67

Vaccine construct	Species	Route	Immune response	Ref
Peptide epitope from MUC1 glycoprotein conjugated to EP54	C57BL6 and BALB/c mice	i.p.	Higher titers of IgG2b, IgG2c and IgM Abs in sera reactive against recombinant MUC1 and MUC1 expressing cell line	Tempero et al. (1997)
CTL peptide epitope derived from Hepatitis B surface Antigen (HBsAg) conjugated to EP54	BALB/c mice	s.c	Ag-specific CD8+ CTL responses against murine P815S target cells expressing an H-2L ^d restricted CTL epitope of the HBsAg	Ulrich et al. (2000)
Nicotine hapten conjugated to EP54	Sprague–Dawley rats	i.p.	Nicotine-specific Abs capable of attenuating nicotine-induced behavioral effects	Sanderson et al. (2003)
Methamphetamine (meth) hapten conjugated to EP54	Rats	s.c/i.p.	Meth-specific Abs in sera capable of altering meth self-administration	Duryee et al. (2009)
Ovalbumin (OVA) conjugated to EP67	C57BL6 BALB/c mice	i.p.	OVA-specific Th1-like Ab class switch and OVA-specific proliferative responses in splenocytes	Morgan et al. (2009)
OVA conjugated to EP67	Young/aged mice	i.p.	Higher Ag-specific humoral responses compared to alum adjuvanted OVA	Morgan et al. (2010)
rPrp1, a protein from cell wall of <i>coccidioides</i> conjugated to EP67	Young/aged mice	i.p.	Higher Ag-specific humoral responses compared alum and CpG adjuvanted rPrp1	Morgan et al. (2010)
Peptide epitope derived from gp70 glycoprotein conjugated to EP54 and EP67	BALB/c mice	s.c	Ag-specific CTL responses and protection against metastatic RAW117-H10 lymphoma lethal challenge	Kollessery et al. (2011)
Live spores of attenuated vaccine strain of <i>Coccidioides posadasii</i> conjugated to EP67	BALB/c mice	s.c	Increased protective efficacy of live vaccine by increasing Ag-IgG1, and IgG2a, and Th1, and Th17 immune responses	Hung et al. (2012)

48.6 Review Questions

1. Describe the principal means by which a molecular adjuvant such as EP67 induces innate and/or acquired immune responses.
2. As we age, our immune response profile gradually shifts toward T helper type II (Th2) dominated responses. With this in mind, describe how a molecular adjuvant like EP67 could be advantageous in the generation of vaccines for the growing elderly population.
3. Describe how a molecular adjuvant like EP67 could accommodate the need for the rapid generation of vaccines to counter new and emerging diseases and bioterrorism attacks.

48.7 Answers

1. By the selective engagement and activation of C5aR-bearing antigen presenting cells.
2. This is because EP67, unlike other conventional adjuvants, drives a T helper type I (Th1) dominated immune response, which could restore an immunologically advantageous Th1/Th2 balance that is lost during the aging process.
3. EP67 can be rapidly generated in large quantities by standard peptide synthesis. Vaccines can be rapidly made in large quantities by the simple covalent conjugation of the target antigen to the N-terminus of EP67. Manufacturing of such vaccines is rapid and inexpensive, requires no

Fig. 48.2 Mechanism of action for EP54 and EP67 molecular adjuvants

additives or preservatives, and vaccination can be accomplished on a large scale by the administration of the EP67-based vaccine dissolved merely in water.

Abstract

Recent advances in molecular neuroscience and neuropharmacology have improved our knowledge of the intricate mechanisms that define and treat infectious, immune and degenerative disorders of the brain and spinal cord. As our knowledge expands, treatment of central nervous system diseases still remains a challenge. One obstacle is drug delivery. Indeed, designed to protect the brain from toxic molecules, the blood–brain barrier also limits therapeutic drug entry into the brain. The dynamic balance between the exclusion and therapeutic delivery remains a key component to improve disease outcomes.

Keywords

Blood–brain barrier • Carrier-mediated transport • Central nervous system • GLUT1 • LAT1 • Lipidization • Prodrugs

49.1 Introduction

A range of disease combating strategies has emerged to circumvent the blood–brain barrier's (BBB) restrictive nature. This includes neurosurgery to permit direct intra-cerebroventricular (ICV) infusion, convection-enhanced delivery (CED), and the use of intra-cerebral drug implants (Pardridge 2005). While each are designed to improve drug delivery to sites of central nervous system (CNS) injury and infection, their applications remain limited (Pardridge 2005; Gabathuler 2010). Osmotic or biochemical disruptions cause aberration in endothelial cell tight junctions (Patel et al. 2009). Less invasive platforms such as chemical or biologically modified drugs and nanoparticle delivery systems show, perhaps, the most significant promise (Juillerat-Jeanneret 2008). This chapter will focus on chemical modifications and prodrugs, and their ability to provide enhanced BBB penetrance for improved treatment of CNS disorders.

49.2 Prodrugs

49.2.1 Background

The development of new treatments for CNS disorders has paralleled the discovery of molecular mechanisms for disease. This information has enabled medicinal chemists to rationally design drugs at the molecular level. In all, drug(s) developed for CNS disease have been broad based and not limited by design or functionality. A drug's major factor in success rests in its ability to cross the BBB and retain function in the brain's microenvironment. It is estimated that 98 % of marketed small molecules do not penetrate the brain and as such severely limit the effectiveness and therapeutic potential (Pardridge 2003). In order to improve the drug's therapeutic benefit, medicinal chemists commonly depend on prodrugs. A prodrug, while often not itself efficacious, is a bioreversible chemical modification to an active compound (Albert 1958). Therefore, chemical or enzymatic cleavage is required in vivo to yield an active molecule. Reversible chemical modification provides the flexibility of adding chemical moieties specifically designed to improve barrier penetrance without negatively affecting the drug's action. Presently, between 7 and 10 % of marketed drugs can be

identified as prodrugs (Stella 2004; Zawilska et al. 2013). Prodrugs are designed to improve upon suboptimal characteristics of existing pharmaceuticals. A compound's solubility, absorption, metabolism, tissue targeting, as well as pharmacokinetics and biodistribution, can be improved (Rautio et al. 2008). Prodrug synthesis is dependent on the presence of reactive functional groups such as hydroxyl, amine, carboxylic, or phosphate moieties, which can generate a range of bonds including ester, amide, carbamates, ethers, and phosphates (Rautio et al. 2008). Bond stability prominently affects systemic release kinetics; therefore, the design of prodrugs requires knowledge of the biological system and desired pharmacological outcome. For example, an esterified prodrug designed to target the CNS may cleave in systemic circulation before reaching the brain; therefore, alternative, more stable bonds such as an amide may be considered to affect brain penetrance.

49.3 CNS Drug Delivery

49.3.1 Blood–Brain Barrier

The restrictive nature of the BBB protects potentially harmful molecules from accumulating within the CNS. Consisting of a continuous layer of endothelial cells connected by tight junctions, the BBB separates circulating blood from the extracellular fluid within the brain (Brightman 1977). The BBB is not limited to molecular restriction, but police the entry of essential molecules, thereby regulating the homeostatic, nutritive, and immune environments of the brain (Quan and Banks 2007; Banks 2009). However, the BBB limits the delivery of drugs aimed to function within the brain, thus providing challenges for drug delivery. Low molecular weight molecules with high lipophilicity commonly cross the BBB by transmembrane diffusion, while other molecules can access the brain by using saturable transport systems (Oldendorf 1974; Banks 2009). Furthermore, drugs that enter the brain are subject to be released out by drug efflux transporters belonging to the ATP-binding cassette (ABC), such as P-glycoprotein (P-gp) and multidrug resistance protein 2 (MRP2) (Fig. 49.1) (Juliano and Ling 1976; Miller et al. 2000; Loscher and Potschka 2005). Thus, using an intricate knowledge of BBB physiology, researchers have developed a number of prodrug strategies designed to specifically enhance brain penetrance by transmembrane diffusion, efflux pump inhibition, or exploiting endogenous transport systems on the surface of the BBB.

49.3.2 CNS Targeted Prodrugs

Multiple prodrug techniques can increase CNS drug penetrance. Specifically, prodrugs containing cleavable chemical moieties improve BBB permeability. Lipidization

approaches, as well as carrier and receptor mediated targeting, can improve the translocation across the blood–brain interface.

49.3.2.1 Lipidization

CNS drug access by transmembrane diffusion is directly linked to its molecular weight, lipophilicity, and the presence of ionizable functional groups at physiological pH (Patel et al. 2009). Specifically, for compounds under 400 Da, passive diffusion across the BBB linearly correlates with an increase in log P (Levin 1980). To improve penetrance of water-soluble molecules, an approach termed lipidization is employed. Here, hydrophobic moieties block hydrogen bonding functional groups on the existing molecule, thus increasing lipophilicity and potentiating brain entry. A prime example of lipidization is morphine and its subsequent prodrugs, codeine and heroin. Morphine, an opioid analgesic, has limited CNS accumulation upon systemic administration (Letrent et al. 1999). Methyl etherification of morphine's phenol group generates codeine. Addition of the methyl ether imparts increased hydrophobicity when compared to morphine, largely due to reduced hydrogen bonding capability (Fig. 49.2). Additionally, heroin, which is even more lipophilic than codeine, results from the diesterification of morphine. Oldendorf et al. studied the ability of morphine and its subsequent prodrugs, codeine and heroin, to enter the CNS after direct injection into the rat common carotid artery. Compared with morphine, codeine and heroin displayed enhanced BBB penetrance, exemplified by 12 and 34 fold increases in CNS uptake respectively (Oldendorf et al. 1972). Therefore, heroin more efficiently enters the CNS, is quickly metabolized in the brain to 6-acetyl morphine, and then subsequently converted to morphine where it can engage opioid receptors (Begley 2004).

Research focusing on chlorambucil, an alkylating agent used clinically for the treatment of chronic lymphocytic leukemia, as a new treatment for brain cancer was hindered by its lack of CNS uptake impart due to its ionization at physiological pH (Greig et al. 1988, 1990). In order to increase CNS permeability, seven lipophilic chloromethyl esters were synthesized. Following intravenous administration, no significant differences in brain uptake were observed between the ester prodrugs and chlorambucil (Greig et al. 1990). The lack of significant egress into the brain is due to ester bond cleavage during systemic circulation before the prodrug is able to reach the brain (Greig et al. 1990). To improve prodrug stability, a chlorambucil tertiary butyl ester prodrug was synthesized. Studies confirmed the tertiary butyl ester prodrug of chlorambucil produced peak brain levels three times that of chlorambucil, while extending its CNS half-life two times (Greig et al. 1990).

Theoretically, lipidization should improve passive diffusion across the BBB and promote CNS accumulation. Unfortunately, the complexity of CNS delivery exemplified

Systemic Circulation

Brain

Fig. 49.1 Prodrug Brain Delivery. Drugs entering systemic circulation may gain access to the brain by transmembrane diffusion. However, most compounds do not possess the necessary physiochemical properties to readily transverse the BBB. Therefore, prodrugs are synthesized to improve brain penetrance. They consist of a drug bioreversibly conjugated to a promoiety, transiently changing the compounds physicochemical properties. Lipidization is used to promote transmembrane diffusion across the BBB. Additionally, when the promoiety is a ligand

for a receptor or carrier on the BBB surface, the prodrug can enter the CNS via receptor or carrier-mediated transport. Prodrugs that lack stability may be cleaved in circulation before reaching the brain. Once in the brain, prodrugs are cleaved to yield the active drug and promoiety. Based upon prodrug design, the promoiety can be inert or have a pharmacological effect of its own. Newly released drugs can now act within the brain for pharmaceutical effect or be pumped out of the CNS by efflux transporters such as P-gp or MRPs

Fig. 49.2 Lipidization of Morphine. Methyl etherification of morphine yields codeine, while diesterification of results in heroin. Both heroin and codeine are more hydrophobic than morphine. Each can readily

cross the BBB and subsequently release morphine for physiological effects within the brain.

in the development of chlorambucil esters is more involved. Indeed, the lack of site-specific delivery limits the effectiveness of lipidization. Simply increasing hydrophobicity will enhance diffusion across all biological membranes. Therefore, increased CNS uptake may be offset by suboptimal pharmacokinetics due to increased plasma clearance, reductions in the area under the curve (AUC), and enhancement on protein binding (Pardridge 2007). Furthermore, lipidization requires the addition of hydrophobic moieties. Molecular weight increases may compromise CNS entry, as for molecules >400 Da, BBB permeability no longer linearly correlates with lipid solubility (Fischer et al. 1998; Pardridge 2007). Therefore, other methods to achieve BBB penetration and appreciable CNS accumulation were explored.

49.3.2.2 Biological Systems of CNS Entry

Certainly, notwithstanding the improved CNS delivery of morphine by its subsequent prodrugs, codeine and heroin, lipidization has limited utility in terms of CNS drug delivery. In addition to passive diffusion of lipophilic small molecules across the BBB, endogenous transport systems located within the brain capillary endothelium allow specific molecules such as amino acids, nutrients, glucose, and vitamins to transverse the BBB (Peura et al. 2013). Thus, bioreversible conjugation of ligands targeting specific endogenous transport systems along the BBB presents a prodrug strategy for CNS delivery (Pavan and Dalpiaz 2011). Research focused on targeting a multitude of receptors or transporters on the surface of the BBB will be expanded in more detail.

49.3.2.3 LAT1

CNS-specific drug delivery is designed to improve drug accumulation within the brain, as well as potentially lower side effects resulting from non-specific distribution. Harnessing endogenous receptors and transporters at the surface of the BBB to enhance prodrug delivery may significantly improve CNS drug delivery. Neutral L-amino acids enter the brain via the large neutral amino acid transporter (LAT1) expressed on capillary endothelial cells of the BBB (Pardridge 1983; Peura et al. 2011). In fact, LAT1 expressed at the BBB has a higher affinity for amino acid substrates than LAT subtypes found in peripheral tissues. This makes LAT1 an ideal target for prodrug delivery to the CNS (Pardridge 1983; Boado et al. 1999). Prodrugs consisting of bioreversible ligands capable of specifically binding LAT1, facilitates entry into the CNS that subsequently metabolize in the brain yielding the active drug is a model investigated by numerous research groups as presented below.

Dopamine prodrugs were studied extensively for Parkinson's disease (PD). CNS delivery of dopamine is difficult due to its ionization at physiological pH, as well as its metabolism after oral administration (Chemuturi and Donovan 2007). Dopamine needs to accumulate in the brain

to exert its therapeutic effect. Currently, levodopa (L-DOPA), which uses LAT1 transporters at the BBB, is a clinically relevant prodrug of dopamine (Gomes and Soares-da-Silva 1999; Peura et al. 2013). L-DOPA is a metabolic precursor converted to dopamine in the brain by aromatic L-amino acid decarboxylase (AAAD). In actuality, a significant portion of administered L-DOPA is converted to dopamine in peripheral circulation; therefore, carbidopa (CD), an inhibitor of AAAD is frequently administered in conjunction with L-DOPA (Lewitt 2008; Huttunen and Rautio 2011). Prodrugs that can more effectively deliver dopamine to the brain than L-DOPA are needed and are currently under development.

To this end, attaching a meta-substituted carboxylic acid analogue of phenylalanine to dopamine a LAT1-targeted prodrug was developed. In situ brain perfusion studies resulted in significant prodrug brain uptake with evidence of carrier-mediated passage of the BBB (Peura et al. 2013). Unfortunately, intravenous administration of the prodrug did not result in improved accumulation of dopamine within the brain; in fact it performed unfavorably in comparison to L-dopa treatment. These results indicate that while LAT1 may be a promising target for CNS drug delivery, more research is needed to translate this targeting into a therapeutic benefit.

L-tyrosine, a natural ligand for LAT1, has been used to generate prodrugs designed for CNS delivery. Particularly, a prodrug of the nonsteroidal anti-inflammatory drug Ketoprofen was synthesized using L-tyrosine as a bioreversible targeting ligand for LAT1 (Gynther et al. 2008). The carboxylic acid functional group of Ketoprofen was derivatized to form a labile ester bond with the phenolic hydroxyl group of L-tyrosine (Gynther et al. 2008). In situ perfusion resulted in enhanced brain uptake of the prodrug, which could be reduced with the co-administration of a 2-aminobicyclo (2,2,1) heptane-2-carboxylic acid (BCH), a specific LAT1 substrate (Gynther et al. 2008). Systemic administration yielded inadequate CNS uptake, potentially due to the instability of the ester bond linkage, exemplifying the challenges associated with CNS drug delivery. An optimal CNS-targeted prodrug must exhibit stability in systemic circulation, impart BBB receptor specificity and binding affinity, gain entrance into the brain parenchyma, and release the active compound, while avoiding efflux pumps to achieve appreciable brain drug concentrations. Directed at improving systemic stability, L-lysine targeted ketoprofen prodrug was synthesized using an amide bond. Amide bonds are inherently more stable than esters due to their reduced susceptibility to chemical or enzymatic cleavage (Vig et al. 2013). Intravenous injection yielded CNS uptake although without a significant difference compared with Ketoprofen (Gynther et al. 2010). Future research may focus on using this targeting strategy with compounds that exhibit less endogenous uptake in order to achieve desired differences in CNS uptake.

49.3.2.4 GLUT1

Physiological brain function is dependent on energy provided by blood borne glucose traversing the BBB via the glucose transporter (GLUT1), which is located on the luminal and abluminal side of BBB endothelial cells (Mueckler et al. 1985; Farrell and Pardridge 1991; Maher et al. 1994). GLUT1 allows for movement of glucose down its concentration gradient and in terms of the CNS glucose is predominantly carried from the blood, across the BBB, to the extracellular fluid of the brain (Carruthers 1990; Regina et al. 1997). Therefore, GLUT1 is an excellent candidate for prodrug CNS delivery.

The idea of conjugating d-glucose to a hydrophilic drug in order to improve its CNS drug delivery was done through GLUT1-mediated mechanisms. Models of d-glucose bound to GLUT1 suggest the hydroxyl group bonded to carbon 6 of glucose do not form any hydrogen bonds that would affect binding affinity (Mueckler and Makepeace 2008). Therefore, ketoprofen and indomethacin prodrugs were synthesized conjugating d-glucose via the hydroxyl group through carbon 6 and forming an ester linkage (Gynther et al. 2009). Rat perfusion models determined both prodrugs were able to cross the BBB and enter brain tissue in a GLUT1 dependent manner (Gynther et al. 2009). The relative weakness of the ester bond may limit effectiveness once administered into systemic circulation, as cleavage may occur before entering the CNS. An L-ascorbic acid (vitamin C) targeted prodrug of ibuprofen was made aimed at improving CNS targeting. GLUT1 is able to transport dehydroascorbic acid, the oxidized form of ascorbic acid, into the brain where it is converted to vitamin C (Rumsey et al. 1997). In addition; L-ascorbic acid also enters the brain by Na⁺-dependent vitamin C transporter (SVCT₂) at the BBB surface (Tsukaguchi et al. 1999). Given that GLUT1 and SVCT₂ are bidirectional transporters, thereby permitting movement of the prodrug out of the brain, a prodrug was developed that could be “locked in” via thiamine disulfide system until ibuprofen release (Zhao and Keating 2007; Portugal et al. 2009; Zhao et al. 2014). Intravenous injections yielded significantly higher CNS concentrations of ibuprofen in prodrug-treated animals compared with those treated with ibuprofen (Zhao et al. 2014). These results suggest CNS targeting combined with a “lock-in” system has potential to improve CNS delivery of BBB impermeable compounds.

49.3.3 Alzheimer's Disease

Alzheimer's disease (AD), which affects more than 24 million people worldwide, is characterized by progressive decline in memory and cognitive function leading to the onset of dementia (Whitehouse et al. 1982; Ferri et al. 2005). Currently, there is no AD cure. Post-mortem studies have

identified two prominent pathological hallmarks of AD. Extracellular senile plaques comprised of aggregated amyloid β -peptide, and intracellular neurofibrillary tangles constituted of hyperphosphorylated tau that contribute to neuronal cell death (Braak and Braak 1991; Lee et al. 2001). Numerous postulations exist regarding AD etiology, such as the cholinergic, genetic, amyloid, and tau hypotheses (Hardy and Allsop 1991; Francis et al. 1999; Mudher and Lovestone 2002). In an attempt to improve the patients overall quality of life, traditional AD therapy aspires to improve the cognitive and behavioral symptoms associated with AD. Clinical drug treatments for AD act within the CNS and, therefore, need to cross the BBB. Numerous prodrugs are under development to provide specific CNS delivery for AD therapeutics, reducing peripheral toxicity, the cause of numerous unwanted side effects.

Currently, moderate AD patients are often prescribed an acetylcholinesterase (AChE) inhibitor (donepezil) in combination with *N*-methyl-D-aspartic acid (NMDA) receptor antagonist memantine (Savonenko et al. 2012). This treatment aims to ameliorate the pathological reduction of acetylcholine caused by loss of cholinergic neurons in the basal forebrain, which is in part responsible for characteristic cognitive deficits in AD (Terry and Buccafusco 2003). Dose escalation during advanced stages of AD cause an increase in peripheral toxicities associated with AChE inhibitors, thereby deeming CNS selective drug development paramount (Bohn et al. 2015). To this end, Bohn et al. developed a “bio-oxidizable prodrug” of a cyclic 1,4-dihydroquinoline carbamate derivative of AChE inhibitor rivastigmine. Once in the CNS, this prodrug converts to a quinolinium salt, which then acts as a pseudoirreversible AChE inhibitor (Bohn et al. 2015). Consequently, the AChE inhibitor becomes “locked in” within the CNS due to the presence of a permanent positive charge (Bohn et al. 2015). Additionally, the positive charge on the active drug promotes rapid systemic elimination, thereby reducing peripheral toxicity. Thus, by analyzing markers of peripheral (salivation) and central (hypothermia and shivering) cholinergic activity, it was deemed the prodrugs improve the balance between peripheral stability and central activation (Bohn et al. 2015). Therefore, this strategy of “bio-oxidizable” prodrug may be used to develop new AChE inhibitors with fewer side effects in the treatment of (AD).

Huperzine A (HUP A), a novel and selective AChE inhibitor, has been found to inhibit AChE more effectively than donepezil and rivastigmine (Cheng et al. 1996; Jia et al. 2013). Jia et al. developed a HUP A prodrug termed ZT-1 in order to improve CNS delivery and reduce its peripheral side effects (diarrhea, vomiting, and nausea) associated with BuChE inhibition. ZT-1, when tested in healthy male volunteers in a Phase I study, was well tolerated and converted to HUP A (Jia et al. 2013). Further clinical investigation is needed to determine the therapeutic viability of ZT-1.

In addition to modifying acetylcholine levels in the CNS, nonsteroidal anti-inflammatory drugs (NSAID) have been investigated as a treatment for AD. NSAIDs may prove beneficial due to their anti-inflammatory effects, which could counteract inflammatory responses (microglial, complement, and cytokine activation) associated with AD (Akiyama et al. 2000). In fact, long-term use of NSAIDs, which inhibit cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2), may have a beneficial effect on the risk of AD (in t' Veld et al. 2001). COX-2 inhibition provides therapeutic effects, while COX-1 antagonism can cause unwanted side effects (MacDonald 2000). Therefore, DP-155, a prodrug consisting of indomethacin covalently attached to lecithin via a 5-carbon linker, which acts specifically as a COX-2 inhibitor, was investigated as a potential AD therapeutic (Dvir et al. 2006). Furthermore, the PK profile of indomethacin cleaved from DP-155 differs from the commercially available compound. Specifically, oral administration of DP-155 in rats resulted in a 2.5 fold increase in brain/plasma concentration ratio compared with native indomethacin (Dvir et al. 2007). DP-155 and indomethacin similarly reduced soluble A β 42 when studied in the tg2576 mouse model of AD (Dvir et al. 2006). Therefore, the potential benefit of DP-155 over traditional indomethacin stems from its selective inhibition of COX-2 in the periphery, thereby limiting side effects, without compromising its therapeutic benefit.

Gastrointestinal (GI) toxicity associated with chronic NSAID administration is concerning in regards to its potential use for a treatment of AD (Gasparini et al. 2004). To this end, a prodrug linking naproxen with dihydropyridine (DHP) via an ester spacer was designed to increase brain delivery and subsequently reduce GI discomfort (Sheha 2012). Oral administration of the DHP-Naproxen increased brain concentrations twofold, while reducing GI side effects compared to naproxen (Sheha 2012). Prodrug strategies aimed at improving the CNS specific targeting of NSAIDs, while subsequently reducing peripheral toxicities, are integral in developing their therapeutic use as a treatment for AD.

49.3.4 Parkinson's Disease

Parkinson's Disease (PD) is a neurodegenerative disorder with an unknown etiology, in which patients present with motor deficits such as slowed movement, rigidity, resting tremor, and decreased dexterity (Lewitt 2008). Loss of dopaminergic neurons projecting from the substantia nigra pars compacta to the striatum is responsible for the motor deficits associated with PD (Fearnley and Lees 1991). The loss of more than 50% of these specific dopaminergic neurons results in Parkinsonian symptoms (Davie 2008). Hence, dopamine replacement therapy is currently the standard

therapeutic option in PD. Dopamine is completely ionized at physiological pH and is unable to cross the BBB (Chemturi and Donovan 2007). Therefore, levodopa (L-DOPA) or 3,4-dihydroxy-L-phenylalanine, a naturally occurring amino acid precursor of dopamine, is used for PD treatment (Cotzias et al. 1967). Essentially L-DOPA acts as a natural prodrug for dopamine. L-DOPA can actively transverse the BBB using LAT1 and is enzymatically converted to dopamine in the CNS via AAAD (Nutt et al. 1984; Lewitt 2008). In practice, a substantial amount of administered L-DOPA is metabolized in peripheral circulation, limiting the amount that actually reaches the CNS and available for conversion to dopamine (Huttunen and Rautio 2011). To circumvent these inherent limitations, L-DOPA is generally co-administered with AAAD inhibitor Carbidopa (Lewitt 2008). Unfortunately, the development of motor complications (dyskinesia, "wearing-off," and on/off fluctuations) often results from the chronic long-term use of L-DOPA (Obeso et al. 2000). Reducing fluctuations in L-DOPA plasma concentrations by improving absorption consistency may reduce associated motor complications, as the clinical response tends to correlate with L-DOPA blood levels (Chan et al. 2005). To this end, LeWitt et al. designed an L-DOPA prodrug termed XP21279 to improve upon the pharmacological limitations associated with immediate-release L-DOPA (IR-LD) therapy. XP21279 utilizes high-capacity nutritional transporters in the GI tract, thereby improving absorption, thus potentially reducing fluctuations (Lewitt et al. 2012). In a phase II, randomized, double blinded study, XP21279 was co-administered with CD (XP21279-CD) and compared with immediate-release CD-L-DOPA (IR-CD-L-DOPA). XP21279-CD reduced variability and increased mean L-DOPA concentrations compared with IR-CD-L-DOPA (LeWitt et al. 2014). Studies of XP21279-CD provide encouraging results towards potentially reducing the motor complications associated with long-term L-DOPA therapy, and its future progress will continue to be monitored.

L-DOPA prodrugs are not limited to those designed to improve absorption and pharmacokinetics. In fact, research suggests oxidative stress may contribute to PD pathogenesis (Olanow 1992). Therefore, multifunctional prodrugs, devised to deliver L-DOPA in conjunction with relevant antioxidants, are under investigation. To this end, Pinnen et al. designed a multifunctional prodrug of acetylated L-DOPA conjugated to methionine (LD-MET) to reduce DA-induced cell death exacerbated by oxidative stress. LD-MET exhibited radical scavenging activity on par with acetylcysteine in invitro assays (Pinnen et al. 2009). Additionally, LD-MET displayed higher and sustained levels of dopamine in the rat striatum compared with L-DOPA administration (Pinnen et al. 2009). Furthermore, a hybrid glutathione-methionine peptidomimetic prodrug of L-DOPA methyl ester was synthesized to improve CNS uptake of L-DOPA methyl ester

and reduce oxidative stress associated with PD (Pinnen et al. 2012). Glutathione (GSH), in which cysteine was replaced with methionine and L-DOPA methylester, was linked through an amide bond. In addition to *in vitro* radical scavenging activity, oral administration in rats yielded sustained and increased striatal DA levels, as well as enhanced plasma concentrations compared to animals treated with L-DOPA (Pinnen et al. 2012). Further investigation is necessary; but conceptually, multifunctional L-DOPA prodrugs provide intriguing options for the development of future PD therapeutics.

Improving motor complications (“wearing off,” dyskinesia, and on/off phenomena) that persist during long-term L-DOPA treatment remains a significant goal in PD therapy. Interestingly, A_{2A} adenosine receptor antagonists have shown promising preclinical results improving the effects of L-DOPA treatment, while reducing associated motor complications (Simola et al. 2008). To this end, Dalpiaz et al. synthesized a dopamine prodrug linking A_{2A} receptor antagonist (7-amino-5-(aminomethyl)-cyclohexylmethyl-amino-2-(2-furyl)-1,2,4-triazolo [1,5-a]-1,3,4-triazine trifluoroacetate) to dopamine by a succinic linker. The prodrug exhibited A_{2A} receptor antagonism, as well as increase dopamine affinity toward striatal D_2 receptors (Dalpiaz et al. 2012). Further pharmacokinetic analysis is necessary, but the progress of A_{2A} adenosine receptor antagonists as a PD therapeutic bears monitoring.

49.3.5 Schizophrenia

Schizophrenia is a complex neuropsychological disorder that is characterized by positive (e.g., hallucinations, delusions) or negative (e.g., poverty of speech, inability to experience pleasure) symptoms (Andreasen and Olsen 1982). Clinical treatment is complicated by the prospect that each type of symptomatic manifestation is derived from a different neurological receptor (Kim et al. 2009). This concept has led to the development of pharmaceuticals that deviate from the traditional first and second-generation anti-psychotics, predominantly dopamine (D_2) and serotonin ($5HT_{2A}$) receptor antagonists (Conn et al. 2008). In fact, it has been hypothesized that while presynaptic dopamine is responsible for positive symptoms, negative and cognitive symptoms may center on glutamate (Howes et al. 2015). To this end, new therapeutic prodrugs derived from the latest advancements in schizophrenia research continue to emerge and will be discussed in detail.

γ -aminobutyric acid (GABA) combined with dopamine antagonists has been reported to improve the cognitive deficits as well as reduce extrapyramidal symptoms (EPS) associated with schizophrenia (Soares et al. 2001; Nudelman

et al. 2008). In practice, this therapeutic paradigm is limited due to GABAs lack of BBB penetrance (Kuriyama and Sze 1971). In order to improve CNS delivery and reduce EPS, an ester prodrug consisting of GABA and typical antipsychotic perphenazine (BL-1020) was designed (Nudelman et al. 2008). BL-1020 exhibited the ability to cross the BBB and release GABA in the brain of orally administered rats. Additionally, the prodrug was effective reducing amphetamine induced hyperactivity and locomotion similar to perphenazine (Geffen et al. 2009). In a randomized, double blind study, BL-1020 exhibited similar improvement in the Positive and Negative Syndrome Scale (PANSS) compared with risperidone. Most importantly, BL-1020 was able to improve patients’ cognitive performance as accessed by the Brief Assessment of Cognition in Schizophrenia (Geffen et al. 2012). Further tests are necessary, but BL-1020 provides a unique therapeutic platform for schizophrenia aiming to treat psychotic symptoms while concurrently reducing ESP and improving cognition.

Treatment strategies for schizophrenia continue to evolve as researchers search for answers outside the realm of dopamine modulation. In fact, much of the focus in the development of new anti-psychotics centers on the modulation of glutamate receptors and its potential benefits for patients with schizophrenia (Weinberger 2007). To this end, LY404039, a novel and selective mGlu2/3 receptor agonist, was developed (Rorick-Kehn et al. 2007). Low oral bioavailability prompted the development and synthesis of LY2140023, a methionine prodrug of LY404039. In a phase II clinical trial, LY2140023 given twice daily (40 mg) was able to significantly improve symptoms of schizophrenia compared with placebo, as assessed by the PANSS (Kay et al. 1987; Patil et al. 2007). Investigation continued with a 24-week phase II trial in which LY2140023 was compared with olanzapine, risperidone, or aripiprazole in patients suffering from schizophrenia. LH2130023 exhibited similar improvements in PANSS compared with traditional antipsychotic treatment during the initial 6–8 weeks, although at week 24, the effect was significantly less for LH2130023 (Adams et al. 2013).

Standard schizophrenia treatment with atypical antipsychotics is contingent on successful CNS entry and accumulation. Even compounds that overcome the impediment of the BBB can have limited efficacy due to efflux pumps such as P-glycoprotein (P-gp). Located on the luminal surface of brain endothelial cells, P-gp can serve as an efflux pump for its substrates, effectively reducing drug concentrations in the brain substantially (Loscher and Potschka 2005). In fact, atypical antipsychotics such as quetiapine (QT) and risperidone act as P-gp substrates, thereby limiting their CNS accumulation and efficacy (Boulton et al. 2002). To this end, Emmert et al. synthesized a dimeric ester QT prodrug designed to act as a P-gp inhibitor as well as enhance QT

accumulation in the CNS. Specifically, dimerization converts a substrate (QT) for P-gp into an inhibitor and upon entry into endothelial cells of the brain can be cleaved by esterases to deliver the QT therapy (Emmert et al. 2014). Certainly, *in vivo* characterization of systemic administration is necessary, but the concept of P-gp inhibition through therapeutic dimerization has potential.

49.3.6 HIV-1

Current HIV-1 treatment, known as highly active antiretroviral therapy (HAART) consists of numerous antiretroviral drugs targeting various steps in the viral life cycle (entry, fusion, reverse transcription, integration, maturation), used in combination to reduce virus below clinically detectable levels and subsequently diminish HIV-1 associated morbidity and mortality (Perelson et al. 1997; Palella et al. 1998; Arts and Hazuda 2012). Despite potent HAART, HIV-1 infection still persists in latently infected CD4+ T-cell populations harboring integrated copies of HIV-1 proviral DNA (Chun et al. 1995). Additionally, virus can persist in anatomical sanctuaries such as the CNS and gut-associated lymphoid tissue (GALT) due to inadequate antiretroviral drug accumulation (Eisele and Siliciano 2012). Particularly, HIV-1 enters the CNS days after infection and can be identified within perivascular macrophages (Wiley et al. 1986; Davis et al. 1992). Subsequently, HIV-1 infection within the brain can result in HIV-associated neurocognitive disorders (HAND), which can be further defined as HIV-associated asymptomatic neurocognitive impairment (ANI), HIV-1-associated mild neurocognitive disorder (MND), or HIV-1-associated dementia (HAD) (Antinori et al. 2007; Spudich and Gonzalez-Scarano 2012). Antiretrovirals used in HAART each penetrate the CNS at various levels; thus, numerous research groups have designed prodrugs to facilitate CNS ART accumulation (Letendre et al. 2008).

Prodrugs designed to improve antiretroviral therapy (ART), such as tenofovir and fosamprenavir, have mainly focused on improving oral bioavailability (Palombo et al. 2009). For example, tenofovir disoproxil fumarate, which is a tenofovir prodrug possessing two additional alkyl methyl carbonate esters, enhances intestinal absorption and subsequent bioavailability (Shaw et al. 1997; Kearney et al. 2004). In addition, fosamprenavir, the phosphate ester prodrug of protease inhibitor amprenavir exhibits increased aqueous solubility, thereby improving oral bioavailability and limiting pill burden (Furfin et al. 2004; Palombo et al. 2009). While these prodrugs are aimed at improving systemic absorption, others have investigated prodrug designs specifically tailored towards improved ART delivery to the CNS as discussed next.

Saquinavir (Saq), a protease inhibitor used in the treatment of HIV-1, is a P-gp substrate, thus limiting its CNS penetration (Kim et al. 1998). Jain et al. synthesized peptide prodrugs of Saq designed to reduce P-gp-mediated drug efflux. Specifically, the hydroxyl group on Saq was modified with amino acids to form Saq conjugated with two valine molecules (Saq-Val-Val) or glycine-valine (Saq-Gly-Val) (Jain et al. 2005). In cell culture models, these modified prodrugs elude P-gp and MRP-2 efflux, thereby increasing their potential tissue distribution to the CNS (Jain et al. 2005, 2008). Additionally, an ascorbic acid (AA) prodrug consisting of vitamin C conjugated to Saq via a succinic acid linker, demonstrated SVCT selective uptake in MDCK-MDR1 cells (Luo et al. 2011). SVCT is also expressed at the BBB and could, therefore, provide an additional mechanism to improve CNS uptake of Saq.

The limited CNS bioavailability exhibited by numerous antiretroviral drugs designed to treat HIV-1 is not simply due to suboptimal physicochemical properties. Transporters located on the surface of the BBB such as P-gp and MDRs serve as efflux pumps, removing drug substrates from the CNS, significantly reducing its accumulation within the brain. To this end, Namanja et al. designed prodrug dimers of abacavir, a reverse transcriptase inhibitor used in HIV-1 treatment. Specifically, the hydroxyl group of each abacavir molecule was linked via an ester bond to a sulfide linker (Namanja et al. 2012). Therefore, dimerization occurs by forming a disulfide bond between the two modified abacavir molecules. This abacavir prodrug dimer effect is twofold; it has the ability to act as a P-gp inhibitor, while releasing abacavir monomers in the reducing environment of the cytosol (Namanja et al. 2012). Further investigation into the pharmacokinetic and biodistribution of this prodrug is necessary, but the multifunctional prodrug dimer approach bears monitoring.

49.3.7 Chemotherapy

Treatment strategies for aggressive brain tumors such as glioblastomas often follow a multimodal approach in which a combination of surgery, radiation, and chemotherapy is used (Castro et al. 2003). Chemical therapy is often limited by the lack of CNS accumulation of marketed chemotherapeutics. Even potent anti-cancer agents such as paclitaxel, which is used to treat breast and ovarian cancers, has limited *in vivo* efficacy against cancers of the brain due to poor BBB penetrance and P-gp efflux (Wani et al. 1971; Heimans et al. 1994; Crown and O'Leary 2000; Taub et al. 2005). Specifically, despite its lipophilicity; lack of BBB permeability may be due to its high protein binding (90 %) and large molecular weight (853.9) (Heimans et al. 1994).

Regina et al. synthesized a paclitaxel-angiopep-2 conjugate (GRN1005) designed to improve CNS delivery and therapeutic efficacy of paclitaxel in brain cancer treatment. Angiopep-2 is a peptide that targets low-density lipoprotein (LDL) receptors at the BBB and is used as a delivery vehicle to enhance brain uptake of paclitaxel (Demeule et al. 2008). Specifically, GRN1005 consists of three molecules of paclitaxel conjugated to angiopep-2 through cleavable ester bonds (Regina et al. 2008). GRN1005 significantly increased brain uptake compared with paclitaxel, independent of P-gp receptor expression (Regina et al. 2008; Thomas et al. 2009). In a Phase I clinical trial involving patients with advanced solid tumors, 25 % of individuals treated with GRN1005 achieved a partial response and reduction in brain lesions (Kurzrock et al. 2012). Further studies in patients with recurrent malignant glioma, resulted in GRN1005 delivering paclitaxel across the BBB in concentrations greater than previously reported for free paclitaxel, although therapeutic efficacy was limited (Drappatz et al. 2013). Research into this angiopep-2 conjugate model, known specifically as engineered peptide compound (EPiC) platform, is ongoing with other cancer agents such as doxorubicin and etoposide (Che et al. 2010).

Temozolamide (TMZ), a DNA alkylating prodrug of methyl-triazenyl imidazole carboxamide (MTIC), is currently used in conjunction with radiation therapy for the treatment of glioblastoma (Stevens et al. 1984; Omuro and DeAngelis 2013). Specifically, TMZ is readily converted to active DNA methylating agent MTIC at physiological pH (Stevens et al. 1987; Friedman et al. 2000). In fact, the ability of TMZ to cross the BBB made it a prime candidate for CNS cancer treatment and today remains a first-line treatment for glioblastoma (Patel et al. 2003; Omuro and DeAngelis 2013). TMZ provides an excellent example of the substantial impact prodrugs can have in the clinical setting.

49.4 Summary and Future Perspectives

Delivery of active pharmaceuticals to the CNS is a monumental task. First, a compound must possess the required physicochemical properties (lipophilicity, molecular weight) to passively diffuse across the BBB (Oldendorf 1974). In specific cases, larger, more polar molecules gain entrance into the CNS via carrier or receptor-mediated transport (Banks 2009). Compounds that successfully transverse the BBB may be subject to efflux by P-gp and MDRs. The chore of a medicinal chemist to design a drug with the appropriate physicochemical properties to enter and remain in the brain is quite daunting. In fact, prodrugs are utilized to overcome such impediments. Furthermore, prodrugs can be designed and synthesized to improve a drug's oral bioavailability, absorption, solubility, and/or tissue distribution (Rautio et al. 2008). In particular, lipidization can be used to enhance pas-

sive diffusion across the BBB but is often limited by its non-specific nature. Therefore, targeting receptors or carrier-mediated transporters on the BBB surface using a ligand-prodrug approach provides the specificity necessary to mediate CNS uptake. Systemic metabolism is another hurdle that must be overcome to successfully target a prodrug to the CNS. Each prodrug consists of a unique bioreversible bond (ester, amide, ether, or carbamate) with inherently different bond strengths. Upon systemic administration, this bioreversible bond needs to be strong enough to endure circulation and reach the CNS as an intact prodrug. Furthermore, once in the brain, the bond must be labile enough to release the active compound. Designing a prodrug with the correct physicochemical properties, with optimized cleavage kinetics, and with CNS-specific targeting is certainly difficult. As CNS drug delivery research progresses, merging of multiple disciplines will be imperative towards the development of improved brain-targeted therapeutics. Just as the disciplines of medical chemistry and biology work together in prodrug development, inclusion of the burgeoning field of nanomedicine is the next natural progression. Nanomaterials for medical applications such as liposomes, polymeric micelles, dendrimers, nanosuspensions, and polymer-drug conjugates allow for the packaging and delivery of drugs in myriad of ways (Moghimi et al. 2005). The power of nanomedicine lies in its versatility and its ability to enhance the function of pharmaceuticals, such as prodrugs (Wagner et al. 2006). In addition to enhancing a drug's pharmacokinetics and pharmacodynamics, nanoparticles can be surface functionalized with targeting ligands designed to improve specific tissue distribution, such as the CNS (Debbage 2009). Nanoparticle designs encapsulating diverse drugs for the treatment of a multitude of diseases are currently being developed (Wong et al. 2012). Nanoformulation of hydrophilic compounds is often challenging due to a lack of stable interaction between the drug and polymer. Therefore, prodrug synthesis by lipidization can increase a drug's formulation potential. The generation of hydrophobic prodrugs of hydrophilic compounds increases the scope and potential of nanomedicine. Hence, the combined efforts of medicinal chemistry, biology, and nanomedicine have the potential to considerably improve CNS drug delivery. A listing of relevant prodrug structures for CNS disease treatments with linked references is seen in Fig. 49.3.

49.5 Review Questions

49.5.1 True/False

1. Prodrug synthesis generates a new compound, which is a derivative of the parent organic compound.
2. Prodrug synthesis by lipidization selectively increases drug penetration across of the blood-brain barrier (BBB).

Fig. 49.3 Prodrug Structures

3. Efflux pumps on the inner surface of the BBB are capable of removing drugs that have already successfully entered the brain.
4. Prodrug entry into the CNS can be mediated by receptors on the surface of brain endothelium.
5. Bond strength and cleavage kinetics are key determinants to the stability and subsequent functionality of prodrugs.

49.5.2 Multiple Choice

6. Factors that contribute to any drug's success to combat brain disease include.
 - (A) Its ability to cross the BBB
 - (B) Can retain function in the brain's microenvironment.
 - (C) Limited CNS drug penetrance for most drugs does not limit the effectiveness and therapeutic potential of any drug
 - (D) *A and B*
 - (E) *A, B and C*
7. Properties of the BBB include all except?
 - (A) Protection against potentially harmful molecules from accumulating within the CNS.
 - (B) Consists of a continuous layer of endothelial cells connected by tight junctions
 - (C) Serves to separate circulating blood from the extracellular fluid within the brain
 - (D) Police the entry of essential molecules, thereby regulating the homeostatic, nutritive, and immune environments of the brain
 - (E) *Prevents entry only of activated macrophages and T cells*
8. What properties of prodrugs serve to facilitate its passage across the blood brain barrier?
 - (A) Contain cleavable chemical moieties that improve BBB permeability.
 - (B) Lipidization, carrier and receptor mediated targeting commonly improve drug's translocation across the blood-brain interface.
 - (C) Resistance to metabolism
 - (D) *A and B*
 - (E) *A, B and C*
9. What consequences of lipidization may potentially reduce CNS penetrance?
 - (A) Increased molecular weight
 - (B) Blocking of functional groups capable of forming hydrogen bonds
 - (C) Enhanced protein binding
 - (D) *B and C*
 - (E) *A and C*
10. L-DOPA prodrugs aim to ameliorate treatment limitations such as _____.
 - (A) Dyskinesias
 - (B) On-Off phenomenon

- (C) Peripheral metabolism
- (D) Absorption constancy
- (E) *All of the above*

Alexander V. Kabanov and Elena V. Batrakova

Abstract

Tremendous efforts in the last several decades have resulted in numerous inventions for central nervous system (CNS) drug delivery systems. Many of these innovative systems have a significant potential for the development of new biomedical applications. The wide variety of strategies reflects the inherent difficulty in transport of therapeutic and imaging agents across the blood brain barrier (BBB). In fact, the effective combination of several approaches, such as encapsulation of drugs into nanoparticles (NPs) conjugated with vector moieties or using micelles of Pluronic® block copolymers along with Pluronic® “unimers” that will inhibit drug efflux transporters in the brain microvessel endothelial cells BMVEC, may give the most promising CNS therapeutic outcomes.

Keywords

Block copolymer • Block ionomer complex • Cell-mediated delivery • Drug delivery • Hydro-philicity • Lipophilicity • Liposome • MDR inhibitor • Micelle • Multidrug resistance • Nanofiber • Nanogel • Nanoparticle • Nanosphere • Nanosuspension • Nanotube • Polyion block

50.1 Introduction

The blood brain barrier (BBB) is one of the most challenging barriers for drug delivery in the body. It significantly restricts the entry of low molecular weight compounds and biomacromolecules to the brain from the periphery. Inefficient delivery of the drugs, DNA and proteins to the brain is a major bottleneck in development of more efficacious and safe modalities for diagnostics and treatment of neurological diseases, especially at early stages of the disease when the BBB remains intact. The low permeability of the BBB is attributed, in large part, to the brain microvessel endothelial cells (BMVEC), which form tight extracellular junctions and have low pinocytotic activity (Pardridge 2005a; Mayhan 2001). Some relatively lipophilic and low molecular weight

substances can transport across the BMVEC by passive diffusion. However, a large number of lipophilic compounds are rapidly effluxed from the brain into the blood by extremely effective drug efflux systems expressed in the BBB (Begley 1996; Tamai and Tsuji 2000; Fromm 2000; Loscher and Potschka 2005). These efflux systems include P-glycoprotein (Pgp), Multidrug Resistance Proteins (MRPs), breast cancer resistance protein (BCRP), and the multi-specific organic anion transporter (MOAT). There is also an enzymatic barrier to drug transport in the BMVEC. Activity of many enzymes that participate in the metabolism and inactivation of endogenous compounds, such as γ -glutamyl transpeptidase, alkaline phosphatase, and aromatic acid decarboxylase is elevated in cerebral microvessels (Minn et al. 1991; Abbott and Romero 1996). These features of the BBB require discovery of new modalities allowing for effective drug delivery to the central nervous system (CNS), which is of great need and importance for treatment of neurodegenerative disorders.

A number of earlier publications and extensive reviews on delivery of small drug molecules and biomacromolecules to the brain are available in the literature (Spector 2000; Alyaudtin et al. 2001; Pardridge 2002; Cornford and Cornford 2002; Begley 2004; Kas 2004; Kabanov and Batrakova 2008b; Banks and Lebel 2002; Roney et al. 2005; Liu and Chen 2005; Gaillard et al. 2005; Liu et al. 2005; Garcia-Garcia et al. 2005; Masserini 2013; Guo et al. 2012; Upadhyay 2014; Patel 2014; Gidwani and Singh 2014; Xu et al. 2014; Krupa et al. 2015). The present chapter describes recent findings in the development of a new generation of polymer nanomaterials for drug delivery to the CNS.

50.2 History and Principles of Drug Delivery Using Polymers

The original discovery of a polymer drug delivery system was published in 1964 by Folkman and Long (Folkman and Long 1964). This work reported that hydrophobic low molecular weight drugs can diffuse through the wall of silicone tubing at a controlled rate. Since then, polymers have occupied a central status in controlled drug release as well as in the fabrication of drug delivery systems (Langer 2001; Duncan 2003). During the past decades a large number of drug delivery systems, mostly in the form of microspheres, films, tablets, or implantation devices, have been designed to achieve sustained drug release by taking advantage of the unique properties of polymers.

There are several fundamental properties of polymers that are useful in solving drug delivery problems. First, polymers can be designed to be intrinsically multifunctional and can, for example, be combined either covalently or non-covalently with drugs to overcome multiple problems such as solubility, stability, permeability, etc. Second, polymers can be easily modified with various targeting vectors to direct drugs to specific sites in the body. Third, polymers can be designed to be environmentally responsive materials, allowing for the controlled and sustained release of a drug at its site of action. Finally, polymers themselves can be biologically active, and this property can be exploited in order to modify the activity of various endogenous drug transport systems within the body to improve delivery and, therefore, drug performance.

Numerous polymer-based therapeutics are on the market or undergoing clinical evaluation to treat cancer and other diseases. Many of them are low molecular weight drug molecules or therapeutic proteins that are chemically linked to water-soluble polymers to increase drug solubility, drug stability, or enable site-specific transport of drugs to target tissues affected by the disease.

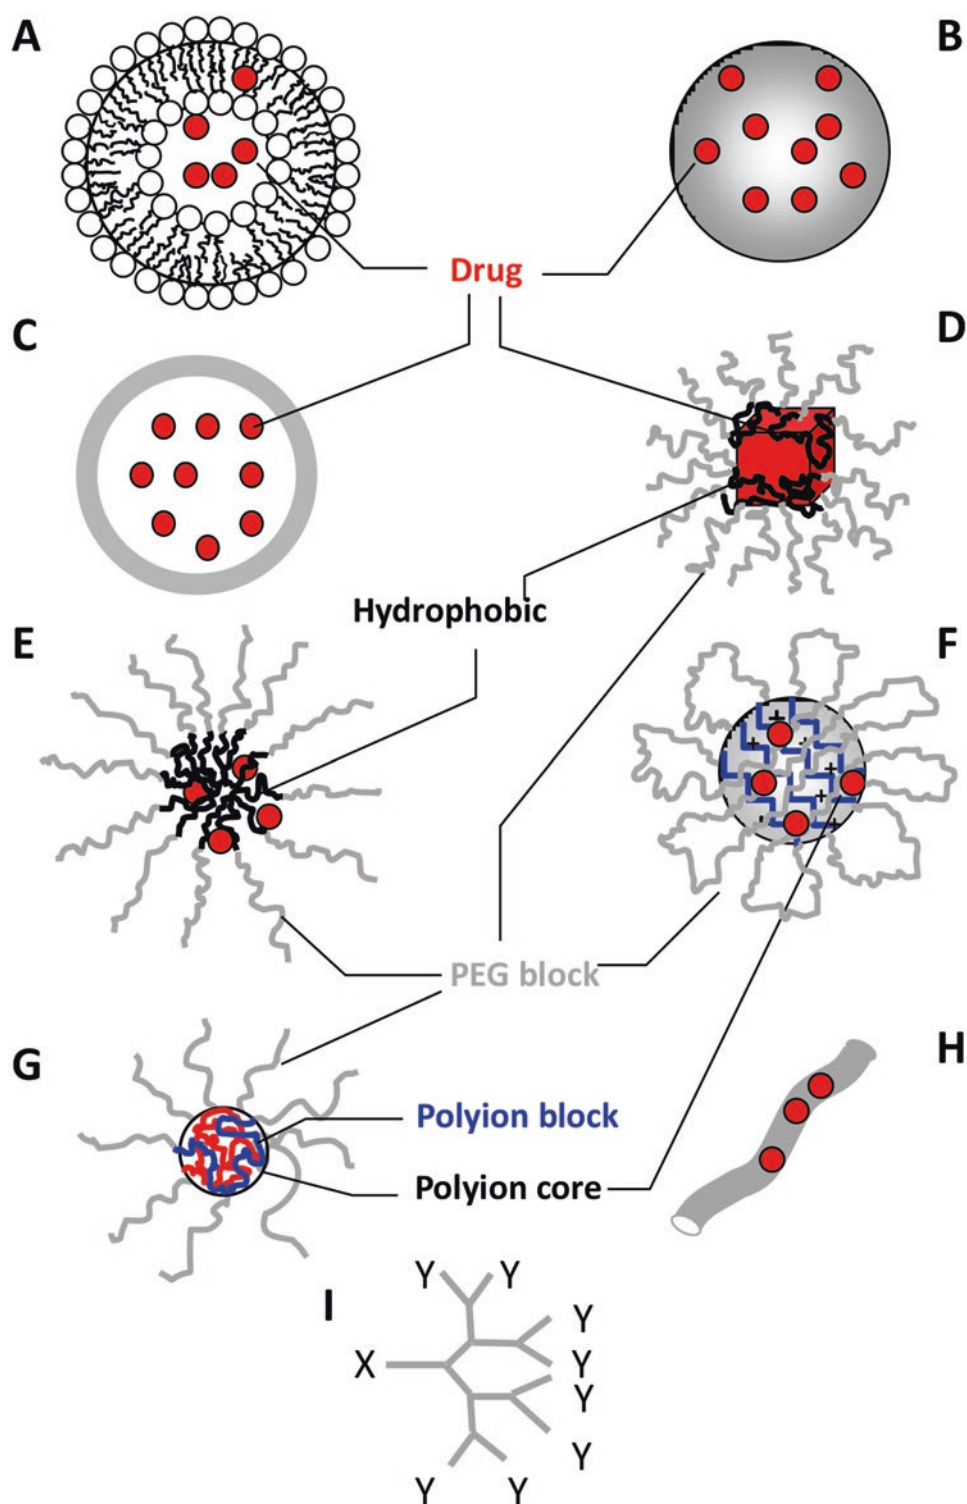

Recently, as a result of the rapid development of novel nanotechnology-derived materials, a new generation of polymer therapeutics has emerged which uses materials and

devices of nanoscale size for the delivery of drugs, genes, and imaging molecules (Kabanov et al. 1995, 2004; Savic et al. 2003; Trentin et al. 2005; Missirlis et al. 2005; Salem et al. 2003; Nayak and Lyon 2005; Gilmore et al. 2008; De Jong and Borm 2008; Oberoi et al. 2013; Musyanovych and Landfester 2014; Spencer et al. 2015; Jain et al. 2015). These materials include liposomes, dendrimers, polymer micelles, polymer-DNA complexes ("polyplexes"), and other nanostructured materials for medical use, that are collectively called nanomedicines. Compared to the first generation of polymer therapeutics, the new generation of nanomedicines is more advanced. They entrap small drugs or biopharmaceutical agents, such as therapeutic proteins and DNA, and can be designed to trigger the release of these agents at the target site. Moreover, they can be targeted not only to the particular organ or tissue, but to a particular cell or even an intracellular compartment. The essence of nanotechnology is the ability to work at the molecular level to create large structures with fundamentally new molecular organization. Materials with features on the scale of nanometers often have properties different from their macroscale counterparts. Many nanomedicines are constructed using self-assembly principles, such as spontaneous formation of micelles or interpolyelectrolyte complexes driven by diverse molecular interactions (hydrophobic, electrostatic, etc.). Nanotechnology focuses not only on formulating therapeutic agents in biocompatible nanocomposites but also on exploiting distinct advantages associated with a reduced dimensional scale within 1–100 nm. Some examples of nanoscaled polymeric carriers involve polymer conjugates, polymeric micelles, and polymersomes (Panyam and Labhasetwar 2003). Because these systems often exhibit similarity in their size and structure to natural carriers such as viruses and serum lipoproteins, they offer multifaceted specific properties in drug delivery applications (Lavasanifar et al. 2002). There is still a lack of understanding in terms of why certain arrangements of small molecules can cause dramatic changes in their behavior. With this in mind, the goal of this chapter is to explore current research in polymeric nanoparticles, where the specific arrangement of the polymeric matter at the nanoscale imparts new properties that are not attainable from simple polymer solutions, and to summarize their applications for drug delivery systems to the CNS.

50.3 Nanocarriers for Drug Delivery

The need for a protective drug carrier for CNS drugs is highlighted by the fact that many drugs have a low hydrolytic stability and are subject to degradation by blood proteins or by enzymes encountered in the BBB. Furthermore, a drug carrier can be targeted via receptor-mediated transport using a brain-specific vector moiety. A single unit of a given drug

Fig. 50.1 Types of nanocarriers for drug delivery. (a) liposomes; (b) nanoparticles; (c) nanospheres; (d) nanosuspensions; (e) polymer micelles; (f) nanogel; (g) block ionomer complexes; (h) nanofibers and nanotubes; (i) dendrimers

carrier can incorporate many drug molecules, resulting in high “payloads” per one targeting moiety. By increasing the payload of the carrier, one might improve the efficacy of the delivery while maintaining a relatively low level of involvement of numbers of targeted moieties and receptors. There

are various types of vehicles proposed for transport of neuropharmaceuticals across the BBB: liposomes, degradable nanoparticles, nanospheres, nanosuspensions, polymeric micelles, nanogels, block ionomer complexes, nanofibers and nanotubes, and dendrimers (Fig. 50.1).

50.3.1 Types of Nanocarriers for Drug Delivery to the Brain

Liposomes are vesicular structures, which are usually composed of unilamellar or multilamellar lipid bilayers (similar to biological membranes) that surround internal aqueous compartments (Fig. 50.1a). The size of the vesicles varies from several nanometers to several microns. Relatively large amounts of drug molecules can be incorporated into either the aqueous compartment (water soluble compounds) or the lipid bilayers (lipophilic compounds) providing the possibility to use liposomes as carriers for drug delivery. The use of liposomes for drug delivery across the brain capillaries has been reported extensively (Umezawa and Eto 1988; Huwyler et al. 2002; Rousseau et al. 1999; Shi et al. 2001; Mora et al. 2002; Thole et al. 2002; Wu et al. 2002; Zhang et al. 2003; Schmidt et al. 2003; Omori et al. 2003; Aoki et al. 2004; Gosk et al. 2004; Chekhonin et al. 2005; Pardridge 2005a; Kundu et al. 2014; Cozar-Bernal et al. 2015; Helm and Fricker 2015). In general, encapsulation of a drug into liposomes prolongs the circulation time of the drug in the blood stream, reduces adverse side effects, and in selected cases enhances therapeutic effects of CNS agents. Conventional liposomes containing hydrocortisone were demonstrated to penetrate the BBB in experimental autoimmune encephalomyelitis (Rousseau et al. 1999). In addition, liposomes prepared using lecithin, cholesterol, and *p*-aminophenyl- α -mannoside were efficiently transported across the BBB into mouse via mannose receptor-mediated transcytosis (Umezawa and Eto 1988). Liposomes conjugated with cationized bovine serum albumin (cBSA) as transport vectors were readily taken up and appeared to be concentrated in intracellular vesicles in porcine brain capillary endothelial cells (PBCEC) (Helm and Fricker 2015). After intravenous application of cBSA-liposomes with a diameter between 120 and 150 nm, confocal fluorescence microscopy showed fluorescently-labeled liposomes in brain capillary surrounding tissue from male Wistar rats, suggesting their successful brain delivery. An interesting approach using thermosensitive liposomes loaded with an antineoplastic agent, doxorubicin (Dox), for treatment of malignant gliomas was reported (Aoki et al. 2004). These liposomes released their content when the tumor core was heated to 40 °C by a brain heating system. Elevated accumulation of the drug in the brain of the heated animals resulted in a significantly longer overall survival time compared to the non-heated animals.

Conventional liposomes normally are cleared rapidly from the circulation by the reticuloendothelial system. Extended circulation time of these carriers can be accomplished with small-sized liposomes (<100 nm) composed of neutral, saturated phospholipids and cholesterol. Further, it was demonstrated that water-soluble polymers such as polyethylene glycol (PEG) attached to the surface of liposomes

reduce adhesion of opsonic plasma proteins, and decrease recognition and rapid removal of liposomes from the circulation by the mononuclear phagocyte system in liver and spleen (Huwyler et al. 2002; Kozubek et al. 2000; Voinea and Simionescu 2002). Using this approach, PEG-coated ("PEGylated") long-circulating liposomes (or "stealth liposomes") were shown to remain in the circulation with a half-life as long as 50 h in humans (Gabizon et al. 1994). Particularly, commercial PEGylated liposome-encapsulated Dox, Doxil®, was already approved for use in the treatment of recurrent ovarian cancer and AIDS-related Kaposi's sarcoma (Gabizon et al. 2003) and was shown to be effective in patients with metastatic breast cancer (Papaldo et al. 2006). Long-circulating PEGylated liposomes were also used for the delivery of high doses of glucocorticosteroids to the CNS to treat multiple sclerosis (Schmidt et al. 2003). The PEGylated liposomes encapsulating prednisolone provided selective targeting to the inflamed CNS in rats (up to 4.5-fold higher accumulation compared to the healthy animals). The mechanism of preferential accumulation of these liposomes in the brain is not fully understood. It appears to be crucial that the liposomes exhibit long-circulating behavior. Their effect is related to either (1) the change in the pharmacokinetics of the encapsulated drug resulting in a greater drug exposure to the BBB or (2) to liposome capture by monocytes/macrophages (in liver, spleen, or blood) followed by cell-mediated transport to the brain. In another study, a novel β -sheet breaker peptide, H102, was delivered across BBB in liposomes following intranasal administration (Zheng et al. 2015). H102 was encapsulated into liposomes to reduce peptide degradation and increase brain penetration for the treatment of Alzheimer's disease (AD). The AUC of H102-loaded liposomes in the hippocampus was 2.92-fold larger than that of the free peptide group. H102 liposomal formulation ameliorated spatial memory impairment of AD model rats, increased the activities of choline acetyltransferase (ChAT) and insulin degrading enzyme (IDE), and inhibited plaque deposition. Noteworthy, H102 liposomes showed no toxicity on nasal mucosa (Zheng et al. 2015).

Attachment of targeting moieties to PEGylated liposomes can direct them to the BBB. The efficient delivery of PEG-liposomes conjugated with transferrin (Tf) to the post-ischemic cerebral endothelium was achieved in rats (Omori et al. 2003). The expression of Tf receptor in the cerebral endothelium was reported to increase with a peak at the first day after induced transient middle cerebral occlusion, which can be employed for drug delivery to the brain after stroke. PEGylated immunoliposomes were also successfully employed to target and transfect brain tissues (Shi et al. 2001). A plasmid DNA was encapsulated within the liposome. Packaging of the DNA in the interior of the liposome prevented degradation of the therapeutic gene by the ubiquitous endonucleases *in vivo*. These liposomes were

directed to Tf receptor-rich tissues, such as brain, liver, and spleen by monoclonal antibodies, OX26, that were linked to the free termini of the PEG chains. When a reporter gene was also coupled with a brain-specific glialfibrillary acidic protein promoter, its expression was achieved predominantly in the brain (Shi and Pardridge 2000).

In addition, considerable work was reported on antibodies to transferrin receptor, OX26, that were linked to the surface of PEGylated liposomes via PEG spacers. Such immunoliposome constructs were used to deliver small drugs, Daunomycin (Huwylar et al. 2002), and Digoxin (Huwylar et al. 2002) as well as plasmid DNA (Shi et al. 2001) to the brain. Notably, OX26-conjugated liposomes selectively distributed to BMVEC but avoided choroid plexus epithelium, neurons, and glia (Gosk et al. 2004). In related work OX26 antibodies directly linked to oligonucleotides (Huwylar et al. 1996) or fibroblast growth factor (Song et al. 2002) enhanced delivery of these molecules to the brain.

Another example of a brain targeting vector with a remarkable species-specificity is reported by Coloma et al. (2000). This vector was genetically engineered from monoclonal antibody to the human insulin receptor, 83-14 MAb, where most of the immunogenic murine sequences were replaced by a human antibody sequence. The intravenously administered antibody showed robust transport to the brain in a rhesus monkey but not in a rat. Furthermore, this vector was also used for targeting liposomes with reporter genes to the brain (Zhang et al. 2003). As a result, the level of gene expression in the brain was 50-fold higher in the rhesus monkey as compared to the rat. In this regard, the new covalent method of coupling IgG to liposomes for the drug delivery to the brain was reported recently (Cozar-Bernal et al. 2015). Functionalized liposomes were prepared with maleimide derivative linked to pegylated phospholipids containing free amino groups, PEG2000-DSPE/PE. The homogeneous population of vesicles prepared by extrusion process with a nanometric size was suitable to further anchor the antibody.

Monoclonal antibody directed insulin or Tf receptors were also utilized to target PEGylated immunoliposomes for transvascular gene therapy of Parkinson's disease (PD) (Pardridge 2005b). In the 6-hydroxydopamine rat model of experimental PD, striatal tyrosine hydroxylase (TH) activity was completely normalized after an intravenous administration of TfmAb-targeted liposomes carrying a TH expression plasmid. Treatment of PD using this approach may be possible with dual gene therapy that seeks both to replace striatal TH gene expression with TH gene therapy, and to halt or reverse neurodegeneration of the nigro-striatal tract with neurotrophin gene therapy.

The mechanism by which immunoliposomes penetrate across the BBB is not fully understood. It was hypothesized that the process involves the binding of immunoliposomes to multiple capillary luminal membrane receptors, fusion of the

liposomes with several vesicular pits into a large vesicle and transcytosis of this vesicle to the abluminal membrane border (Cornford and Cornford 2002). Studies by electron microscopy support this hypothesis (Faustmann and Dermietzel 1985).

In addition to approaches pursuing delivery across the intact BBB, the methods are developed to target sites in the brain under conditions when the integrity of the BBB is compromised by the progressing disease. For example, PEGylated immunoliposomes were coupled with the monoclonal anti-GFAP antibodies (Chekhonin et al. 2005). Experiments with cell cultures demonstrated specific and competitive binding of these immunoliposomes to embryonic rat brain astrocytes. Administered intravenously into rats, the immunoliposomes displayed typical kinetics with elimination half-lives of 8–15 h. Being incapable of penetrating the unimpaired BBB, these immunoliposomes, can be used to deliver drugs to glial brain tumors that express GFAP or to other pathological loci in the brain with a partially disintegrated BBB (Chekhonin et al. 2005).

Another approach involving temporal opening of the BBB using liposomes was proposed by Zhang et al. (2004). An endogenetic bioactive peptide, RMP-7 ("cereport") that is known to open tight junctions in the BBB by affecting bradykinin 2 receptors, was linked to conventional liposomes. It was demonstrated that transport of vectorized liposomes loaded with HRP was increased three times in an *in vitro* model of the BBB compared to the non-vectorized vehicles (Zhang et al. 2004). The opening of the tight junctions in the BBB following traumatic brain injury (TBI) was utilized to enable accumulation of stealth liposomes in the brain (Boyd et al. 2015). Dual-radiolabeled PEGylated liposomes were administered either immediately after induction of TBI or at increasing times post-TBI to mimic the likely clinical scenario. Significantly enhanced accumulation of liposomes was occurred in mice subjected to TBI compared to anaesthetized controls, and the accumulation was greater in the injured versus the contralateral side of the brain. Nevertheless, potential toxicological implications of such approach still need to be addressed.

Overall, liposomes have been extensively studied for CNS drug delivery showing increased drug efficacy and reduced drug toxicity. At present, the translation potential of targeted to BBB liposomes is well-recognized (Park 2002; Patel 2014). This drug delivery system represents a platform based on a proven technology, and already entered clinical trials (Immordino et al. 2006). While the examples presented suggest that the liposome technology provides a promising approach for CNS drug delivery, a considerable limitation of liposomes is their relatively low loading capacity for water-insoluble drugs and biomacromolecules. In addition, despite improvements in the targeting efficacy, major proportion of liposomes is found accumulated in the liver as a consequence of inadequate time for the communication between the target and targeted liposomes (Kundu et al. 2014).

Nanoparticles (NPs) are solid species of nanoscale size usually composed of an insoluble and biodegradable polymer or polymer blend (Fig. 50.1b). Generally, the methods of preparation of such NPs are simple and easy to scale-up. The drug is captured within the particle upon its preparation and is released upon degradation of the polymer in the body. The use of NPs as carriers for drug and gene delivery has been an area of intensive research and development for over a decade (Moghimi et al. 1990; Moghimi and Szebeni 2003; Gref et al. 1994; Peracchia et al. 1998; Torchilin 1998; Calvo et al. 2002; Vinogradov et al. 1999, 2004b; Lemieux et al. 2000; Alyaudtin et al. 2001; Gupta et al. 2003; Kreuter 2004; Liu et al. 2005; Roney et al. 2005; Liu and Chen 2005; Cui et al. 2005). The surface of such carriers is often modified by a PEG brush to increase the stability of NPs in dispersion and extend circulation time of NPs in the body (Peracchia et al. 1998; Torchilin 1998; Calvo et al. 2002). To allow for efficient transcytosis across the BMVEC the particle size must be kept small and not exceed ca. 100–200 nm.

For example, poly(butyl)cianoacrylate NPs were successfully used to deliver a wide range of drugs to the CNS, which were either incorporated into the particle structure or absorbed onto the particle surface (Calvo et al. 2001, 2002; Alyaudtin et al. 2001; Kreuter et al. 2003; Kreuter 2004; Steiniger et al. 2004). Prior to administration in the body, the NPs were coated with a PEG-containing surfactant, Tween 80. After the administration, they also absorbed apolipoprotein E available in the blood. The resulting coated NPs were transported across the cerebral endothelial cells by endocytosis via the low density lipoprotein (LDL) receptor. They localized in the ependymal cells of the choroid plexuses, the epithelial cells of ventricles, and, to a lower extent, in the capillary endothelial cells. The list of the drugs delivered to the CNS in these constructs include, analgesics (dalargin, loperamide), anti-cancer agents (Dox), anticonvulsants (NMDA receptor antagonist, MRZ 2/576), and peptides (dalargin and kytorphin) (Steiniger et al. 2004; Kreuter et al. 2003). Particularly, incorporation of MRZ 2/576, into such NPs prolonged the anticonvulsive activity of the drug almost twofold compared to the drug alone (Friesen et al. 2000). Dox bound to the NPs was successfully used for treatment of an aggressive human cancer, glioblastoma, resulting in increased survival times in rats (Steiniger et al. 2004). Enhanced transport of Dox in the NPs to the brain involved bypassing the P-glycoprotein (Pgp) and MRP efflux systems in the BBB that impede the delivery of the drug alone. Moreover, an ability of NPs and microspheres (MPs) with incorporated Celecoxib (CXB), a selective COX-2 inhibitor, was tested in rats with malignant gliomas (Vera et al. 2014). Uncoated and polysorbate 80-coated CXB-NPs are prepared by nanoprecipitation. Cerebral cortex images showed a marked increase of fluorescence when the surfactant-coated NPs were administered to rats. These results suggest that

both CXB formulations (MPs and NPs) are adequate systems to enhance the effects of chemotherapy in the treatment of malignant brain tumor. In another example the NPs were coupled with chelators (desferioxamine or D-penicillamine) and proposed for treatment of AD and other CNS diseases by reducing oxidative stress in the brain (Liu et al. 2005); (Cui et al. 2005). Another nanoformulation based on poly (D, L-lactide-co-glycolide) NPs loaded with cerebrolysin, a neuroprotective agent, was reported to have a superior neuroprotective efficacy than free drug in a rat model of concussive head injury (Ruozi et al. 2014). These findings have potential clinical relevance with regard to nanodelivery of different therapeutic agents across the BBB. In order to increase targeted CNS delivery of polymer-based NPs, MR-guided focused ultrasound with intravascular microbubbles (MBs) was suggested to locally and reversibly disrupt the BBB with submillimeter spatial accuracy (Nance et al. 2014).

However, a concern regarding the toxicity associated with this delivery approach has somewhat hampered further development for specific therapeutic applications (Olivier et al. 1999). The methods for preparation of NPs commonly employ the use of organic solvents that may result in degradation of immobilized drug agents, especially biomacromolecules. Another key issue is that it is virtually impossible to define the in vivo fate of polymers, especially in the brain, which is a regulatory requirement (Patel 2014). To this end, using a biodegradable nanoparticle platform is of great interest (Hunter et al. 2014). The development of such platforms carries broad implications for the treatment of a variety of CNS diseases.

Nanospheres are hollow nanosized particles (Fig. 50.1c) that can be prepared by microemulsion polymerization or covering the surfaces of colloidal templates with thin layers of the desired material followed by selective removal of the templates (Hyuk Im et al. 2005). The carboxylated polystyrene nanospheres (20 nm) were evaluated for drug delivery to CNS (Yang et al. 2004). It was demonstrated that these carriers accumulated in the brain in vivo following cerebral ischemia and reperfusion. The intravenously injected nanospheres remained in the vasculature under normal conditions. However, during cerebral ischemia-induced stress that leads to the opening of tight junctions between endothelial cells the extravasation of the nanospheres to the disease site was increased (Kreuter 2001). Therefore, polystyrene nanospheres may have potential clinical applications for CNS delivery of drugs and imaging agents during ischemia and stroke.

Nanosuspensions of hydrophobic drugs have also attracted attention as drug delivery systems (Rabinow 2004). These systems represent crystalline particles of a solid drug, which are often stabilized by nonionic PEG-containing surfactants (Fig. 50.1d) (Jacobs et al. 2000). They can be manufactured by a variety of techniques such as media milling, high-pressure homogenization or by employing emulsions

and microemulsions as templates (Friedrich and Muller-Goymann 2003; Friedrich et al. 2005). The major advantages of the nanosuspension technology include its simplicity and general applicability to most drugs including very hydrophobic compounds (Muller et al. 2001; Friedrich et al. 2005). It was suggested that similar to regular NPs (described above), the surface modification of nanosuspensions with Tween 80 may increase the delivery of these particles to the brain (Muller et al. 2001). Currently nanosuspensions of anti-retroviral drugs are evaluated in animal models for CNS delivery and treatment of HIV infection in the brain using cell-mediated delivery approach described below (H. Gendelman, University of Nebraska Medical Center) as well as by Dr. Sarmento's group in Portugal (Gomes et al. 2014). It was reported that nanosuspension-based approaches may help providing solutions for antiretroviral drug delivery to the CNS by potentially prolonging systemic drug circulation, increasing the crossing and reducing the efflux of active compounds at the blood–brain barrier, and providing cell/tissue-targeting and intracellular drug delivery.

Polymeric micelles represent core-shell structures that spontaneously form in aqueous solutions of amphiphilic block copolymers (Fig. 50.1e). Block copolymers are polymers containing at least two chains of different chemical nature, for example, a hydrophilic and a hydrophobic chain. In aqueous solutions above a threshold concentration, called a “critical micelle concentration” (CMC) the individual block copolymer molecules termed “unimers” form micelles composed from dozen to a couple of hundred of molecules. The size of the micelles usually varies in the range of from 10 to 100 nm. The hydrophobic chains of the block copolymers segregate forming a hydrophobic core of the micelles while the hydrophilic chains (often PEG) form a hydrophilic protective shell. Polymer micelles can incorporate considerable amounts (up to 20–30 % wt.) of hydrophobic compounds. The resulting nanomaterials can serve as carriers for drug delivery (“*micellar nanocontainers*”) (Kataoka et al. 2001; Kwon 2003; Torchilin 2004, 2005; Allen and Cullis 2004; Moghimi and Agrawal 2005; Tao and Uhrich 2006; Aliabadi and Lavasanifar 2006). The core-shell architecture of polymeric micelles is essential for their pharmaceutical application. The core is a water-incompatible compartment that is hidden from the aqueous exterior by the hydrophilic chains of the corona, preventing premature drug release and degradation. The hydrophilic shell maintains the micelles in a dispersed state and decreases undesirable drug interactions with cells and proteins through steric-stabilization effects. Upon reaching the target the incorporated drug is released from the micelle via diffusion mechanisms. Polymeric micelles have been extensively evaluated in multiple pharmaceutical applications as drug delivery systems (Kabanov et al. 1989b; Kabanov and Alakhov 2002; Jones et al. 2003; Torchilin et al. 2003; Lee et al. 2005b; Aliabadi et al. 2005; Uchino et al. 2005; Bronich et al. 2005; Yan and

Tsujii 2005; Gaucher et al. 2005; Miyata et al. 2005), and carriers for diagnostic imaging agents (Torchilin 2002). Several clinical trials have been completed or are underway to evaluate polymer micelles for the delivery of anti-cancer drugs for chemotherapy of tumors (Danson et al. 2004; Valle et al. 2004); (Nishiyama et al. 2003). Polymeric micelles formed by Pluronic®, PEG-phospholipid conjugates, PEG-b-polyesters, or PEG-b-poly(L-amino acid)s were proposed for drug delivery of poorly water-soluble compounds, such as amphotericin B, propofol, paclitaxel, and photosensitizers (Lavasanifar et al. 2002; Kwon 2003; Adams and Kwon 2004; Vakil and Kwon 2005). It was also emphasized that using polymeric micelles one can significantly increase the drug transport into the brain.

One of the early studies of targeted drug delivery to the brain used micelles of Pluronic® block copolymers as carriers for CNS drugs (Kabanov et al. 1989b, 1992c). These micelles were conjugated with either polyclonal antibodies against brain α_2 -glycoprotein or insulin to target the receptors at the luminal side of BMVEC. Both the antibody-conjugated and insulin-conjugated micelles were shown to effectively deliver a drug or a fluorescent probe incorporated into the micelles to the brain tissue in vivo (Kabanov et al. 1992a). Studies that monitored animal behavior as a means to determine the pharmacological activity of dopamenergic compounds, such as mobility and grooming were performed. It was demonstrated that incorporation of a neuroleptic, haloperidol, into the Pluronic® micelles vectorized with insulin resulted in 25-fold enhancement of the neuroleptic effects compared with the free drug. Vectorization of the drug-loaded micelles with antibodies lead to an even more pronounced (up to 500-fold) enhancement of the neuroleptic effects. Subsequent studies demonstrated that the insulin vectorized micelles undergo receptor-mediated transcytosis in BMVEC from luminal (blood) to abluminal (brain) side (Batrakova et al. 1998).

A new type of functional polymer micelles with cross-linked ionic cores was recently developed (Bronich et al. 2005). Instead of using amphiphilic block copolymers these micelles are prepared using double hydrophilic block copolymers with nonionic (PEG) and ionic blocks. The micelles are self-assembled by reacting the ionic block with a condensing agent of an opposite charge. The ionic chains incorporated into the core of the micelles were chemically cross-linked and then the condensing agent was removed. The resulting cross-linked micelles contain a hydrophilic ionic core, which is swollen in water, and a hydrophilic PEO shell. The core can incorporate various hydrophilic drugs and imaging agents, which can be then delivered to the target site in the body. Overall, this strategy has potential for the development of novel modalities for delivery of various drugs to the brain, including selected anti-cancer agents to treat metastatic brain tumors as well as HIV protease inhibitors to eradicate HIV virus in the CNS.

Nanogels are a new family of hydrophilic carriers that were recently developed for targeted delivery of biomacromolecules and other drug molecules to the brain (Vinogradov et al. 1999, 2004b, 2005a, b). Nanogels represent a nanoscale size polymer network of cross-linked ionic, e.g., polyethyleneimine (PEI), and nonionic PEG chains (Fig. 50.1f). It swells in an aqueous solution and collapses upon binding of a drug through ionic interactions. Because of the effect of PEG chains, the collapsed nanogel forms stable dispersions with the particles size of ca. 80 nm. Nanogels can spontaneously absorb biomacromolecules including oligonucleotides (ODNs), plasmid DNA and proteins as well as small charged molecules. A key advantage is that the nanogels display very high loading capacities, 40–60 % “payload” by weight, which is not achieved with conventional nanocarrier systems. The transport of ODNs incorporated in the nanogel particles across an in vitro model of the BBB was recently reported (Vinogradov et al. 2004a). To enhance delivery across the BBB the surface of the nanogels were modified by either Tf or insulin (Vinogradov et al. 2004b). Both peptides were shown to increase transcellular permeability of the nanogel and enhance delivery of ODNs across BMVEC monolayers. Overall, the nanogels were shown to be a promising carrier for CNS drug delivery, although only in the early stages of development. *Block ionomer complexes* are formed as a result of the reaction of double hydrophilic block copolymers containing ionic and nonionic blocks with biomacromolecules of opposite charge including oligonucleotides, plasmid DNA and proteins (Fig. 50.1g) (Kabanov and Kabanov 1995; Nguyen et al. 2000; Zhang et al. 2003; Jaturanpinyo et al. 2004; Harada and Kataoka 1999, 2003). For example, block ionomer complexes were prepared by reacting trypsin or lysozyme (that are positively charged under physiological conditions) with an anionic block copolymer, PEG-poly(R, α -aspartic acid) (Jaturanpinyo et al. 2004; Harada and Kataoka 1999). Such complexes spontaneously assemble into nanosized particles having core-shell architecture. The core contains polyion complexes of the biomacromolecules and ionic block of the copolymer. The shell is formed by the nonionic block. These nanomaterials were shown to efficiently deliver DNA molecules in vitro and in vivo into a cell and release them at the site of action (Roy et al. 1999; Nguyen et al. 2000; Harada-Shiba et al. 2002; Junghans et al. 2005). To improve stability of the complexes in the body the biopolymer and block ionomer can be additionally cross-linked with each other (Jaturanpinyo et al. 2004; Harada and Kataoka 2003) or the polyion chains of the block ionomer within the core can be cross-linked using degradable links. The advantages of such systems in drug delivery applications include simplicity and versatility of the design allowing the incorporation of considerable amounts of different biomacromolecules. Furthermore, block ionomer complexes are environmentally

responsive nanomaterials allowing for biomacromolecule release in response to an external stimulus such as change of pH (acidification), concentration and chemical structure of elementary salt, etc.

Nanofibers and nanotubes (Fig. 50.1h) have considerable promise in futuristic biomedical applications, for example, for sustained drug release from implants, or as channels for tiny volumes of chemicals in nanofluidic reactor devices, or as the “world’s smallest hypodermic needles” for injecting molecules one at a time. These nanomaterials have a prototype in nature. In an organism, microtubules and their assembled structures are critical components for a broad range of cellular functions—from providing tracks for the transport of cargo to forming the spindle structure in cell division. There are various types of synthetic nanofibers and nanotubes manufactured from carbon, silicon, or diverse natural or man-made polymers. They can be vapor-grown (Che et al. 1998), self-assembled from peptide amphiphiles (Guler et al. 2005; Bull et al. 2005) or electrospun manufactured from virtually any polymer material (Dzenis 2004; Gilmore et al. 2008). Carbon nanotubes and nanofibers have lately attracted great attention in nanomedicine including their potential use as drug carriers, although there are also considerable concerns associated with their safety (Muller et al. 2006; Lange et al. 2003). Self-assembled nanofibers can be designed to incorporate diverse chemical functionalities and thus may have a variety of applications for delivery of small drugs, biomacromolecules or imaging contrast agents (Bull et al. 2005). Electrospun continuous nanofibers are unique since they represent nanostructures in two dimensions and macroscopic structures in another dimension (Fong et al. 1999; Dzenis 2004). They are safer to manufacture than the carbon nanotubes since there is less risk of air pollution.

At present a few studies of nanofibers and nanotubes are focused on CNS drug delivery. One study evaluated electrospun nanofibers of a degradable polymer, PLGA, loaded with anti-inflammatory agent, dexamethasone for neural prosthetic applications (Abidian and Martin 2005). A conducting polymer, poly(3,4-ethylenedioxythiophene), was deposited to the nanofiber surface and the coated nanofibers were then mounted on the microfabricated neural microelectrodes, which were implanted into brain. The drug was released by electrical stimulation that induced a local dilation of the coat and increased permeability.

In the future, nanotubes and nanofibers can be administered systemically, if the problem of their toxicity is addressed, for example, by appropriate polymer coating. In this respect, the continuous nanofibers are more likely to be used in implants or tissue engineering applications.

Dendrimers exhibit a highly branched, 3D architecture and comprise an initiator core, several interior layers composed of repeating units, and multiple active surface terminal groups (Lee et al. 2005a). The branches and surface groups of dendrimers

increase exponentially in number with the generation (G) of the dendrimers, whereas the diameter of dendrimers increases by about 1 nm with the generation. The most remarkable property of dendrimers is their low polydispersity and high functionality (Xu et al. 2014). Dendrimers with amphiphilic structure are particularly interested as drug carriers. The loading of dendrimers with drug molecules is achieved by hydrophobic/hydrophilic interactions. Modification of the degree of branching may allow the encapsulation of different molecules within this structure (Lee et al. 2005a).

In vivo delivery of siRNA to the brain by carbosilane dendrimer was reported by Serramia et al. (2015). Functional validation was performed by using specific siRNA against HIV-1 Nef to interfere to HIV-1 infectivity. The second generation of carbosilane dendrimer transported efficiently siRNA into the brain in BALB/c mice. Moreover, this dendrimer successfully delivered and transfected siRNA to HIV-infected human primary astrocytes and achieved gene silencing without causing cytotoxicity (Serramia et al. 2015). The internalization properties and diffusion of G4 and G4-C12 modified polyamidoamine (PAMAM) dendrimers in the CNS of live animals was described in (Albertazzi et al. 2013). 100 nM G4-C12 PAMAM dendrimer induced dramatic apoptotic cell death of neurons in vitro. On the contrary, G4 PAMAM does not induce apoptotic cell death of neural cells in the sub-micromolar range of concentration and induces low microglia activation in brain tissue after a week. Noteworthy, different PAMAM dendrimer surface functionalization resulted in dramatic effects on their ability to diffuse in brain parenchyma after intracerebroventricular administration, and improved the neural cell internalization.

Overall, dendrimer-based drug formulations provided efficient drug delivery in the brain tissues. In addition, targeting to specific organs and a reduction in the toxicity of the free drug to non-target organs, and an increase of therapeutic index could be achieved. These results highlight the potential of dendrimer-based nanoformulations in the treatment of neurological disorders. The main drawbacks of dendrimers as drug carriers are a significant entrapment in the mononuclear phagocytic system in the liver and spleen, and a relatively high toxicity due to their high density of positively charged functional groups.

50.3.2 Cell-Mediated Delivery of Nanocarriers to the Brain

A distinct case of the vehicle-mediated CNS drug delivery employs specific cells carriers that can incorporate micro- and nano-containers (such as liposomes, micelles, and block-ionomer complexes) loaded with drugs and act as perfect Trojan horses by migrating across the BBB and carrying drugs to the site of action (Daleke et al. 1990; Fujiwara et al. 1996;

Jain et al. 2003; Khan et al. 2005; Batrakova et al. 2011; Haney et al. 2011, 2012; Zhao et al. 2011a, b; Batrakova and Kabanov 2013). It is documented that many neurological diseases, such as PD, AD, Prion disease, meningitis, encephalitis and HIV-associated dementia, have in common an inflammatory component (Perry et al. 1995). The process of inflammation is characterized by extensive leukocytes (neutrophils and monocytes) recruitment (Anthony et al. 1997, 2001; Blamire et al. 2000; Persidsky et al. 1999). These cells have a unique property of migrating toward the site of inflammation via the processes known as diapedesis and chemotaxis (Kuby 1994). Interestingly, prior reports indicate that monocytes traffic primarily between adjacent endothelial cells, i.e., paracellularly through the junctional complexes (Pawlowski et al. 1988; Lossinsky and Shivers 2004). Their combat arsenal consists of uptake of the foreign particle, producing toxic compounds, and liberation of substances stored in intracellular vesicles via exocytosis. Therefore, brain inflammation that develops in patients with neurodegenerative disorders may support targeted cell-mediated drug delivery to the brain.

It has been shown that cells capable of phagocytosis, such as macrophages or monocytes/neutrophils, can endocytose colloidal nanomaterials, for example, liposomes, and subsequently release them into the external media (Daleke et al. 1990; Jain et al. 2003). To accelerate the transport of monocytes/neutrophils to the brain site, the drug-containing liposomes were additionally loaded with magnetic particles (Jain et al. 2003). Magnetic liposomes demonstrated about a tenfold increase in brain levels compared to non-magnetic liposomes when local magnetic field was applied. It is noteworthy that both cell types showed preferential uptake of liposomes containing negatively-charged lipids (such as phosphatidylserine), or liposomes modified with polyanion than liposomes containing only neutral lipids (such as phosphatidylcholine) (Fujiwara et al. 1996). This suggests that by engineering the surface of the nanomaterials one may modulate their uptake into and release from the cell carriers to optimize the therapeutic regimen. The phosphatidylserine-containing negatively charged liposomes were shown to increase therapeutic activity of an encapsulated antifungal agent, chloroquine, against *C. neoformans* infection in the mouse brain (Khan et al. 2005). The chloroquine-loaded liposomes accumulated inside macrophage phagolysosomes and resulted in a remarkable reduction in fungal load in the brain even at low doses compared to the free drug at high doses, thus increasing the antifungal activity of macrophages. T lymphocytes were also proposed as a potential therapeutic drug carriers for cancer treatment (Steinfeld et al. 2006). The kinetics of loading and release of NPs coated with cytotoxic antibiotic Dox into the cells were examined. It was suggested that the immune cells can accomplish target-specific and sheltered transport to the diseased site.

In our research, we developed and optimized a cell-based delivery system for a potent anti-inflammatory polypeptide, catalase (Batrakova et al. 2007, 2011; Kabanov and Batrakova 2008a; Brynskikh et al. 2010; Haney et al. 2011, 2012, 2013; Zhao et al. 2011a, b; Klyachko et al. 2012, 2014) for the treatment of PD. A packaging of catalase into a polyion complex micelle (“nanozyme”) with a synthetic polyelectrolyte block copolymer protected the enzyme against degradation in cell-carriers, and improved therapeutic outcomes. We demonstrated that macrophages (1) efficiently accumulate catalase NPs and slowly release them *ex vivo* (Batrakova et al. 2007; Zhao et al. 2011a; Klyachko et al. 2014), and in PD mice providing sustained catalase blood levels (Brynskikh et al. 2010); (2) cross the BBB and deliver catalase to the inflamed brain (Zhao et al. 2011b; Haney et al. 2013; Klyachko et al. 2014); and (3) discharge catalase to neural cells, decreasing inflammation and ultimately producing potent neuroprotection in PD mouse models (Brynskikh et al. 2010; Haney et al. 2013; Klyachko et al. 2014). Noteworthy, the optimization of the drug nanoformulation is crucial for the successful delivery in living cells. Thus, the macrophage-based approach offers a paradigm switch for CNS delivery of nanotherapeutics. A formulation design for drug carriers typically works to avoid entrapment in monocytes and macrophages focusing on small size NPs with a PEG corona (perpetuate a stealth effect). In contrast, the best nanozymes for delivery in macrophages reported by us (Klyachko et al. 2014) have a relatively large size (*c.a.* 200 nm) that resulted in improved loading capacity and release from macrophages. Furthermore, the cross-linking of nanozymes with the excess of a non-biodegradable linker ensured their low cytotoxicity, and efficient catalase protection in cell-carriers.

The ability of host cells to home diseased sites after *ex vivo* manipulations is a fundamental requirement and a major problem for their use as vehicles to target locally acting gene therapy to specific diseased sites. It was demonstrated that in the short term, up to 2 h after re-implantation, macrophages accumulate primarily in the lungs and, to a lesser extent, in the liver and spleen rather than in the target diseased tissue. A small proportion of manipulated macrophages (ranging from 0.2 to 28.8%) homes to the diseased site of interest following systemic administration. However, the presence of labeled macrophages in these sites was found to persist for at least 6–7 days in both of these mouse studies (Audran et al. 1995). Therefore, increasing the amount of cell carriers reaching the target site appears to be a crucial point in this type of drug delivery system. We demonstrated that macrophages can serve as a “depot” for drug nanoformulations increasing area under the curve (AUC), half-life, and mean residence time in blood circulation, when compared to the NPs administered alone (Zhao et al. 2011b). Accordingly, bioavailability of the nanozyme for the brain,

spleen, kidney, and liver was substantially increased. Importantly, inflammation induced in the brain (or peripheral organs) attracted macrophages loaded with nanozyme resulting in the increased drug accumulation in these tissues. In contrast, effect of inflammation on cell-free nanozyme accumulation levels was negligible, except brain. Thus, nanozyme-loaded macrophages targeted diseased sites and improved transport across the blood brain barrier. The engaging natural immune cells such as monocyte-macrophages as drug carriers provides a new perspective for therapeutic delivery for PD and also likely a range of other inflammatory and degenerative diseases (Zhao et al. 2011b).

50.3.3 Permeability Enhancers for CNS Drug Delivery

There are a number of efflux mechanisms within the CNS that influence drug concentrations in the brain. Some of them are passive while others are active. Recently much attention has been focused on the so-called multi-drug efflux transporters: Pgp, MRP1, and BCRP, MOAT that belong to the ABC cassette (ATP-binding cassette) family (Pardridge 1998; Tamai and Tsuji 2000; Begley 2004). Cerebral capillary endothelium expresses a number of efflux transport proteins, which actively remove a broad range of drug molecules before they cross into the brain parenchyma. Pgp is the most thoroughly investigated brain efflux transport protein with broad affinity for dissimilar lipophilic and amphiphilic substrates (Tsuji and Tamai 1997). As a consequence, the therapeutic value of many promising drugs, such as protease inhibitors for HIV-1 encephalitis (ritonavir, nelfinavir, and indinavir) (Kim et al. 1998), anti-inflammatory drugs (prednesolone, dexamethasone and indomethacin) for treatment of microglial inflammation during idiopathic PD and AD (Tsuji and Tamai 1997; Perloff et al. 2004), neuroleptic agents (amitriptyline and haloperidol) (Uhr et al. 2000), analgesic drugs (morphine, beta-endorphin, and asimadoline) (Moriki et al. 2004), as well as anti-fungal agents (itraconazole and ketoconazole) (Miyama et al. 1998), is diminished, and cerebral diseases have proven to be most refractory to therapeutic interventions. Moreover, delivery of many anticancer agents (Dox, vinblastine, taxol, etc.) to the brain for treatment of brain tumors (Tsuji 1998), and drugs for treatment of epilepsy (carbamazepine, phenobarbital, phenytoin, and lamotrigine) (Potschka et al. 2002) is also restricted by the Pgp drug efflux transporter.

An emerging strategy for enhanced BBB penetration of drugs is co-administration of competitive or noncompetitive inhibitors of the efflux transporter together with the desired CNS drug. First generation low molecular weight Pgp inhibitors (cyclosporine A, verapamil, PSC833, etc.) are substrates of the drug efflux transporter, which compete for the active site with the therapeutic agent (Kemper et al. 2003).

Second generation inhibitors (LY335979, XR9576 and GF120918) are non-competitive inhibitors, which allosterically bind to Pgp, inactivating it and increasing drug transport to the brain (Kemper et al. 2004). Despite their high efficiency in cell culture models, the small therapeutic range of these inhibitors, high in vivo toxicity, and fast clearance are the main obstacles for their therapeutic application.

Recently, a new class of inhibitors (nonionic polymer surfactants) was identified as a promising component of drug formulations. These compounds are two- or three-block copolymers arranged in a linear AB or ABA structure. The A block is a hydrophilic PEG chain. The B block can be a hydrophobic lipid (BRIJs, MYRJs, Tritons, Tweens, and Chremophor), or a poly(propylene glycol) (PPG) chain (Pluronics®) (Fig. 50.2).

Studies in multidrug resistant (MDR) cancer cells, polarized intestinal epithelial cells, Caco-2, and polarized BMVEC monolayers provided compelling evidence that selected Pluronic® block copolymers can inhibit drug efflux transport systems (Miller et al. 1997; Batrakova et al. 1998, 1999, 2001a, b, 2003a). Specifically, in primary cultured BMVEC monolayers, used as an in vitro model of BBB, the inhibition of drug efflux systems, Pgp and MRP was associated with an increased accumulation and permeability of a broad spectrum of drugs in the BBB, including low molecular drugs (Batrakova et al. 1998, 1999) and peptides (Witt et al. 2002). These effects were most apparent at concentrations below the CMC (Miller et al. 1997; Batrakova et al. 1998). It was suggested that the unimers, are responsible for the inhibition of Pgp and MRPs efflux transport system. Incorporation of the probe into the micelles formed at high concentrations of the block copolymer decreases its availability to the cells and reduces the transport of this probe in BMVEC.

Recent findings suggest that effects of Pluronic® on drug efflux transport proteins involve interactions of the block copolymers with the cell membranes (Batrakova et al. 2001d, 2003a). It was demonstrated that a fine balance is needed between hydrophilic (PEG) and lipophilic (PPG) components

in the Pluronic® molecule to enable inhibition of the drug efflux systems (Batrakova et al. 2003b). Overall, the most efficacious block copolymers are those with intermediate lengths of PPG block and relatively hydrophobic structure (HLB < 20), such as Pluronic® P85 or L61 (Batrakova et al. 1999). The hydrophobic PPG chains of Pluronic® immerse into the membrane hydrophobic areas, resulting in alterations of the membrane structure and decreases in its microviscosity ("membrane fluidization"). Pluronic® at relatively low concentrations (e.g., 0.01 %) inhibits the Pgp ATPase activity, possibly due to conformational changes in the transport protein induced by the immersed copolymer chains in the Pgp-expressing membranes (Batrakova et al. 2001a). In particular, Pluronic® P85 displayed the effects characteristic of a mixed type enzyme inhibitor—decreasing maximal reaction rate (V_{\max}) and increasing Michaelis constant (K_m) for ATP as well as Pgp-specific substrates such as vinblastine (Batrakova et al. 2004b). The magnitude of these effects for vinblastine was as high as over 200-fold V_{\max}/K_m change (interestingly, MRP1 ATPase activity was affected less, which could explain somewhat smaller effects of Pluronic® on this transporter). In contrast, at high concentrations (e.g., 1 %), binding of Pluronic® to the membrane actually resulted in restoration of Pgp ATPase activity. This could be due to the segregation of the block copolymer molecules in the 2D clusters in the membrane, which diminishes its interactions with the transport proteins.

Various drug resistance mechanisms, including drug transport and detoxification systems, require consumption of energy to sustain their function in the barrier cells. Because of this fact, mechanistic studies have focused on the effects of Pluronic® block copolymers on metabolism and energy conservation in BMVEC (Batrakova et al. 2001a). The basis for such studies was the earlier reports that Pluronic® block copolymers can affect mitochondria function and energy conservation in the cells (Kirillova et al. 1993). Recent studies have demonstrated that exposure to Pluronic® P85 induced significant decrease in ATP levels in BMVEC monolayers (Batrakova et al. 2001d). The observed energy depletion was due to inhibition of the

Fig. 50.2 Pluronic® block copolymers with various numbers of hydrophilic EO (n) and hydrophobic PO (m) units are characterized by distinct hydrophilic-lipophilic balance (HLB). Due to their amphiphilic character these copolymers display surfactant properties including ability to interact with hydrophobic surfaces and biological membranes. In aqueous solutions at concentrations above critical micelle concentration (CMC) these copolymers self-assemble into micelles

cellular metabolism rather than a loss of ATP in the environment. The study of Rapoport et al. suggested that Pluronic® P85 can be transported into the cells and decrease the activity of electron transport chains in the mitochondria (Rapoport et al. 2000). Remarkably, the ATP depletion induced by Pluronic® appears to be tightly linked to the specific cell phenotype, since this effect is observed selectively in the cells that overexpress Pgp (as well as MRPs) (Batrakova et al. 2001c, 2004a; Kabanov et al. 2003a, b). We suggested that inhibition of ATP production in high energy-consuming cells, such as cells overexpressing Pgp, results in the rapid exhaustion of intracellular ATP, i.e., ATP depletion (Batrakova et al. 2001a). Further, our recent studies indicate that these differences were related to the differences in the major fuel sources used by MDR or sensitive cells (fatty acids vs. glucose respectively). It was shown that Pluronics affected the stage of the electron entrance in the mitochondrial electron transport chain, presumably due to the interaction of the hydrophobic block of the copolymer with fatty acids, which decreased fuel transport into the mitochondria matrix. In contrast, Pluronics exerted only mild effect on the glucose-based respiration in drug-sensitive cells. Overall, the energy depletion (decreasing ATP pool available for drug transport proteins) and membrane interactions (inhibiting of ATPase activity of drug transport proteins) are critical factors collectively contributing to a potent inhibition of the drug efflux systems by Pluronic® (Batrakova et al. 2001a) (Fig. 50.3).

Fig. 50.3 Schematic illustrating twofold effects of Pluronic® block copolymers with intermediate lipophilicity on Pgp and MRPs drug efflux system. These effects include (a) decrease in membrane viscosity (“fluidization”) resulting in inhibition of Pgp and MRPs ATPase activity, and (b) ATP depletion in BMVEC. Extremely lipophilic or hydrophilic Pluronic® block copolymers do not cross the cellular membranes and do not cause energy depletion in the cells

The effect of Pluronic® P85 on drug transport to the brain was evaluated in animal experiments (Batrakova et al. 2001b). Brain delivery of a Pgp substrate, digoxin, administered intravenously in the wild-type mice expressing functional Pgp, was greatly enhanced in the presence of Pluronic® P85. It was found that the digoxin brain/plasma ratios in the Pluronic® treated animals were practically the same as those in the knockout mice, an animal model that is deficient in both *mdr1a* and *mdr1b* isoforms of Pgp. This suggests that co-administration of Pluronic® with the drug in mice resulted in inhibition of Pgp in the BBB of the wild-type animals (Batrakova et al. 2001b).

One possible concern in these studies is that by virtue of inhibiting the ATP in BMVEC, the copolymer may display toxic effects on the BBB. However, the ATP depletion was found to be transient; following removal of the block copolymers from BMVEC monolayers the initial ATP levels were restored (Batrakova et al. 2001a). Although there were significant decreases in cellular ATP following Pluronic® treatment, even during peak depletion of ATP by Pluronic® there was no evidence of loss of barrier functions of BBB as demonstrated using ³H-mannitol as a permeability marker both in vitro and in vivo (Batrakova et al. 1998, 2001a). Moreover, Pluronic® does not affect the glucose transporter, GLUT1, and only slightly inhibits the lactate transporter, MCT1, the two transporters playing an important role in the brain metabolism (Batrakova et al. 2004a). Pluronic® also does not inhibit the amino acid transporters, LAT1, CAT1, and SAT1, in the BBB (Zhang et al. 2008). A histochemical examination of the tissue sections obtained from animals treated with Pluronic® revealed no pathological changes in the BBB. Importantly, no cerebral toxicity of any kind has been observed in the human Phase I and Phase II studies of SP1049C, a Pluronic®-based formulation of Dox to treat MDR tumors (Danson et al. 2004; Valle et al. 2004). It is possible, that this formulation, evaluated in human trials, can be adopted for use with CNS drugs to enhance drug delivery to the brain.

50.3.4 Chemical Modification of Polypeptides with Fatty Acids and Amphiphilic Block Copolymers

Delivery of potentially therapeutic polypeptides and proteins to the brain is significantly hampered by the BBB. The hydrophilicity, the lack of stability due to enzymatic or chemical degradation, and the lack of transport carriers capable of shuttling polypeptides across cell membranes all play a part in precluding most polypeptides from transport into the brain (Lee 1991). Several approaches to modify polypeptides to alter their BBB permeability have been attempted. First, conjugation of proteins with wheatgerm agglutinin (Raub and Audus 1990; Banks and Broadwell 1994) or cationic groups

("cationization") (Kumagai et al. 1987) (Triguero et al. 1989, 1991) was shown to enhance delivery of polypeptides to the brain through adsorptive endocytosis. The cationized polypeptides demonstrated enhanced permeability and greater accumulation in the brain *in vitro* and *in vivo*. However, toxicity and antigenicity of cationized polypeptides could be an issue for their medical use (Bickel et al. 2001). Further, vectors targeting polypeptides to insulin and Tf receptors (monoclonal antibodies) have been considered to enhance passage of these compounds to the brain through receptor-mediated endocytosis (Bickel et al. 2001; Frank et al. 1986; Duffy and Pardridge 1987; Friden et al. 1991). Thus, potential therapeutic polypeptides, basic fibroblast growth factor and brain-derived neurotrophic factor, were conjugated to OX26, which resulted in increased entry of these polypeptides to the brain and increased drug neuroprotective effects (Zhang and Pardridge 2001; Song et al. 2002).

Another approach, artificial hydrophobization of polypeptides with a small number of fatty acid residues (e.g., stearate or palmitate) has been shown to enhance cellular uptake (Kabanov et al. 1989a). Specifically, this technique involves point modification of lysine or N-terminal amino groups with one or two fatty acid residues per protein molecule. As a result of such modification, the protein molecule remains water-soluble but also acquires hydrophobic anchors that can target even very hydrophilic proteins to cell surfaces (Slepnev et al. 1995). To obtain low and controlled degrees of modification, a system of reverse micelles of a surfactant, sodium bis-(2-ethylhexyl)sulfosuccinate (Aerosol OT) in octane was used as a reaction medium (Kabanov et al. 1987b) (Fig. 50.4). Over a dozen water-soluble polypeptides (enzymes, antibodies, toxins, cytokines) have been modified by this method (Kabanov et al. 1987a, 1989a; Alakhov et al. 1990; Chekhonin et al. 1991; Robert et al. 1993, 1995; Slepnev et al. 1995). Further studies of interactions of the fatty acylated polypeptides with cells were also conducted (Kabanov et al. 1989a; Hashimoto et al. 1989; Alakhov et al. 1990; Colsky and

Peacock 1991; Melik-Nubarov et al. 1993; Slepnev et al. 1995; Ekrami et al. 1995; Chopineau et al. 1998; Kozlova et al. 1999). Modification of water-soluble polypeptides, such as HRP, resulted in enhanced polypeptide binding with the cell membranes and internalization in many cell types (Slepnev et al. 1995). The point modification does not inhibit the specific activity of the polypeptides in the cells. To the contrary, in selected cases, when polypeptides are known to exhibit their effects in cells through binding with a cell surface receptor (e.g., *Staphylococcus aureus* enterotoxin A and recombinant α -interferon) the modification resulted in significant (10 to 100-times) enhancement of these effects (Alakhov et al. 1990; Kabanov et al. 1992b). The increased activity of selected modified polypeptides in cells can possibly be explained by their concentration at the cell membrane, which promotes their binding with receptors (Kabanov et al. 1992b). Furthermore, insulin modified with one palmitic acid residue produced a prolonged hypoglycemic effect compared to the native insulin after intravenous injection and was shown to be less immunoreactive than the native insulin (Hashimoto et al. 1989).

The relevance of this technology to CNS delivery emerged from the studies by Chekhonin et al. (1991, 1995). Those studies showed that modification of the Fab fragments of antibodies against gliofibrillar acid protein (GFAP) and brain specific alpha 2-glycoprotein (alpha 2GP) with stearate led to an increased accumulation of the modified Fab fragments in the brain in a rat. Furthermore, a neuroleptic drug conjugated with the stearylated antibody Fab fragments was much more potent compared to the free drug. In comparison, fatty acylated Fab fragments of non-specific antibodies did not accumulate in the brain but instead accumulated in the liver, while stearylated Fab fragments of brain-specific antibodies displayed preferential accumulation in the brain (Chekhonin et al. 1991). The mechanism by which the stearylated Fab-fragments were directed to the brain was not elucidated at that time. It was not clear also whether the Fab

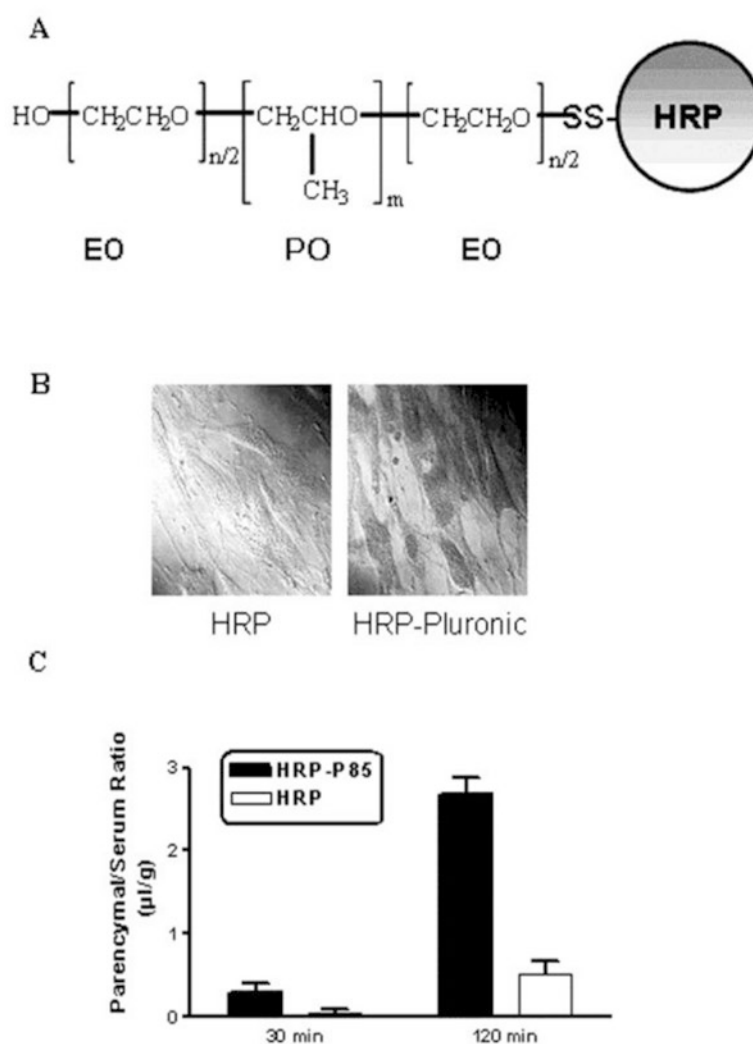

Fig. 50.4 Chemical modification of the protein with a water-insoluble reagent in the reverse micelles of Aerosol OT in octane. (1) Protein molecule incorporates into the inner water pool of the reverse micelle, acquiring a monolayer cover of the hydrated surfactant molecules. (2) The modifying reagent incorporates into the surfactant layer of the

micelle coming into contact with the modified group of the protein. (3) Following the completion of the reaction the modified protein is precipitated and the surfactant and excess of the reagent are removed by adding cold acetone. Proteins modified with fatty acid residues with controlled and low degree of modification are obtained

fragments actually crossed the BBB or remained associated with the luminal surface of the brain capillaries. Subsequent studies using bovine brain microvessel endothelial cells (BBMEC) as an *in vitro* model of BBB (Chopineau et al. 1998) demonstrated that stearylation of ribonuclease A (approx. 13.6 kDa) increases the passage of this enzyme across the BBB by almost tenfold. Of the three fatty acid derivatives analyzed—myristic, palmitic and stearic, the latter was the most active. A possible mechanism for the entry of the fatty acylated polypeptides to the brain is adsorptive endocytosis. Given the characteristics of the BBB transport for nonessential free fatty acids as reviewed elsewhere, (Banks et al. 1997) it is unlikely that the modified polypeptides are able to use those transporters. Thus, use of free fatty acid receptor mediated transport by the modified polypeptides is not likely. However, if such a pathway is feasible, it should be more pronounced when the essential fatty acids, such as linoleic, are used to modify polypeptides (Edmond 2001; Edmond et al. 1998).

A similar principle was used in the case of a protein modification with Pluronic® block copolymers (Fig. 50.5); the designed conjugates had different balance between hydrophilic and lipophilic properties (Batrakova et al. 2005). The cell binding and transport of Pluronic® P85 and L121 modified HRP were increased up to 6 and 10 times, respectively, compared with the native HRP. A method of conjugation using biodegradable and non-biodegradable links was also varied. As expected, the modification of the protein via a biodegradable link (Fig. 50.5a) resulted in the most effective transport of the protein across the brain microvessel endothelial cell monolayers. It is likely, that being highly hydrophilic the HRP molecule requires a highly lipophilic moiety to obtain the optimal hydrophilic-lipophilic balance of the conjugate. Such a lipophilic group has a tendency to remain associated with the cellular membrane as an anchor. Therefore, a biodegradable link allowed the polypeptide molecule to separate from its lipophilic moiety and enter the brain after the conjugate passed membranes of the barrier cells. Data obtained by confocal

Fig. 50.5 Effect of HRP modification with Pluronic block copolymer on transport across the BBB in an *in vitro* and *in vivo* models. (a) HRP conjugated with Pluronic P85 via the biodegradable bond; (b) confocal microphotograph of BBMEC monolayers treated with rhodamine-labeled HRP and Pluronic-HRP for 2 h; (c) blood-to-brain transport of HRP and Pluronic-HRP in mice

microscopy visualizes this effect. Modification of the protein with Pluronic® P85 via biodegradable link drastically enhanced the transport of HRP into the cells and its accumulation in the cytoplasm, nuclei, and other cellular organelles (Fig. 50.5b). It was suggested that the protein conjugate was initially bound to the cellular membrane through the Pluronic® moiety incorporated into the lipid bilayer followed by cleavage of the HRP molecule from the Pluronic® anchors. In vivo studies demonstrated that (1) hydrophobization with stearyl group or (2) amphiphilic modification with a Pluronic® block copolymer had increased the rate of HRP penetration across the BBB and increased accumulation of HRP by the brain (Fig. 50.5c). Overall modification with Pluronic® block copolymers appeared to be more promising for HPR delivery to the brain. In this case the permeability of modified protein in the BBB in vivo was increased almost fourfold with no statistically significant effects on the protein peripheral pharmacokinetics or entry into the parenchymal space.

50.4 Review Questions

- What are the main features of the BBB that restrict drug transport to the brain?
- Describe the properties of polymers that are useful for drug delivery systems.
- What are the advantages of nanoscaled polymeric carriers?
- List types of nanocarriers for drug delivery. Describe their structure, principal differences, advantages and limitations.
- Describe cell-mediated drug delivery to the CNS.
- Explain how the drug efflux transporters affect drug transport to the brain? List examples of drug efflux transporters expressed in the BBB.
- Describe three generations of inhibitors of drug efflux transporters in the BBB.
- Describe the effects of Pluronic block copolymers on drug efflux transporters in the BBB.
- How is the chemical modification of polypeptides with fatty acids and amphiphilic block copolymers applied to increase delivery of polypeptides to CNS?
- Which of the following molecules can penetrate across the BBB through passive diffusion?
 - Lipophilic low molecular weight compounds*
 - Hydrophilic low molecular weight compounds
 - Lipophilic high molecular weight compounds
 - Hydrophilic high molecular weight compounds
- What size of polymer nanocarriers is the most appropriate for drug delivery?
 - 0.1–1 nm
 - 1–100 nm
 - 100–1000 nm
 - 1–100 μm
- Which types of drugs can be incorporated into polymeric micelles?
 - lipophilic compounds*
 - hydrophilic compounds
 - charged compounds
 - proteins compounds
- What does CMC mean?
 - colloidal microemulsion complex
 - cell monocarrier
 - critical micelle concentration*
 - contrast multi-compound
- Which polymer is used to stabilize nanoparticles in an aqueous dispersion?
 - polystyrene
 - polymethacrylic acid
 - DNA
 - PEG
 - polycyanoacrylate
- Which type of cells can be used for cell-mediated delivery?
 - brain microvessel endothelial cells
 - neurons
 - macrophages*
 - astrocytes
 - erythrocytes

50.5 Answers

- The low permeability of the BBB is attributed, in large part, to the brain microvessel endothelial cells (BMVEC), which form tight extracellular junctions and have low pinocytotic activity. There is also an enzymatic barrier to drug transport in the BMVEC and overexpression of drug efflux transporters on the luminal side of BMVEC.
- There are several fundamental properties of polymers that are useful in solving drug delivery problems. First, polymers can be designed to be intrinsically multifunctional and can, for example, be combined either covalently or non-covalently with drugs to overcome multiple problems such as solubility, stability, permeability, etc. Second, polymers can be easily modified with various targeting vectors to direct drugs to specific sites in the body. Third, polymers can be designed to be environmentally responsive materials, allowing for the controlled and sustained release of a drug at its site of action. Finally, polymers themselves can be biologically active, and this property can be exploited in order to modify the activity of various endogenous drug transport systems within the body to improve delivery and, therefore, drug performance.
- Nanoscaled polymeric carriers have several advantages. Because these systems often exhibit similarity in their size

and structure to natural carries such as viruses and serum lipoproteins, they offer multifaceted specific properties in drug delivery applications. They entrap small drugs or biopharmaceutical agents, such as therapeutic proteins and DNA, and can be designed to trigger the release of these agents at the target site. Moreover, they can be targeted not only to the particular organ or tissue, but to a particular cell or even an intracellular compartment.

4. There are various types of vehicles proposed for transport of neuropharmaceuticals across the BBB: liposomes, degradable nanoparticles, nanospheres, nanosuspensions, polymeric micelles, nanogels, block ionomer complexes, nanofibers and nanotubes, and dendrimers. Each of them has advantages and limitations. The overall advantages of polymer-based nanocarriers are:
 - a. Increase drug solubility
 - b. Improve drug pharmacokinetics and biodistribution
 - c. Increased protection of the drug in the blood stream and long circulation
 - d. Target solid tumors by enhanced permeability and retention (EPR) effect
 - e. Decrease side effects (diminish drug extravasation into normal tissues)
 - f. Ability to vectorize the particle and capability of receptor-mediated transport across the BBB
 - g. Drug resistance
 - h. Triggered release

The limitations may include: (a) disassembly upon dilution in the blood stream for non-crosslinked aggregates; (b) low loading capacity; (c) entrapment in the mononuclear phagocytic system as present in the liver and spleen; (d) toxicity (especially for positively charged polymer nano-carriers)

5. A distinct case of the vehicle-mediated CNS drug delivery employs specific cells carriers that can incorporate micro- and nano-containers (such as liposomes, micelles, and block-ionomer complexes) loaded with drugs and act as perfect Trojan horses by migrating across the BBB and carrying drugs to the site of action. It is documented that many neurological diseases, have in common an inflammatory component. The process of inflammation is characterized by extensive leukocytes (neutrophils and monocytes) recruitment. These cells have a unique property of migrating toward the site of inflammation via the processes known as diapedesis and chemotaxis.
6. Cerebral capillary endothelium expresses a number of efflux transport proteins, which actively remove a broad range of drug molecules before they cross into the brain parenchyma. Among them are: Pgp, MRP1, and BCRP, MOAT that belong to the ABC cassette (ATP-binding cassette) family.
7. The first generation is a low molecular weight Pgp inhibitors (cyclosporine A, verapamil, PSC833, etc.), which

compete for the active site with the therapeutic agent. The second generation inhibitors (LY335979, XR9576 and GF120918) are non-competitive inhibitors, which allosterically bind to Pgp, inactivating it and increasing drug transport to the brain. Despite their high efficiency in cell culture models, the small therapeutic range of these inhibitors, high in vivo toxicity, and fast clearance are the main obstacles for their therapeutic application. The third generations is a new class of inhibitors (nonionic polymer surfactants). These compounds are two- or three-block copolymers arranged in a linear AB or ABA structure. The A block is a hydrophilic PEG chain. The B block can be a hydrophobic lipid (BRIJs, MYRJs, Tritons, Tweens, and Chremophor), or a poly(propylene glycol) (PPG) chain (Pluronics®).

8. Recent findings suggest that effects of Pluronic® on drug efflux transport proteins involve interactions of the block copolymers with the cell membranes. Pluronic® at relatively low concentrations (e.g., 0.01 %) inhibits the Pgp ATPase activity, possibly due to conformational changes in the transport protein induced by the immersed copolymer chains in the Pgp-expressing membranes. In contrast, at high concentrations (e.g., 1 %), binding of Pluronic® to the membrane actually resulted in restoration of Pgp ATPase activity. In addition, Pluronic® block copolymers can affect mitochondria function and energy conservation in the cells. Recent studies have demonstrated that exposure to Pluronic® P85 induced significant decrease in ATP levels in BMVEC monolayers. Overall, the energy depletion (decreasing ATP pool available for drug transport proteins) and membrane interactions (inhibiting of ATPase activity of drug transport proteins) are critical factors collectively contributing to a potent inhibition of the drug efflux systems by Pluronic®.
9. Artificial hydrophobization of polypeptides with a small number of fatty acid residues (e.g., stearate or palmitate) has been shown to enhance cellular uptake in BMVEC. This effect can possibly be explained by the increased concentration of the polypeptides at the cell membrane, which promotes their binding with receptors.

Abstract

Macromolecular therapeutics have been developed to improve the efficacy and safety profile of varied therapeutic agents for different disease more than 50 years ago. *N*-(2-hydroxypropyl) methacrylamide (HPMA) copolymers as a drug delivery platform have been extensively studied and applied in the clinical trials. Recently, the application of HPMA copolymers in the treatment of non-cancerous diseases such like infectious diseases and musculoskeletal diseases has also been explored widely. In this chapter, different formulations of macromolecular therapeutics will be discussed. The design principles illustrated in the development of HPMA copolymer drug conjugates are also valid for other hydrophilic polymers, and they will be the principal focus of our discussion. Active targeting of HPMA copolymers based on targeting moieties and passively targeting HPMA copolymers based on the Enhanced Permeability and Retention (EPR) effect for cancer disease and Extravasation through Leaky Vasculature and subsequent Inflammatory cell-mediated Sequestration (ELVIS) mechanism for inflammation disease will also be discussed in this chapter.

Cancer therapy • Central nervous system (CNS) • Hydroxypropyl methacrylamide HPMA copolymers • Targeting

51.1 Introduction

Water-soluble polymers have been widely used as carriers of drugs, genes, oligonucleotides and for modification of proteins, liposomes, surface of biomaterials. Drug conjugated to synthetic macromolecules was initiated by Jatzkewitz 60 years ago when researchers first used the water-soluble polymer polyvinyl pyrrolidone as a drug depot for the biologically active primary amine mescaline (Jatzkewitz 1955). Since then, the field was expanded and developed dramatically beyond depot effects. Numerous water-soluble polymer-drug

conjugates, PEG-protein conjugates, lysosomotropic polymer-drug conjugates and block copolymer micelles were synthesized in the 1960s and 1970s (De Duve et al. 1974; Abuchowski et al. 1977). “Polymer therapeutics” was coined by Ruth Duncan to describe polymeric drugs, polymer protein conjugates, block copolymer polymeric micelles to which a drug is covalently bound and polyplexes developed as non-viral vectors for gene interfering ribonucleic acid (siRNA) delivery (Duncan 2003). The rationales for polymer-drug conjugates include prolong the blood circulation time, reduce the side-effects of the drug, improve drug targeting and overcome drug resistance. Conjugation of low molecular weight drugs to polymers would prolong their resident time in blood circulation resulting in enriched bioavailability. The delivery system based on synthetic water-soluble polymer would render hydrophobic drugs better solubility and limit the cellular uptake to the endocytic route. Based on EPR

(Enhanced Permeability and Retention) effect (Matsumura and Maeda 1986), polymer conjugation would facilitate the passive targeting of drugs to the solid tumor (Maeda 2010). The newly discovered ELVIS (Extravasation through Leaky Vasculature and Inflammatory cell-mediated Sequestration) mechanism (Yuan et al. 2012; Wang and Goldring 2011; Ren et al. 2011, 2014) explains macromolecular therapeutics' preferentially accumulate in inflammatory tissues (Liu et al. 2010) in general and inflammatory arthritis in particular (Wang et al. 2004; Yuan et al. 2012; Liu et al. 2008).

In this chapter, we will focus mainly on the development of *N*-(2-hydroxypropyl) methacrylamide (HPMA) copolymer drug conjugates as the design principles illustrated are also valid for other hydrophilic polymers. HPMA copolymers based macromolecular therapeutics are active against many cancer models and have been evaluated in several clinical trials (Kopeček et al. 2000). In 1994, HPMA copolymer-doxorubicin (FCE28068) was the first HPMA copolymer drug conjugate to enter clinical evaluation (Vasey et al. 1999). To achieve the controlled release and better solubility of paclitaxel, Pharmacia developed the HPMA copolymer-paclitaxel

(PNU166945) (Meerum Terwogt et al. 2001). Beyond oncology, HPMA copolymer is also applied to treat rheumatoid arthritis when conjugated with glucocorticoids (Yuan et al. 2012). In addition, there is great potential for these technologies to be extrapolated into neurological applications.

51.2 Structure of Macromolecular Therapeutics

The structure of macromolecular therapeutic agents can vary due to different types of the payload (Duncan 2003). While micelles, dendrimers, liposomes, nanoparticles and polymer-drug conjugates all share the concept of macromolecular therapeutics, they can be very different in their structures (Vikas et al. 2015). Different delivery systems are also applied to deliver different candidates because of their own unique properties. For example, macromolecular payloads prefer the liposomes, nanoparticles and micelle delivery systems, while polymeric delivery systems (e.g., HPMA copolymers) favor small molecular payloads (Fig. 51.1).

Fig. 51.1 A schematic representation of some macromolecular drug delivery systems. (a) Liposomes (~100–400 nm) are small spherical artificial vesicles typically made with lipid bilayers, (b) Nanosphere (~20–200 nm) are typically made with biodegradable polymers for sustained drug release, (c) Nanocapsules (~10–1000 nm) can encapsulate relatively large amounts of drugs and nucleic acids such as DNA, microRNA,

siRNA (small interfering RNA) and shRNA (small hairpin RNA), (d) Dendrimers (~3–20 nm) are monodisperse macromolecules that can be used to encapsulate or covalently conjugate drugs, targeting moieties and imaging agents, (e) Micelles (~10–100 nm) are self-assembled amphiphilic particles that can encapsulate both lipophilic or lipophobic drugs stabilized by surfactants (Adapted from Orive et al. (2009), with permission)

51.2.1 Liposomes

Liposomes have been defined as a vesicle for drug delivery since the 1960s (Bangham et al. 1965). Liposomes are composed of phospholipid membrane surrounded by the aqueous environment. The structure of the liposomes membrane is a double layer with fluidity. The shape of liposomes is basically spherical. Liposomes can be categorized into multilamellar vesicle (MLV) (Gentile et al. 2014), small unilamellar the liposome vesicle (SUV) (Lokappa and Ulmer 2011) and large unilamellar vesicle (LUV) (Moyano et al. 2008) according to the number of lipid layers and the size of the liposome. Most of the clinically used liposome formulations have to be decorated with inert water-soluble polymers (e.g., PEG, HPMA copolymer, etc.) to ensure their stealth against the mononuclear phagocyte system (MPS). While this modification may enlarge the size of the liposome, its half-life in circulation will be improved. The surface decorating polymers can also be used to introduce various targeting moieties or imaging probes. Liposome size can vary from 100 to 400 nm in diameter and plays a critical role in complement activation and MPS clearance of the delivery system (Drummond et al. 1999; Devine et al. 1994). Vesicles larger than 100 nm require additional strategies to prevent surface opsonization (Koo et al. 2005).

51.2.2 Nanoparticles

Nanoparticles can be categorized as drug nanoparticles, solid nanoparticles, polymer-based nanoparticles, lipid-based nanoparticles and nanocapsules. Drug nanoparticles are the dispersion of water-insoluble drug particles of drug formulations in the nanosize range in an aqueous environment. Drug nanoparticles can be achieved by breaking down the bigger particles by high-pressure homogenization method or by special crystallization techniques. Polymer-based nanoparticles are commonly composed of poly(lactic acid) (PLA), poly(glycolic acid) (PGA), poly(lactic acid-co-glycolic acid) (PLGA), poly(ϵ -caprolactone) (PCL), and poly(methylmethacrylate) (PMMA). Chemical synthesis, salting-out, emulsification-diffusion, nanoprecipitation and freeze-drying methods are used to obtain polymer-based nanoparticles. Lipid-based nanoparticles mostly composed of fats or waxes and can be obtained by homogenization. For certain applications, nanoparticles may be tailored into different shape: namely sphere nanoparticles (Kocbek et al. 2007), cube nanoparticles (Verma and Ahuja 2015), rod-like nanoparticles (Wang et al. 2014), hollow spherical nanoparticles (Chen et al. 2014) and random shape nanoparticles.

51.2.3 Micelles

A formulation of micelle can be achieved by the self-assembly (aggregation) of amphipathic macromolecules

when they are added to aqueous solution. Critical micelle concentration (CMC), is defined as the concentration above which the micelle will form. The amphipathic macromolecules used for micelle formulations can be classified into three types: 1. The molecule is composed of the one polar end (hydrophilic group) and one non-polar end (hydrophobic group) (Koizumi et al. 2006). 2. Two polar ends with the non-polar center (Chen et al. 2013). 3. Two non-polar ends with the polar center (Nederberg et al. 2011). Shapes of micelles can be sphere (Chen et al. 2013), ellipsoid cylinder and monolayer micelle (Wiedwald et al. 2010). To improve micelle stability, Liu et al. prepared poly(2-cinnamoyl ethyl methacrylate-*b*-acrylic acid) which forms polymeric micelles in water (Henselwood and Liu 1997; Liu 1997) and cross-linked the core segment by photochemically induced polymerization of the cinnamoyl side groups which decreases the free volume of the core. The core density may increase and the size of the micelles might decrease because of the crosslinking.

51.2.4 Dendrimers

Dendrimers (Fig. 51.2) are highly uniformed, branched or star-shaped macromolecules. Dendrimers can be synthesized by divergent (Li et al. 2014) or convergent approaches (Kushwaha and Tiwari 2013). They are often of uniform molecular weight and very low polydispersities. Dendrimers also have modifiable surface functional group as well as internal cavities (Jansen et al. 1994). For example, Newkome et al. (Newkome et al. 1991) have synthesized a dendrimer containing hydrophobic interior and hydrophilic surface functionality. During or after synthesis of dendrimers, the drug molecules can be physically entrapped or chemically conjugated to the dendrimer (Thanki et al. 2013).

51.2.5 Polymer-Drug Conjugates

Polymeric-drug conjugates, are generally consisted of a polymeric backbone, active drugs, targeting moiety and signaling moiety, as illustrated in Fig. 51.3. The primary structure of the conjugates and the chemical bonds by which the components are linked to the backbone can be designed base on the conjugates applications (Miller et al. 2008), drug properties (Liu et al. 2010; Wang et al. 2007a) and biological rationales (Kopeček 1984; Kopeček et al. 1991; Putnam and Kopeček 1995). The shape of HPMA-copolymer conjugates (Nakamura et al. 2015), the length of the backbone (Nakamura et al. 2015), the number of the side chain and the length of the side chain (Kopeček et al. 2000) can be managed to some degree by different synthetic strategies. Reversible addition-fragmentation chain transfer (RAFT) polymerization is commonly used to manage the molecular

The polymer backbone is shown in black, linker region in green, drug in red and additional components (for example, a targeting residue) in blue. (a) Two examples of more ‘simple’ polymer–drug conjugates containing doxorubicin (left) and

paclitaxel (right) that have progressed to clinical trial. (b) A multivalent receptor-targeted conjugate containing galactosamine (light blue) to promote liver targeting. (c) Polymeric combination therapy containing the aromatase inhibitor aminoglutethimide (red) and doxorubicin (blue) (Adapted from Duncan (2006), with permission)

weight and polydispersity of the polymer conjugates which will affect the distribution, accumulation and the elimination of the conjugates on living organism (Moad et al. 2008; Vikas et al. 2015).

51.3 Targetability of HPMA Copolymer Conjugates

The targeting of the polymeric conjugates to pathology is essential for a drug delivery system. The drug targeting mechanisms are generally categorized into active targeting and passive targeting (Zhou and Kopeček 2012).

51.3.1 Active Targeting

Active targeting is the method using the target moiety, such as antibody, specific low molecular weight ligands, etc., to direct the payload to preferentially accumulate at the site of pathology. Active targeting always takes advantages of the different pathological features of the lesion when compared to the normal tissue. The preferential interaction of the antigen expressed on the cell surface of a particular disease lesion and the targeting moiety of the delivery system will facilitate the active targeting process. As one may speculate, this strategy can lower the side effect of the drug by reducing unnecessary drug exposure to the normal tissues.

51.3.1.1 Antibody Mediated Targeting

Conjugate bound with specific antibodies is called antibody-targeted polymer conjugates. While such conjugation would significantly improve the polymer-drug conjugates' diseases targeting ability, the original antigen binding affinity of the antibodies conjugated to polymeric drug carriers can be compromised due to the chemical modification process (Tappertzhofen et al. 2014). Recently, a new method has been developed, attempting to address this problem (Pechar et al. 2011). A heterodimeric coiled coil structure can be formed with a highly specific interaction between peptide K ((VAALKEK)₄) and peptide E ((VAALEKE)₄). Benefiting from such molecular recognition, a cytostatic drug-bearing HPMA copolymer peptide E conjugate was synthesized, and self-assembled with peptide K tagged BCL1 leukemia cells specific scFv of B1 mAb, to obtain an antibody-polymer drug conjugate with largely intact antibody targeting ability.

51.3.1.2 Folate Mediated Targeting

Folate shows high affinity to its receptors, folate binding proteins. This unique property has established folate as a popular active targeting moiety to assist the intracellular transportation and drug/drug delivery systems (Campbell et al. 1991) (Kranz et al. 1995). The folate receptors are highly expressed on the cancer cells (Yoo and Park 2004), which would facili-

tate the active targeting of folate bearing polymer conjugates to the cancer lesion. The conjugates can be transported intracellularly via receptor-mediated endocytosis. Unlike liposomes, micelles and nanoparticles, the hydrophobicity of folate affect polymer-drug conjugate more because it can be hidden within the polymer random coil but not on the surface like in the other nanomedicine formulations. To overcome this limitation, researchers introduced the positive charges into the HPMA copolymer conjugates (Niewoehner et al. 2014). Folate receptor (FR) positive Hela cells were used to test the drug-cell binding affinity. In the presence of folate-modified cationic HPMA copolymers, FR antibody bounded cells decreased from 71.2% to only 34.0%. This indicates that the positive charge could probably amplify the binding efficiency of folate to its receptor due to the close proximity of conjugates to the cell surface by the electronic adhesion. To avoid non-specific binding by the positive charge in the circulation, the researchers applied charge shielding/deshielding approach. Charge shielding groups 2,3-dimethylmaleic anhydride (DMA) can be specifically hydrolyzed at tumor extracellular environment (pH 6.8). Then the conjugates show the charge-reversible ability, leading to the faster endocytosis into the cells of cancerous lesion than the normal tissue (pH 7.4). This technique may improve the folate-mediate targeting of HPMA copolymer conjugates to cancer.

51.3.1.3 Transferrin Mediated Targeting

Similar to folate, transferrin is another well-studied targeting moiety because of the overexpression of its receptor on the cancer cells surface (Tomita et al. 1991) and brain microvascular endothelial cells (Roberts et al. 1993). The binding of transferrin to its receptor would lead to its endocytosis. Iron in plasma will bind with transferrin and dissociate from it in the acidic compartment of the cell. Copolymers consist of the hydrophobic monomer lauryl methacrylate (LMA), a reactive anhydride functional methacrylate (TMA), and a large polyethylene glycol methacrylate monomer was copolymerized and conjugated to transferrin. This docetaxel containing, transferrin receptor targeting conjugate shows the enhanced cancer cell killing properties in in vitro cytotoxicity studies (Roy et al. 2014).

51.3.2 Passive Targeting

In 1979, the antitumor protein drug neocarzinostatin (NCS) was conjugated with a synthetic copolymer of styrene maleic acid copolymer (SMA) which was called SMANCS (molecular weight 16,000 g/mol) by Maeda (Maeda et al. 1979). This antitumor protein drug conjugate exhibited many unique properties, including prolonged half-life in circulation (20-fold), improved tumor-targeting capacity (2000 fold intra-tumor concentration than plasma), no immunogenicity and higher lipophilicity (Fang et al. 2011;

Fig. 51.4 Schematic representation of different mechanisms by which nanocarriers can deliver drugs to tumors. Polymeric nanoparticles are shown as representative nanocarriers (circles). Passive tissue targeting is achieved by extravasation of nanoparticles through increased permeability of the tumor vasculature and ineffective lymphatic drainage (EPR effect). Active cellular targeting (inset) can be achieved by func-

tionalizing the surface of nanoparticles with ligands that promote cell-specific recognition and binding. The nanoparticles can (i) release their contents in close proximity to the target cells; (ii) attach to the membrane of the cell and act as an extracellular sustained-release drug depot; or (iii) internalize into the cell (Adapted from Peer et al. (2007), with permission)

Maeda et al. 1984; Maeda and Konno 1997). These properties led to the conceptualization of the Enhanced Permeability and Retention effect (EPR effect) (Matsumura and Maeda 1986) showed in Fig. 51.4. With the advantage of EPR effect, SMANCS became the first macromolecular anticancer drug approved in 1993 in Japan (Fang et al. 2011; Maeda and Konno 1997). The EPR effect has been observed in the applications of many nanomedicine formulations, such as polymer conjugates, polymeric micelles and liposomes (Seymour et al. 1987; Dand et al. 2013). Most HPMAC copolymers utilize the EPR effect to achieve better tumor targeting and delivery of drugs. EPR effect is a tumor vasculature-dependent phenomenon. Most tumors are well vascularized with high density and the rapid growth of blood vessels leads to irregular vascular alignment and defects of the junction between endothelial cells. The increased local fenestration of macromolecules paired with the ill-developed lymphatic drainage at the tumor lesion lead to the local

accumulation of macromolecules over time (Folkman 1995; Fang et al. 2011; Hashizume et al. 2000; Jain 1999; Jain et al. 2002; Roberts and Palade 1997).

Wang et al. first described macromolecules' Extravasation through Leaky Vasculature and their subsequent Inflammatory cell-mediated Sequestration (ELVIS) (Wang and Goldring 2011). It explains the passive targeting of the HPMAC copolymer-dexamethasone conjugate (P-Dex) to inflammations (Yuan et al. 2012; Quan et al. 2010). Unlike the traditional understanding of EPR effect that macromolecules only can passively target to solid tumors (not inflammation) due to the leaky vasculature and impaired lymphatic drainage, they found although the extravasated macromolecules are cleared from the inflammatory tissue quickly, rapid internalization by inflammatory infiltrates and locally activated cells provide the mechanism for the sustained retention of the macromolecular drug conjugate at the site of inflammation.

51.4 Clinical Tests on HPMA Copolymer-Anticancer Conjugates

Cancer is the second leading cause of death in the United States. One of every four deaths in the United States is from cancer. In the past 60 years, synthetic water-soluble polymers, including HPMA copolymers have been used extensively as anticancer drug carriers due to their high biocompatibility and chemical functionality. All polymer conjugates used as anticancer agents in clinical trials are in effect macromolecular prodrugs. HPMA copolymers as an anticancer drug carrier are non-toxic, non-immunogenic and have multiple side chains to carry drug and targeting moiety payload (Duncan and Kopeček 1984; Duncan 2009; Kopeček et al. 2000). The rationale for HPMA copolymer anticancer drug conjugation, from the biological point, is to ensure that the drug would reach the pharmacological target and has limited access to sites of non-specific toxicity. Moreover, the drug must be released at a concentration and rate, which should be able to maximize its therapeutic action. It is important to control polydispersity as the molecule weight variation has a high impact on general and cellular pharmacokinetics with consequent implications for efficacy and toxicity. The antitumor HPMA copolymers target to the tumor through EPR effect which shows a significantly increased tumor drug concentration.

Many achievements have been made in the clinical evaluation of HPMA copolymer anticancer drug conjugate. For example, a Phase I clinical trial using HPMA copolymer-doxorubicin to treat breast cancer showed signs of activity coupled with fivefold decreased anthracycline toxicity in chemotherapy-refractory patients (Vasey et al. 1999). Phase II studies utilized 17 breast cancer patients, 29 non-small cell lung cancer patients and 16 colorectal cancer patients (Seymour et al. 2009). The study has expanded and confirmed the early indications that HPMA copolymer doxorubicin has therapeutic activity against some advanced solid neoplasms. Of the 14 evaluable patients with breast cancer 21 % had partial responses, and these were all anthracycline-naïve patients and it is possible that free doxorubicin could also have been effective in these patients. Three chemotherapy-naïve patients of 26 non-small cell lung cancer patients had partial responses. In contrast, none of the 16 evaluable patients with colorectal cancer responded (Seymour et al. 2009). HPMA copolymer doxorubicin has the extended plasma circulation of the polymer conjugate, an important prerequisite for passive accumulation within tumor tissues comparing with free doxorubicin and its delivery is determined largely by its kinetics and biodistribution (Duncan 2009). Failure of traditional chemotherapy results in recurrence and development of virulent multi drug resistance (Persidis 1999). To deal with this, the majority of cancers are being treated by a combination of drugs. HPMA copolymer-doxorubicin conjugate and HPMA copolymer-photosensitizer conjugate were the first combination therapy using polymer

bound to drugs (Krinick et al. 1994). Experiments results show that combination therapy achieved the better cure than either therapy alone (Kopeček et al. 2000; Zuluaga and Lange 2008; Matthew Peterson et al. 1996).

Paclitaxel is a well-known antitumor agent with proven efficacy in ovarian, breast and non-small cell lung cancer (Huizing et al. 1995). Intravenous administration of paclitaxel is hindered by poor water solubility of the drug and associated with unpredictable side effects. PNU166945 is a novel polymer-conjugate derivative of paclitaxel, which uses HPMA polymer as the polymeric carrier. This compound is water soluble, no toxicity and provides a wide platform for specific tumor targeting (Meerum Terwogt et al. 2001). HPMA copolymer paclitaxel was administered as a 1 h intravenous infusion every 3 weeks to a total of 12 patients in phase I clinical trial (Meerum Terwogt et al. 2001). However, this trial was discontinued before reaching dose-limiting toxicity because of there is potential neurotoxicity at higher doses found in the preclinical animal study (Meerum Terwogt et al. 2001). Plasma pharmacokinetic was measured over 48 h using HPLC and showed a linear relation for both HPMA copolymer-paclitaxel and released paclitaxel. The results suggest an improved pharmacokinetic behavior with potential controlled release of paclitaxel.

51.5 Non-cancerous Diseases

Beyond oncology, people are afflicted by many chronic conditions such as autoimmune diseases, musculoskeletal disorders and infectious diseases. Rheumatoid arthritis (RA) is a chronic, systemic and inflammatory autoimmune disease, which manifests in multiple joints of the body. One in five adults in the United States report having doctor diagnosed arthritis (CDC 2013). Currently, there is no cure for rheumatoid arthritis. Commonly used medications for treatment of the disease include non-steroidal anti-inflammatory drug (NSAIDs), glucocorticoids (GCs) and disease-modifying antirheumatic drugs (DMARDs) (Yuan et al. 2012). For oral administration of NSAIDs such as ibuprofen, only a small amount of drug can be absorbed and reach at the arthritic joints (Gallo et al. 1986; Mäkelä et al. 1981). The NSAIDs conjugated to the macromolecular carrier would target to the inflammation site after parenteral administration (Larsen et al. 1989). The therapeutic effects of NSAIDs are mediated primarily through nonselective inhibition of cyclooxygenase (COX), inhibiting both the cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). However, they will not prevent joint destruction and only show a small impact on inflammation and also the application of NSAIDs are limited due to the side effects, especially GI and renal toxicity (El Desoky 2001). Glucocorticoids (GCs), which are immunosuppressive and anti-inflammatory, have been widely used for controlling

the symptoms of inflammatory diseases (Kirwan et al. 1995). However, the side-effects associated with long-term GC treatment (e.g., immunodeficiency, weight gain, growth impairment, fluid retention and secondary osteoporosis, etc.) have hampered their clinical application (Canalis et al. 2007; Barber et al. 1993). To address this challenge, polymeric glucocorticoids have been proposed (Timofeevski et al. 1996). As a major breakthrough, HPMA copolymer-dexamethasone conjugate was designed and synthesized. Due to the high anti-inflammation potency and high toxicity, dexamethasone (Dex) was selected as the prototype drug candidate to be conjugated to HPMA copolymer via a hydrazone bond, which is acid-cleavable (Kratz et al. 1999). The general idea is that after systemic administration, HPMA copolymer-Dex (P-Dex) conjugate will passively target to the inflammatory joints and be quickly internalized by the synoviocytes via endocytosis and gradually release the free drug to exert its anti-inflammation effect locally without triggering systemic GC side effect of. While the *in vivo* data proved that this general design works very well, some chemistry problem remains. Due to the initial polymer analogous reaction approach that was taken, the drug content in P-Dex varies from batch to batch. To solve this problem, a new acid-cleavable, Dex containing monomer (MA-Gly-Gly-NHN=Dex) was synthesized to achieve precise control of Dex loading in the conjugate (Wang et al. 2007a). In the inflammatory joint, P-Dex treatment has a long-lasting inflammation resolution effect, which is critical and indirectly supports the long-term presence of Dex in the arthritic joints (Wang et al. 2007a; Liu et al. 2008). The mechanism underlining the P-Dex' targeting to arthritis is different from the classical EPR effect as the intimal lymphatic is intact in most of the arthritic joints and the passive targeting is initiated by their selective extravasation through the leaky vasculature of the inflamed synovial tissues (Yuan et al. 2012). As discussed in the passive targeting section, this novel passive targeting mechanism was called "ELVIS", which represent the macromolecular pro-drugs' Extravasation through Leaky Vasculature and the subsequent inflammatory cell-mediated Sequestration. The fast sequestration of P-Dex by the activated synoviocytes and potentially inflammatory infiltrates explains the passive targeting of P-Dex to inflammations (Quan et al. 2010; Wang and Goldring 2011; Yuan et al. 2012).

HPMA copolymer-drug conjugates have also been used to treat musculoskeletal diseases. Bone-targeting HPMA copolymer conjugates were designed for the treatment of osteoporosis and other musculoskeletal conditions (Wang et al. 2003, 2004, 2006, 2007b; Pan et al. 2006, 2008a, b; Miller et al. 2008). HPMA copolymer-D-Asp₈ conjugates show extensive targeting potential to the skeleton. D-Asp₈ (D-aspartic acid octapeptide) is an anionic peptide being used as bone-targeting moieties for HPMA polymer conjugates (Wang et al. 2003). It was showed that FITC-labeled

HPMA copolymer D-Asp₈ conjugate at 0.5 g/kg dose has a very strong binding at the high bone turnover sites such as primary spongiosa and metaphyseal areas in mice (Wang et al. 2003). The conjugate was also bound to the bones of osteopenic animal model in rat with the same dose in mice (Miller et al. 2008). Besides D-Asp₈ as bone targeting moieties, bisphosphonates are also commonly used as bone targeting moieties for HPMA copolymer conjugates (Russell 2011; Fleisch 1981). Instead of recognizing only resorption sites in skeletal tissues of D-Asp₈, alendronate (ALN) directs the delivery system to both formation and resorption sites (Wang et al. 2007b). Based on a previous study (Wang et al. 2003, 2006), alendronate-containing conjugates with relatively low molecular weight show higher binding to the bone than D-Asp₈ containing conjugates. Prostaglandin E₁ was selected as the first anabolic compound to be conjugated to the HPMA copolymer bone targeting polymers (Pan et al. 2006, 2008a). The high molecular weight, multiblock, backbone degradable bone targeted HPMA copolymer PGE₁ conjugate showed higher accumulation in the bone of OVX rat model and a higher efficacy in promoting bone formation in an osteoporosis rat model (Pan et al. 2008b, 2013).

51.6 Linker Chemistry

To achieve on-site drug release and reduce the drug toxicity to other organs, linker design between drug and HPMA copolymer are very important. There are several criteria for the linker design, such as the polymer-drug linker must be stable in the circulation until it reaches the targeted site. The polymer-drug linker should also be able to release the drug at optimum rate at the target (Duncan 2006). The use of unsuitable polymer-drug linkers which are either too stable to release drug on target site or not stable enough that degraded before the arriving the target site would lead to undesirable treatment outcome. pH-sensitive or peptidyl polymer-drug linkers are most frequently used in drug delivery (Duncan 2003, 2006). pH-sensitive linker was widely used to deliver anti-tumor agents as the tumor tissues are often associated with acidosis. Their eventual subcellular trafficking into the acidic endosomal/lysosomal compartments would provide another mechanism for the drug activation. One of the most widely used low pH sensitive linker is the hydrazone bond (Kratz et al. 1999). It is formed by a reaction between hydrazine and ketone in the presence of acidic catalyst. The hydrazone bond has been used to link doxorubicin onto HPMA copolymer to treat solid tumor. The drug was released within 48 h *in vitro* at pH 5 and it correlated well with the antitumor activity *in vivo* (Etrych et al. 2001). Another pH-sensitive linker being widely used is *cis*-aconityl linkage which is being reported in the use of anticancer drug immunoconjugates (Choi et al. 1999). Many pH-sensitive chemical structures

have been synthesized for drug delivery system. The release rate could be tuned to meet the therapeutic requirements. Besides tumor site release, the pH-sensitive linker has also been used as a cleavable structure in bone targeting and inflammation targeting (Wang et al. 2005; Yuan et al. 2012).

Speaking of bone targeting and on site release, cathepsin K-specific peptide linkage is also widely used in the bone-targeting copolymer conjugates. Cathepsin K is predominantly expressed in osteoclasts which make the cathepsin K-specific peptide the best linker candidate to release therapeutic agents from bone-targeting copolymer conjugates (Wang et al. 2005; Miller et al. 2008). Oligopeptide Gly-Phe-Leu-Gly is designed for degradation by the lysosomal cysteine proteases, particularly cathepsin B (Duncan et al. 1983). This linker is stable in the body circulation and can release the drug over a 24–48 h period in vitro and in vivo (Rejmanová et al. 1985).

Recently, new linkers that can be cleaved by tumor associated protease legumain have been developed (Stern et al. 2009). Self-immolative linkers, which form stable bonds between a macromolecular scaffold and its reporter groups are able to facilitate enhanced conjugate disassembly upon a specific activation event (Blencowe et al. 2011). These self-immolative linkers showed high loading capabilities and excellent solubility and stability characteristics. Bioresponsive coiled-coil peptide linkers which are noncovalent and biologically inspired are formed by heterodimerization of two complementary peptide sequences (Apostolovic et al. 2010). This linker offered several potential advantages including facile access to combination therapeutics and rapid production of compound libraries to screen for structure-activity relationships. Not only act as a linker, coiled coil peptides may also direct intracellular transport and trafficking (Apostolovic et al. 2010).

51.7 HPMA Copolymer for the Treatment of CNS Diseases

As described above, numerous macromolecular therapeutics, especially HPMA copolymer drug conjugates have been developed for the treatment of cancer and non-cancerous diseases. We believe some of the benefits of these delivery systems can be further extrapolated to diseases of the central nervous system (CNS). There is a wide range of pathological conditions associated with human brain, including infections, stroke, hypoxia, poisoning by teratogens (including alcohol), chronic degenerative disease and traumatic injury. Currently, no therapies are yet available to fully restore lost function or slow ongoing neurodegeneration in the brain. The poor brain permeability limited by blood brain barrier prevents the macromolecular therapeutics transport into the brain (Shlosberg et al. 2010; Pardridge et al. 1992). The blood brain barrier restricts the entry of macromolecules and low molecular

weight compounds from the periphery. Approximately 98% small molecular weight drugs and almost 100% larger molecular weight peptides and proteins do not cross the blood brain barrier (Pardridge 2004). To achieve a brain targeting drug delivery and sufficient therapeutic drug concentration in the brain, the presence of blood brain barrier seems to be the main limiting factor. In the past few years, some notable developments in systemic and local macromolecular drug delivery system for CNS diseases have been reported (Neuwelt et al. 2008). The advantage of systemic drug delivery is their non-invasive nature and use of traditional routes of administration. The drawback of the systemic drug delivery is the large dosages, which may be needed to achieve therapeutic drug concentration in the brain. To overcome this limitation, modification of a delivery vehicle with site-specific ligands that increase its penetration through blood brain barrier is frequently used (Weinstein et al. 1978; Béduneau et al. 2007). The pharmacokinetic properties of these drug delivery systems must increase the bioavailability of the drug and the time it remains in the circulation as well as reducing the drug clearance by the MPS (Siwak et al. 2002). To fulfill these requirements, polymeric drug delivery system seems to be one of the most promising solutions to shuttle drugs into the brain effectively (Liu et al. 2010).

Amphiphilic copolymers poly(*N*-(2-hydroxypropyl) methacrylamide-co-laurylmethacrylate) or P(HPMA-co-LMA) designed by Zentel group are able to mediate drug transportation to the brain (Hemmelmann et al. 2012). They show the P(HPMA-co-LMA) copolymers enhance the permeability of Rhodamine 123 across the blood brain barrier without affecting the integrity and barrier function. With the in vitro and in vivo experiments results, they showed that the delivery system is suitable for a host of potential drugs. The random P(HPMA-co-LMA) copolymer having 10 mol% of lauryl side chains is the most efficient delivery system (Hemmelmann et al. 2011, 2012).

HPMA copolymer based hydrogels have been invented to treat physical injury of the central nervous system specifically traumatic spinal cord injury (Fawcett and Asher 1999; Zhong and Bellamkonda 2008). The hydrogel is a biomaterial implantation at the injury site to support the injured neuron tissue and act as a platform for the axon to attach and grow. The hydrogel could also carry drugs for the local delivery (Geller and Fawcett 2002; Nisbet et al. 2008; Zhong and Bellamkonda 2008). Arginine-glycine-aspartic acid (RGD) peptide sequences and aminosugar sequences which could promote tissue organization and regeneration were conjugated to the HPMA copolymer hydrogel to treat CNS trauma (Woerly et al. 1993; Begovac and Shur 1990; Ruoslahti and Pierschbacher 1987; Plant et al. 1997). In vitro studies suggested that RGD containing HPMA copolymer hydrogels have the potential of facilitating tissues regeneration in the injured CNS such as spinal cord injury (SCI). In vivo studies confirmed the in vitro findings and showed that the hydrogels

were able to bridge tissue defects in the acutely injured spinal cord, support cellular ingrowth, angiogenesis, and axonogenesis within the structure of the hydrogel network, which was similar to those of the developing spinal cord (Woerly et al. 1999). To further investigate whether the hydrogel could restore the functions to the chronically injured spinal cord, HPMA copolymer hydrogel was implanted into the cavity that formed in the rat spinal cord 3 months after a severe injury when the functional deficit had reached a plateau (Woerly et al. 2001). The results showed that long-term implantation not only reduces the volume of the cavity but also induced tissue repair and axonal regrowth with extended long distance throughout the graft, accompanied by gradual functional recovery. This hydrogel offers two advantages: it can be combined with either genetically-engineered cells (Loh et al. 2001) or human stem cells and these cells develop successfully within the polymer before implantation.

All the findings above show that HPMA copolymer has the potential to be a CNS drug delivery carrier candidate. HPMA copolymer hydrogel system shows the potential to repair CNS lesions caused by trauma. It is a simple and safe scaffold for neuronal regeneration. It could also incorporate different growth factors and cells to further potentiate their repair capability. Amphiphilic copolymer P(HPMA-co-LMA) has the potential to transport drugs through blood brain barrier while maintaining the barrier integrity. It is the most efficient drug delivery system to delivery various drug crosses the blood brain barrier.

Traumatic brain injury (TBI) is a major cause of physical or cognitive morbidity or even mortality all over the world. The pathophysiology of TBI is complicated and consists of primary injury (mechanical damage to the head) and secondary injury mechanisms including cerebral edema, inflammation, and oxidative stress. Currently, there are no treatments. The synthetic glucocorticoid dexamethasone (Dex) is widely used for its anti-inflammatory and immunosuppressive effects. As we mentioned in the previous sections, Dex has a significant positive effect on inflammation. As a glucocorticoid, it could insert into the cell membrane and inhibit lipid peroxidation propagation reactions as part of the secondary injury of TBI. However, there are also significant challenges in using steroids as a therapeutic option for TBI. Dex, as a glucocorticoid, has many side effects after long term or short term treatment. Also, it is not water-soluble which is also a barrier in the treatment of TBI. In our group, we synthesized HPMA copolymer dexamethasone conjugate (P-Dex) to treat severe traumatic brain injury in mice. The preliminary results showed the accumulation in cerebral cortex after traumatic brain injury. P-Dex also showed a significant positive effect on preventing the activation of microglia and inhibition of lipid peroxidation at the injured cortex, which could reduce the damage of cerebral cortex caused by reactive oxygen species. The preliminary study validates the significant potential of P-Dex in the treatment of traumatic brain injury.

51.8 Summary

In the past decades, polymer therapeutics have been developed for not only anti-tumor treatment but also used to treat numerous other diseases. The advantages of macromolecular therapeutics have been recognized for its diverse functionality, targetability and potential to improve the treatment of a variety of diseases (Li and Wallace 2008; Liu et al. 2010; Yuan et al. 2012; Hemmelmann et al. 2012; Rihova and Kubackova 2003). As being discussed in this chapter, targeted drug delivery to the skeleton, inflammation, tumor and CNS system using HPMA copolymer has great potential for further therapeutic development.

51.9 Review Questions

1. What is the ELVIS mechanism?
2. What is the structural difference between liposomes and micelles?
3. Describe three targeting moieties used to modify the copolymers to achieve active targeting property and what are they used for.
4. Describe two linkers used for the HPMA copolymer drug conjugates and what are they designed for.

51.10 Answers

1. HPMA copolymers' passively targeting and retention at the site of inflammation can be attributed to their Extravasation through Leaky Vasculature and subsequent Inflammatory cell-mediated Sequestration. This process is termed as ELVIS mechanism.
2. Liposomes are spherical vesicles composed of phospholipid bilayer membrane encapsulating an aqueous core. Both the aqueous core and the lipid bilayer can be used for drug loading purpose.
Micelles are formed by aggregation of surfactant molecules (e.g., lipids, amphiphilic polymers) with a hydrophobic core and a hydrophilic corona. The hydrophobic core can be used for drug loading purpose.
3. Refer to 3.1 Active targeting.
4. Refer to 6. Linker chemistry.

Abstract

Central nervous system (CNS) diseases represent a class of complex disorders for which cures have been largely unmet due to the general lack of knowledge regarding underlying pathogenic mechanisms. Gene-based therapies directed at ameliorating neurodegenerative diseases exhibit great potential due to rapid scientific advances made regarding delivery modalities, neurosurgical methods, neuroimaging, and molecular biological manipulation. Given these breakthroughs, the diseased CNS presents a neuroimmunological challenge as gene delivery many times requires invasive surgical procedures and a majority of the gene delivery platforms incite transient, and sometimes, inflammatory events that possess the potential to exacerbate disease-related processes. In this chapter, we will discuss the most current literature on gene therapy for CNS disorders by detailing the neuroimmunological profiles of presently available gene transfer platforms, approaches that have been made to minimize vector-mediated inflammation, and current state of gene therapy clinical trials for neurodegenerative diseases.

Keywords

Gene therapy • Immunotherapy • Neurodegeneration • Vaccination • Viral vector

52.1 Vector Selection Rationale

To derive an informed decision in the selection of an appropriate gene therapeutic vehicle for the treatment of a specific neurologic disease, the following must be considered: vector

capacity, tropism, genome maintenance, vector-mediated transgene expression duration and levels, and safety profile. The size of the therapeutic transcription unit is many times employed as an initial criterion to focus vector choice. This category also includes a given vector's ability to harbor multiple transcription units, thereby potentially affording reconstruction of a complex biochemical pathway (i.e., dopamine biosynthesis for Parkinson's disease). Potential applications for several presently available vector platforms are restricted by insert size limitations and are sometimes excluded if multi-gene delivery is a prerequisite for therapy.

Cell type specificity is also an important issue when developing a gene-based therapeutic intervention for neurodegenerative disorders. It would be most beneficial if the vector of choice could transduce and express in cell types that comprise only the specific disease-affected pathway. Vector tropism can be regulated through modulation of cellular receptor interactions by one or more of the following approaches: alteration of virus docking proteins, utilization of alternate viral serotypes, pseudotyping, and introduction

of tethered ligands for cellular receptors into the viral envelope. Once a vector is optimally targeted to the brain region of interest, therapeutic transgene expression can be restricted to selected cell populations via the utilization of cell type-specific promoters and/or transcriptional elements (Wagner et al. 1992; Zatloukal et al. 1992; Zabner et al. 1999; Toyoda et al. 1998; Beer et al. 1998). Strict spatial control of transgene expression is vital to ensure the correct cells will manufacture the gene product. This control, in turn, reduces the risk that ectopic transgene expression will occur and lead to untoward effects on adjacent neurological pathways.

Most neurodegenerative disorders evolve insidiously over many years thus requiring gene-base modalities to impart therapeutic benefit for several decades of an individual's lifetime. To this end, a vector genome should be stably maintained within the transduced cell for extended periods of time. Vector genome maintenance is, therefore, a critical factor in selection of an appropriate gene therapy vehicle for neurodegenerative diseases. Vector genomes can exist as episomes and/or integrated forms within nuclei of host cells. Mitotically active cells, such as those of the progenitor and glial lineages, eventually exhibit diminished episomal vector-mediated transgene expression. However, the post-mitotic property of CNS neuronal populations does not exclude the utilization of episomal vectors since genomes can be maintained without progressive therapeutic vector loss due to mitosis. Integrating vectors circumvent this issue but their use raises safety concerns including their potential to transactivate proximal proto-oncogenes and to disrupt essential host genes via insertional mutagenesis.

Another similar issue regarding vector selection relates to the desired levels and duration of gene product expression for treatment of neurodegenerative disorders. Depending upon the vector and transcriptional elements chosen, pharmacologic or physiologic levels of transgene expression can be achieved for time periods of short or long duration. As with other selection criteria, the decision of which level/duration of expression is preferred rests heavily on what aspect of the particular disorder is to be targeted and at which time during the disease course the intervention is to be implemented. Early interventions may require maintenance of long-term physiologic levels of transgene expression (i.e., neuroprotective strategies) since the neural networks may be primarily intact at this time. A vector/promoter combination that safely and stably maintains gene expression at nearly physiologic levels in the CNS would serve as a potential candidate for such early treatment approaches. Treatment modalities that are implemented after presentation of clinical symptoms may require long-term pharmacologic levels of transgene product to restore function to a brain region decimated by disease.

Safety is of utmost concern regarding the application of novel gene therapeutic strategies within the brain. Many

presently available vectors trigger immunogenic and/or inflammatory responses when introduced into the CNS. These responses are known to arise from the humoral and/or cell-mediated arms of the immune system, and the magnitude differs depending upon which vector type is employed. For example, repeat administration of early generation viral vectors has been shown to lead to lower transgene expression and serious inflammation, likely the result of a primed immune system (Byrnes et al. 1996). Therefore, a vector that is stably maintained and that can express its transgene for extended periods of time would be a more favorable choice as a gene therapeutic vehicle for neurodegenerative conditions. Another aspect that is often overlooked regarding gene therapy safety is the role of transgene products in the elaboration of immune responses and toxicity. Transgene products that are of foreign origin, ectopically expressed, or pharmacologically expressed harbor the potential to induce cytotoxicity and/or immune responses. Research addressing these issues is imperative to elucidate the role of transgene products in the elaboration of these potentially harmful responses, and how such responses can be successfully circumvented. Utilization of regulatable transcriptional or post-transcriptional elements in delivery vectors to provide "fine-tuning" of therapeutic transgene expression levels is a way to minimize harmful clinical outcomes.

52.2 Gene Transfer Platforms

Genetic material can be delivered to cells by two broad classes of vectors: nonviral and viral. Nonviral gene transfer modalities include the use of plasmid DNA directly or in an encapsulated state. Such approaches are deemed the safest due to the lack of inflammatory and/or immunogenic components, but require repeated administration to maintain therapeutic gene expression. Viral vectors exploit the evolutionary achievements of viruses to propagate, package and transfer genetic material from cell to cell and organism to organism. Via genetic modification of mammalian viruses, it is possible to specifically target gene expression in desired cellular populations. Adenovirus, Adeno-associated virus (AAV), lentivirus, and Herpes simplex virus (HSV)-based vectors as they have been utilized for central nervous system (CNS)-directed gene therapy will be discussed below. These vector types represent a subset of the more commonly used viral vectors for CNS gene delivery.

52.2.1 Nonviral Gene Transfer

Although viral gene delivery systems have proven more efficient for use in the nervous system, viral vector production requires special expertise and equipment, and remains time

and labor intensive. As an alternative to viral vectors, transfection techniques utilizing cationic lipids have shown promise for use with cells of the nervous system and may prove to exact fewer adverse effects. Conventional nonviral systems (reviewed in Anwer et al. (2000)), which rely on passive cell targeting through charge interactions, possess several practical advantages over viral delivery of transgenes. These include decreased production time and costs as well as greater safety, since there is no risk of viral vector recombination.

For more than a decade, there have been a variety of reports demonstrating the use of lipid reagents for transfection of cells comprising the nervous system with very modest transfection efficiencies, even after optimization (Holt et al. 1990; Jiao et al. 1992; Kaech et al. 1996; Loeffler et al. 1990; Matter-Sadzinski et al. 1992). However, more recently our laboratory showed dramatically improved transfection efficiencies in the mouse CNS using the cationic lipids Tfx-10 and Tfx-20 (Promega) to deliver DNA with a microprocessor-controlled injector, suggesting further work towards optimization of lipid transfection is warranted for gene transfer applications requiring direct intracranial administration of therapeutic DNA-lipid complexes (Brooks et al. 1998).

Less invasive methods of delivering nonviral vectors to the CNS would be more desirable. Despite the minimal inflammatory profile of intracranial delivery of DNA-lipid complexes, the potential exists for surgery-induced adverse events, while the relatively limited volume of distribution obtained from stereotactic infusion makes the approach rather infeasible when attempting to treat diseases that involve expansive regions of the brain. To that end, methodologies have been developed to enable the injection of modified DNA-lipid complexes into the bloodstream that are designed to hone to the brain, and sub-regions thereof, to more widely deliver their therapeutic payload. Nonviral gene delivery systems in particular lend themselves to targeting strategies aimed at achieving higher transfer efficiency and tissue specificity, since they can withstand a wider range of chemical and physical conditions used to incorporate targeting moieties. They also allow for more flexibility and ease-of-use when mixing targeting ligands with plasmid DNA and the lipid delivery reagents.

To approach systemic infusion of targeted DNA-encapsulated liposomes, the liposome formulation requires further modification. Whereas in the case of direct stereotactic injections, cationic liposome-DNA complexes can be used, such complexes highly aggregate in physiological saline leading to inefficient and variable dissemination of the transfection complex when delivered via the bloodstream (Matsui et al. 1997; Mahato et al. 1997). The use of neutral (uncharged) liposomal mixtures in combination with inert and biocompatible polymer polyethylene glycol (PEG) produces sterically stabilized liposomal structures (Papahadjopoulos et al. 1991). Inclusion of PEG is also believed to prevent the binding of

opsonins circulating within the bloodstream, thereby significantly decreasing phagocytic cell recognition and clearance (Moghimi and Patel 1992). Physical targeting of these “pegylated liposomes” through the use of ligands and antibodies has been employed to enhance the efficiency of gene transfer to many specific cell types (reviewed in Anwer et al. (2000)), including the CNS (Pardridge 2003).

The blood–brain barrier (BBB) has long-served as a major obstacle to liposome-based gene delivery to the CNS via systemic administration. Zhang and colleagues have employed a pegylated immunoliposome-mediated method for systemic administration of plasmids expressing tyrosine hydroxylase (TH) in a rodent 6-OHDA model of Parkinson’s disease (PD; Zhang et al. 2004). A plasmid construct expressing TH, the rate-limiting enzyme in the dopamine biosynthetic pathway, was encapsulated within pegylated immunoliposomes and injected systemically into Parkinsonian rats. High-level transgene expression within the striatum and transient correction of apomorphine-induced rotation behavior were observed, indicating that these nonviral gene transfer reagents were capable of traversing the BBB. In addition, a time-course experiment showed that TH enzyme activity within the striatum diminished substantially from Day 3–9 post-treatment. In a recent follow-up study, this group demonstrated that transient gene expression profiles derived from immunoliposome-targeted gene delivery appear to be the result of plasmid degradation *in vivo* (Chu et al. 2006). Immune responses generated against pegylated immunoliposomes are thought to be minimal *in vivo*, but if multiple injections are required to subvert disease progression, then the adaptive immune response may play a role in clearing and/or degrading this gene-based therapeutic.

Recent development of using exosomes as a small interfering RNA (siRNA) carrier, although still in its early days, may be considered a major advance for the field of macromolecular drug delivery. Alvarez-Erviti et al. delivered siRNA to the mouse brain by systematic injection of targeted exosomes (Alvarez-Erviti et al. 2011). To reduce immunogenicity, they prepared exosomes from self-derived immature murine dendritic cells. Targeting was achieved by engineering the dendritic cells to express a fusion of exosomal membrane protein Lamp2b and a neuron-specific rabies viral glycoprotein (RVG) peptide. Purified exosomes were loaded with exogenous siRNA by electroporation. The authors demonstrated *in vitro* and *in vivo* that intravenous injection of RVG-targeted exosomes delivered Glyceraldehyde-3-Phosphate Dehydrogenase (GAPDH) siRNA specifically to neurons, microglia and olivodendrocytes in the mouse brain, resulting in a specific gene knockdown. To show the therapeutic potential of their approach, they showed that delivery of RNAi targeting Beta-secretase 1 (BACE1), which mediates the formation of β -amyloid plaque and is associated with Alzheimer’s disease pathogenesis, led to BACE1 inhibition

and a significant decrease in brain β -amyloid levels of wild-type mice.

Apparently, exosomes have several advantages over existing non-viral delivery vehicles. First, exosomes derived from a patient's own cells should display less immunogenic properties than any foreign delivery carriers. Second, exosomes are relatively stable in the blood as they avoid opsonins, coagulation factors and complement, most likely attributed to their surface expression of CD55 and CD59 (Clayton et al. 2003). Third, dendritic cell-derived exosomes express the tetraspanin CD9 on their surface (Thery et al. 1999), which facilitates direct membrane fusion with the target cell and contents-delivery directly into the cytosol. This mode of entry bypasses the endosomal-lysosomal pathway and circumvents the need for endosomal-escape strategies. Finally, the small size of exosomes (50–100 nm in diameter) allows the particles to evade rapid clearance by the mononuclear phagocytes systems which clears particles >100 nm in size and enhance passage through vessel fenestrations and passage through the extracellular matrix.

52.2.2 Adenovirus Vectors

Adenoviruses (Ad) are a family of non-enveloped, double-stranded DNA viruses that generally cause mild respiratory infections in mammals. Over 50 serotypes have been identified. Ad-based vectors are attractive candidates for gene delivery to the CNS, as high vector titers can be generated, and these episomally maintained vectors can efficiently infect and express transgenes in a variety of cell types including the non-dividing cells of the CNS (Akli et al. 1993; Bajocchi et al. 1993; Davidson et al. 1993; Le Gal La Salle et al. 1993; Smith et al. 1996a, b, c). First generation vectors consisted of constructs that lacked genes for the potent regulatory proteins E1A, E1B, and E3. Although high titers could be obtained (approximately 10^{13} viable particles per ml) the immunological and physiological complications that resulted from Ad vector transduction in the CNS were serious. This robust response was due to enhanced cytotoxic T lymphocyte (CTL) activity to viral proteins and/or the expressed transgene product (Michou et al. 1997; Tripathy et al. 1996). Vigorous inflammation precludes repeated administration of this vector. As a consequence of these findings, second generation vectors were developed that additionally lacked the E2A gene. The resultant inflammatory response elicited by these vectors was reduced but still fairly substantial. In an effort to completely remove viral genes from the system, helper virus-dependent or so-called “gutless” forms of Ad vectors were developed (Mitani et al. 1995; Parks et al. 1996; Morsy et al. 1998; Hardy et al. 1997). These forms possess a large transgene capacity (up to 28 kb) and do not express any viral proteins. High multiplicities of infection (MOIs) have

been used to infect greater than 85 % of neurons with little if any cytotoxicity or adverse physiological effects up to 7 days post-infection (Cregan et al. 2000). Gutless Ad vectors direct expression of therapeutic genes in vivo with moderately high efficiency among gene therapy vectors. Gutless Ad constructs, but not first-generation Ad vectors, mediate sustained transgene expression in the brain even in the presence of anti-Ad immunity (Thomas et al. 2000, 2001). Another study, conducted by Zou and colleagues, compared transgene expression from first-generation Ad vectors to gutless Ad vectors in brain. Two months following transduction, the helper-dependent vectors exhibited higher transgene expression and elicited lower numbers of brain-infiltrating macrophages and T cells than first generation Ad vectors (Zou et al. 2000), further speaking to the improved safety profile of this Ad vector iteration.

52.2.3 Adeno-Associated Virus Vectors

Adeno-associated virus (AAV) is a non-pathogenic member of the parvovirus family. Its single-stranded DNA viral genome requires co-infection with either adenovirus or HSV for its own replication/propagation. Wild-type AAV encodes two viral gene products, Rep and Cap, which function in replication/integration and structural stability, respectively. The inverted terminal repeats (ITR) sequences promote extrachromosomal replication and Rep-mediated genomic integration of the flanked transgene. Newer methods of packaging have led to titers approaching 10^9 transducing units/10 cm plate and have eliminated the need for helper Ad which assures that negligible levels of contaminating Ad helper virus are present in the preparation (Xiao et al. 1998). Once packaged, the unique Cap protein of AAV allows for high-degree virion purification. Helper virus-free AAV vectors elicit transient and minimal inflammatory reactions when delivered in vivo, an observation likely due to the lack of associated viral gene expression and the facility to highly purify vector stocks (Xiao et al. 1997; Lo et al. 1999; Bueler 1999; Kaplitt and Makimura 1997).

Recombinant AAVs utilizing the cis-acting 145 bp ITRs to flank vector transgene cassettes provide a packaging capacity of up to 4.7 kb for foreign DNA. In muscle, molecular assembly of the AAV vector genomes occurs through intermolecular recombination between two ITRs, leading to genome concatemerization (Yang et al. 1999). This aspect of AAV vector biology has led to attempts to develop transsplicing or recombination-based overlapping vector approaches for the transfer of large therapeutic genes. Transsplicing or hybrid dual AAV vectors have been successfully exploited to reconstitute oversized gene expression. Dual AAV vectors are generated by splitting a large transgene expression cassette in two separate halves each packaged in

a single normal size (<5 kb) AAV vector (Duan et al. 2001; Thery et al. 1999; Yan et al. 2000). The reconstitution of the full-length expression cassette is achieved upon coinfection of the same cell by both dual AAV vectors followed by one of the following: ITR-mediated tail-to-head concatemerization of the 5' and 3' genomes followed by splicing (dual AAV trans-splicing vectors); homologous recombination between overlapping regions contained in 5' and 3' genomes (dual AAV overlapping vectors); or a combination of the two (dual AAV hybrid vectors). Recently Dickson group have developed a triple trans-splicing vector system, in which three independent AAV vectors carrying sequential exonic parts of the human Duchenne muscular dystrophy (DMD) coding sequence (Koo et al. 2014). The three exonic parts of DMD coding sequence are able to express the full-length protein as a result of trans-splicing events conjoining three vectors via their inverted terminal repeat sequences. This method of triple-AAV-mediated trans-splicing could be

applicable to the delivery of any large therapeutic gene (>11 kb) into postmitotic tissues (muscles or neurons) for the treatment of various genetic diseases.

The existence of numerous characterized AAV serotypes allows for use of alternative capsid types in the event serotype-specific neutralizing antibodies are generated or extant, thus extending the utility of the vector platform in the setting of pre-existing AAV immunity. Moreover, each serotype exhibits distinct patterns of transduction within the major tissues of mammals (Table 52.1). In general, AAV1, 5 and 9 exhibit higher transduction efficiencies than vectors packaged with other serotype capsid in all regions assessed within the CNS (Alisky et al. 2000; Burger et al. 2004; Aschauer et al. 2013; Markakis et al. 2010). AAV4 transduces specific cell types, such as ependyma and astrocytes in the subventricular zone, with higher efficiency (Liu et al. 2005; Benraiss et al. 2012). More recently, AAV9 has been shown to cross the BBB and transduce neurons and glia in

the brain and spinal cord following intravenous injection (Duque et al. 2009; Foust et al. 2009; Gray et al. 2011). The varying serotypes not only dictate transduction efficiency, but they have been shown to modulate transgene expression kinetics. The underlying mechanism(s) is unknown, but may be due to differences in virion uncoating and intracellular trafficking within the transduced cell (Thomas et al. 2004).

AAV vectors, when delivered into the CNS, are capable of expressing transgene products for periods of time in excess of 4 years. This has been demonstrated in both rodent and non-human primate studies (Kaplit et al. 1994; Bjorklund et al. 2000; Chirmule et al. 2000; During et al. 2001; Guy et al. 1999; Lo et al. 1999; McCown et al. 1996; and Bankiewicz personal communication). The pattern and duration of gene expression in these studies suggests that the AAV vectors once introduced into host cells adopt a transcriptional configuration that supports stable expression. This characteristic could lie in the physical status of the AAV vector genome (integrated vs. episomal) following transduction of a given host cell. The ability of wild-type AAV to specifically integrate into human chromosome 19 is intriguing if this property could be translated to AAV-derived vectors (Kotin et al. 1990). The ability to integrate creates the potential for stable, long-term expression of a transgene for the treatment of neurological disorders. Wu and colleagues presented a method for detecting integrated AAV vector genomes and provided some evidence that integration into CNS cells occurs, however, the specificity of this integration site is yet undetermined (Wu et al. 1998). More recent data generated by the laboratory of Mark Kay suggest that concatenated, non-integrated AAV genomes exist in greater abundance than integrating forms (Chen et al. 2001). To this end, more thorough studies detailing the genome status of AAV vectors in vivo must be conducted.

The risk of integration-induced oncogenesis appears to still be a theoretical concern despite a recent report. In long-term rodent studies with AAV vectors there was a significant increase in the incidence of hepatocellular carcinoma in mice treated with an AAV vector (Daly et al. 2001; Donsante et al. 2001). Systematic investigation was conducted to establish the genesis of the AAV vector/tumor association. These studies employing sensitive quantitative polymerase chain reaction (PCR) failed to yield evidence that the tumors arose from an insertional mutagenesis event. In a separate study, mice were injected with varying doses of AAV vectors with no evidence of hepatic tumors. These data argue that the hepatic malignancies likely arose by administration of contaminants with the AAV vector stocks and not because of genomic perturbations induced by the vector. However, more recent data compel reexamination of the propensity of AAV to produce chromosomal alterations. In that study, which was entirely performed in cultured human HeLa cells, AAV vector proviral integrations were found associated with chromosomal deletions and rearrangements most frequently on chromosome 19,

nearby but not precisely at the site of wild-type AAV integration (Miller et al. 2002). Multiple explanations for this finding are unexplored and thus its significance is unclear. Assuming safe integration of AAV vectors is demonstrated, a major limitation that will likely persist is the limited transgene size capacity exhibited by these vectors. This shortcoming will prove troublesome when cell-specific promoters and/or transcriptional enhancer elements must accompany the desired therapeutic gene for the purposes of directed expression. One group has attempted to circumvent this issue by developing heterodimeric AAV vectors where transfer of a transcription unit of approximately 9 kb can be achieved (Sun et al. 2000).

52.2.4 Lentivirus Vectors

Replication-defective lentiviral vectors derived from Human Immunodeficiency Virus (HIV) are another promising gene transfer vehicle for CNS applications as they can transduce both dividing and non-dividing cells, do not encode viral proteins, have an approximate 9-kb insert capacity, and are capable of sustaining stable gene expression for greater than a year (Kordower et al. 1999, 2000; Reilly 2001; Wang et al. 2000). To ensure against the generation of replication-competent HIV virions, the packaging system has been divided into four plasmids and four accessory HIV genes have been deleted from those packaging-assisting plasmids. Titers with this approach yield stocks of $1\text{--}5 \times 10^9$ infectious units (Bensadoun et al. 2000; Naldini et al. 1996b).

HIV-based lentiviral vectors when pseudotyped with the vesicular stomatitis virus (VSV) G protein (VSV-G) are principally neurotropic (Desmaris et al. 2001). Entry, proviral derivation and expression appear to occur efficiently in non-dividing neurons without the requirement for disruption of the nuclear envelope (Naldini et al. 1996a, b). Whereas, lentiviral vectors integrate chromosomally in dividing cells, the status of the proviral genome in neurons is less well studied. However, recent evidence garnered from the creation of feline immunodeficiency virus (FIV)-derived vectors devoid of integrase activity suggests that in non-dividing cells, transgene expression levels are equivalent to vectors capable of integrating into the host cell chromosome (Saenz et al. 2004). Efforts to test whether lentiviral vector proviral genomes can be rescued by HIV infection have also been informative. If the vectors retain necessary packaging sequences they are inefficiently rescued (Evans and Garcia 2000; Follenzi et al. 2000). However, self-inactivating (SIN) vectors, which possess major deletions within the U3 and U5 regions of the long terminal repeat (LTR) regions of the lentiviral genome, are unable to be rescued (Iwakuma et al. 1999; Yu et al. 1986).

Lentiviral vectors have been examined with respect to their potential elicitation of immune responses in the brain and within visceral organs. The data available indicate that in the CNS lentiviral vectors are minimally immunogenic, if

optimized vector production and purification protocols are followed (Baekelandt et al. 2003). Systemic immunization preceding injection of lentiviral vectors into the CNS determined that pre-existing anti-lentiviral immunity, regardless of the transgene, did not affect transgene expression (Abordo-Adesida et al. 2005). Furthermore, Abordo-Adesida and colleagues showed that the transgene, but not the virion or vector components, is chiefly responsible for providing antigenic epitopes to the activated immune system, following systemic immunization with lentivirus.

Even though they are more limited in number, rodent and non-human primate studies performed to date have shown that HIV vectors encoding for glial cell line-derived neurotrophic factor (GDNF) provide robust functional and structural neural protection in models of PD and provide an encouraging approach for gene therapy. Kordower and colleagues injected lentiviral vectors expressing GDNF into the striatum and substantia nigra of nonlesioned aged rhesus monkeys and young adult rhesus monkeys treated 1 week prior with the PD symptom-inducing neurotoxicant, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP; Kordower et al. 2000). Treatment with these vectors augmented dopaminergic functioning and reversed a set of behavioral deficits. More recently, Brizard et al. were able to utilize a similar GDNF-expressing lentiviral vector to demonstrate functional reinnervation from remaining dopaminergic nerve terminals in the 6-hydroxydopamine (6-OHDA) rat model of PD (Brizard et al. 2006).

Lentivirus vectors have also been used in the development of potential Alzheimer's disease (AD) therapeutics. Dodart and colleagues recently delivered varying alleles of the apolipoprotein E (apoE) gene, which encodes for a lipid-binding protein with Amyloid beta ($A\beta$) fibrillogenesis modulation activity, to AD mouse models to determine if expression of different alleles led to differential amyloid deposition (Dodart et al. 2005). Lentiviral delivery of the apoE4 allele, one that is believed to enhance the risk of human AD, led to increased $A\beta$ deposition as measured by immunocytochemistry and enzyme-linked immunosorbent assay (ELISA). Conversely, lentiviral vector-mediated expression of the apoE2 allele resulted in a significant reduction in amyloid burden, which is suggestive of a potent dominant negative effect of apoE2 over mouse apoE on brain $A\beta$ deposition. These findings are exciting but more experimentation is warranted to determine the actual biological function of apoE and how modulation of its activity could alter normal physiology.

52.2.5 Herpes Simplex Virus Vectors

Herpes simplex virus type 1 (HSV-1) is a naturally neurotropic virus capable of establishing latent infection within neurons, but also possesses the ability to infect a wide range of cellular targets. The cellular receptors responsible for

virion docking and uptake have been cloned, including the herpes virus entry mediator A (HveA) and C (HveC, nectin-1; Kwon et al. 1997; Montgomery et al. 1996; Hsu et al. 1997; Warner et al. 1998; Geraghty et al. 1998). Not surprisingly, these receptors (or homologues) are expressed on a variety of cell types. The HSV life cycle involves long periods of latency, and to that end, the virus has evolved a number of elaborate and highly efficient mechanisms to avoid detection and elimination by immune cells (Banks and Rouse 1992). These properties have led to the development of two forms of HSV-1-based delivery vectors capable of *in vivo* and *in vitro* gene transfer to the nervous system: recombinant and amplicon vectors (Dobson et al. 1990; Andersen and Breakefield 1995; Andersen et al. 1992; Breakefield and DeLuca 1991; Breakefield et al. 1992; Fink et al. 1992; Glorioso et al. 1994; Wolfe et al. 1992).

52.2.5.1 HSV Recombinant Vectors

Recombinant HSV vectors comprise a wild-type HSV genome rendered replication defective via disruption/deletion of an indispensable viral gene(s). Typically, the immediate-early gene loci, which encode for potent transactivation proteins that initiate the viral lytic cycle, are targeted for insertion of therapeutic transcription units via homologous recombination (Marconi et al. 1996, 1999). Following construction, recombinant vectors are packaged into infectious virions using an engineered eukaryotic cell line that supplies the absent viral gene product(s) *in trans* (Andersen et al. 1992; Dobson et al. 1990). The genome of recombinant vectors, at present, can accommodate approximately 30 kb of genetic material. Recombinant vectors are also attractive gene transfer vehicles for CNS disorders because they can be propagated to relatively high titers (10^8 – 10^9 plaque-forming units/ml). In addition, the threat of insertional mutagenesis is greatly diminished as the vector genome persists episomally within post-mitotic cell nuclei.

Immune responses arising from infusion of recombinant HSV vectors can arise from any of the following sources: viral particle components, co-purified packaging cell debris, low-level *de novo* viral gene product expression, and transgene expression itself. What appears to be a major source of immune response elicitation is related to *de novo* expression of the intact viral transcription units. Recombinant HSV vectors, although replication-defective, harbor virtually intact segments of the HSV genome. These open reading frames (ORFs) are expressed at low levels even in the absence of immediate-early gene products, augmenting the potential for antigen processing and subsequent major histocompatibility complex (MHC) Class I presentation (Kriskey et al. 1998; Johnson et al. 1992). Detailed assessment of immune responses elicited against HSV recombinant vectors within the brain have been lacking. However, insights may be gleaned from studies employing the amplicon vector platform, which have received, immunologically speaking, more investigational attention.

52.2.5.2 HSV Amplicon Vectors

The HSV-1 amplicon is a uniquely designed eukaryotic expression plasmid that harbors two non-protein encoding virus-derived elements: an HSV origin of DNA replication (OriS) and the cleavage/packaging sequence ("a" sequence) (Federoff et al. 1992; Frenkel 1981; Frenkel et al. 1982; Geller and Breakefield 1988; Geschwind et al. 1994; Spaete and Frenkel 1982, 1985; Stow and McMonagle 1982). Both *cis* sequences are specifically recognized by HSV proteins to promote the replication and incorporation of the vector genome into viable viral particles, respectively. This highly versatile plasmid can be readily manipulated to contain desired promoters, enhancers, and transgenes of substantial size (~130 kb) (Wade-Martins et al. 2001). Heterologous transcription units either singly or in combination can be cloned into the amplicon plasmid using conventional molecular cloning techniques, and the resultant construct is packaged into enveloped viral particles for subsequent transduction of cells or tissues.

Amplicon plasmids are dependent upon helper virus function to provide the replication machinery and structural proteins necessary for packaging amplicon vector DNA into viral particles. An engineered replication-defective HSV derivative that lacks an essential viral regulatory gene has conventionally provided helper packaging function. These helper viruses are similar to the recombinant HSV vectors discussed above in that they retain a majority of the HSV genome. The final product of helper virus-based packaging contains a mixture of varying ratios of helper and amplicon virions. The titers obtained from helper virus-based amplicon packaging range from 10^8 to 10^9 expressing virus particles/ml. More recently, helper virus-free amplicon packaging methods have been developed by providing a packaging-deficient helper virus genome via a set of five overlapping cosmids or a bacterial artificial chromosome (Fraefel et al. 1996; Saeki et al. 1998, 2001; Stavropoulos and Strathdee 1998). This packaging strategy requires the co-transfection of eukaryotic cells that are receptive to HSV propagation (i.e., BHK, Vero) with packaging-incompetent HSV genomic DNA, amplicon DNA, and any accessory HSV genes shown to enhance amplicon titers (Bowers et al. 2001). Crude vector lysates are then purified by a series of ultracentrifugation steps and titered by expression or transduction-based methodologies (Bowers et al. 2000). The titers obtained from helper virus-free amplicon packaging typically range from 10^7 to 10^8 expressing virus particles/ml. The lack of contaminating helper virus in these stocks, and thus loss of immunosuppressive proteins like ICP47, has also made the HSV amplicon a powerful delivery platform for infectious disease and cancer vaccines (Hocknell et al. 2002; Tolba et al. 2001, 2002; Willis et al. 2001).

Similar to recombinant HSV vectors, immune responses arising from infusion of HSV amplicon stocks can arise from

several sources and such responses are dependent upon the packaging system employed. Immune response-eliciting sources include viral particle components, co-purified packaging cell debris, low-level *de novo* viral gene product expression (helper virus-based packaging only), and the expressed transgene. Early generation helper virus-based packaging methods lead to vector stocks that contain substantive levels of contaminating helper virus. Due to the identical physical properties of amplicon and helper virus particles, preferential purification of amplicon particles is not possible. The replication-defective helper virus, comparable to the recombinant HSV vectors described above, expresses viral proteins at low levels within transduced cells. These viral proteins exhibit cytotoxic activity and can potentially undergo antigenic processing and subsequent immune presentation.

Wood and colleagues were the first investigators to examine the immune responses elicited against early iterations of packaged HSV amplicon stocks. For their studies they utilized an amplicon expressing the reporter gene product β -galactosidase and packaged using a recombinant HSV helper virus (*tsK*), which possessed a temperature-sensitive mutation in the ICP4 gene locus (Wood et al. 1994). Although *tsK* is replication-defective at the non-permissive temperature of 39 °C, viral gene product-associated cytotoxicity remains observable. Administration of these amplicon stocks induced a vigorous inflammatory response. Elevated MHC Class I expression and microglial activation was evident by 2 days post-infection, which was followed by MHC Class II cell recruitment, T cell activation, and macrophage influx at 4 days following delivery of helper virus-contaminated amplicon stocks.

In a more recent study, our laboratory described the innate responses elicited upon stereotactic delivery of HSV amplicon vectors packaged via two different methods (Olschowka et al. 2003). C57Bl/6 mice were injected with sterile saline, β -galactosidase-expressing amplicon (HSVlac) packaged by a conventional helper virus-based technique, or a helper virus-free HSVlac preparation. Animals were sacrificed at 1 or 5 days post-transduction and analyzed by immunocytochemistry and quantitative Reverse transcription polymerase chain reaction (RT-PCR) for various chemokine, cytokine, and adhesion molecule gene transcripts. All injections induced inflammation with blood-brain barrier opening on Day 1 that was similarly enhanced following all treatments. By Day 5, mRNA levels for the pro-inflammatory cytokines (IL-1 β , TNF- α , IFN- γ), chemokines (MCP-1, IP-10) and an adhesion molecule (ICAM-1) had fully resolved in saline-injected mice and to near baseline levels in mice receiving helper virus-free HSVlac. In contrast, mice injected with helper virus-packaged amplicon stocks elicited elevated inflammatory molecule expression and immune cell infiltration even at Day 5. In aggregate, these studies demonstrated helper virus-free ampli-

con preparations exhibit a safer innate immune response profile when delivered directly to the brain, presumably due to the absence of helper virus gene expression, and provide support for future amplicon-based CNS gene transfer strategies. What remains to be assessed experimentally in greater detail is the role, albeit minor, that virion structural components, packaging cell-derived debris and transgene product appear to play in the activation of the innate immune response by helper virus-free amplicon stocks. In addition, the role of pre-existing HSV immunity in modulating host responses to brain-delivered HSV vectors remains understudied.

52.3 Neuroimmunotherapy

Awareness of brain “immunocompetence” has increased significantly in recent decades. Immunomodulatory molecules are expressed in the brain by microglia, astrocytes and neurons in the presence of an inducing stimulus, including the infusion of gene transfer vectors. Additionally, macrophages, T cells, and B cells traverse the blood–brain barrier and survey the brain as part of their normal physiologic function (Hickey 2001). Furthermore, chronic activation of brain-resident inflammatory processes has been shown to underlie the pathophysiology of several neurodegenerative diseases such as AD and PD. One of the central features of AD is the excessive accumulation of amyloid beta ($A\beta_{1-42}$), a 42-amino acid peptide, in extracellular senile plaques. Moreover, the AD brain is decorated with complement proteins that bind to $A\beta$ peptides and aid in opsonization for eventual clearance by microglia. In response to accumulating $A\beta$, microglia in the AD brain express an array of potent cytokines and chemokines that are likely neurotoxic and may contribute to cell loss (Hanisch 2002; McGeer and McGeer 2003; Strohmeyer and Rogers 2001).

Inflammatory processes may also contribute to the degeneration observed in PD brain. PD is characterized by the destruction of dopamine-containing neurons in the substantia nigra (SN), resulting in a loss of dopaminergic afferents to the basal ganglia and eventual motoric dysfunction (Olanow 2003; Olanow et al. 2003). Pathologically, PD brain exhibits a region-specific accumulation of Lewy bodies, which are intraneuronal inclusions comprised of aggregated α -synuclein and other cellular proteins (Hald and Lotharius 2005). A variety of pro-inflammatory mediators have been detected in human PD and animal models of the disease (reviewed by McGeer and McGeer (2004)). Moreover, epidemiological evidence has shown that chronic treatment with nonsteroidal anti-inflammatory drugs (NSAIDs) reduces the risk of AD and PD compared to those who take NSAIDs on a non-regular dosing regimen (Standridge 2004; Schiess 2003). While it appears that numerous cytokine and chemokine molecules are closely associated with and likely contribute to neurodegeneration in AD and PD, it is uncer-

tain whether these inflammatory mediators impart beneficial effects during pathogenesis.

A promising, yet inherently complex, means of preventing $A\beta$ accumulation in AD or α -synuclein in PD relates to the use of the host immune system to mount specific immune responses against the self-peptides, $A\beta$ and α -synuclein (Klyubin et al. 2005; Masliah et al. 2005). The findings from a variety of immune-based strategies speak to the promise of such approaches, but also reveal the potential for morbid complications, especially in the case of AD vaccination. Therefore, it is imperative that as immunotherapeutics are designed to prevent and/or treat neurodegenerative diseases the underlying inflammatory processes are taken into account.

52.3.1 Immunotherapeutic Approaches to Treating Neurodegenerative Diseases

Two principal immunotherapeutic strategies for diseases afflicting the CNS have been pursued: passive and active vaccine-based approaches. Passive immunization involves the transfer of antiserum, purified antibodies, or an antibody-encoding gene via gene delivery to a recipient to prevent the accumulation of or to promote the removal of a central pathogenic factor. For example, passive immunization achieved by administration of $A\beta$ -specific antibodies has shown promise in preclinical studies. The laboratories of Drs. Holtzman and Ashe have independently reported the benefits of systemic delivery of $A\beta$ -specific antibodies to AD mice (Dodart et al. 2002; Kotilinek et al. 2002). Treated mice exhibited a marked reduction in amyloid accumulation and a significant improvement in memory-oriented behavioral tests. Using a similar passive immunization approach, Bard et al. showed that peripherally administered monoclonal antibodies against the amyloid β -peptide enter the CNS of platelet-derived growth factor promoter (PDAPP) mice (Bard et al. 2000). Additionally, these passively administered antibodies promoted the clearance of pre-existing amyloid, thus reducing the plaque burden. Prophylaxis against amyloid pathology required multiple injections of high-titer antibody in all studies. Approaches that provide for the stable production of $A\beta$ -specific antibody in situ, such as via gene transfer, may represent a more viable therapeutic option.

52.3.2 Single Chain Antibodies as Passive Immunotherapeutics

One gene-based passive vaccination approach that may serve in this capacity involves the use of single-chain antibodies (scFv's). ScFv's are composed of the minimal antibody-binding site formed by non-covalent association of the V_H

and V_L variable domains joined by a flexible polypeptide linker. Human scFv-phage libraries are available and allow for high affinity human scFv antibodies to be selected from combinatorial libraries. Thus far, phage display has proven to be a powerful tool for rapidly generating and isolating recombinant antibodies. Selection by phage display entails binding of phage populations expressing antibody molecules on the tip of the phage particle to a specified antigen (i.e., α -A β peptide). The antigen is immobilized on a microtiter plate well, incubated with phage and then washed to remove non-specifically bound phage. Phages are eluted from antigen, re-expanded and the entire process is repeated for several more cycles, a process termed “panning”. At each cycle, the fraction of specifically bound phage increases while the diversity of antibody sequences decreases until the population consists of only phages that can bind antigen with roughly equivalent panning efficiencies (Malone and Sullivan 1996). The phage clones identified with strong affinity to the target antigen are then amplified in *E. coli* (Haidaris et al. 2001).

Sequences encoding eucaryotic secretion signals (i.e., kappa light chain leader) can be appended to the scFv genes and subsequently be cloned into gene transfer vectors. Cells transduced by a given gene transfer vector will act as a nexus of scFv expression, leading to a gradient of secreted scFv to act extracellularly on pathogenic factors such as A β . Further antibody engineering makes it possible to manipulate the genes encoding these antibodies to allow for expression within mammalian cells. Genetically fusing the scFv to intracellular targeting signals allows for specific subcellular expression (Zhu et al. 1999). These intracellular antibodies, termed intrabodies, are capable of modulating target protein function in at least three important ways. Intrabodies can: (1) block or stabilize macromolecular interactions; (2) modulate enzyme function by sequestering substrate, occluding an active site or keeping the enzyme in an active or inactive conformation; and (3) divert proteins to alternative intracellular compartments (for review (Richardson and Marasco 1995)). Intrabodies have been utilized for both phenotypic and functional knockouts of target molecules. For example, scFv's directed against the extracellular domain of ErbB-2 Receptor Tyrosine Kinase 2 (ErbB-2) fused to an endoplasmic reticulum (ER) signaling domain have been expressed intracellularly and successfully target to the ER lumen. These targeted scFv's were capable of binding newly synthesized ErbB-2 and preventing its transit through the ER to the cell surface resulting in functional inactivation of this protein (Beerli et al. 1994). Below we will discuss in details scFv preclinical development in a number of neurodegenerative diseases.

52.3.2.1 Prion Disease

A number of studies have reported to use scFv to target prion proteins (Leclerc et al. 2000; Heppner et al. 2001; Cardinale

et al. 2005; Donofrio et al. 2005; Luginbuhl et al. 2006; Filesi et al. 2007; Flego et al. 2007; Miyamoto et al. 2007; Padiolleau-Lefevre et al. 2007; Polymenidou et al. 2008; Wuertzer et al. 2008; Campana et al. 2009; Muller-Schiffmann et al. 2009; Shimizu et al. 2010; Skrlj et al. 2010, 2011; Fujita et al. 2011; Petsch et al. 2011; Zhang et al. 2011; Kubota et al. 2012; Moda et al. 2012). Many of the scFvs are capable of inhibit cellular prion protein (PrP^c) aggregation and reduce prion protein scrapie associated (PrP^{Sc})-related cellular toxicity. Our group has led an effort to develop passive immunomodulation therapy with recombinant AAV2 delivered anti-PrP^c scFv in a mouse model of prion disease (Wuertzer et al. 2008). Our results showed that the secreted anti-PrP^c scFvs could bind to PrP^c and prevent the formation of the proteinase K-resistant PrP^{Sc}. Treatment with rAA2-scFv delayed the onset of the prion disease in a mouse TSE model. Another approach of deliver for scFv is through scFv expressing cells. Donofrio et al. produced RD-4 rhabdomyosarcoma cells expressing anti-PrP 6H4 scFv (Donofrio et al. 2005). Filesil et al. generated PC12 cells that express secreted version of anti-prion scFv (Filesi et al. 2007). In both studies, the secreted anti-PrP scFv inhibited PrP^{Sc} formation. More recently, Fujita and colleagues established a Ra2 microglial cell line expressing anti-PrP 3S9scFv. Microglia are known to infiltrate the prion lesions. Delivery of the anti-PrP scFv by Ra2 microglial cells showed a slight but significant improvement in survival time when the microglial cells were injected into mice 7 weeks after 22 L scrapie prion infection (Fujita et al. 2011).

52.3.2.2 Alzheimer's Disease

The first anti-A β scFv for the treatment of Alzheimer's disease was produced based on the variable regions of an anti-A β IgM 508 antibody (Frenkel et al. 2000). This scFv, named 508 F(Fv), could lead to the disaggregation of A β fibrils and prevent toxic effects in cultured PC-12 cells. By screening a naïve human scFv phage library with A β 1–28 and A β 1–40 Liu et al. selected two positive scFv clones, H1v2 and C1, which bound to the N-terminal or C-terminal of A β , respectively (Liu et al. 2004). Liu et al. also showed that H1v2 but not C1 could inhibit A β aggregation in vitro (Liu et al. 2004). Likewise, engineered scFv antibody based on mAb WO-2, which recognize A β 2–8 could inhibit A β fibrils formation, disaggregate A β fibrils, and reduce A β oligomer toxicity (Robert et al. 2009).

Anti-A β scFvs can be easily delivered with AAV vectors. Tg2576 mouse AD model injected with rAAV2 expressing anti-A β scFv had detectable scFv in the hippocampal neurons 1-year post injection. The mice with rAAV2-CAscFv59 injection showed decreased levels of amyloid deposits without obvious neurotoxicity (Fukuchi et al. 2006). Another study of AAV1 delivered anti-A β 1–16, A β 40, and A β 42 achieved widespread scFv expression in the mouse

brain. Intracranial delivery of AAV1 expressing anti-A β scFvs did not show any adverse effect and achieved about 20–50 % reduction in amyloid deposits in CRND8 mice (Levites et al. 2006). Wang et al. demonstrated that intramuscular delivery of rAAV2-scFv against A β was also safe and effectively reduced total A β levels in the brain (Wang et al. 2009). We intrahippocampally delivered rAAV1-A β -scFv in a 3xTg-AD mouse model and found reduced A β and hyperphosphorylated tau levels and improve cognitive functions (Ryan et al. 2010). All above studies demonstrated the safety and efficacy of AAV delivered long-term expression of anti-A β scFvs as a viable AD treatment option.

52.3.2.3 Huntington Disease

In the past decade, various intracellular anti-Huntingtin (Htt) immunotherapies have been developed as a potential treatment options for Huntington disease (HD) (Butler et al. 2012), including anti-Htt scFvs. A scFv (C4) recognizing the 17 N-terminal Htt was identified by screening the human phage display library (Lecerf et al. 2001). Co-expression of this C4 scFv and the expanded repeat Htt-polyQ-GFP reduced the number of Htt aggregates in COS-7 cells (Lecerf et al. 2001). In organotypic slice cultures, co-transfection of the C4 scFv could reduce the malonate-induced cell death in mutant Htt-expressing cells (Murphy and Messer 2004). Further study showed that C4 scFv specifically targets the soluble portion of the mutant Htt N-terminal fragment and therefore may shift the equilibrium of the mutant Htt aggregation (Miller et al. 2005). The C4 scFv had been tested in vivo in a *Drosophila* HD model that expresses Htt exon 1-Q93. The survival rate of this model with scFv expression increased by 70 %. The C4 scFv expression also prevented neurodegeneration and prolonged the lifespan of the HD flies (Bortvedt et al. 2010; Wolfgang et al. 2005). Striatum delivery of AAV2/1 expressing C4 scFv in B6.HDR6/1 mice reduced mutant Htt aggregates in neurons. Striatal expression of C4 scFv seemed to be well tolerated and did not exhibit any adverse effects in mice (Snyder-Keller et al. 2010). However, the efficacy of the AAV delivered C4 scFv decreases over time and age of the animals. In an effort to improve the efficiency of C4 scFv, Butler and Messer generated a scFv fusion protein with a PEST domain. The C4 scFv-PEST fusion protein retained the anti-mutant-Htt function and has increased proteasomal degradation of the mutant Htt (Butler and Messer 2011). The collective data have established the efficacy of C4 scFv in targeting the mutant Htt in vitro and in vivo.

52.3.2.4 Parkinson's Disease

α -synuclein (SYN) has become a major target for PD immunotherapy as aggregated SYN-containing Lewy bodies in nigral dopamine neurons (Mezey et al. 1998; Spillantini et al. 1997). Our laboratory has generated conformation-

specific humanized scFvs against SYN. These scFvs can be efficiently expressed in mammalian cells through transductions with HSV vector carrying the scFvs expression cassette (Maguire-Zeiss et al. 2004). Emadi et al. identified 10 anti-SYN scFvs by screening naïve human phage display libraries. A strong scFv recognizing the C-terminal of SYN could inhibit SYN aggregation in vitro (Emadi et al. 2004). Co-expressing of anti-monomeric SYN scFv and SYN in mammalian cells prevented SYN aggregation and reduced SYN-mediated cellular toxicity (Lynch et al. 2008; Zhou et al. 2004). Similarly, scFv against oligomeric SYN could also prevent SYN aggregation and rescue cytotoxicity (Emadi et al. 2007).

52.3.3 Active Vaccination

In contrast to passive means of preventing pathogenic protein accumulation in the CNS, active immunization involves using antigen to stimulate the host to produce vigorous immune responses, including the elicitation of antibodies and cytotoxic cells. This more conventional immunization method is many times preferable since long-term immune memory to a specific antigen can be readily maintained.

52.3.3.1 Alzheimer's Disease

Recent publications have highlighted the potential of active A β peptide-based immunization in the treatment of AD (Janus et al. 2000; Morgan et al. 2000; Schenk et al. 1999). Schenk et al. used a transgenic model that overexpresses a mutant Amyloid Precursor Protein (APP) V717F mini-gene driven by the platelet-derived growth factor promoter (PDAPP; Schenk et al. 1999). PDAPP mice immunized and boosted with A β _{1–42} peptide with complete and incomplete Freund's adjuvant, respectively, before the onset of AD-like pathology, were protected from development of plaque formation, neuritic dystrophy, and astrogliosis. Treatment of older PDAPP animals (11 months) with existing pathology resulted in reduced plaque burden and slower progression of AD-like neuropathology. A β -directed vaccination was assessed by other laboratories in a model of AD that overexpresses mutant human β APP₆₉₅ (K670N/M671L; Swedish mutation) and presenilin-1 (PS1) mutations under the control of the hamster prion promoter (PSAPP; Morgan et al. 2000; Takeuchi et al. 2000). Neuropathologically, these animals demonstrate compact amyloid plaques but no dramatic neuronal loss in either the hippocampus or association cortices. Behaviorally, PSAPP mice exhibit learning and age-related memory deficits as amyloid accumulates. Following vaccination with A β , PSAPP mice were protected from learning and age-related deficits as well as a partial reduction in amyloid burden. There were no apparent deleterious effects of the vaccination.

These groundbreaking studies provided impetus for the implementation of Phase I and II clinical trials where human aggregated A β and a potent adjuvant (QS-21) was used to immunize individuals with advanced AD. While some of the patients enrolled in the Phase II trial generated anti-A β antibody titers (Lee et al. 2005), the trial was halted due to the occurrence of aseptic meningoencephalitis in a subset of responders (based on the antibody titer) and non-responders. Postmortem analyses of two patients that died showed that the encephalitic response was characterized by infiltrating CD4 cells but not CD8s, giant nucleated cells, or macrophages (Ferrer et al. 2004; Gilman et al. 2005). Most intriguing was the observation that these brains harbored low A β plaque load strongly suggesting that active A β immunization could alter A β accumulation patterns (Nicoll et al. 2003). This trial not only demonstrated that immunization against A β may be effective but underscored the requirement that AD vaccines require fine-tuning to greatly diminish the likelihood of eliciting brain inflammation.

52.3.3.2 Parkinson's Disease

The discovery that SYN can transmit from cell to cell in a prion-like fashion suggests that immunization might be a viable option for the treatment of PD with synucleinopathies. The first SYN vaccine that enters clinical testing is AFFITOPE® PD01 developed by AFFiRiS (Masliah et al. 2005). The AFFITOPE® PD01 vaccine consists of a peptide carrier conjugate and is formulated with aluminum hydroxide as immunological adjuvant. The SYN peptides are 7 amino acids in length, thus too short to induce a SYN-specific T cell response avoiding T cell autoimmunity. T cell helper epitopes of the carrier protein provide T cell help to activate the B cell response. AFFITOPE® PD01 has been designed to prevent cross-reactivity of the antibodies induced with the other synuclein family members such as β -syn. Preclinical studies involving the subcutaneous administration of AFFITOPE® PD01 have demonstrated the induction of a SYN-specific humoral immune response. Experiments done in transgenic mouse models of synucleinopathies showed that immunization with AFFITOPE® PD01 reduces the level of cerebral SYN and attenuated SYN-triggered neuropathological alterations including neuronal cell loss and dendritic density. Furthermore, PD01 treated animals show superior cognitive functions as assessed by the Morris water maze test. In the phase I clinical trial, two different doses of PD01 (15 and 75 μ g) were safe and well tolerated, meeting the primary endpoint of the trial. Fifty percent of the vaccinated patients generated SYN-specific antibodies as measured in serum samples. Additionally, vaccine-induced antibodies were detectable in cerebrospinal fluid. Furthermore, analysis of clinical endpoints revealed a trend towards functional stabilization of the vaccinated groups compared to non-

vaccinated control patients. The promising phase I clinical data warrant later phase clinical testing.

52.4 Current Neurological Gene Therapy Clinical Trials

Gene therapy is a promising option for a number of neurodegenerative diseases. The potential benefits of using viral platform for correcting diseases are enormous, and as a result considerable efforts have been made to develop and test in patients (Table 52.2).

52.4.1 Parkinson's Disease

PD presents an excellent clinical target for viral vector gene therapy as PD exhibits defined locations of pathology and a specific neurotransmitter deficit. To date, several gene therapy approaches have been developed to treat the major motor symptoms of PD, all with the use of AAV or lentivirus vector platform (Table 52.2). Each of the clinical approaches has focused on aspects of the basal ganglia.

The first PD gene therapy approach has attempted to ameliorate motor symptoms by altering the neurochemical conductivity of neurons mediating the motor behavior. AAV/GAD (Aromatic L-Amino Acid Decarboxylase) was delivered to the subthalamic nucleus. GAD catalyzes the synthesis of gamma aminobutyric acid, the major inhibitory neurotransmitter in the CNS, potentially providing lost inhibitory control in the basal ganglion motor system, thus restoring appropriate transynaptic balance (Luo et al. 2002). Given the positive safety and tolerability findings in a Phase I study (Kaplitt et al. 2007), a Phase II trial was initiated with 45 subjects that included both treatment and sham groups (LeWitt et al. 2011). Although the results proved significant on the primary measure (UPDRS motor-off scale), the effects were quite modest. Moreover, many other measures were not significant, even though five subjects were removed from the analysis due to injection targeting issues. The modest nature of these Phase II results led to a discontinuation of the program.

A second approach has attempted to attain therapeutic level of dopamine by overexpressing enzymes that contribute to dopamine synthesis. One clinical investigation used AAV2 to deliver L-DOPA-converting enzyme AADC (Aromatic L-Amino Acid Decarboxylase) in the putamen. In the Phase I clinical trials, no toxicity occurred from the vector infusion into the putamen, but the therapeutic outcomes were modest at best (Christine et al. 2009). A long-term follow-up to the phase I study (Christine et al. 2009) found a significant elevation in the positron emission tomography (PET) value 4 years after the vector delivery (Mittermeyer

Table 52.2 Gene therapy clinical trial for neurodegenerative diseases

Study	Phase	Viral vector	Therapeutic gene	Delivery target	Results
<i>Parkinson's disease</i>					
Kaplitt et al. (2007)	I	AAV2	GAD	Subthalamic nucleus	Well tolerated; advanced to PhII
LeWitt et al. (2011)	II	AAV2	GAD	Subthalamic nucleus	Mixed results; program suspended
Christine et al. (2009)	I	AAV2	AADC	Putamen	Well-tolerated; improved motor rating scales
Muramatsu et al. (2010)	I	AAV2	AADC	Putamen	Well-tolerated; no further testing
Marks et al. (2008)	I	AAV2	Neurturin (CERE-120)	Substantia nigra and putamen	Well-tolerated; advanced to PhII
Marks et al. (2010)	II	AAV2	Neurturin (CERE-120)	Putamen	Well-tolerated; mixed results
Kells et al. (2010)	I	AAV2	GDNF	Putamen	NA
Rafii et al. (2014)	I/II	Lentivirus	AADC, TH and GTPCH	Putamen	Well tolerated with moderate motor behavior improvement; Open label
<i>Alzheimer disease</i>					
Tuszynski et al. (2005)	I	Retrovirus	NGF	Ex vivo implantation; forebrain	Well tolerated; improved in the rate of cognitive decline
Rafii et al. (2014)	I	AAV2	NGF (CERE-110)	Nucleus of Meynert	Safe and well-tolerated for 2 years

et al. 2012). Another identical Phase I trial was initiated that used the same AAV-AADC vector (Muramatsu et al. 2010). Again there were no adverse events attributed to the vector infusion. But the outcome measures reflected only modest improvements. To overcome the efficacy issue, another Phase I trial has been initiated with the goal of obtaining greater putamen transgene expression through increased dosage and CED (convexional enhanced delivery) technique (Clinical Trials. Gov identifier: NCT01973543). This ongoing Phase I study should provide more definitive evidence as to whether a significant level of efficacy can be achieved with an improved gene delivery method. A different open label clinical study used a lentiviral vector expressing AADC as well as TH (tyrosine hydroxylase) and GTP-CH1 (guanosine 5'-triphosphate cyclohydrolase1) (ProSavin), with the latter two enzymes also significantly contributing to dopamine's synthesis (Palfi et al. 2014). In this phase I/II study, no serious adverse events related to the study drug or surgical procedure were found. A significant improvement in mean UPDRS part III motor scores off medication was recorded in all patients at 6 month and 12 months compared to baseline.

The third gene therapy strategy has employed a neurotrophic factor delivery approach to confer trophic support to the dopaminergic and surrounding neuronal populations. The first trophic factor approach has used AAV2 to deliver neurturin (CERE-120), related to glial cell line-derived neurotrophic factor (GDNF). Both the phase I (Marks et al.

2008) and phase II (Marks et al. 2010) trials found no adverse effects but did not find significant improvement in the primary endpoint measures up to 12 months post AAV infusion. However, 15–18 months later, significant improvements were found. A subsequent Phase II study was initiated where the AAV2-neurturin was infused into both putamen and the substantia nigra. However, this double-blind trial failed to demonstrate significant changes in the primary endpoint, precluding a further Phase III trial. Another ongoing neurotrophic factor gene therapy has used AAV2 to express GDNF. In this clinical trial, an improved delivery approach, CED, has been adopted to broaden the transgene coverage area (Kells et al. 2010).

52.4.2 Alzheimer's Disease

The gene therapy approaches for AD have been focused on nerve growth factor (NGF). The first clinical trial of NGF therapy was ex vivo NGF gene delivery in eight individuals with mild AD. Autologous fibroblasts genetically modified to express human NGF were implanting into the forebrain (Tuszynski et al. 2005). Evaluation of the Mini-Mental Status Examination and AD Assessment Scale-Cognitive subcomponent suggested improvement in the rate of cognitive decline. PET scans showed significant increase in cortical 18-fluorodexyglucose after treatment. Brain autopsy

from one subject indicated robust growth responses to NGF. These positive findings suggested that long-term growth factor treatment had the potential to improve symptoms and modify neurological disease progression.

Another clinical study of NGF gene therapy employed AAV2 to deliver NGF (CERE-11) directly to the forebrain region (Rafii et al. 2014). The Phase I clinical trial of CERE-110 with dose escalation demonstrated that surgical delivery of CERE-110 to the brain results in the long-term expression of bioactive NGF. Clinicians also observed apparent stabilization of brain cell metabolic activity in treated subjects, which may reflect a slowing of cell deterioration. The treatment was well tolerated at all doses levels. The positive results of Phase I trial supported the initiation of an ongoing multicenter, double-blind, placebo-controlled Phase II trial.

52.4.3 Safety of Gene Therapy

The first gene transfer trials were approved in 1989, but the field has yet to live up to its promise and hype. The initial progress in gene therapy in the 1990s was followed by a string of tragedies. The first was in 1999, when 18-year-old Jessie Gelsinger died of complications from an inflammatory response shortly after receiving a dose of experimental adenovirus vector in a gene therapy trial for a rare liver disorder. His death halted all gene therapy trials in the US for a time, sparking a much-needed discussion on how best to regulate experimental trials and report health problems in volunteer patients. Between 1999 and 2006, the use of retrovirus to deliver gene therapy to patients for various immune disorders caused nine cases of leukemia (including one death) and three patients acquired a bone marrow disease (Pike-Overzet et al. 2006). In 2007, a 36-year-old woman with a 15-year history of rheumatoid arthritis, died of fungus infection and subsequent multi organ dysfunction after receiving an investigational gene therapy product in a clinical trial (Evans et al. 2008). A gene intended to reduce inflammation and disease was delivered into the affected joint using recombinant AAV2 vector expressing TNF- α antagonist. These unfortunate incidents raised important safety concerns, and the federal and local regulatory agencies such as FDA (Food and Drug Administration), RAC (Recombinant DNA Advisory Committee), IRB (Institutional Review Board) and IBC (Institutional Biosafety Committee) have since developed comprehensive requirements for gene therapy clinical trials to ensure the right and safety of human research subjects.

All the clinical trials of CNS gene therapies that have been tested so far display a favorable safety profile; the most consistent adverse events reported for all the studies were related to the stereotactic surgical procedure, which was similar to the stereotaxic surgical procedure used for deep brain stimulation approved by European regulatory agencies and FDA. Additionally, a substantial placebo effect observed in

all three Phase II PD studies indirectly verified the safety of stereotaxic procedure (Palfi et al. 2014; Markakis et al. 2010; LeWitt et al. 2011).

Another concern in the field involves the potential impact of preexisting neutralizing antibodies to viral vectors. However, with regard to the brain, neutralizing antibodies so far has appeared not to contribute to any local inflammatory reaction, transgene expression, or long-term bioactivity (Bartus 2012).

Immune responses against the transgene are perhaps a greater concern. Most gene transfer trials would deliver wild-type human genes, which would not be expected to generate an immune response under normal circumstances. However, in standard gene replacement approaches in patients with genetic diseases, the patients may not produce any of the missing protein in any form. In this case, the treated patients might view the wild-type protein expressed from vector-transduced cells as a foreign protein. This could cause a humoral response limiting the efficacy of a secreted protein, and/or a cytotoxic T-lymphocyte response against transgene-expressing cells. Recent studies of using AAV9 to deliver GFP to the brain in rats and nonhuman primates indicated that transduction of antigen-presenting cells, such as astrocytes, within the CNS could lead to immune-mediated clearance of transduced cells (Ciesielska et al. 2013; Samaranch et al. 2014). Not only could this cause a loss of transgene expression, but the destruction of transduced cells could lead to deleterious adverse effects. In nonhuman primates injected with AAV9/GFP vectors (modeling the expression of a foreign antigen), treated animals developed severe ataxia requiring euthanasia within a few weeks of injection (Samaranch et al. 2014). Thus, it is advisable to place restrictions on trial subjects to exclude those that would be at high risk of developing an immune response against the wild-type expressed protein.

52.4.4 Efficacy of Gene Therapy

Despite the promising safety profile of the gene therapy trials for CNS diseases in Phase I, all the phase II clinical trials either yielded mixed results or displayed modest improvement that did not meet the primary end points (LeWitt et al. 2011; Palfi et al. 2014; Marks et al. 2010). In light of the consistent disconnect between preclinical and clinical success in gene therapy, we need to take a step back from the clinic and reexamine the predictive power of animal models, the approaches of gene delivery, and the selection criteria of trial patient subjects.

The fact that most of gene therapy programs produced robust and positive data in the most widely accepted animal models of neurodegenerative diseases but failed to replicate the magnitude or consistency of these effects in patients necessarily raises a question of whether the predictive validity of these models is sufficient for establishing preclinical proof of concept. In the case of PD, the overreliance of acute toxin-based PD models (e.g., 6-OHDA and MPTP model) limits

our exploration of treatment options and models that encompass more the pathogenic variables. As more than 90 % of PD cases are idiopathic and the pathogenesis is multifactorial, derived from environmental factors acting on genetically predisposed individuals with aging, a double/multiple-hit model that can incorporate both environmental insults and genetic susceptibility will provide better prediction for the therapeutic potential of gene therapy.

Another major concern highlighted in the PD gene therapy trials included weak transgene expression and protein product transport issues in the pathological brain tissue. In addition to improved delivery technologies such as CED, there are foreseeable advantages of alternating the vector serotype or using engineered vectors to improve transduction directly. Current AAV gene therapy clinical trials all use AAV serotype 2. As we discuss previously, AAV2 has the relatively weakest transduction efficiency in neurons and glial cell types compared to other serotypes. Although AAV2 displays a desirable safety profile and has obtained regulatory approval for clinical testing, it is worthy the research effort to develop improved vectors for better transduction.

The third consideration for the improvement of the efficacy of gene therapy is the selection criteria of patient subjects for trials. A recent exploratory analysis of the AAV2-neurturin phase II data suggests that earlier-stage PD subjects (defined here as those 5 or fewer years postdiagnosis) showed much greater clinical benefit from AAV2-neurturin than did those treated at 10 or more years postdiagnosis (Bartus et al. 2013). This raises the age issue in the gene therapy strategy for neurodegenerative diseases, particularly with regard to neurotrophic factor intervention. It is of great importance to determine whether earlier-stage patients might indeed respond far better and more reliably than those currently enrolled in experimental treatments. Progress in clinical biomarker research, especially for presymptomatic neurodegenerative diseases, will undoubtedly shape the earlier intervention efforts and may help establish surrogate endpoints to allow a more biometrically equilibrated scoring system.

52.5 Future Outlook

The future of gene-based immunotherapy for neurological disease remains mired in many unknowns. The most informed choice of vector platform, gene regulation system, and immunotherapeutic strategy will depend on numerous non-mutually exclusive factors: the specific neurodegenerative disease, the disease stage, the underlying inflammatory mechanisms associated with the disease, the interplay between those events and those inherent to the proposed vector systems following CNS delivery, and the therapeutic transgene itself. Another major challenge that faces this field involves the heterogeneity of human immune responses. It is therefore imperative that research continues

to better understand vector associated antigens and transgene product related immune responses in the context of the host nervous system. Thus far, the safety profile of AAV and more limited experience with lentiviral vector transduction portend demonstration of clinical benefit. However, delivery and anatomical issues unique to the targeted disease entity remain a challenge that is likely surmountable. We envision that the pre-screening of clinical trial participants would allow for the derivation of custom therapeutics (O'Toole et al. 2005; Rosenberg 2005). These considerations will be important in the conceptual design and the clinical implementation of gene-based immunotherapeutics for diseases afflicting an organ system formerly regarded, and unfortunately so, as an immunoprivileged region of the human body.

52.6 Review Questions

1. What are the two formats of non-viral gene transfer modalities
2. What is the rationale for viral vector selection?
3. What are the potential safety issues for gene therapy in CNS disorders?
4. What are the currently common viral vector platforms for gene transfer?
5. List three vectors that have been developed to increase packaging capacity of AAV virus?
6. Which AAV serotypes can effectively transduce microglia?
7. What are the two forms of HSV-1 based delivery vectors cable of gene transfer to the nervous systems?

52.7 Answers

1. lipid and exosomes
2. vector capacity; tropism; duration and levels of transgene expression; safety profiles
3. surgery complications; preexisting neutralizing antibodies; immune response against the transgene
4. Adenovirus, lentivirus, HSV, and AAV
5. dual trans-splicing vector; dual overlapping vector; dual hybrid vector
6. AAV1 and AAV4
7. recombinant HSV vector and Amplicon vector

Abstract

A wide range of neuroimaging techniques have been developed which aid in the clinical diagnosis of neurological diseases and are valuable tools for research into basic physiological mechanisms and effects of new therapies to combat neurological disease. This is a rapidly evolving field as new imaging techniques with enhanced sensitivity and specificity are constantly being developed and made available to the clinician and research community. This chapter will provide an introduction to the basic mechanisms, capabilities and applications of neuroimaging methods, allowing the neuroscience student to gain an appreciation of the range of available imaging techniques and the potential for use as serial non-invasive monitors of the progression and treatment of neurodegenerative disease in animals and humans.

Keywords

Magnetic resonance imaging • Magnetic resonance spectroscopy • Neurodegeneration • Positron emission tomography • Single photon emission computed tomography

53.1 Introduction

Neuroimaging techniques include nuclear medicine studies such as positron emission tomography (PET) and single photon emission computed tomography (SPECT). Morphological imaging methods include magnetic resonance imaging (MRI) and computed tomography (CT). Studies of brain physiology and biochemistry include PET, SPECT, CT perfusion, MRI perfusion, magnetization transfer MRI (to assess myelin loss), ^1H and ^{31}P magnetic resonance spectroscopy (MRS) and magnetic resonance spectroscopic imaging (MRSI). These methods provide a broad array of techniques for serial non-invasive measurement of alterations in brain physiology and biochemistry, which are early and sensitive indicators of many neurological diseases. Although struc-

tural imaging techniques are not always sensitive indicators of neurological disease, functional and molecular imaging methods, including SPECT, PET and physiological MR techniques, have great value as they can reveal abnormalities before structural atrophy or focal CNS lesions are visible.

Neuroimaging techniques can be broadly classified by the information content of the images. Morphological information can be obtained from MRI and CT, sensitivity and specificity of MRI for detecting brain lesions is improved over CT (Brugieres et al. 1995) due to improved soft tissue contrast of MRI (Ell et al. 1987; Kim et al. 1996). In addition, MRI or CT can be combined with nuclear medicine techniques to provide anatomical detail allowing clear identification of the location of radioactive probes. Physiological information, including tissue perfusion mapping, mapping of receptor densities, and mapping of tissue biochemistry can be accomplished using MRI, MRSI, SPECT, and PET. Functional information, mapping of neuronal activity, can be obtained using functional MRI and PET, as well as other imaging modalities not covered in this chapter including electroencephalography (EEG), which records the electrical activity

of the brain and magnetoencephalography (MEG) which provides spatially resolved maps of the electrical activity of the brain. This chapter will cover the basics of signal generation, signal acquisition and some examples of the information obtained in MRI, MRSI, SPECT and PET as an introduction to this broad and fascinating field.

53.2 Principles of Imaging

53.2.1 Basic Principles of MRI

MRI methodology is a complex and intriguing field of study. In this chapter, the basic mechanisms of MRI signal production and acquisition are introduced to allow the student of the neurosciences to develop a base understanding. Excellent textbooks are available for more advanced study of the details (Haacke et al. 1999; Liang and Lauterbur 2000; Slichter 1996; Gillard et al. 2005).

53.2.1.1 Signal Source

The signal in magnetic resonance imaging (MRI) and spectroscopy (MRS) rely on the magnetic properties of nuclei (Baier-Bitterlich et al. 1998). Nuclei with a non-zero *spin quantum number* ($I \neq 0$) will possess a *magnetic moment vector* μ . The magnetic moments are a result of the paramagnetic fields produced by the interaction of charged particles within the nucleus. The spin quantum number of the nucleus will be zero ($I=0$) if both the mass number and the atomic number of the nucleus are even. These nuclei will not have a nuclear magnetic moment and hence are not observable using magnetic resonance techniques. Any nucleus with an odd atomic number or an odd mass number will have a non-zero spin quantum number ($I \neq 0$). These nuclei will have a nuclear magnetic moment and thus can produce a signal.

For nuclei with $I=1/2$, including ^1H observed in MRI, the magnetic moment vector μ of the nuclei will either be parallel or anti-parallel to the externally applied magnetic field (Fig. 53.1). The magnetic moment of a nucleus can be related to its angular momentum by the magnetogyric ratio of that nucleus defined by (Harris 1983; Krane 1987):

$$\gamma = \frac{\mu}{I} \quad (53.1)$$

where μ is the nuclear magnetic moment vector of a nuclear isotope, and I is the angular momentum (spin) quantum number of a nucleus. The magnetogyric ratio is constant for each nuclear isotope. The sum of all magnetic moments is the macroscopic magnetic moment, named *the Net Magnetization Vector* \mathbf{M} , which is defined as:

$$\mathbf{M} = \sum (\mu_+ + \mu_-) \quad (53.2)$$

Fig. 53.1 The precession of the nuclear magnetic moment vectors μ about the static magnetic field vector B_0 . The angle of the precessional cone is given by θ . The precessional frequency is given by the Larmor frequency ω

where μ_+ and μ_- represent magnetic moments in the parallel and anti-parallel state for a two quantum states ($m_I = \pm 1/2$) of a spin $1/2$ magnetic nucleus ($I = 1/2$) such as the proton.

53.2.1.2 Precession and the Larmor Equation

The two states of different energy are not exactly parallel and anti-parallel to the external magnetic field. The magnetic moments are at an angle θ relative to the magnetic field due to the quantized energy states of the subatomic particles. The force of the magnetic field B_0 on the magnetic moments μ forces these nuclear magnetic moments into a precessional motion (Fig. 53.1). The frequency of precession, also called *Larmor* frequency, is proportional to the magnetic field according to the Larmor equation:

$$\omega = \gamma * B_0 \quad (53.3)$$

where ω is the rotational frequency of the net magnetization produced by excitation of the nuclear magnetic moments (rad/s), and γ is the gyromagnetic ratio, constant for a given nucleus. B_0 is the magnetic field strength at the nucleus measured in Tesla (T) or Gauss (G). $1 \text{ T} = 10,000 \text{ G}$. As an example, the resonance frequency of protons is 64 MHz at 1.5 T.

The net magnetization vector \mathbf{M} is the source of MR signal. The time evolution of the net magnetization vector \mathbf{M} is the signal source in magnetic resonance. Motion of \mathbf{M} will create an oscillating magnetic field. This oscillating magnetic field will create an induced voltage in a receiving coil. This induced voltage in the receiving coil over time is the signal.

53.2.1.3 Resonance

When a nucleus is exposed to a secondary magnetic field (B_1) that has an oscillation identical in frequency and direction to its own Larmor precession, the nuclei absorb energy from the external source. The secondary magnetization is applied at the Larmor frequency, which is typically in the radiofrequency (RF) range, thus the brief application of the B_1 field is referred to as an RF pulse. Absorption of energy from the RF pulse results in a phase coherence in individual nuclei during the process of changing from the low energy to the high energy state. The net effect of B_1 is a tipping of M_0 (net equilibrium magnetization) away from the Z (longitudinal) axis (parallel to B_0) towards the X,Y (transverse) plane. The force of B_0 on the transverse component of M now rotates M_{xy} at the Larmor frequency. The rotating magnetization causes a voltage in a coil “tuned” to the Larmor frequency to pick up the signal by magnetic induction (Fig. 53.2). The resulting angle between the Z axis and M (typically 90°) is called *flip* angle and depends upon the amplitude and duration of the RF pulse.

53.2.1.4 Signal Detection and Time Evolution

Faraday’s law of induction states that if a receiver coil is magnetically coupled to an oscillating magnetic field, a voltage is induced in the receiver coil. Therefore, as M precesses at the Larmor frequency in the transverse plane, a voltage is induced in the coil. This voltage constitutes the *MR signal*. The magnitude of the signal depends on the magnitude of M in the transverse plane. The amount of magnetization in the

longitudinal plane gradually increases (T_1 relaxation). At the same time, but independently, the net magnetization in the transverse plane gradually decreases due to loss of phase coherence (T_2 relaxation). As the magnitude of transverse magnetization decreases, so does the magnitude of the voltage induced in the receiver coil (Fig. 53.2). The evolution and decay of the net magnetization, M is picked up by the receiver coil resulting in the magnetic resonance signal, the *free induction decay (FID)*.

When the RF pulse is switched off, M realigns with the Z axis at a rate $(1/T_1)$ slower than the rate of signal loss $(1/T_2)$. In order to do so, M must transfer the energy gained to the surrounding molecules. This process is referred to as T_1 relaxation (spin–lattice relaxation). As T_1 relaxation occurs, M returns to *equilibrium* (M_0).

53.2.1.5 Magnetic Field Gradient used to Generate MRI

The magnetic field dependence of the signal’s frequency is used as a basis for spatial encoding of the magnetic resonance signal. This is done using magnetic field gradients. Magnetic field gradients cause a linear shift in magnetic field with position. This allows one to use a single chemical species, such as water, as a signal source for imaging (MRI). Sophisticated spatial encoding schemes have been developed to allow multidimensional spatial encoding.

The Larmor equation demonstrates the basis of these encoding schemes. As the magnetic field changes, so does the frequency. In one dimension, application of a magnetic field gradient of 10 gauss/cm (1 Tesla (T)=10,000 gauss (g))

Fig. 53.2 Application of a secondary magnetic field (B_1) rotating at the Larmor frequency has the effect of tipping the net magnetization (M) away from the equilibrium position (M_0) along the longitudinal axis and towards the transverse plane. After the brief application of B_1 , rotation of M in the transverse (X-Y) plane at the Larmor frequency (B) induces a Free Induction Decay (FID) signal in a pickup coil (C)

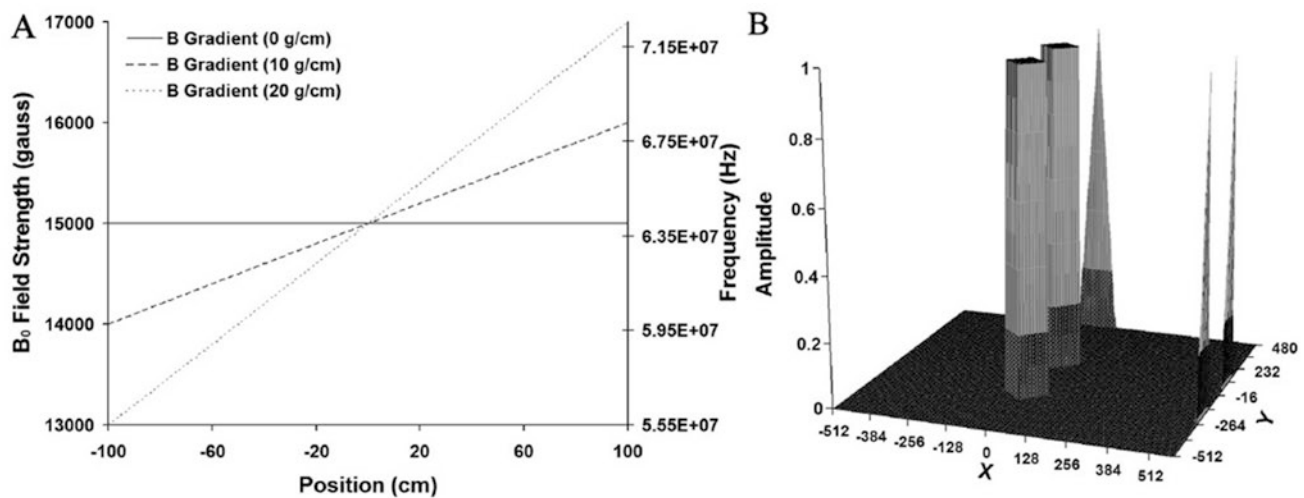

Fig. 53.3 Magnetic field gradients used for frequency encoding spatial position. (a) Magnetic field strength as a function of position in the magnet for three gradient strengths. (b) Arbitrary object within the MRI

system (*center*) and the frequency readout (signal) from a gradient applied during signal acquisition along the x-axis (rear) and the y-axis (*right*)

produces a field shift in the water frequency of 64 MHz (1.5 T) of 42,667 Hz/cm. The basis of the use of the magnetic field gradient for spatial encoding is displayed in Fig. 53.3.

53.2.1.6 Fourier Transform: Frequency Analysis of the Time Domain MR Signal

The time domain MR signal is difficult to visually interpret, hence the signal is transformed into a spectrum which is intensity on the vertical axis and frequency on the horizontal axis. This is performed mathematically by the Fourier transform. The Fourier transform is performed according to the equation:

$$f(\omega) = \int_{-\infty}^{\infty} f(t) e^{-i\omega t} dt \quad (53.4)$$

where ω = frequency (radians/s), t = time (s), $i = \sqrt{-1}$, $f(\omega)$ is the frequency domain signal (spectrum) and $f(t)$ is the time domain signal (MR signal, free induction decay or spin echo).

53.2.1.7 Spin Echo

Signal loss in the free induction decay (FID) can be partially refocused using a second application of B_1 with a duration and amplitude that produces a 180° flip angle of \mathbf{M} (180° pulse). This has the effect of placing individual magnetic moments, which are no longer in phase with the central frequency, in a position to realign with spins at the central frequency.

Pulsed magnetic resonance experiments are represented by parallel time lines of the applied pulses and the signal (Fig. 53.4a). We will introduce this formalism here to explain the spin-echo and, in the next section, the spin-echo MRI pulse sequence. The first line is the time line of the applied

B_1 pulses, also referred to as radiofrequency, or RF pulses because they are applied at the Larmor frequency, which are typically in the radiofrequency range.

53.2.1.8 Spin-echo Magnetic Resonance Imaging (MRI)

Three dimensions of spatial encoding are required for MRI. These three dimensions are independently applied by (1) signal production from a thin slice by using a frequency selective excitation in the presence of a magnetic field gradient (slice selection), (2) acquiring the spin-echo signal in the presence of a magnetic field gradient (frequency or read-out gradient) and (3) acquiring the spin-echo signal after producing a spatially dependent phase shift which is incremented in the second dimension (phase encoding gradient). The pulse sequence diagram showing the application of the frequency selective RF pulses, the slice, phase and frequency encoding gradients and the spin-echo signal acquired are shown in Fig. 53.5. The spin-echo acquisition is repeated for each value of phase encoding gradients to fill in the second dimension of the single slice MRI, requiring repetition of the sequence 256 times for 256×256 image resolution. The raw MRI is acquired in the time domain, which requires Fourier transform of the signal into the frequency domain for display (Fig. 53.6).

53.2.2 Modification of Signal Intensity

The power and versatility of magnetic resonance techniques lie in the ability to modify signal intensity based on the biophysical properties of the spins of interest (primarily tissue water). Signals can be “weighted” (signal amplitude altered)

Fig. 53.4 Time evolution of the spin-echo signal. (a) Pulse sequence diagram showing (top) the timing of the applied 90 and 180° RF pulses (B_1) and (bottom) the time evolution of the spin-echo signal. (b) Vector diagram of the time evolution of the spin-echo signal. Clockwise from top-left: Equilibrium magnetization is rotated by the 90° RF pulse, signal evolves and individual spins lose phase coherence, reducing signal intensity, a 180° RF pulse is applied which places out of phase magnetic moments in position to rephase at a time (τ) equal to the time of dephasing before the 180° pulse, allowing the refocusing of the signal (spin-echo)

Fig. 53.5 Pulse sequence for the generation of spin-echo MRI

based on the magnetic relaxation properties (T_1 and T_2), water diffusion (random molecular motion), or the interaction of the hydration layers of membranes and proteins with free water (magnetization transfer). Tissue perfusion can be mapped by the introduction of contrast agents or inversion of signal from water in arterial blood supply of the tissue. In addition, signal can be suppressed from tissue based on frequency (fat or water suppression), position (suppressing motion artifacts from unwanted tissue), or preferentially viewed based on moving vs. static water (angiography or suppression of motion from flowing blood).

53.2.2.1 Magnetic Relaxation, T_1 and T_2

Spin-Lattice Relaxation (T_1)

T_1 relaxation is the process of releasing the energy absorbed by the magnetic nuclei during the application of the RF pulse. This process occurs by releasing the energy to the surrounding molecules (lattice) returning the spin system to the equilibrium condition (M_0). The rate at which this process occurs in tissue depends on the molecular environment and varies with tissue type, providing a means of generating contrast between tissues with otherwise similar signal intensities

Fig. 53.6 MRI signal, 2 dimensional Fourier transform and grey scale representation of the Fourier transformed data. *Left*: grey scale representation of the single slice MRI of a spherical phantom filled with

water. *Center*: spectral representation of the Fourier transformed data. *Right*: image represented in gray scale, the standard viewing method

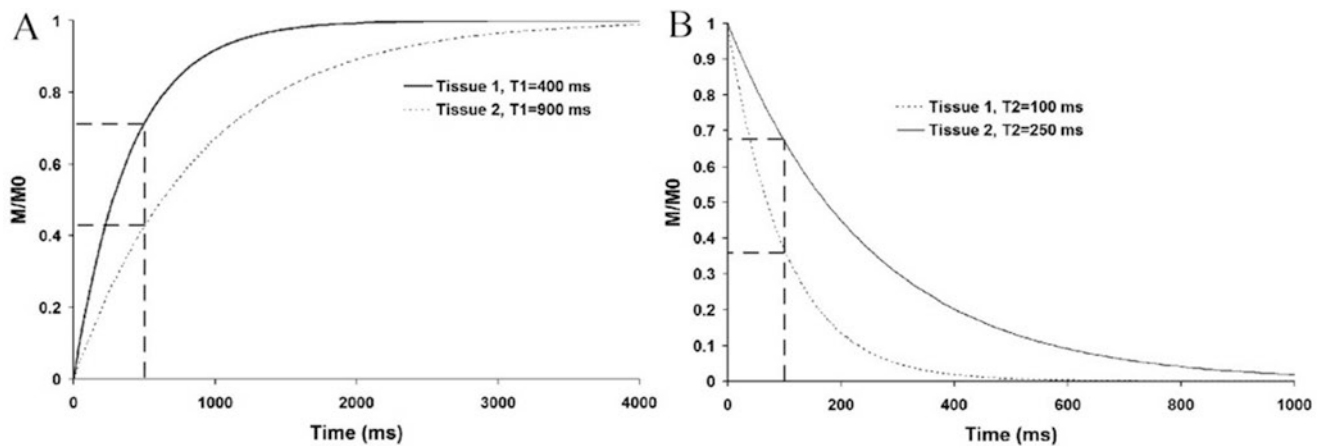

Fig. 53.7 T_1 and T_2 relaxation curves. (a) Recovery of the net magnetization along the Z (B_0) axis after a 90° RF pulse. Dotted lines demonstrate the amount of Z magnetization after a 500 ms delay (TR), proportional to the signal intensity after the second 90° RF pulse. This demonstrates the contrast available in tissue of similar water content (M_0) with different T_1 by reducing TR. (b) decay of signal in the trans-

verse plane (X-Y) with echo time (TE). *Dotted lines* demonstrate the amount of longitudinal (X-Y) magnetization (signal) with a 100 ms spin echo (TE), proportional to the signal intensity during the acquisition of a 100 ms echo. This demonstrates the contrast available in tissue of similar water content (M_0) with different T_2 by increasing TE

(water content). T_1 relaxation occurs exponentially after an RF pulse with a time constant of T_1 according to the equation:

$$M_z(t) = M_0(1 - e^{-t/T_1}) \quad (53.5)$$

where: $M_z(t)$ is the time dependent amplitude of the Z component of the magnetization (along B_0), which approaches the equilibrium magnetization (M_0) over time (t) with the time constant T_1 . Since MRI acquisition typically requires multiple excitations, adjusting the repetition time (TR) between successive excitations reduces the net magnetization according to TR/T_1 and alters the T_1 based contrast. As a result, signal intensity within each volume element in the

MR image (voxel) has intensity modified by the average T_1 of tissue within the voxel according to the repetition time of the acquired image. This occurs as illustrated in Fig. 53.7a. Figure 53.7a shows the Z-magnetization recovery curves for two different tissues, one with a T_1 of 400 ms and one with a T_1 of 900 ms. In order to recover full magnetization, a delay (TR) of $5 \times T_1$ is required. Using a short TR (500 ms, dashed lines) the tissue with the 400 ms T_1 has recovered to 71 % of M_0 while the tissue with the 900 ms T_1 has only recovered to 43 % of M_0 . The signal intensity will be proportional to the recovery of the net magnetization after the second 90° RF pulse, providing a signal that is 65 % more intense for the shorter T_1 tissue even if the original signal

intensity (M_0 , proportional to water content) is identical, providing improved tissue contrast and a mechanism for detecting altered cell content (pathology) within tissue.

Spin-Spin Relaxation (T_2)

The spin echo (Sect. 53.2.1.6) demonstrates that the 180° RF refocusing pulse reverses off-resonance effects (spins at a slightly different frequency than the Larmor frequency) after the 90° RF pulse allowing a signal to be generated at a time after the original signal loss. However, the natural process of energy exchange between adjacent molecules causes a loss of signal coherence by exchange of spin states with loss of phase coherence. This loss of signal cannot be refocused. The exchange of spin states with no net loss of energy in the spin system is referred to as spin-spin relaxation (T_2). Signal loss as a function of echo time (or TE) is given by:

$$M = M_0 e^{-TE/T_2} \quad (53.6)$$

where TE=echo time and T_2 is the average T_2 of the tissue. As a result, signal intensity within each volume element in the MR image (voxel) has intensity reduced by the average T_2

of tissue within the voxel according to the echo time of the acquired image. T_2 effects on the signal intensity in two different tissues with the same water content (M_0) at an echo time of 100 ms is shown by the dashed lines in Fig. 53.4b. Tissue with shorter T_2 (100 ms) refocuses 37 % while the longer T_2 tissue (250 ms) refocuses 67 % of the original signal, demonstrating significant contrast between tissues of different T_2 using a long echo time acquisition. This demonstrates the contrast available in tissue of similar water content (M_0) with different T_2 by increasing TE. It should also be noted that the signal intensity will be modified at the same time by TR and T_1 through the choice of TR, thus a long TR is typically chosen for purely T_2 weighted images. An example of T_2 weighted imaging and calculation of a T_2 map from multiple TE images from mouse brain can be seen in Fig. 53.8.

Multiple echoes may be refocused from one excitation by application of multiple 180-degree RF pulses, allowing the acquisition of a series of echoes within one TR. For example, if one echo is acquired at very early echo time and a second echo is acquired at 100 ms, two images can be acquired. If long TR is used so that the second echo is purely T_2 weighted, then the first echo with almost no T_2 weighting due to short

Fig. 53.8 T_2 mapping data set, 3/8 T_2 weighted images with (a): TE=15 ms, (b) TE=60 ms, (c) TE=120 ms and (d) T_2 map created by fitting eight echo imaging sequence to (53.6)

TE and no T_1 weighting due to the long TR will have contrast based purely on the tissue water content (M_0). This image would be referred to as *proton density weighted*, as the signal intensity in each voxel is proportional to the free water content.

53.2.2.2 Diffusion

Symmetrical application of magnetic field gradients around the refocusing pulse in a spin echo will refocus the signal from static molecules. However, microscopic molecular motion (Brownian motion) will cause dephasing of individual magnetic moments to a degree which is dependent on the freedom of the molecular motion of the water in cells. Freedom of the molecular motion is affected by the size and shape of the cell and is modified in different cell types. Signal intensity is modified by:

$$ADC_w = \log(S_0 / S) * b \quad (53.7)$$

where b is the strength of the diffusion weighting, and ADC_w is the apparent diffusion weighted coefficient of water. A high b -value produces low signal intensity in tissue with a high ADC_w . ADC_w is given in mm^2/s , a value which depends on the temperature and viscosity of the liquid or solid under measure. Since we are typically looking at water in MRI, the diffusion of water is what is measured. Free water, at typical body temperature (38°C) is approximately $2.2 \times 10^{-3} \text{ mm}^2/\text{s}$. However, water in tissue is not free to diffuse as a result of barriers, the cell membrane, and is reduced according to the size and shape of the cell. Shorter distances between cell walls result in a lower diffusion rate. Areas of free water in tissue, such as cerebral spinal fluid or large arteries and veins, show similar diffusion rates to free water. Tissue diffusion values in cells range from 0.6 to $1.0 \times 10^{-3} \text{ mm}^2/\text{s}$. In addition, if the cell is not spherical, which is typically the case in brain, ADC_w is dependent on the direction of diffusion weighting.

Diffusion can be measured separately in various directions by application of diffusion gradients in different directions during individual measurements. In order to obtain an approximation of the average diffusion of water in an asymmetrical cell, measurement of diffusion in three orthogonal directions (for example, along X, Y, and Z directions) are obtained and averaged. However, this is an approximation and a true value can only be obtained by determination of the **diffusion tensor**. This requires a minimum of six individual measurements. This can be understood once the student is familiar with the definition of a tensor.

A tensor is a mathematical representation of a three dimensional shape using a three by three matrix (Fig. 53.9, (53.8)). The matrix represents the total magnitude of the object in each of nine directions, three of which are equal due to symmetry (e.g. $D_{xy} = D_{yx}$) of the other three cross components, reducing the problem to six dimensions. Hence,

Fig. 53.9 Example of a non-spherical cell with directional dependence of diffusion. Primary laboratory frame of reference are given by x, y and z axes, while the primary axes of diffusion are given as λ_{11} (major), λ_{22} (intermediate) and λ_{33} (minor). Determination of the values of elements of the diffusion tensor allows determination of the magnitude and direction of the primary axes of diffusion (eigenvalues)

six directions of diffusion measurement are the minimum needed to define the diffusion tensor. More measures can be used to improve the accuracy of the measurement through cross correlation of multiple measures.

$$\vec{D} = \begin{bmatrix} D_{xx} & D_{xy} & D_{xz} \\ D_{yx} & D_{yy} & D_{yz} \\ D_{zx} & D_{zy} & D_{zz} \end{bmatrix} \quad (53.8)$$

The diffusion tensor can then be *diagonalized* to generate a diffusion tensor of the form:

$$\vec{D} = \begin{bmatrix} \lambda_1 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & \lambda_3 \end{bmatrix} \quad (53.9)$$

to determine the primary *eigenvalues* (λ_1 , λ_2 , λ_3) as designated in Fig. 53.9. These data can be used to generate pixel by pixel maps of mean diffusivity ($D_{av} = 1/3 * (\lambda_1 + \lambda_2 + \lambda_3)$) and fractional anisotropy (FA), which is given by the equation:

$$FA = \frac{1}{\sqrt{2}} \sqrt{\frac{(\lambda_1 - \lambda_2)^2 + (\lambda_2 - \lambda_3)^2 + (\lambda_1 - \lambda_3)^2}{\lambda_1^2 + \lambda_2^2 + \lambda_3^2}} \quad (53.10)$$

FA ranges from zero for a spherical cell to one for an infinitely long cell with zero cross sectional area.

Determination of the principle eigenvalues (λ_1 , λ_2 , λ_3) also allows determination of the principle direction of the cell orientation, which is the orientation of λ_1 in the laboratory (X, Y, Z) frame. Principle direction of the cell can be used to determine fiber orientation in white matter tracts and provide additional delineation of anatomical structure. A map of λ_1 orientation is produced using a red-green-blue encoding in

Fig. 53.10 Diffusion tensor imaging results from a mouse brain imaging study at 7 T. (a) mean diffusivity (D_{av}) (b) Fractional Anisotropy (FA), (c) Color coded FA orientation map

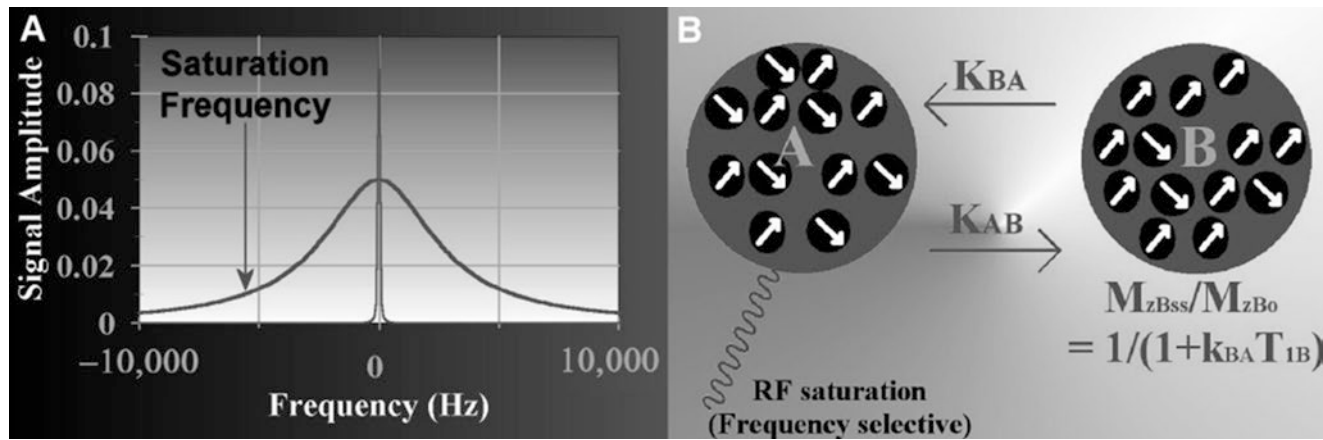

Fig. 53.11 Magnetization transfer MRI. (a) Off-resonance application of a saturation pulse will saturate the signal from macromolecules with short T_2 (broad line) while leaving the narrow water resonance (center line) unaffected. (b) Saturation of macromolecules (spin pool A) causes

reduction of the free water signal (spin pool B) measured as reduction in intensity of MRI (M_{zBss}/M_{zBo}) inversely proportional to the exchange rate of free water with the water in the macromolecular hydration layer (k_{BA}) times the T_1 of free water (T_{1B})

each pixel to represent the direction of the primary eigenvalue, with red representing L-R orientation, blue representing inferior-superior (foot to head) direction and green representing the anterior-posterior direction. Intermediate angles are represented by linear combinations of the three primary colors. An example of DTI from a mouse brain showing the D_{av} , FA, and RGB encoded λ_1 direction maps are displayed in Fig. 53.10.

53.2.2.3 Magnetization Transfer

T_2 of protons on molecules are dependent on molecular motion. Large molecules such as membranes and proteins with slow molecular motion have a very short T_2 (less than 1 ms). As a result, the linewidth of these molecules is very broad compared to free water. The relationship between linewidth (full width at half maximum) and the T_2 of molecules is given by:

$$\Delta\nu = \frac{1}{\pi * T_2} \quad (53.11)$$

Where $\Delta\nu$ =linewidth (full width at half maximum). As a result, selective saturation of the protons on large molecules and membranes without affecting the magnetization of free water can be accomplished by a narrow bandwidth RF pulse 4–20 kHz off resonance from the free water signal. Application of the saturation pulse for several seconds is required for a steady state to develop between the saturated macromolecules and exchange of the free water with the hydration layer of the macromolecules, developing a partial saturation (signal loss) in the free water. Signal loss by this mechanism is proportional to the exchange rate of water in the hydration layer of the membranes and macromolecules (Fig. 53.11). Determination of the degree of magnetic saturation is done using two images, one without the saturation

pulse and one with the saturation pulse. The two images are then divided to determine the spatial distribution of the magnetization transfer ratio (MTR) according to the equation:

$$MTR = \frac{M_0 - M_{ss}}{M_0} \quad (53.12)$$

where M_{ss} = signal intensity in the presence of steady state saturation and M_0 = signal intensity in the absence of the off-resonance macromolecule saturation. A more complete description of the magnetization transfer effect can be found in a review article by Henkelman et al. (2001).

53.2.2.4 Perfusion

Cerebral perfusion is a marker for metabolic activity of the brain with normal hemodynamic function. Cerebral perfusion has been used extensively for detection of disease and mapping of brain activation in health and disease. MRI methods for mapping cerebral perfusion include (1) qualitative bolus tracking after injection of magnetic contrast agents (also referred to as dynamic contrast enhanced, or DCE MRI) and (2) quantitative arterial spin-tagging. Each method is described along with the relative strengths and weaknesses, below.

Bolus Tracking (or dynamic contrast enhanced, DCE) Perfusion MRI

Injection of a bolus (typically in 5 s or less) of magnetic contrast agent causes signal intensity changes in tissue as the bolus passes through the tissue. Magnetic contrast agents used are typically chelated gadolinium (e.g. Gd-DTPA) complexes, which reduce T_1 and T_2^* of blood and tissue, increasing signal

in T_1 and reducing signal in T_2^* weighted images. Advanced rapid magnetic resonance imaging techniques, such as echo planar imaging (EPI) are capable of acquiring multiple slices covering the human brain in 1–3 s, allowing the dynamic tracking of the spatial distribution of the injected contrast agent. Signal intensity versus time is then analyzed for each voxel (volume element) in each acquired image to determine (1) time to peak contrast (mean transit time, MTT), (2) area under the bolus passage signal, proportional to cerebral blood volume (CBV). By mass analysis, cerebral blood flow (CBF) can then be determined by the relation:

$$MTR = \frac{CBF}{CBV} \quad (53.13)$$

Examples of the signal change over time after bolus injection is shown in Fig. 53.12 for a representative normal flow area (MTT_1) and an area with compromised cerebral perfusion (MTT_2). While this method is robust, it suffers from a number of issues related to absolute quantitation of the CBF including, but not limited to partial volume effects, nonlinear relationship between signal intensity change and contrast agent concentration, and determination of the input function of the bolus required for accurate quantitation. In clinical practice, MTT maps are the preferred method for visualizing areas of reduced CBF.

Arterial Spin-Tagged Perfusion MRI

Quantitation of the CBF can be an important factor in studies of therapeutic intervention. The method of arterial spin-labeled (ASL) perfusion MRI allows quantitative determination of the perfusion rate in units of ml/100 g tissue/min. However, the technique requires exceptional instrumental

Fig. 53.12 Simulated examples of the time course of signal changes after Gd-bolus administration. Voxelwise analysis of the time series of images is used to create maps of mean transit time (MTT), cerebral blood volume (CBV), corresponding to the area under the curve, and cerebral blood flow (CBF) according to (53.13). The delayed curve (MTT_2) corresponds to an area of compromised CBF

stability, as the result depends on accurate determination of the difference between two images on the order of a few percent. With the appropriate acquisition parameters to achieve sufficient signal to noise ratio (>100) and current instrument stability, this technique is feasible, especially in high field clinical systems. Currently, arterial spin-tagged perfusion measures are not widely used in clinical settings.

Arterial spin-tagged perfusion MRI is performed by inverting the water protons in the blood of the arteries supplying blood to the tissue of interest. Typically, in brain, the carotid arteries are used as the supply. The original description of the method (Detre et al. 1992; Williams et al. 1992) uses a continuous narrow band RF inversion of the protons in the arterial blood, outside of the imaged slice, before and after excitation to cause a steady-state loss of signal in cerebral tissue. The signal loss is related to tissue perfusion (Detre et al. 1992) by:

$$f = \frac{\lambda}{T_{\text{lapp}}} \left(1 - \frac{M_{\text{ss}}}{M_0} \right) \quad (53.14)$$

$$\frac{1}{T_{\text{lapp}}} = \frac{1}{T_1} + \frac{f}{\lambda} \quad (53.15)$$

Where:

And: f = flow rate, λ = water extraction fraction of tissue from blood (0.8–1.0), M is the MRI signal intensity with (M_{ss} = steady state) and without (M_0) inversion of the protons in the water of the inflowing blood. One potential complication with this method is the effect of magnetization transfer, which occurs with the continuous inversion pulse. This can be balanced by reversing the gradient so that the spatial location of the inversion is above the head when acquiring the M_0 image. This effect is reduced, but not eliminated using more recent pulsed arterial spin labeling techniques (Kim 1995; Kwong et al. 1995).

53.2.2.5 Relaxometry, Quantitative DWI and Quantitative MT

Perfusion is not the only quantitative method available using magnetic resonance techniques. T_1 , T_2 , apparent diffusion coefficient of water (ADC_w), and MT effects can be quantitatively mapped using the appropriate series of measurements. For example, acquisition of MRI data collected in a series of echo times can be processed to create an image, which is a quantitative map of T_2 (Fig. 53.8). Each effect requires its own set of measures, but in principle all methods for modifying signal intensity in MR can be quantified. With the exception of DWI, quantitative mapping is not typically done in a clinical setting due to the time required for additional measures and additional processing required for these data. Advances in MRI are increasing the speed of acquisition, which may allow quantitative

techniques to precisely define alterations in neuronal cell alterations, physiology and metabolism as research into multidimensional quantitative MRI defines the sensitivity and specificity of combining these methods to diagnose neurological disease.

53.2.2.6 Functional MRI

Functional activation of brain regions causes a flux in the oxygen level and the perfusion rate in the activated tissue. These dynamic changes generate dynamic contrast changes in the MRI signal. This was first demonstrated in 1992 (Kwong et al. 1992) and has developed into a popular method among neuroscientists for mapping task related activity as well as brain functional connectivity.

The mechanism leading to signal change in MRI is the reduction of deoxyhemoglobin in the blood in the activated area. This effect occurs because the vasculature reacts to the increased demand for oxygen and glucose in the activated area by overcompensating, a physiological process known as “luxury perfusion”. During luxury perfusion, the deoxyhemoglobin levels in the blood drop. Deoxyhemoglobin is paramagnetic and will cause reductions in T_1 and T_2/T_2^* . The signal intensity change with brain activation has been referred to as the Blood Oxygenation Level Dependent (BOLD) effect.

Images are acquired continuously during an fMRI study using single shot methods such as echo planar MRI. This allows a single slice to be acquired in tens of milliseconds and allows the entire brain volume to be imaged every second or two. The result is thousands of images that require alignment, timing corrections, and statistical analysis for determining areas of activation. Such computational power was not widely available until the 1990s. Functional MRI is normally performed using a task-based protocol with images taken continuously and the task performed with a precise timing synchronized to the image acquisitions. This “block design” allows the statistical analysis of images with pixelwise correlation between signal intensity changes and the timing of the task. An example can be seen in Fig. 53.13.

Figure 53.13 shows the result from an alternating decision/motor task where the subject is presented a number from 1 to 5 and presses the corresponding finger on both hands. A recording device on each hand with separate buttons for each finger record the responses. This task was performed repeatedly during the time period indicated in red. Between the decision/motor task, subjects rested while an alternating red-green checkerboard pattern flashed in the eyepieces used for presentation inside of the magnet. Activation of the visual cortex correlated with the green time bars as seen in the blue-green overlay on the MRI. Bilateral activation of the motor strip as well as some frontal cortex activity is apparent during the decision/motor task.

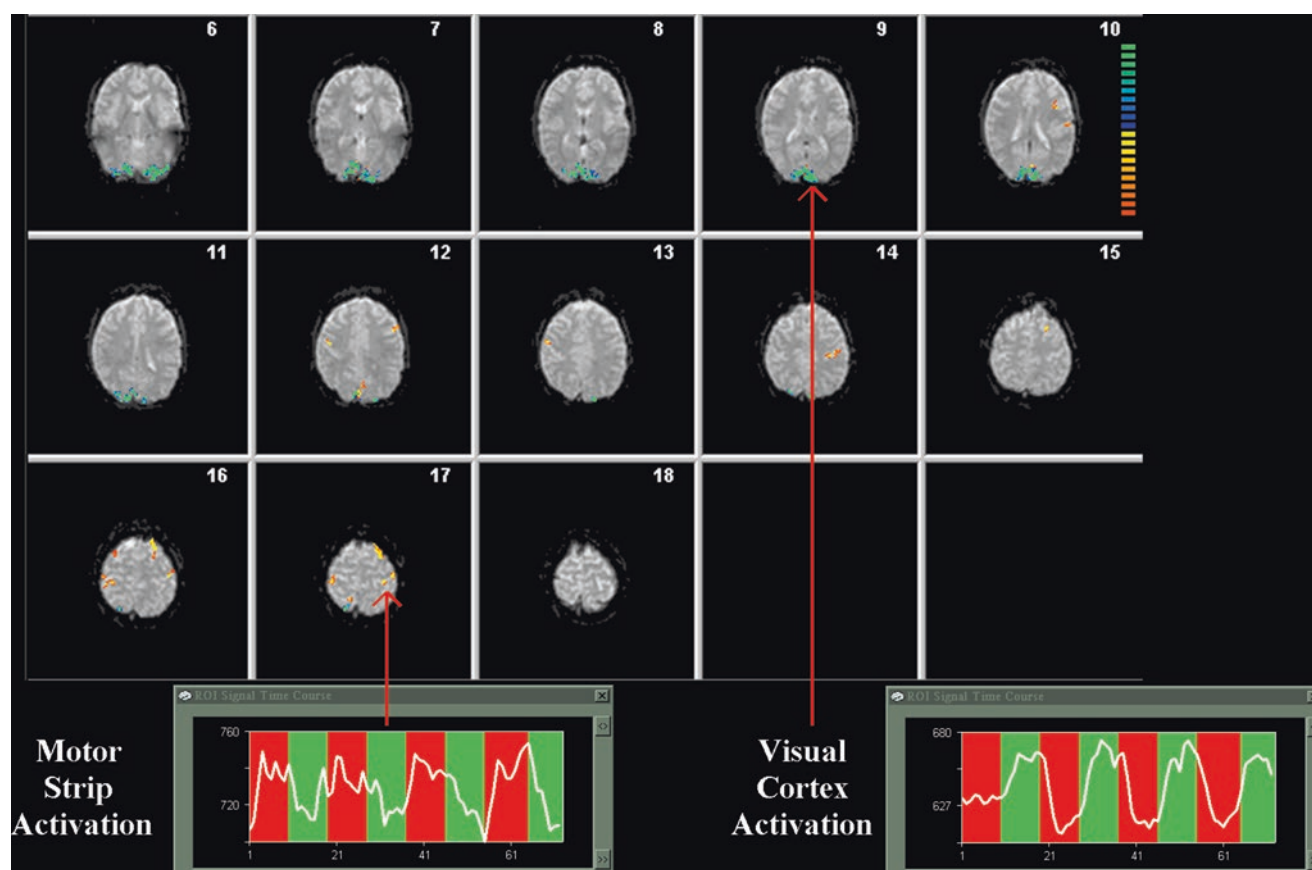

Fig. 53.13 Result from a functional MRI scan with dual protocols

53.2.3 Magnetic Resonance Spectroscopy (MRS) and Spectroscopic Imaging (MRSI)

Prior to the development of MRI in the 1970s magnetic resonance was a well-developed technique used for chemical analysis by spectroscopic analysis of chemicals in sample preparations. This capability has been extended to image guided localized magnetic resonance spectroscopy of tissue in-vivo. Localized spectroscopy uses frequency selective pulses in the presence of a gradient for volume selective excitation and spectroscopic imaging uses phase encoding gradients for spatial encoding of the spectroscopic signals. Many sophisticated pulse sequences have been developed for in-vivo localized spectroscopy and are in use in research and clinical MRI systems worldwide. The difficulties of in-vivo spectroscopy are primarily low spatial resolution due to the low signal intensity. As a result long acquisition times are required to overcome the low signal intensity by signal averaging. Despite this difficulty, in-vivo spectroscopy is unique in the ability to perform non-invasive analysis of chemical composition of tissue without biopsy and allows the serial non-invasive determination of tissue chemistry with treatment. While any nucleus with

a magnetic moment can be studied using MRS and/or MRSI, here we will focus on the most frequently used nucleus for study of brain, the proton (^1H).

Frequency shifts of nuclei on different molecules (spectroscopy) are caused by the electron cloud of a molecule. Electron cloud density, and hence field shifts due to the electron cloud, are specific to each molecule. According to the Larmor equation, this results in a frequency shift of the ^1H signal for each proton on each molecule, developing a specific “frequency fingerprint” for each molecule. The areas of the peaks are proportional to the concentration of each molecule in the region sampled. These areas are analyzed by fitting the peak areas with one of a variety of spectroscopic analysis software packages. An example of the spectrum from a region of mouse brain acquired at 7 T is shown in Fig. 53.14.

^1H MRS applies frequency selective pulses in order to generate signal from a single volume of interest defined using MRI. The signal is acquired in the absence of a magnetic field gradient in order to detect the minor frequency shifts due to the electron clouds around atoms (chemical shift). ^1H MRSI uses either a slice selective excitation or volume selective excitation with spatial encoding over the region using phase encoding gradients. This produces an

Fig. 53.14 Example of a ^1H MR spectrum from a ^1H MRSI data set with a nominal spatial resolution of $2.34\ \mu\text{l}$ ($1.5 \times 1.25 \times 1.25\ \text{mm}$) in mouse brain. Original: Spectrum obtained from the region. Fit: Overall fit using models of known spectra of metabolites including, but not limited to N-acetyl aspartate (NAA), glutamate (Glu), glutamine, creatine (Cre), choline (Cho) and myoinositol (mI). Components: Individual peaks contributing to the overall spectra of metabolites and Residual: Subtraction of the fit from the original spectrum. The frequency scale is given in ppm ($(\text{frequency}/\text{Larmor frequency}) \times 10^6$) to create a frequency scale insensitive to the magnetic field strength

array of volume selective spectra over the region selected. This technique provides improved spatial resolution and the ability to reformat data post-acquisition to allow precise localization of spectra within the slice or volume selected. These advantages come at the expense of acquisition time (typically 15–30 min in human clinical systems).

Several technical challenges need to be overcome for successful application of ^1H MRS/MRSI. The range of metabolite frequencies are relatively narrow, requiring excellent B_0 homogeneity over the region from which data are obtained. This requirement is significantly more difficult to achieve in MRSI (collecting multiple spatially resolved spectra simultaneously over large brain regions) than localized MRS (single spectrum from a small region in the brain). While MRSI is in general used in research laboratories, localized ^1H MRS is most frequently used in clinical applications due to speed of acquisition and reduced technical challenges. ^1H MRS/MRSI requires the suppression of water, as the metabolite concentrations are in the millimolar (mM) concentration range while pure water is 53 M, each water molecule having two equivalent protons, produces a signal intensity of 110 M, five orders of magnitude greater than the signals from the metabolites.

Water suppression requires excellent system stability and the elimination of “stimulated echoes” from residual water after application of the suppression technique(s).

Most MRS/MRSI studies of brain use creatine as an internal concentration standard, as creatine has a long T_2 and has relatively constant concentration in most cell types. Advanced methods exist to allow quantitation of the metabolites measured using MRS/MRSI. These methods include the referencing of signal to the internal water signal and referencing in-vivo signal amplitude to signal amplitudes from chemical samples of known concentration. Quantitation requires the correction of signal amplitude for T_1 and T_2 of the metabolites for each acquisition technique. Ideal acquisition parameters for quantitative measurements employ minimum echo time (TE) and a long repetition time (TR) to minimize magnetic relaxation corrections and reduce the chance that changes in relaxation times with pathology could affect the determination of metabolite concentrations.

53.2.4 Computed Tomography Methods, X-ray Computed Tomography (CT), Single Photon Emission Computed Tomography (SPECT) and Positron Emission Tomography (PET)

Computed tomography techniques share a common mechanism for spatial encoding. A two dimensional projection of the object (similar to a standard X-ray or a single read out in MRI without phase encoding) at multiple angles can be reconstructed into two or three dimensional images. Data are acquired by rotation of a set of detectors either opposite a radiation source as in CT, or around the subject in the case of internal radiation sources as in SPECT and PET. This method can also be used with MRI by combining gradients to provide a series of readouts at multiple angles (typically from 64 to 256), however modern MRI acquisition techniques are more efficient, therefore this technique is rarely used in MRI.

Reconstruction of images from tomographic methods are performed using the reverse Radon transform (Herman 1980) which uses the series of angular projections to reconstruct images. The resulting data set can be displayed as a rotating three-dimensional movie or resliced in any direction to display a series of two-dimensional slices.

X-ray CT uses a high intensity X-ray beam and a series of detectors that rotate around the subject. Modern CT scanners use multiple sets of X-ray sources and detectors to simultaneously acquire multiple slices (currently, up to 64) to speed acquisition. This allows full brain coverage at high spatial resolution in a matter of seconds. High doses of X-ray (about 5 rads) are typical exposures for this type of exam.

SPECT detects emitted gamma rays from radioactively labeled molecules or cells. The position of the emitted

gamma ray is determined by an array of crystal detectors covered by a collimator, which limits the angles from which gamma rays can enter the detector. Collimators consist of either a lead shield with a pinhole for three-dimensional tomographic acquisitions or a series of slots for two dimensional, planar (2D) acquisitions. Sensitivity of SPECT is limited by the area of the collimators opening. This concept can be understood by thinking of a pinhole collimator placed at a distance from the center of the subject being scanned. For example, if a 1 mm diameter pinhole is placed 10 cm from a mouse, the area covered on the surface of the sphere prescribed by the opening of the collimator (radius = 10 cm) is 1257 cm^2 ($4\pi r^2$). The gamma ray capture area of a 1 mm pinhole (0.5 mm = 0.05 cm radius) is 0.008 cm^2 (πr^2). Emission of gamma rays from the radioactive tracers is isotropic (equal probability of travel in any direction) the fraction of total gamma rays captured by the pinhole will be $0.008/1257 = 6 \times 10^{-6}$. Sensitivity can be increased by increasing the size of the pinhole, at the expense of spatial resolution or increasing the number of detectors in order to increase the counts for each angular projection. Recent technical developments have introduced multiple pinhole collimators (9–12) per detector array and multiple detectors for a significant increase (factor of 40) in detection sensitivity. The relatively low sensitivity of SPECT is typically compensated by using high doses of radioactive label, typically 50–500 microcuries to allow detection of labeled molecules or cells down to the nanomolar (10^{-9} M) concentration range.

PET uses positron emission to increase sensitivity of detection over SPECT. Once a positron is emitted from the radioactive atom on the labeled molecule, it travels a short distance (2–5 mm, depending on the energy of the emitted positron) and undergoes an annihilation reaction with an electron. Annihilation, occurs because the positron is antimatter to the electron. The reaction creates two 0.511 MeV gamma rays which then travel 180° away from each other. PET scanners employ a ring of detectors (typically 1024) and coincidence detection (simultaneous detection of two gamma rays) to improve detection sensitivity and filter out background radiation. As a result of the high capture cross section of the ring of detectors and the virtual elimination of background radiation, sensitivity is enhanced approximately four orders of magnitude compared to SPECT. This allows detection of lower concentrations of tagged molecules and cells down to the picomolar (10^{-12} M) concentration range with lower doses of radioactivity injected into the subject (typically around 10 mCi).

Positron emitting nuclides have very short half lives, on the order of minutes to 2 h. This makes operation of a cyclotron and a radiochemistry laboratory essential to the use of PET scanners. ^{18}F is the longest radionuclide with a half-life of 1.87 h, making a central production facility within a city feasible for radiopharmaceuticals employing this nuclide.

Most clinical PET facilities have on-site cyclotrons and radiopharmaceutical laboratories to allow the use of short-lived isotopes in clinical studies.

One difficulty with some SPECT and PET images is the potential lack of anatomical detail, especially in studies of receptor distribution where widespread distribution of the label in tissue may not occur. Two methods are used to overcome this problem, coregistration to anatomical images and simultaneous acquisition of anatomical images. Coregistration is typically performed for images lacking anatomical detail using fiducial markers visible in both scan sets to allow spatial registration of the SPECT or PET images to anatomical images such as CT or MRI. A more robust and time efficient method is the use of SPECT/CT or PET/CT scanners in which anatomical and tracer studies are acquired simultaneously providing anatomical images acquired simultaneously with SPECT or PET image acquisition.

53.3 Information Content

Effective use of imaging methods requires the understanding of the type of information available from each scanning technique. As neuroscientists, it is necessary to consider pathophysiological correlates of disease when designing and interpreting imaging studies. Some current research is focusing on correlation of histopathology and neuroimaging in animal models of neuronal disease (Nelson et al. 2005; Boska et al. 2005) which will serve to validate and refine the interpretation of imaging results. Consideration of expected pathology is required for experimental design and application of the most appropriate imaging methods to specifically address a particular physiological question. In the previous section, the basic principles of imaging methods were presented to allow the neuroscience student to understand the signal source and methods used to obtain imaging information. We will build on this to obtain a broad view of the basic capabilities of each imaging method and examples of the information available by use of the method.

53.3.1 Magnetic Resonance Techniques

The wide variety of morphological, physiological, and biochemical information available from the multitude of MR techniques allow sophisticated combinations of methods to be applied to individual neurological studies. This is one reason that MRI is often the best choice for neuroimaging studies, as the combination of multiple methods in one study can provide a wide array of coregistered information on the effects of disease and experimental therapies on brain function and biochemistry.

53.3.1.1 T_1 , T_2 , and Proton Density Weighted MRI

The use of T_1 , T_2 and proton density weighted images comprise the bulk of clinical MRI scans due to the ability to detect cellular alterations in tissue and determine morphological changes with exquisite soft tissue contrast. As a result, brain lesions, especially white matter lesions, tumors, and damaged regions from vascular disease are visible typically as dark areas on T_1 and bright areas on T_2 weighted images.

While these imaging modalities are sensitive to cell type, the combination of T_1 , T_2 and proton density are not specific to cell type or the type of alteration in normal cell physiology. Improved specificity can be obtained by combining these MRI scans with other types of information including clinical manifestations of disease, other neuroimaging scans and advanced analytical methods to improve diagnostic accuracy.

Use of T_1 and T_2 weighted images can be used to determine grey matter, white matter, and CSF content in neuroimages and determine the volume of multiple brain structures. Reduced volumes of gray matter, basal ganglia, and subthalamic nuclei have been found in various neurological diseases, the details of which are beyond the scope of this chapter. Good reviews are available for findings from HIV dementia (Boska et al. 2004), Alzheimer's disease (Chong and Sahadevan 2005; Kantarci and Jack 2004; Masdeu et al. 2005), Parkinson's disease (Krabbe et al. 2005; Seppi and Schocke 2005) and the hippocampus in a wide range of neurological diseases (Geuze et al. 2005). Generally, decreased volumes of affected brain structures, such as the substantia nigra in Parkinson's disease and atrophy of the grey matter in dementia such as Alzheimer's disease have been found in these studies. Scientific investigation continues into this area and as imaging and analysis software improves and the definition of changes due to disease are better defined, the use of these data in clinical diagnosis and patient management will be put into practice.

Recent studies have also shown that neuronal depolarization will cause increases in T_1 and T_2 . T_1 was shown to increase by 13 % while T_2 increased by 88 % at 1.5 T in a rat model of spreading depression (Stanisz et al. 2002). While this effect has not been studied in great detail, it is possible that this effect could be a source of detecting abnormalities in neuronal polarization with careful quantitation of T_1 and T_2 in neuronal diseases.

It will be apparent to the neurosciences student that this field, even in the case of one of the best characterized and most studied imaging modalities, standard MRI, that new information is acquired rapidly, advanced through the acquisition of data in biologically characterized animal studies and translated to well characterized human disease states. This process is cyclical, as advances in imaging methods will improve the classification of human neurological disease, leading to improved characterization and more refined human study. Advances in data processing

methods through computer science advances, developments of imaging data correlated with biological data, and advanced statistical analyses will be primary areas of imaging research for the advancement of disease characterization and detection sensitivity and specificity of imaging methods for many years to come.

Contrast enhancement of brain lesions was an early method of analyzing lesions and remains an important method of lesion characterization (Figs. 53.15a and 53.16b) (Smirniotopoulos et al. 2007). Gadolinium based contrast agents for human MRI exams were first approved in 1988. The brain parenchymal enhancement (increased signal intensity) seen with MRI contrast agents on T_1 -weighted MRI sequences reflects rather simplistically blood-brain barrier (BBB) breakdown. This type of brain parenchymal enhancement is the "delayed static" appearance of the contrast in the brain and it is easily performed at even the most basic imaging centers. The relative ease of imaging brain parenchymal enhancement (inject the contrast and then obtained a T_1 -weighted image) continues to make this a powerful biomarker clinically used for analyzing disease processes. However, parenchymal enhancement is very non-specific and can be secondary to a number of etiologies. Enhancement helps to detect many pathological entities including primary tumors, secondary tumors, active demyelination, stroke, vasculitis, granulomatous disease and infection (viral, fungal or bacterial).

In primary brain tumors enhancement is useful for determining tumor grade and survival of patients with astrocytomas and oligodendrogliomas. These are the two largest categories of primary brain tumors. The presence of enhancement in these tumor types typically indicates higher grade tumor and shorter survival but this relationship isn't seen for all tumors. Some tumors will enhance, have longer survival and behave like true low grade tumors. Also, other low grade primary tumors such as pilocytic astrocytoma almost always enhance. Secondary tumors, e.g. metastatic disease, in the brain universally enhances making this an extremely useful characteristic for disease detection. The analysis for metastatic disease given the relative frequency of cancers that can metastasize to the brain (lung, breast, renal, ovarian, colon, testicular, etc.), the sensitivity for detecting even punctate (1–2 mm) metastatic disease, and the growing elderly population guarantees the continued analysis of "delayed static" contrast enhancement.

Active demyelination has a stage of BBB and contrast enhancement helps to detect these active lesions. There are short comings for using gadolinium enhancement to define active demyelinating disease. Demyelinating lesions that are active may not enhance. Demyelinating lesions may have only short time periods of enhancement and may not demonstrate enhancement on surveillance MRIs obtained at 6 month or 1 year intervals.

Fig. 53.15 Left frontal lobe abscess secondary to *Staphylococcus Aureus*. (a) Smooth thin rim enhancing lesion in the left frontal lobe on T1-weighted image after contrast administration. (b) T1-weighted image pre-contrast demonstrates the rim of the lesion to be grey and not hyperintense. Surrounding hypointensity is vasogenic edema (star). (c) The T2-weighted rim is hypointense likely secondary to the presence of free radicals (arrow). (d) A cerebral blood volume (CBV) map from

DSC sequence demonstrates low flow consistent with an abscess. Some abscess will have slightly increased CBV. (e) Diffusion weighted image demonstrates a hyperintense central fluid component and a hypointense rim (arrow). (f) The ADC map demonstrates that the central fluid is markedly restricted likely due to presence of high protein and cellular content. The rim is not restricted (arrow). The surround vasogenic edema has elevated ADC

The necessity for utilizing contrast enhancement of the brain in the analysis of stroke has decreased markedly over the last 15 years. Diffusion weighted imaging (DWI) has become the primary sequence for analyzing for acute and subacute strokes secondary to the rapidity by which DWI becomes positive and the wide availability of DWI on new MRI scanners. There are several characteristics of contrast enhancement in stroke that can be useful. Secondary to an occluded or nearly occluded artery vascular enhancement occurs immediately and this is diagnostically a more specific pattern of enhancement. The presence of leptomeningeal enhancement in stroke occurs around day 2/3 and parenchymal enhancement begins day 3/4 on MRI. These factors can help define the age of an ischemic stroke of unknown onset. The parenchymal pattern of enhancement of larger strokes is gyriform and this pattern can also guide one to the diagnosis of ischemic stroke in patients presenting at a time later than the acute or early subacute setting. Gyriform enhancement

can also be seen, but less commonly, with seizure activity, encephalitis or infiltrating tumor. Leptomeningeal enhancement is non-specific and can be seen after the placement of a carotid stent, secondary to tumor or due to infection/inflammation. The analysis of the MRI study findings needs to be done in context of the complete clinical setting of a patient and all MRI sequences need to be analyzed in aggregate in order to optimize the diagnosis.

Another pattern of enhancement that is diagnostically useful is the presence of a ring enhancing lesion (Figs. 53.15a and 53.16b). Ring enhancing lesions are a common abnormality patients might have and are associated with numerous pathologies that are undergoing current research for effects of treatment or changes in cognition. The main differential diagnosis for a ring enhancing lesion is a high grade primary tumor, metastatic disease, abscess or active multiple sclerosis lesion. Less common entities with ring enhancement are subacute ischemic stroke, resolving hematoma, lymphoma in an

Fig. 53.16 Right anterior temporal lobe glioblastoma multiforme. (a) T2-weighted image demonstrates a mass (*arrows*) in the anterior right temporal lobe with vasogenic edema posterior. (b) The gadolinium enhanced image demonstrates a thick and irregularly rimmed enhancing mass. (c) The CBV map demonstrates high perfusion in the medial temporal lobe

where no enhancement is present in the peritumoral (perienhancement) region (*arrow*). (d) DWI image demonstrates the rim and most of the center of the mass to have higher signal. (e) The ADC map demonstrates predominantly mild restricted diffusion in the rim of the mass and in the center of the mass. The vasogenic edema has elevated ADC values (*star*)

immunoincompetent, and radiation necrosis. Enhancement characteristics can help improve the specificity of diagnosis such as the partial ring enhancement typically seen in demyelinating lesions. Abscesses have thin rims of enhancement whereas tumors usually have thickened and irregular rims of enhancement. The ring enhancement of a subacute stroke would likely have associated gyriform enhancement indicating ischemia as an underlying etiology. Advanced MRI imaging techniques such as perfusion imaging, diffusion imaging and spectroscopy have helped delineate the underlying etiological factors of ring enhancing lesions.

53.3.1.2 Diffusion Weighted MRI (DWI)

The primary use of DWI in clinical practice is detection of acute stroke lesions. Within minutes after a stroke, a low diffusion area of brain is visible in the majority of stroke cases. In a diffusion weighted image, this appears as a bright area,

as tissues with low diffusion lose less signal during the diffusion weighting. Signal abnormalities usually do not appear before 16 h on T₁ and 8 h on T₂ weighted images (Yuh et al. 1991). Diffusion weighting requires a long echo acquisition, so the appearance of bright areas on DWI can be either from low diffusion or increased T₂ signal which occurs in late acute to chronic infarcts. In order to eliminate confusion from this effect, two images are acquired, one with no diffusion weighting and one (or more) with high diffusion weighting. This allows the calculation of a parametric image of the apparent diffusion coefficient of water (ADC_w). Acute stroke lesions typically appear as bright on DWI and dark on ADC_w maps. As stroke lesions age, the cells in the lesion begin to break down after cell death and leave an area of edema. As the stroke lesion progresses towards cellular breakdown and edema, both diffusion and T₂ increase. After days to weeks, the diffusion “pseudonormalizes” to a value

equivalent to normal brain tissue, progressing to high diffusion. A combination of ADC_w , T_1 and T_2 maps can be used to characterize the age of the stroke lesion (Nagesh et al. 1998; Welch et al. 2001).

Diffusion is altered in other types of brain lesions and is not specific for stroke (Wang et al. 1998). The range and types of diffusion alterations are an area of active research. Combination of DWI, T_1 , T_2 , MT and perfusion may serve to more precisely characterize lesions from neurological diseases (Dijkhuizen and Nicolay 2003).

53.3.1.3 Diffusion Tensor Imaging (DTI)

Multiple metrics can be calculated from diffusion tensor imaging data, typically mean diffusivity (D_{av}) and fractional anisotropy (FA). Analysis of brain pathology using DTI metrics can be performed by lesion analysis, whole brain histograms of FA and D_{av} , tractography and analysis of otherwise normal appearing white matter. Fractional anisotropy has been studied in numerous diseases and detects abnormalities in otherwise normal appearing white matter by conventional MRI. This demonstrates the increased sensitivity to disease within the brain that DTI metrics can resolve. Abnormal FA in normal appearing white matter has been found to occur in multiple sclerosis, radiation injury, aging, schizophrenia, and amyotrophic lateral sclerosis (Cosottini et al. 2005; Foong et al. 2000; Filippi et al. 2001; Kitahara et al. 2005; Salat et al. 2005). Fractional anisotropy maps or DTI in general for acute stroke analysis has not been found to add significant clinical information in the setting of acute stroke therapy, although, active investigation in this area continues.

DTI can provide insight into microstructural changes in the brain in traumatic brain imaging (Cubon et al. 2011). The analysis of white matter changes by tract-based spatial statistics (TBSS) can even potentially quantitate how changes in different DTI parameters reflect mild (mean diffusivity) or severe injuries (fractional anisotropy).

Brain lesion analysis is also an active area of research. DTI metrics have been found to help differentiate between tumor types and promises to provide a sensitive method for abnormal tissue characterization. Fractional anisotropy has already been found to correlate with the cell density of brain tumors (Beppu et al. 2003; Beppu et al. 2005). The ability of FA to correlate with cell density likely accounts for the sensitivity of FA to tissue typing in brain lesions. Fractional anisotropy has been found to differentiate between low grade and anaplastic astrocytomas, to help differentiate between brain metastasis and high grade gliomas, and there is evidence that FA may help to detect tumor infiltration not visible by conventional MRI (Goebell et al. 2006; Tsuchiya et al. 2005; Holmes et al. 2004). Other DTI metrics have been utilized in brain lesion analysis and the early findings point to the breadth of future possibilities. Fractional anisotropy maps or DTI has not been found to add significant clinical information for determining the core or

penumbra of an infarct in the setting of acute stroke therapy, although, active investigation in this area continues. Fractional anisotropy has been found to be a measure that correlates with functional outcome in motor deficits related to stroke with rFA values in the corticospinal tract at day 30 correlating with the degree of motor deficit at 2 years ($P < 0.001$) (Puig et al. 2013). FA at day 30 was the only independent predictor of long-term motor outcome (Puig et al. 2013).

Apparent diffusion coefficients (ADCs) or mean diffusivity (MD), which are essentially the same parameter, are also useful measures of diffusion imaging (DI) analysis calculated from diffusion weighted imaging (ADC) or diffusion tensor imaging (ADC or MD). These parameters help delineate etiologies of brain lesions. ADC values typically in lymphoma are lower than in GBM (Toh et al. 2008). The decreased ADCs in lymphoma in general is the result of extensive areas of hypercellularity and GBMs usually have limited areas of restricted diffusion secondary to hypercellularity (Hakyemez et al. 2005). The distribution of high diffusion signal and relative restricted diffusion in a lesion can help differentiate abscess, glioblastoma multiforme and metastatic disease. Abscesses tend to have cavities of marked restricted ADC (Fig. 53.15e, f) and high diffusion signal whereas the necrotic cavities of tumors have higher ADC values (Fig. 53.16d, e) (Erdogan et al. 2005; Hakyemez et al. 2005). The opposite is true for the rims of these lesions and this is usually a better differential point between these two entities. This is due to the fact necrotic tumor cavities can have mild to moderate restricted diffusion mainly from cellular debris and hemorrhage. The rims of abscess are lower in signal with elevated ADC values (Fig. 53.15e, f) while the rims of GBMs and metastatic lesion tend to have lower ADC values (elevated DWI signal) due to cellularity (Fig. 53.16d, e) (Chang et al. 2002; Hakyemez et al. 2005). The peritumoral ADC/DWI analysis helps to differentiate GBM from metastatic disease secondary to the peri-enhancing region of tumor invasion that is seen with GBM and not mets (Jaeger et al. 2009; Wang et al. 2009).

Restricted diffusion (lower ADC values) in brain tumors has been shown to be associated with decreased survival and tumor grade (Zulfiqar et al. 2013; Kono et al. 2001). However, lower ADC values in high grade tumors have not universally been found to predict survival (Gupta et al. 2013). These disparate findings indicate that this is an active area of research. The restricted diffusion in brain tumors is thought to be primarily an effect of increased cellularity (hypercellularity) but measurement of the hypercellularity is confounded by presence of vasogenic edema, necrosis, hemorrhage, and calcifications.

The diffusion tensor data can also be utilized to perform white matter tractography (Jellison et al. 2004). Tractography is the virtual dissection of white matter tracts within the brain and provides a novel method to analyze the white matter tracts in disease states. Tractography in combination with

other DTI metrics and other MRI techniques such as perfusion and spectroscopy opens the door for currently uncharted areas of research. Previously there was nearly no indication of the intricate connections present in the white matter on conventional MRI. DTI tractography can be used to map out numerous fiber tracts including but not limited to the corticospinal tracts, superior occipitofrontal fasciculus, inferior occipitofrontal fasciculus, uncinate fasciculus, superior longitudinal fasciculus, arcuate fasciculus, and inferior longitudinal (occipitotemporal) fasciculus, (Jellison et al. 2004). With advancements and refinements in acquisition of DTI data, there likely will be improvements to tractography which will provide further advances in the “virtual dissection” of the white matter tracts.

A very exciting and innovative application of DTI and tractography that will have profound clinical application is analysis of brain lesions. There has already been early work defining tumor growth and metastases within major white matter tracts (Witwer et al. 2002; Hlatky et al. 2006; Yu et al. 2005). This application will provide measures of white matter tract displacement and tumor invasion that will be defined with great specificity. Previously estimates of white matter tract invasion could only be made by gross estimates of where the white matter tracts were expected to lie based on cross-sectional MRI or CT studies. However, current methods of DTI tractography cannot reproducibly demonstrate the true size of fiber bundles (Kinoshita et al. 2005).

53.3.1.4 Magnetization Transfer (MT) MRI

MT MRI is sensitive to areas of demyelination, as the MT effect from myelin is particularly strong. The use of MT MRI for the detection and characterization of lesions due to multiple sclerosis has been well studied (Atalay et al. 2005). Quantitative analysis of the magnetization transfer ratio (MTR) of gray matter in the earliest stages of the disease demonstrate statistically significant reduction in the basal ganglia of these patients (Audoin et al. 2004). In general multiple advanced MR techniques, including MTR maps, ^1H MRSI, quantitative T_1 and T_2 mapping, diffusion tensor imaging, and studies of blood flow have led to a more sophisticated understanding of the disease from the early view of simply an immune mediated demyelination process to the understanding of disease effects on neurons, axons, and oligodendrocytes (Minagar et al. 2005).

MT MRI has been shown to be sensitive to other minor structural abnormalities caused by neurological disease. MTR maps were analyzed with a statistical package to demonstrate that areas of epileptic activity which were not detected visually demonstrated statistically reduced MTR in the epileptic focus (Rugg-Gunn et al. 2003). When MT MRI was combined with DWI, reductions in both MTR and ADC_w were found in the epileptic focus of patients (Ferini-Strambi et al. 2000).

More advanced quantitation methods for MT MRI have been shown to be sensitive to white matter tracts and axonal density (Yarnykh and Yuan 2004) as well as being sensitive to the earliest events in stroke lesions (Jiang et al. 2001) including early detection of ruptures in the blood–brain barrier which may be susceptible to hemorrhagic transformation (Knight et al. 2005).

53.3.1.5 Perfusion MRI

Perfusion in cerebral tissue with normal vasculature is controlled by metabolic demand, allowing use of regional quantitative perfusion measures to detect neurodegeneration in a variety of diseases. Perfusion measures have been a cornerstone of nuclear medicine (SPECT and PET) studies for characterizing brain regions affected in neurological disease.

MRI perfusion studies have been used primarily to study perfusion deficits in stroke lesions. The mismatch between DWI and perfusion deficit may represent tissue at risk for damage (Neumann-Haefelin et al. 1999) which may be salvaged using thrombolytic therapy. However this interpretation of mismatch between DWI and perfusion MRI is controversial and study of this effect is an area of active research (Rowley 2005).

Brain tumor imaging is a growing area of clinical application of MRI perfusion studies. MRI perfusion studies have been found to provide valuable information when evaluating multiple facets of the imaging of gliomas, metastatic disease, abscesses, radiation necrosis, and meningiomas. The grading of gliomas pre-operatively has been found to be enhanced by utilizing MRI perfusion (Law et al. 2003; Law et al. 2004). Also, the determination if a lesion is a high-grade glioma or a metastatic lesion, the differentiation of which is markedly important clinically, can be facilitated utilizing MRI perfusion as well as MRS (Law et al. 2002). The differentiation of an abscess from a ring enhancing glioma is also potentially facilitated by MRI perfusion (Holmes et al. 2004). A significant problem that can occur with MRI perfusion is leakage of the contrast through the blood brain barrier on the first pass so that the appearance of the perfusion curve is distorted and a true evaluation of the tumor perfusion is not obtained. This is unfortunately a potentially frequent occurrence since blood brain barrier disruption is a hallmark of high-grade gliomas.

Studies of perfusion deficits in other neurological diseases have been hindered in MRI by the difficulties in quantitation of cerebral perfusion in bolus tracking perfusion measures. Arterial spin-labeling techniques have been successfully employed in recent studies of human disease including Alzheimer’s disease (Alsop et al. 2000; Johnson et al. 2005). Arterial spin-labeling perfusion measures are greatly enhanced at high field due to increased signal to noise and increased T_1 , improving reliability of the technique

(Wang et al. 2002). Increased availability of high field (3 T and above) clinical MRI systems will allow greater use of quantitative perfusion measures to assess neurodegenerative disease in clinical practice.

Arterial spin labeling (ASL) is a potentially beneficial methodology for measuring perfusion and given technical advances is becoming readily available in a time efficient scan on commercial available scanners. Previously ASL imaging had lengthy exams times and decreased spatial resolution. A great advantage for ASL is that no contrast agent needs to be administered so IV access isn't a problem and the exam can be safely performed in patients with poor renal function. This eliminates the risk of developing nephrogenic systemic fibrosis that can occur with gadolinium based contrast agents. Also, ASL doesn't suffer from the vascular leakage phenomena that plagues contrast based perfusion techniques (Boxerman et al. 2006). EPI techniques are routinely used for ASL to improve signal to noise ratios and temporal resolution but EPI introduces distortions in areas of magnetic field susceptibility at the base of the brain, around hemorrhages and increases them in areas of metal (Covarrubias et al. 2004; Petcharunpaisan et al. 2010). Fast 3-D sequences have been introduced that reduces image distortions and provide high signal to noise ratio (Wolf and Detre 2007).

Arterial spin labeling research has demonstrated that DSC perfusion exams can potentially be replaced by ASL (Lehmann et al. 2010; Warmuth et al. 2003). ASL exams have been found to correlate to the histopathology of brain tumors (Noguchi et al. 2008). Others have found ASL techniques useful for grading tumors but report challenges with inter-observer variability (Kim et al. 2008). ASL has been shown to be advantageous in determining glioma recurrence versus radiation necrosis (Ozsunar et al. 2010).

ASL techniques have been demonstrated to be useful in stroke, Alzheimer's disease, Parkinson's disease (PD) and MS. ASL using a 3D GRASE technique mapped changes of delayed bolus arrival time and reduced CBF in patients with ischemic stroke (Wolf et al. 2014). The findings match those of DSC imaging (Wolf et al. 2014). Used in isolation, CBF quantified with ASL was a good diagnostic marker for dementia (Bron et al. 2014). This was not surprising since hypoperfusion of brain tissue precedes atrophy in dementia. However, the study indicated only little added diagnostic value when combining ASL with the structural MRI data, which did not significantly improve over accuracy of structural MRI atrophy marker by itself (Bron et al. 2014). ASL indicated preserved perfusion in the degenerated brain regions of PD patients compared with healthy controls, and decreased perfusion in other regions, including the posterior parieto-occipital cortex, precuneus and cuneus, and middle frontal gyrus (Melzer et al. 2011). Studies have indicated that the neurovascular abnormalities observed in PD are dependent on the neurotransmitter

dopamine and this tight neurovascular coupling is unique (Chen et al. 2013; Choi et al. 2006). In patients with multiple sclerosis ASL provides insight into the disease pathophysiology with decreased CBF found in the bilateral thalami and right frontal lobe (Ota et al. 2013). Also, T1-hyperintense lesion volume was negatively correlated with regional CBF in areas such as both thalami (Ota et al. 2013).

These studies demonstrate the utility and robustness of ASL in research paradigms, applicability across the pathological spectrum and importance of correlating with other radiological modalities. An investigation of one technique compared to another radiological sequence can help confirm accuracy (Wolf et al. 2014). Multidisciplinary research teams and analysis utilizing clinical information strengthens the results of imaging research and provides for greater insight into disease pathogenesis. This is particularly well demonstrated by Chen et al. with the neurotransmitter dopamine (Chen et al. 2013).

Dynamic contrast enhancement (DCE) is a methodology that analyzes the T1 enhancement characteristics (blood-brain barrier (BBB breakdown)) of lesions temporally. Standard enhancement is a delayed static analysis of BBB breakdown. DCE is challenging due to having to image lesions with high temporal resolution, good contrast and appropriate coverage. The needed temporal resolution goal is <10 s but <5 s per imaging phase is often preferable. Quantitative Imaging Biomarker Alliance (QIBA) has put together a paper providing guidelines for standardization of DCE exams (RSNA, QIBA, Profile: DCE MRI Quantification, 2012). Limitations of these guidelines include that they are for 1.5 T MRI and do not take into account characterization differences of the available gadolinium contrast agents. The intrinsic relaxivity of a gadolinium agent affects the optimal imaging parameters (e.g. optimal flip angle for imaging contrast is partly determined by Ernst's angle).

The DCE technique has been widely applied to brain tumor analysis since DCE allows for evaluation of angiogenesis and blood vessel leakiness. DCE gives insight into brain lesion etiology, brain tumor grade, survival, tumor progression after treatment or pseudoprogression (Jain et al. 2011; Cha et al. 2006; Suh et al. 2013). Parameters analyzed from DCE data include:

K^{trans} Volume transfer constant between blood plasma and EES (transfer constant)

v_e Volume of extravascular extracellular space per unit volume of tissue

v_p Blood plasma volume per unit volume of tissue

However, numerous other parameters can be calculated (Bergamino et al. 2014). High-grade gliomas showed higher K^{trans} (0.050 vs. 0.010 in median value, $p=0.002$) and higher v_e (0.170 vs. 0.015 in median value, $p=0.001$) than low-grade gliomas. Receiver operating characteristic curve analysis showed significance in both K^{trans} and v_e for glioma

grading. However, there was no significant difference in diagnostic performance between K^{trans} and v_e (Choi et al. 2013). Analysis of DCE correlates with survival and it has been found patients with gliomas, survival was worse for groups of patients with high contrast transfer coefficient K^{trans} and plasma volume v_p obtained in tumor (Nguyen et al. 2014). DCE analysis can be applied to looking at tumor response to chemotherapy or radiation therapy. This application may in the future delineate what tumors are responding earlier to a treatment than standard imaging analysis of tumor volume on contrast enhanced images or T2 weighted images. Patients who are not responding to treatment then may have their therapy altered. DCE analysis has been found to be able to predict brain metastatic response with whole brain radiation therapy using principal component analysis (Farjam et al. 2014). Computing a couple of principal component coefficients is a much faster process than fitting PK modeling (Farjam et al. 2014). DCE is also being applied to study treatment responses in brain tumors. This is particularly important since anti-angiogenic drugs are of growing importance for brain tumor treatment and DCE MRI should help to measure effects of treatment on the BBB. BBB changes should give an early indication of tumor response to such treatments.

Analysis of DCE has been applied to other fields of work such as that related to stroke risk factors, ischemic strokes and multiple sclerosis plaques. It has been demonstrated that DCE analysis of carotid artery plaques can provide insight into the neovascularization (Truijman et al. 2013) and this data may be predictive of future risk of recurrent stroke. Also, the analysis of permeability may help predict what ischemic stroke lesions will result in symptomatic hemorrhagic transformation and/or malignant edema (Hoffmann et al. 2011). This work was based on CT but MRI would likely provide additional interesting analysis.

The pattern of enhancement of lesions such as seen with MS may give insight into potential different underlying pathophysiology (Absinta et al. 2013; Gaitan et al. 2011). This analysis then might allow for evaluation of treatment effects and prediction of treatment success in MS patients.

There is increasing interest in using DCE to identify more subtle BBB abnormalities, such as those which occur with normal ageing, Parkinson's disease, Alzheimer's disease, type II diabetes, HIV, cerebral microvascular disease, and non-enhancing multiple sclerosis lesions (Armitage et al. 2011). This work is particularly challenging given the subtle differences of signal change in these tissues in general with DCE and the difficulty of accurately tracking small signal changes overtime. To do these exacting studies work needs to be done to determine to what extent scanner noise, drift, intrinsic tissue properties and imaging sequence parameters affect the interpretation of post-contrast signal enhancement in different tissues and over the range of values relevant to

subtle BBB disorders (Armitage et al. 2011). If this is not done, systematic errors introduced by drift and intrinsic tissue parameters may be erroneously perceived as BBB differences between patients (Armitage et al. 2011). This type of analysis of subtle BBB changes has been applied to the study of normal appearing white matter in patients with MS in the periventricular location, a common location for MS lesions, demonstrated abnormal permeability that changed with treatment which indicated the level of permeability was correlating with the generalized MS inflammatory activity (Cramer et al. 2014).

53.3.1.6 Functional MRI

Functional MRI (fMRI) is extensively used in research for mapping task specific brain activation and continues to find greater clinical applications. Numerous paradigms have been used to test an expansive array of brain functions. A test may map areas of function for memory, motor function (hand, face, foot), sensory (pain, thermal, light touch, vibratory), multiple aspects of language and vision. Given the complexities of the brain there are numerous potential paradigms that are utilized for any one function. For instance, one might utilize passive listening or a reading paradigm to map language. It has been shown that more interactive paradigms such as word generation, verb generation, sentence completion or rhyming likely generate greater language activation (Pillai and Zaca 2011). Word generation might consist of the subject being presented letters and then the subject is to think of words that start with the letters being presented. Verb generation would consist of the subject being presented nouns and the subject is to think of actions for that noun.

A somewhat straightforward application of fMRI clinically is utilizing it to determine areas of brain function in relationship to a tumor that is going to be resected. The basis of performing fMRI in brain tumor patients is done in order to give guidance to achieve maximal tumor resection with preservation of function. However, the application of the technique for surgical guidance must be approached with caution. The tumor itself may alter the underlying physiology fMRI activation relies upon and give spurious results. The tumor may have infiltrated areas of function and the functional tissue may lie within the tumor itself and not be demonstrable by fMRI. People with brain tumors can have difficulties with performing even simple tasks and it can be difficult to determine if subjects are successfully performing tasks such as language and memory. Also, there is no accepted standard statistical thresholds to use for defining the activation blobs/regions (Chang et al. 2010). Despite these shortcomings fMRI performs robustly and provides useful guidance. Additionally, it is best to perform fMRI exams on MRI machines maximized for high signal (e.g. high tesla (at least 3 T) and high channel coils (32 channel preferred)).

The analysis of fMRI results in the setting of brain tumors gives a particular opportunity to validate fMRI results against the physical structure of the brain. The physical changes and how this affects patient function and fMRI results has provided validation for fMRI technique. Also, direct cortical mapping during operation on brain lesions provides another level of corroborating the validity of fMRI in general and more specifically the validity analyzing functional disruption in the setting of brain tumor. When fMRI was compared to direct cortical mapping, Spena et al. found mixed results (Spena et al. 2010). fMRI related by direct cortical mapping to sensorimotor correlated 92.3 % but to language was found to have a correlation of 42.8 % (Spena et al. 2010). It is not surprising that direct cortical mapping provided a better correlation to sensorimotor than language functions given the greater simplicity of measuring sensorimotor function. Language is a more complex function to test and differs to a greater extent between the test in the fMRI environment compared to mapping in the operating room. Some of the issues in this comparison may have also been the examinations were performed at only 1.5 T which would result in lower signal generation and only a fixed statistical threshold was utilized for the fMRI analysis. A fixed statistical threshold is a sound scientific approach but when analyzing fMRI in tumor patients this can be misleading given the variable functional response (Chang et al. 2010). However, Giussani et al. reviewed language fMRI studies in 2010 and had negative results (Giussani et al. 2010). They found fMRI compared to direct cortical stimulation gave contradictory results, no agreement in the literature on what task to use and fMRI maps capacity for function not what is required for function (Giussani et al. 2010). Pillai et al. and Bizzi et al. had much more encouraging results for language mapping (Pillai and Zaca 2011; Bizzi et al. 2008). Kapsalakis et al. in 2012 found highly encouraging results in tumor patients for fMRI with DCS correlating to fMRI results 91.9 % for sensory-motor cortex, 100 % for visual cortex and 85.4 % for language (Kapsalakis et al. 2012). Patients with better functional conditions performed better, as would be expected. DCS was felt to be particularly necessary for language mapping giving the lower correlation of the fMRI results (Kapsalakis et al. 2012). It should be kept in mind that despite the apparent intuitive strength of DCS for defining function via disruptive electrical signals in the brain DCS is surprisingly poorly understood (Borchers et al. 2012).

Resting state fMRI is an emerging technique that is broadly being applied to numerous neurological conditions. In addition to the brain networks associated with motor, sensory, vision, dorsal attention and language networks such as the executive network and default mode network can be seen (Fig. 53.17) (Guerra-Carrillo et al. 2014). Secondary to the ability with RS fMRI to demonstrate numerous brain networks

Fig. 53.17 Resting state fMRI with default mode network. There is decreased activation in the right hemisphere parietal lobe (yellow arrow) and frontal lobe (green arrow) due to the tumor in the right parietal lobe. Images calculated with MELODIC from FSL

via a single acquisition RS fMRI is providing exquisite insight into the functional brain changes with associated neurocognitive findings in many disease processes. RS fMRI has been successfully applied to analyzing brain function in multiple sclerosis (MS), Parkinson's disease, mild cognitive impairment and Alzheimer's disease. Numerous correlations can be utilized in combination with RS fMRI to enrich the data analysis and deepen the understanding of neurocognitive dysfunction. Such analysis can be focused on how neurological dysfunctions correlate with RS fMRI findings, how other studies such as nuclear medicine demonstrates physicochemical correlations to RS fMRI and RS fMRI can demonstrate changes overtime.

Clinical symptoms can be analyzed and correlated with cognitive changes within the brain. For instance fatigue is a common and possibly disabling symptom in MS patients. Fatigue severity in MS patients was negatively correlated utilizing RS fMRI with functional connectivity of basal ganglia nuclei with medial prefrontal cortex, precuneus and posterior cingulate cortex (Finke et al. 2014). Furthermore, fatigue severity was positively correlated with functional connectivity between caudate nucleus and motor cortex (Finke et al. 2014). No association of fatigue severity was observed with grey matter density, white matter integrity and basal ganglia volumes within patients (Finke et al. 2014). This study exemplifies how a specific symptom in a certain disease etiology can be clearly begun to be elucidated with RS fMRI when conventional imaging techniques fail. This then allows the opportunity for treatment interventions and measuring the RS fMRI initial state and RS fMRI response after treatment. This type of data could potentially then be useful to predict which patients might benefit and which patients might not benefit from a certain therapy. This type of analysis has been performed with aerobic exercise which was found to increase hippocampal volume and connectivity and improve memory in MS subjects (Leavitt et al. 2014). Aerobic exercise represents a cost-effective, widely available,

natural, and self-administered treatment with no adverse side effects that may be the first effective memory treatment for multiple sclerosis patients (Leavitt et al. 2014).

In Parkinson Disease (PD) RS fMRI has been analyzed overtime and in relationship to cognition and motor function (Olde Dubbelink et al. 2014). In an fMRI study in PD, a progressive loss of resting-state functional connectivity was demonstrated over a period of 3 years for multiple brain regions, especially in the posterior parts of the brain. The strong correlation with decreasing cognitive performance supports the pathophysiologic role of reduced functional connectivity in cognitive decline and the development of dementia in PD (Olde Dubbelink et al. 2014). Further analysis of RS fMRI combined with DATSCAN and neuropsychological testing was performed to demonstrate how the physiochemical changes with PD effects brain networks and how these findings are reflected in cognition (Lebedev et al. 2014). For the range of deficits studied, better executive performance was associated with increased dorsal fronto-parietal cortical processing and inhibited subcortical and primary sensory involvement. This profile was also characterized by a relative preservation of nigrostriatal dopaminergic function. The profile associated with better memory performance correlated with increased prefronto-limbic processing, and was not associated with presynaptic striatal dopamine uptake. SBR ratios were negatively correlated with modularity of the “cognitive network,” suggesting integrative effects of the preserved nigrostriatal dopamine system on this circuitry (Lebedev et al. 2014). This research demonstrates the complexities and layers of evaluation which are available to a neuroscience researcher and how multiple techniques can be utilized to gain a better understanding of a disease process rather than any singular technique itself. It is likely the complex interaction of multiple systems at different levels interacting that produce the clinical presentation and response in a particular patient.

fMRI analysis of the default mode has been utilized to demonstrate in subjects with Alzheimer’s disease that there is associated decreased activity in the posterior cingulate gyrus and in the hippocampi (Greicius et al. 2004). This suggests that hypometabolism seen in the posterior cingulate gyrus on PET studies in Alzheimer’s disease may be explained by hippocampal dysfunction (Greicius et al. 2004). Resting state fMRI has further been utilized to analyze behavioral effects on the hippocampi, e.g. how exercise training in the elderly benefits their brain (Burdette et al. 2010). Network analysis of a group undergoing exercise training demonstrated increased connectivity of the hippocampus and the hippocampus was consistently shown to be within the same network group as the anterior cingulate gyrus in the subjects undergoing exercise training (Burdette et al. 2010). Additionally this was coupled with demonstration of increased blood flow in the hippocam-

pus in the exercise training group using arterial spin labeling technique (Burdette et al. 2010).

53.3.1.7 ¹H MRSI

Proton MRS detectable metabolites are primarily N-acetyl aspartate (NAA), choline (Cho), creatine (Cre), glutamate (Glu), glutamine (Gln), and myoinositol (mI). NAA is found predominately in the neurons and the typical physiological intraneuronal concentrations is 9–12 mM (Urenjak et al. 1992), and as such is widely used as a marker of neuronal density. However, biochemical studies suggest the possibility of multiple roles for the metabolite NAA including an energy metabolism reserve (Bates et al. 1996; Heales et al. 1995), a supply of acetyl-Coenzyme-A for the tricarboxylic acid cycle in mitochondria (Mehta and Namboodiri 1995; Miller et al. 1996), a source of N-acetyl-aspartylglutamate (a neuropeptide that is involved in neurotransmission), a source of glutamate (a neuroexcitatory molecule which itself is a source for gamma-amino butyric acid) (Miller et al. 1996) and a role as an osmotic regulator (Taylor et al. 1995). NAA is synthesized exclusively in the mitochondria of neurons and decreases in NAA may be due, at least in part, to mitochondrial dysfunction (Goldstein 1969; Heales et al. 1995; Mehta and Namboodiri 1995). Neuronal cell death induces an irreversible loss of NAA due to localization of NAA in the neuron (Urenjak et al. 1992), while reversible loss of NAA is likely associated with reversal of mitochondrial dysfunction or replacement of damaged mitochondria within the neurons. The choline peak (Cho) is due to total levels of mobile choline containing compounds. Cho mainly consists of glycerophosphocholine and phosphocholine, compounds involved in phospholipid metabolism in brain tissue. Choline concentrations are known to be elevated in multiple sclerosis (MS) during periods of active demyelination (Simone et al. 2001). Total creatine (Cre) concentration [Cre] is the amount of creatine plus phosphocreatine in brain tissue. Cre is part of the creatine kinase energy metabolism buffer system used to maintain ATP levels in times of acute mismatch between oxidative adenosine triphosphate (ATP) supply and ATP demand. The [Cre] reflects the health of systematic energy use and storage (Miller 1991). Total [Cre] tends to remain relatively constant in most cell types, although the [Cre] in glial cells is four times that in neuronal cells (Petroff et al. 1995) and is known to be elevated in multiple sclerosis and epilepsy where gliosis is significant. mI may also act as a marker of glial cell numbers (Chang et al. 1999) and as an osmoregulator or intracellular messenger (Ross 1991).

Lactate [Lac] is seen as a result of numerous etiologies such as secondary to anaerobic glycolysis in tumors. Hypoxic insult can also cause an elevation of Lac. Lipid occurs in the same spectral region as Lac and can obscure Lac. It is often difficult to separate these two peaks from each other but lactate has a classic doublet appearance. The presence of lactate

can be confirmed by utilizing a TE of 136 ms causing the lactate doublet to invert (appear upside down in the spectrum) due to j-coupling (Yablonskiy et al. 1998). Lipids indicate the presence of necrosis or disruption of myelin sheaths. A higher level of lipid in a brain tumor generally indicates a high-grade malignancy. Lipids are best seen on spectra obtained with short TEs. However, contamination of the spectrum with scalp fat or bone marrow in the skull can result in a lipid peak, so care must be taken to interpret spectra with an understanding of the technical details of the acquisition.

¹H MRS and MRSI have been demonstrated to be a sensitive method for early detection of neuronal dysfunction or loss, reflected by loss of NAA. The application of MRS adds specificity to the diagnosis of a lesion relative to MR imaging alone (Ross and Michaelis 1994; Howe and Opstad 2003; Nelson 2003).

MR spectroscopy is used extensively in clinical practice to help differentiate tumor from non-tumor lesions in the brain. The Cho/Cr and NAA/Cho ratios can be utilized to help accomplish this task (Poptani et al. 1995; Moller-Hartmann et al. 2002). Increased Cho/Cr and decreased NAA/Cho are positive indications of a brain tumor (Poptani et al. 1995; Moller-Hartmann et al. 2002). The lipid and lactate peaks are more variable in tumor and non-tumor lesions but can also aid in tumor diagnosis. There are a number of disease processes, such as multiple sclerosis plaques, that cannot always be differentiated by spectroscopy from a brain tumor.

Tumor grading can be challenging with MR spectroscopy and there are overlaps between the appearance of the spectra from different grades of astrocytomas and oligodendrogliomas. The Cho peak and the Lip/Lac peaks tend to demonstrate increases as an astrocytoma progresses from low-grade to glioblastoma multiforme (GBM) (Howe et al. 2003; Nelson et al. 2002). Due to the complexity and necrosis in GBMs the peak values are somewhat variable (Howe et al. 2003). The Cr and the NAA peaks are decreased in low-grade GBM (Nelson et al. 2002). Myo-inositol is increased in low grade astrocytomas and is decreased in high grade astrocytomas (Castillo et al. 2000). The Lip and Lac peaks can be used to separate low-grade from high-grade (anaplastic) oligodendrogliomas in which they have been found to be significantly elevated (Rijpkema et al. 2003). In low grade oligodendrogliomas, glutamate and glutamine have been found to be elevated and this may help to differentiate oligodendrogliomas from other brain tumors such as astrocytomas (Rijpkema et al. 2003).

Gliomatosis cerebri can demonstrate subtle changes on MR spectroscopy. The subtle changes likely result in part from the infiltrative nature of the tumor and that a component of the spectrum represents normal brain. It has been described that the Cho/Cr levels may be normal and that only an elevated MI level will be detected in gliomatosis cerebri (Mohana-Borges et al. 2004). Also, there may be normal

Cho/Cr levels, associated decreased NAA and Lip/Lac present (Pyhtinen 2000).

It can be critical to obtain a MRSI study over the entire complex heterogeneous areas of a brain lesion in order to institute appropriate therapy, plan surgeries and accurately diagnose the brain lesion (Nelson 2003). MRSI, rather than the single voxel techniques, helps to define the spatial heterogeneity that is present in brain lesions and also contributes to defining the spatial extent of brain lesions. Two-dimensional MRSI performed at multiple levels or a single three-dimensional MRSI sequence can be performed to accomplish this task. MRSI can be used to help differentiate infiltrating primary brain tumors from metastatic disease. With metastatic tumors in the brain the spectral abnormality will not extend beyond the area of enhancement but with primary infiltrating brain tumors the spectral abnormality will persist outside of the area of enhancement.

Diagnosing radiation necrosis versus tumor recurrence is also a useful and accurate application of intracranial MR spectroscopy (Nelson 2003; Schlemmer et al. 2001). Radiation necrosis will have large Lip and Lac peaks without elevated Cho whereas tumor would have elevated Cho. MRSI is particularly useful for distinguishing recurrent tumor versus radiation necrosis given its ability to spatially sample multiple areas of a lesion (Chernov et al. 2005).

53.3.2 CT

Computed tomography of the brain revolutionized the care of neurological patients and was instrumental in helping to elucidate many disease processes after its introduction. However, the advantages of utilizing CT to image the brain have been greatly reduced by MRI's markedly better CNS contrast, MRI's physiologic imaging abilities and the metabolic information obtainable from PET or SPECT imaging. CT still plays an important role in the setting of trauma due to its proven ability to detect hemorrhages that require surgical intervention. CT also is advantageous in the trauma setting since it is often too difficult to adequately screen a patient for an emergent MRI and to monitor the acute trauma patient in the MRI scanner. Hemorrhages appear hyperdense acutely on CT and CT can accurately demonstrate subdural, epidural, parenchymal, intraventricular, and subarachnoid hemorrhages. CT exquisitely demonstrates the skull and skull base and is unsurpassed in detecting fractures.

CT has limited ability to differentiate the type of insult occurring in the brain and usually a brain lesion results in a lower density than the surrounding tissues. Lesions with calcification, hemorrhage, or high cellularity (such as lymphoma, primitive neural ectodermal tumors, medulloblastomas or small cell lung cancer metastases) will result in increased density. Iodinated contrast agents administered intravenously help evaluate lesions in the brain for blood brain barrier break-

down and the contrast helps improve lesion conspicuity. However, an intravenous gadolinium contrast enhanced MRI is more sensitive to detecting evidence of blood brain barrier breakdown than a contrast enhanced CT (Mihara et al. 1989).

CT has been shown to be able to detect early changes in the development of Alzheimer's disease (de Leon et al. 1993), although it has been found that other technologies, such as MRI and PET imaging, show changes better than CT. Also, in the analysis of seizure patients CT can demonstrate numerous parenchymal pathologies but a MRI examination is often a better evaluation (Heinz et al. 1989). CT is particularly useful when evaluating seizure patients for small calcified lesions such as in neurocysticercosis, periventricular calcifications of tuberous sclerosis, or the cortical calcifications present in Sturge-Weber syndrome.

A non-contrasted CT is often performed as the initial evaluation of the brain in the stroke patient secondary to CTs availability and CTs ability to exclude hemorrhage. The non-contrasted brain CT is also the neuroimaging study that was utilized in major stroke treatment studies (Furlan et al. 1999; Tissue plasminogen activator for acute ischemic stroke. The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group 1995). The non-contrasted brain CT offers limited information compared to MRI but recently with the development of CT perfusion of the brain additional information can now be obtained. CT perfusion moves CT imaging from static morphological imaging to providing physiological data that has already been shown to be useful for stroke imaging (Lev et al. 2001; Wintermark et al. 2006).

Multiple parameters can be calculated with CT perfusion imaging of the brain and include cerebral blood flow, cerebral blood volume, time-to-peak, and mean transit time (Wintermark et al. 2006). The information obtainable with CT perfusion is very powerful and when combined with computed tomographic angiography (CTA) the studies can be used as a substitute for MRI when evaluating stroke patients (Schramm et al. 2004).

CTA is a method for relatively non-invasively imaging the arteries and veins of the brain. The ability to create a CTA examination of the circle-of-Willis became possible with the advent of spiral CT, however, the quality of the examinations and the robustness of the techniques were greatly improved with the advent of multislice CT. The speed of acquisition continues to advance at a remarkable rate. With a 64-slice CT scanner the whole brain can be imaged in seconds with submillimeter slice thickness. The importance of being able to scan fast when performing CTA of the brain cannot be overstated given that a main application is evaluating patients with subarachnoid hemorrhage for the presence of cerebral aneurysms. Patients with subarachnoid hemorrhage often have mental status changes that make it difficult or impossible for them to follow directions and to lie still for an extended period of time. CTA is now often used to screen

patients with subarachnoid hemorrhage for cerebral aneurysms in order to determine if an aneurysm is present and what type of therapy (surgical clipping or intravascular coiling) is appropriate. Performing a CTA examination of the neck and circle-of-Willis fast is also optimal for decreasing the amount of venous contamination present. Venous enhancement on a CTA examination can obscure fine details such as the presence of small aneurysms.

The evaluation of acute stroke patients with CTA is being performed to evaluate for the underlying vascular etiology (Smith et al. 2006). CTA can nicely demonstrate areas of stenosis or thrombosis in the arteries. The presence of a large vessel intracranial occlusion in an acute stroke patient has been found to even be an independent predictor of poor outcome (Smith et al. 2006). Also, computed tomographic venography has been found to be beneficial for evaluating patients for the presence of venous thrombosis.

53.3.3 Single Photon Emission Computed Tomography (SPECT)

SPECT in general has a greater clinical availability compared to Positron Emission Tomography (PET). Secondary to SPECT's greater availability, proven capabilities and its lower cost it is an often used clinical and research imaging modality. SPECT is very useful for evaluating brain perfusion and has demonstrated utility for evaluating the brain perfusion of many disease processes including stroke, Alzheimer's disease and other dementias, Parkinson's disease, seizure patients, and brain tumors. Perfusion is just one parameter that can be measured with SPECT and there are many different radiotracers that can be used with SPECT for neurotransmitter system imaging (Kegeles and Mann 1997). The Ioflupane I-123 SPECT scan (DaTscan) can help differentiate between parkinsonian syndromes and essential tremor. An analysis of the utility of this scan demonstrated therapies were changed 63 % of the time secondary to the scan results (Sadasivan and Friedman 2015).

Thallium-201 SPECT and fluoro-deoxyglucose (FDG) PET are both used to help differentiate residual brain tumor and brain tumor recurrence from radiation necrosis. Thallium-201 SPECT has been found to be just as good or even better for tumor detection than FDG PET (Stokkel et al. 1999; Kahn et al. 1994; Maria et al. 1998). Thallium-201 SPECT can also be utilized to help differentiate lymphoma from toxoplasmosis which is an important question in immunocompromised patients particularly patients with human immunodeficiency virus (Young et al. 2005). Difficulties have been found when evaluating immunocompromised patients in the clinical setting and this may in part be due to the difficulty of evaluating small lesions (Licho et al. 2002).

There are numerous psychiatric applications of SPECT and these include evaluation of major depressive disorder, obsessive compulsive disorder, and schizophrenia (Alves et al. 2006; Topcuoglu et al. 2005; Novak et al. 2005). Studies have been performed evaluating these diseases and other psychiatric disorders at their initial presentations, during disease progression, and what the associated imaging changes are with medical intervention. There are many continued opportunities for investigation utilizing SPECT in psychiatry particularly whether it is utilizing a newly formulated radiotracer, utilizing advanced analytical techniques or combining SPECT data with MRI data.

SPECT has been found to be quite useful when evaluating patients with seizures (McNally et al. 2005; Tae et al. 2005). SPECT imaging is commonly used for the ictal study of seizure patients in order to define areas that are the seizure focus. It has in general been much easier to perform ictal SPECT than ictal PET. Advanced analytical techniques of SPECT imaging have helped to improve the data analysis and utilization of the SPECT data in the evaluation of seizure patients but further improvements and validation of the techniques are required (Knowlton et al. 2004).

53.3.4 Positron Emission Tomography (PET)

The information obtained from a PET scan depends on the radiotracer used and there is a wide array of radiotracers that can be used by the neuroscientist when analyzing the brain. PET using fluoro-deoxyglucose (PET-FDG) has wide clinical and research availability and has many applications in the neurosciences. PET-FDG can be used to study numerous pathologies including tumors, strokes, dementia, addiction disorders, schizophrenia, depression, seizures, and developmental abnormalities. There are a greater number of tracers that have been developed for PET than SPECT that allow in-vivo mapping of numerous neurotransmitter systems in humans (Kegeles and Mann 1997).

PET-FDG has been used extensively to investigate brain tumors including astrocytomas, oligodendrogliomas, meningiomas, lymphomas, metastatic disease, and the differentiation of tumor necrosis from tumor recurrence. In the evaluation of brain tumors PET-FDG has been found to help determine the grade of malignancy and can provide predictive prognostic information (De Witte et al. 2000; Borgwardt et al. 2005; Kaschten et al. 1998). Carbon-11-methionine has also been found useful, if not better, than PET-FDG for predicting histological grade and the prognosis of gliomas (Kaschten et al. 1998). Carbon-11-methionine is felt to be superior to FDG secondary to its sensitivity and clearer delineation of tumors (Van Laere et al. 2005; Pirotte et al. 2004), although, it is not as readily available for clinical use and investigation as FDG. Thallium-201 SPECT as mentioned in the previously section also has been shown to perform as

good if not better than PET-FDG in brain tumor analysis (Kahn et al. 1994; Maria et al. 1998; Stokkel et al. 1999).

Evaluating dementias with PET imaging is another area that has generated a lot of attention as well as clinical and research applications. The ability of PET scanning to help differentiate whether a patient has Alzheimer's disease has generated great interest due to the large number of individuals affected. PET-FDG is the radiotracer that is routinely utilized in the evaluation of dementias. PET-FDG can help to determine if a patient has Alzheimer's disease, mild cognitive impairment, and if a patient with mild cognitive impairment is likely to convert to Alzheimer's disease (Mosconi et al. 2004; Anchisi et al. 2005). Frontal-temporal dementia, vascular dementia and lewy body dementia diagnosis can also be facilitated with PET-FDG (Mirzaei et al. 2003; Higdon et al. 2004; Kerrouche et al. 2006).

Amyloid and Tau PET imaging are both adding significant new opportunities for evaluating patients who have memory dysfunction. The ability to have tracers that can define these abnormal proteins within the brain in-vivo makes it possible to detect and quantitate the disease processes leading to dementia at stages where therapy is potentially more effective. Pittsburgh compound B (PIB) was the first and is the most extensively studied of such compounds for detecting AB plaques (Shokouhi et al. 2014). PIB has been demonstrated to have increased uptake in patients with Alzheimer's and has been confirmed to be present in AB plaques post-mortem. Tau imaging has advanced rapidly and can now help to further refine the diagnostic biomarkers in-vivo also being able to detect the neurofibrillary tangles appearing in the transentorhinal cortex, followed by the entorhinal cortex and the hippocampus, and subsequently the neocortex in Alzheimer's disease (Okamura et al. 2013). Also, other tauopathies, such as chronic traumatic encephalopathy, can be detected and diagnosis facilitated (Mitsis et al. 2014).

The utility of imaging patients who have or potentially have Parkinson's disease can be valuable in multiple ways including early confirmation of the diagnosis, predicting clinical course, and to evaluate the results of therapies. When evaluating Parkinson's disease both PET-FDG and 6-[(18)F] fluoro-L-dopa (FDOPA), a common presynaptic dopaminergic radiotracer, can be effectively utilized (Kaasinen et al. 2006). FDG and FDOPA PET has been shown to be an indicator of the severity of Parkinson's disease and at patient's initial evaluations can be used to predict the clinical prognosis (Kaasinen et al. 2006). The differentiation by PET-FDG of Parkinson's disease, progressive supranuclear palsy and multiple system atrophy may also be facilitated given differences of metabolism that have been found (Juh et al. 2004).

Therapeutic induced changes of brain metabolism can be evaluated for both surgical and medical interventions (Zhao et al. 2004; Hershey et al. 2003; Hilker et al. 2002). These type of inquiries provide knowledge that can be used to judge

an intervention's success, how an intervention's success may have been produced, and potentially to predict early on in a treatment paradigm what long term success may be obtained.

There are several possible applications of PET imaging for seizure evaluation. PET-FDG again has been the predominant radiotracer that has been utilized for seizure evaluation, although, numerous radiotracers have been studied. Pre-operative evaluation of temporal lobe epilepsy is a frequently performed application of PET-FDG and PET-FDG is able to help predict the success of surgical resection (Theodore et al. 1997; Kim et al. 2003). PET as already mentioned usually studies the seizure patient in the interictal state since it is difficult to perform ictal PET studies. PET-FDG can also be a predictor of verbal decline after anterior temporal lobectomy—a surgery performed to help control complex partial seizures (Griffith et al. 2000). It has also been shown that PET-FDG is beneficial for evaluating for seizure foci in a general epilepsy population (Swartz et al. 2002).

53.4 Summary

This chapter has presented an overview of the mechanisms and applications of neuroimaging for the student of neuroscience with a view towards providing an understanding of the potential of neuroimaging techniques in neuroscience research. As the field progresses, methods for whole brain analyses, development of new detection methods and new radiotracers combined and coregistered will provide whole brain non-invasive histology for diagnosis of disease and tracking the effects of new therapies in animal models of neurological disease and, eventually, human subjects. Research techniques being developed will combine multiple coregistered techniques combined with molecular and histological analyses to provide sensitive and specific characterization of the gamut of combined neuroimaging methods for diagnosis and monitoring of neurological diseases.

53.5 Review Questions

- Diffusion weighted images become positive in acute stroke in:
 - 16 h
 - Minutes
 - 8 h
 - 1 Day
- Advantages of diffusion tensor imaging include:
 - Demonstrates abnormalities when conventional MRI is normal.
 - Provides functional maps of brain activity.
 - It is indispensable for planning stroke therapy.
 - Can be used to calculate perfusion metrics.
- Perfusion imaging data can be used to create maps that:
 - allow for “virtual dissection” of white matter tracts.
 - are used for creating MR angiograms.
 - can be utilized to determine tissue at risk for damage in patients with stroke.
 - show peaks of lactate in tissue damaged by stroke.
- Multivoxel magnetic resonance spectroscopic imaging (MRSI) does **not**:
 - help define the spatial heterogeneity of brain lesions.
 - provide less useful information than single voxel spectroscopy for distinguishing radiation necrosis versus recurrent tumor.
 - allow for accurate diagnosis of brain lesions.
 - demonstrate the same metabolic peaks as single voxel spectroscopy.
- Computed tomographic brain imaging:
 - continues to have great utility when evaluating trauma patients.
 - demonstrates acute hemorrhages as hypodense.
 - has replaced MRI for many imaging applications.
 - provides better metabolic information than PET or SPECT.
- Computed tomographic perfusion imaging:
 - has already been utilized in major stroke treatment studies.
 - can be utilized to evaluate brain diffusion.
 - has limited utility for evaluating stroke patients.
 - allows multiple parameters such as cerebral blood volume and mean transit time to be calculated.
- When evaluating seizure patients CT is particularly useful for:
 - demonstrating the periventricular calcifications of tuberous sclerosis.
 - demonstrating small soft tissue cortical lesions not detected by MRI.
 - demonstrating the cortical tubers in patients with tuberous sclerosis.
 - demonstrating the brainstem calcifications of Sturge-Weber syndrome.
- SPECT imaging of the brain:
 - is more expensive than PET imaging.
 - has been nearly replaced with PET imaging.
 - availability is a major problem in the United States.
 - is very useful for evaluating brain perfusion.
- SPECT imaging does not have:
 - many radiotracers that can be utilized.
 - many brain perfusion applications.
 - the ability to analyze brain tumors with Thallium-201.
 - undisputed ability to evaluate for lymphoma in patients with human immunodeficiency virus.

10. PET imaging:
 - (a) has fewer radiotracers that can be utilized than SPECT.
 - (b) has few imaging applications for which FDG is used.
 - (c) *has the ability to differentiate tumor necrosis from tumor recurrence.*
 - (d) lacks clear ability to differentiate Alzheimer's disease from mild cognitive impairment.
11. Which of these statements is true?
 - (a) T2-weighted images become positive in a stroke at around 24 h.
 - (b) Diffusion images allow for an estimation of the mean transit time.
 - (c) MR spectroscopy utilizes radiotracers.
 - (d) *CTA is used to screen for cerebral aneurysms.*
12. MR spectroscopy does not:
 - (a) *demonstrate increased myo-inositol in high grade astrocytomas.*
 - (b) potentially only demonstrates subtle findings for gliomatosis cerebri.
 - (c) demonstrate increased myo-inositol in low grade astrocytomas.
 - (d) show glutamate and glutamine elevations in low-grade oligodendrogliomas.

and Pawel S. Ciborowski

Abstract

Proteomic and genomic technologies, particularly when combined as functional genomics, are promising experimental approaches to creating expression profiles of proteins and their connection to disease specific changes, starting with transcription and ending at the level of posttranslational modifications. It seems that molecular mechanisms underlying many neurodegenerative disorders may have common features. In a short amount of time, proteomics underwent unprecedented development from its early stages of collecting high numbers of protein identifications in a single experiment. Quantitative mass spectrometry of proteins is now a standard approach in all laboratories. However, analytical techniques based on principles of liquid chromatography are dominating and advancing the field. Further technological developments such as single cell analysis, will further facilitate a more precise view of changes occurring in proteomes resulting from alterations in biological systems. Another big step will be to go beyond slowing down or stopping neurodegenerative processes, and push the immune system to repair damage and promote regeneration. To what extent this is possible and how soon it can be accomplished remains an open question. It is certain, however, that understanding functions of complex biological systems, such as duality of neurotoxic/neurotrophic function of mononuclear phagocytes in the brain during inflammation, will require coordinated monitoring of a large number of parameters simultaneously and well-designed proteomic, genomic, and neuro-imaging experiments.

54.1 Introduction

Upon successfully sequencing the human genome, it was shown that it consists of a considerably smaller number of genes (20,000–25,000 protein coding genes) (International Human Genome Sequencing Consortium et al. 2004) than expected, with the number of proteins greatly exceeding the number of genes. This had a big impact on how we envision the human genome, along with that of other species, and how

we approach proteomic analysis. Isoforms and proteoforms, which are products of one gene modified by one or more of 354 posttranslational modifications (<http://www.abrf.org/index.cfm/dm.home?AvgMass=all>) or alternative splicing events, are only one part of the complexity because function and biological role can also depend on cytoplasmic, sub-cellular compartments, and/or extracellular localization. Interactions with other proteins and non-proteinaceous molecules add yet another layer of complexity. At the same time, we observed unprecedented development of mass analyzers with increased sensitivity, resolution, mass accuracy and dynamic range. Considering this, it is clear that the recent 15 years have had a tremendous impact on shaping the proteomic field.

54.2 Proteomics and Genomics: Omics Technologies for Global Oversight of Complex Biological Systems

While the word *genomics* was first coined by Dr. Thomas H. Roderick, a geneticist at the Jackson Laboratory in Bar Harbor, ME, in 1986 (Yadav 2007), proteomics as a scientific field emerged in mid-1990 along with technological advances in analysis of proteins and peptides. Two-dimensional polyacrylamide gel electrophoresis (2D SDS-PAGE), originally developed in the late 1970s (Barritault et al. 1976), was rapidly advanced to the next level with immobilized pH gradient (IPG) strips (Corbett et al. 1994). This improvement allowed for the analysis of gene products containing over 2000 proteins in a mixture (Gianazza 1995) with increasing reproducibility. Mass spectrometry of proteins and peptides has developed quickly, providing new methods and reagents for quantitative analysis such as Isotope Coded Affinity Tags (ICAT), isobaric Tags for Relative and Absolute Quantitation (iTRAQ) (Ross et al. 2004), Stable Isotope Labeling with Amino acids in Culture (SILAC) (Oda et al. 1999) and Sequential Window Acquisition of all Theoretical Mass Spectra (SWATH) mass spectrometry, which was first introduced in the ABSciex qTOF (TripleTOF) system (Sturm et al. 2008). Development of user friendly kits for protein sample preparation and extraction has enabled non-protein chemists to isolate proteins, fractionate complex samples, and develop their own protocols in a similar way to the development of expression vectors and systems (Feuerstein et al. 2005). Growth of various databases followed by their integration, along with new and improved algorithms for database searches, has opened the door for high throughput experiments with substantially increased quality of protein identification and quantification (Ku and Yona 2005). Thus it became a reality to identify fingerprints of change induced by infection, malignant transformation, exposure to toxic agents, or differentiation (Pang et al. 2006). As a result of this advancement, substantial progress in prognosis and monitoring of disease progression and the discovery of new biomarkers and drug targets was and

is widely expected. Concurrently, gene sequencing and gene arrays, which can be used to measure changes in expression levels to detect single nucleotide polymorphisms (SNPs) or to genotype or target re-sequencing, were rapidly advancing technologies that provide fast and low cost mapping of whole genomes. Gene array and gene sequencing techniques, which have been used in studying biological systems for many years, provided an enormous amount of valuable information and led to many discoveries and advancements, including completion of the Human Genome Project (International Human Genome Sequencing Consortium et al. 2004). Due to the development of these technologies, we are able to generate unprecedented amounts of data containing information about the function of biological systems under investigation. This created a bottleneck of data analysis and a demand for better statistical and bioinformatics tools for data analysis.

Reproducibility and orthogonal validation, as well as data integration, remain a substantial challenge to be tackled in years to come. Figure 54.1 shows a general overview of top-down and bottom-up experimental approaches. The top-down approach deals with system modeling leading to hypothesis, prediction, and simulation of behavior of an organism under various physiological conditions. The bottom-up approach studies individual pieces on a discovery basis and combines all the information in an effort to understand how the system in question works as a whole (Fig. 54.1). In proteomics, a third approach known as middle-down is based on generating peptides that are longer than in bottom-up proteomics but shorter than intact proteins in top-down proteomics are analyzed by mass spectrometry (Forbes et al. 2001). Proteomics offers a number of additional and unique benefits. For example, proteins, which are the functional products of an expressed gene, can be posttranslational modified and their sub-cellular localization can be altered in a different physiological state. This important information cannot be obtained using gene arrays but is available from proteomic studies.

Results from studies of biological systems led to the conclusion that individualized diagnosis, clinical evaluation, and treatment is inevitable. In many instances, the amount of sample available for diagnostic purposes is limited, resulting in the demand for more sensitive techniques and instrumentation and the development of single cell analysis. Automated and simplified steps of sample processing, combined with highly sensitive and specific measurements, will improve what currently contributes to the loss of important markers in a limited sample.

54.3 Proteomics Technologies

A variety of technologies are being developed to support qualitative and quantitative measurements of protein changes in proteomes and to address important issues in proteomics as a global overview of protein makeup (Petricoin and Liotta

Fig. 54.1 Top-down and bottom-up approach in studying systems biology. There are three components contributing equally to study biology systems: theoretical, conceptual, and experimental approaches. All of

these approaches more and more heavily depend on implementation of effective bioinformatics tools. Hypothesis driven and discovery driven projects equally participate in studying systems biology

2003; Rohlf and Southan 2002; Woods et al. 2014; Patel 2014). Therefore, selection of the proteomic platform to be used in addressing any particular question is of utmost importance. A summary of proteomic workflows is presented in Fig. 54.2, which is divided into three major groups: top-

down, middle-down and bottom-up. Top-down analysis is based on isolation, analysis, and characterization of intact protein to reveal its function. Fourier transformed ion cyclotron resonance mass spectrometry (FT-ICR) (Marshall et al. 1998) facilitates such approach in protein identification as a

Fig. 54.2 A summary of proteomic platforms. The three primary methods of proteomic analysis involving mass spectrometry are top-down, middle-down, and bottom-up. While each requires different methods of sample preparation, they all have the same outcome; identification and quantification of samples, which leads to complete proteomic profiling

result of the random fragmentation of an intact molecule. In contrary, the bottom-up approach is based on up-front fragmentation of the protein in question using various proteolytic enzymes with known specificity (Millea et al. 2006; Chalmers et al. 2005). In these experiments, trypsin is most commonly used. The important question remains to be whether more information will be obtained from the bottom-up approach, which is protein identification on a cost of protein characterization, or from the top-down approach, which is distinguishing differences between two similar proteins/proteoforms. Of course, the ideal situation is to obtain both answers from one type of analysis. Handling mixtures of peptides generated from complex protein mixture (bottom-up approach) will be very different from sample processing at the protein level prior to analysis (top-down approach). Therefore, integration of these two will be a technological challenge in coming years because in order to make significant contributions, both approaches will require collaboration of scientists with diverse expertise with cross-disciplinary nature. Methods representing top-down approaches are used for separation of intact proteins using either gel electrophoresis or liquid chromatography. Chemical or metabolic labeling, as well as label free techniques, are widely used for bottom-up studies. With the middle-down approach, larger size protein fragments are generated and analyzed by tandem mass spectrometry with front-end liquid chromatography separation. In these experiments, label free techniques are used. A summary of technologies most commonly used in proteomics is presented in Table 54.1. Our intension here is that this summary not only

presents past experience, but also serves as guidance for the design of proteomic workflow in future studies.

The most commonly used proteomic platform is the combination of liquid chromatography and tandem mass spectrometry. In first dimension, tryptic digested peptides are fractionated on a strong cation exchange column and collected fractions are further fractionated on Reverse-Phase High Performance Liquid Chromatography (RP-HPLC) with direct infusion to the mass spectrometer. Alternatively to SCX, an OFFGEL fractionation based on isoelectric point is quite often used. OFFGEL platform was introduced by Agilent, Inc. in 2006.

The majority of analytical techniques currently used for proteomic profiling have a liquid chromatography based step of fractionation. This will be RP-HPLC directly interfaced with mass spectrometer and off-line fractionations such as strong cation exchange (SCX) chromatography, IEF (OFFGEL technology), immunodepletion or all configurations of pull-down and enrichment steps. Multidimensional fractionation is an essential step but we have to keep in mind that extending pre-profiling fractionation may not always work towards our advantage, since every analytical step will introduce some degree of variability.

Enrichment of specific proteins or group of proteins is certainly the main goal of pre-fractionation. For example, immunodepletion of the most abundant proteins from serum or cerebrospinal fluid samples will facilitate detection of low abundant proteins in complex samples (Ramstrom et al. 2005; Chromy et al. 2004; Fountoulakis et al. 2004). However, the

Table 54.1 Summary of analytical and preparative methods most commonly used in proteomic studies

Method	Description	Applications
1D SDS PAGE	Fractionation based on approximate molecular weight (m.w.)	Preparative/analytical
IEF	Fractionation based on isoelectric point (pI). In addition to IPG strips used for first dimension separation as part of 2DE, includes OFFGEL technology	Preparative/analytical
2 D electrophoresis (IEF/SDS PAGE)	High resolution separation/fractionation based on pI and m.w., long and complex procedure. IPG strips with variety ranges of pH are available. 2DE DIGE using differential labeling of proteins with fluorescent Cy dyes	Preparative/analytical
LC-MS/MS	Chromatographic one or two dimensional fractionation followed by mass spectrometric peptide sequencing and protein identification	Analytical
Capillary Zone Electrophoresis (CZE)	Fractionation based on m.w. or pI, directly connected to tandem mass spectrometry	Analytical/preparative
HPLC/FPLC	Fractionation based on physico-chemical features of protein (m.w., pI, hydrophobic profile)	Preparative/analytical
SELDI-TOF	Fractionation based on selective binding to activated surfaces followed by MS determination of m.w., automatic fast sample processing combined with mass spectrometry	Analytical
MALDI-TOF	Requires high resolution mass spectrometry for protein identification based on peptide fingerprinting. High density plate spotters combined with micro-capillary RP-HPLC fractionation are available	Analytical
Protein Arrays	Identification/separation techniques based on protein—protein interactions. Requires high quality and well characterized antibodies.	Analytical

remaining amount of proteins will be quite different between samples. A published report of the Human Proteome Organization (HUPO) Human Plasma Protein Project (HPPP) showed that almost all laboratories participating in this international effort used some mean of sample pre-fractionation. Eventually, 3020 proteins were included in a database set from 15,677 proteins reported (Omenn et al. 2005). Enrichment using TiO₂ columns for phosphoproteins and phosphopeptides or affinity columns to selectively pull down ubiquitination is to facilitate identification and quantification of low abundant modified proteins. If enrichment is at the

protein level, samples can be used for top-down profiling. In many instances, proteins are proteolytically digested and enrichment is performed at the level of peptides. Such samples are used for bottom-up analyses.

2D SDS-PAGE, which has been used for about 40 years, combines two modes of separation: isoelectric focusing and polyacrylamide gel electrophoresis (O'Farrell 1975; Barritault et al. 1976). Development of immobilized pH gradient (IPG) strips made this method much more user friendly and, most importantly, much more reproducible. This allowed construction of computerized protein databases based on two-dimensional separation (Celis et al. 1990). Although the resolution, thus reproducibility, of 2D SDS-PAGE remains a limitation, especially in high molecular mass ranges or for hydrophobic proteins, advancements in protein sequencing by electrospray ionization (ESI-MS/MS) or Matrix Assisted Laser Desorption Ionization Time-of-Flight/Time-of-Flight (MALDI-TOF/TOF) mass spectrometry made it possible to identify proteins directly from the protein "spots" in 2D SDS-PAGE. This method is used for top-down proteomics. Difference Gel Electrophoresis (DIGE) compares two samples, one labeled with Cy 3 and the other labeled with Cy 5 fluorescent dye. These two samples are mixed together and analyzed in one 2D SDS-PAGE experiment. Common proteins are represented by yellow spots while different colored spots, which are detected with a laser-based scanner, represent differentially expressed proteins. This is another example of further technological advancement.

Another tool for protein profiling is Surface Enhanced Laser Desorption Ionization Time-of-Flight (SELDI-TOF) (Hutchens and Yip 1993). This technology utilizes a matrix-assisted laser desorption ionization time of flight mass spectrometer for detection, along with one one step chromatography to reduce complexity of the analyzed sample. The latter involves the use of proprietary Protein Chips initially commercialized by Ciphergen, Inc. and now offered by BioRad Laboratories. This is an analytical tool with relatively low resolution and mass accuracy in addition to high variability of intensities. Nevertheless, the big advantage of this method is ease of use for fast screening and collection of information regarding properties and conditions associated with binding of the proteins of interest to ion-exchange, hydrophobic, Immobilized Metal Affinity Chromatography (IMAC), and/or normal phases, which can be utilized with success in translation to preparative methods using corresponding HPLC column (Enose et al. 2005). This technology is also susceptible to relatively high variability in the analyses of multiple SELDI-TOF spectra. Jeffries et al. (Jeffries 2005) developed an algorithm, which greatly improved spectra alignment and thus improved reproducibility. MALDI-TOF instruments with higher resolution than SELDI-TOF, combined with various chromatographic techniques, have

also been used but did not produce convincingly better results than SELDI-TOF (Coombes et al. 2005).

A separate field of so-called “hyphenated methods” has been developed and deals with combining two or more methods together in succession. The first component of the combined methods will deal with separation/fractionation of an analyzed sample, followed by an in-line connected detection system. Hyphenated techniques were developed and became popular in the 1970s and 1980s—more than 30 years ago, and remain a vital part of current technological advancement (Murray et al. 1975; Lee et al. 1976). Examples of the most commonly used hyphenated methods in proteomics are LC-MS (liquid chromatography combined with mass spectrometry), GC-MS (gas chromatography combined with mass spectrometry) (Kazakevich et al. 2005) and LC-UV-SPE-NMR (liquid chromatography, UV detection, solid phase extraction, and nuclear magnetic resonance) (Exarchou et al. 2005). Sample fractionation prior to detection and/or analysis usually leads to enhanced analytical outcome. Hyphenated techniques are also meeting a big challenge in proteomic analyses; dealing with an extremely large and dynamic range of protein levels (Julka and Regnier 2005; Kusnezow et al. 2006).

Protein arrays attempt to occupy another space in proteomic technologies. While this approach is similar in concept to gene arrays, protein arrays are based on antigen-antibody interaction rather than hybridization of complementary strands of nucleic acid. As much as antigen—antibody interaction is very specific, it also depends on the quality of well standardized antibodies. This is much harder to accomplish. Therefore, accuracy and reproducibility of protein array data highly depends on proper experimental design, normalization procedures, eliminating systematic bias, and appropriate statistical analysis. Eckel-Passow and co-authors made several excellent suggestions about how experiments should be designed and analyzed to avoid false results (Eckel-Passow et al. 2005). For example, the authors propose to use several different clustering tools instead of a single cluster analysis for verification of results in discovering differences in a class of molecules, e.g. cytokines. Another obstacle in working with protein microarrays is maintaining stability of protein structures, which is critical for proper folding and thus interaction with the binding partner. Another side of this problem is exposure of the interacting surface/epitope while immobilized on the chip's surface. This technology, although not as popular now, is slowly gaining ground in biomedical research with increasing potential of applications in clinical diagnosis. Similar to DNA microarrays, protein arrays are commercially available as user-friendly kits, made specific for various microorganisms and diseases, with improved and sophisticated fluorescent tags. For those working in the area of drug development, protein microarrays are vehicles of accelerated discoveries. Protein arrays also make it possible to screen functions such as protein-antibody, protein-protein, protein-ligand, protein-

drug, and enzyme-substrate interactions. They can also be used to perform multi-analyte diagnostic assays. For others, protein microarrays are envisioned as tools for the exploration and understanding of pathological processes, kinetics of changes at the molecular level, drug candidates, and interactions between molecules such as lipids, nucleic acids, carbohydrates, etc. Protein microarrays are a powerful tool when proteomic analysis is narrowed to a group of proteins such as growth factors, chemokines, cytokines etc. These classes of proteins already have a great number of pre-required, well-characterized and highly specific antibodies reacting with high affinity. Such protein arrays (chips) were immediately developed and are successfully used in monitoring markers of immune responses (Kastenbauer et al. 2005) complementing DNA arrays (Ho et al. 2005).

In summary, one should decide which platform to use based on questions that are asked. The experimental design and sample processing should align with the type of biological material being investigated. Investigation of proteomes of body fluids and culture supernatants or lysates of whole cells, tissues or cellular compartments/organelles would all require a different platform to be used and this can be determined from reviewing already published studies. Along with improvements of sensitivity, resolution, mass accuracy, dynamic range and speed of data acquisition of new generations of mass spectrometers, proteomic data are becoming massive and reduction of sample complexity is inevitable. Otherwise analysis of such massive data and interpretation becomes very complicated.

54.4 Biomarkers

Biomarkers in disease can be defined as quantifiable analytes or factors reflecting changes in an individual's physiological state. These changes, or biological responses, can be found at the molecular, cellular, and/or whole organism level. They play a critical role in assessing disease outcome, particularly in patient treatment, how these treatments will be individualized and/or modified in future clinical trials and how they will affect directions in drug development. Therefore, biomarkers must provide objective measures of normal versus pathogenic processes and responses to treatment whether this leads to cures, improvement, or only maintenance of a patient's health. Thus, biomarkers are absolutely essential for early diagnosis of any disease, whether it be a slowly progressing pathological process or acutely developing infection.

HIV associated neurocognitive disorders (HAND) and in its extreme form, HIV associated dementia (HAD), is a good example in discussing the importance and qualities of reliable biomarkers. HAND is a brain pathology that develops over a long period of HIV-1 infection, ranging in progression

from subclinical to end stage. Once started, this slowly progressing disease ultimately leads to death. Currently, HAND is diagnosed by a battery of neuropsychiatric and psychological tests and it is impossible to predict and measure the time of onset and progression. The main reason for this is a lack of appropriate molecular biomarkers, which inform us about mechanisms of brain injury triggered by HIV-1 in the brain.

Given this information, what would constitute a good and reliable biomarker of HAND? We expect that regardless of whether a biomarker is found in the CSF or plasma of diseased people, it will give us an insight into the cellular mechanisms of an ongoing infection. This insight is important for those who are designing new clinical trials or regimes of existing treatments. Whether or not a biomarker enters clinical trial is based on vague measures, which might be influenced by the subjective impact of the examiner, causing an additional risk of inaccurate results. Thus, an ideal biomarker should inform us as precisely and as objectively as possible about the mechanism, status, and prediction of therapy and disease. The ideal biomarker should also help in the design of “individualized” therapy for the most effective clinical result. In our example of HAND, an activation of mononuclear phagocytes recruited in high numbers due to on-going inflammation led to conclusions that up- or down regulated proteins originating from these cells due to HIV-1 infection might be good candidates for biomarkers. Such approach, however, should be considered with caution. Our studies (Ciborowski et al. 2004) showed that although HIV-1 down-regulates MMP-9 expression in monocyte derived macrophages in *in vitro* studies, the net level of this protein in the CSF of HAD individuals as well as its net proteolytic activity is increased due to recruitment of high numbers of these cells to the inflamed brain.

Recent and quick development of nanotechnology, not only in drug delivery but also in diagnostics and monitoring, together with the technological boom of miniaturization, made it possible to use lower amounts of sample for analysis while sustaining the same level of sensitivity and specificity. Single cell analysis and tissue laser dissections are becoming a reality, although we have to be aware that not all proteins or their modified forms can be effectively detected at this level. Unlike in genomics, the proteomics approach does not have the luxury of *in vitro* amplification of proteins. Besides improving the yield of proteins of interest during sample preparation, limitations of detection in laboratory tests still exist, creating an analytical challenge. Nevertheless, there are numerous examples in which proteomics was successfully used to discover new biomarkers. Commercial tests, on the other hand, are almost always based on assays utilizing different principles, e.g. ELISA (Sandhu et al. 1991; Hampel et al. 2004).

It is also important to note that an effective biomarker can be a specific fragment of protein that is present in the diseased state but not under normal conditions. Currently, many biomarkers of this nature have been identified to be measures

of neurodegenerative disease. In several cases, the biomarker is a misfolded protein, showing a slightly different molecular weight from its corresponding wild type. In Alzheimer’s disease (AD), an existing biomarker of this type is the A β ₄₂ fragment of α -amyloid protein (Olsson et al. 2003). The accumulation of internalized misfolded Tau protein has also been found to correlate with the progression of AD, as well as frontotemporal dementia (FTD) (Wu et al. 2013; Rademakers et al. 2012b). Likewise, the aggregation of α -synuclein into Lewy Bodies has emerged as a biomarker for Parkinson’s disease (PD) (Luk et al. 2012).

54.5 Proteomics in Biomarker Discovery

There are four necessary key components for performing proteomic (global) experiments: (1) identification of differences generated within a system under various physiological conditions, (2) fractionation of complex mixtures of proteins and other molecules, (3) identification of differentially expressed proteins and their interacting partners, and (4) data analysis, which includes algorithms for database searches, tools for statistical analysis, and tools for bioinformatics analysis. The choice of method, instrumentation, and experimental approach should be selected based on the questions being asked and answers being sought.

As we collectively accumulate knowledge and experience on how proteomic experiments should be conducted in order to yield the most information, a shift from full unbiased profiling to targeted proteomics has been observed. Therefore, the majority of studies are now focused on specific groups of proteins or even single proteins and their interacting partners whose function(s) and/or interaction(s) are significant in biological processes. The expectation is that these studies will generate results that will be translated to the development of commercial diagnostic tests. The major bottleneck in this process at this time is the processing of increasingly complex data generated by proteomic studies.

Proteomics cannot exist without interdisciplinary research, grouping experts from a wide variety of specialties who understand and are able to communicate about issues related to protein chemistry and bring proteomics to the level of functional studies. Currently, research teams combining a relatively narrow group of scientists including protein chemists, mass spectrometrists, and bioinformaticians are pushing the levels of sensitivity and accuracy of analytical instrumentation to unprecedented levels, but experiments still remain at the stage of comparing two conditions only. Therefore, to benefit more from proteomics we need to organize international groups/consortia to tackle prioritized problems. One example is global proteomic analysis such as the Human Plasma Proteome Project (Omenn et al. 2005), which can be accomplished only through international collaborations of laboratories equipped

with various types of mass spectrometers and capable of performing complex analyses. Undoubtedly, efforts of this and other currently on-going international initiatives, e.g. Human Brain Proteome Project (<http://www.hbpp.org/>), will build a foundation for new discoveries and functional studies. Everyone in the broad research community will benefit from this work, particularly a rapidly growing number of smaller proteomics laboratories and programs with research goals focused on specific question(s) of biological importance. The most exciting potential lies in functional studies combining proteomic and genomic approaches.

54.6 Proteomics of Cerebrospinal Fluid

The total volume of cerebrospinal fluid (CSF, Liquor cerebrospinalis) in an adult human is about 130–150 mL and production is relatively constant under normal physiological conditions at the rate of approximately 0.4 mL/min (more than 500 mL daily). This means that turnover of CSF is at the rate of 4 volumes daily. A significant decrease in CSF secretion and turnover is associated with neurological diseases such as Alzheimer disease and chronic hydrocephalus (Silverberg et al. 2004; Tsunoda et al. 2002). Thus, CSF levels are highly reflective of the physiological status of the CNS.

Cerebrospinal fluid, which surrounds the brain and spinal cord, acts as an intermediate between blood and nervous tissues. Functions of the CSF include buoyancy, acid base buffering and delivery of electrolytes, signaling molecules, transport molecules and micronutrients to the brain parenchyma (Silverberg et al. 2004). CSF is produced predominantly by choroids plexus, specialized vascular tissue located in the brain ventricles (Serot et al. 2003). Choroid plexus tissues are intraventricular structures composed of villi covered by a single layer of ciliated, cuboid epithelium. The plexuses secrete cerebrospinal fluid, synthesize numerous molecules, carry nutrients from the blood to the CSF, reabsorb brain metabolism by-products and participate in brain immunosurveillance (Serot et al. 2003). Active transport across the choroid plexus is bidirectional, which allows for macromolecular transport out of the CSF. Blood flow to the choroid plexus is approximately six–times greater than that of the equal volume of brain tissue, suggesting that the choroid plexus is very metabolically active (Silverberg et al. 2004).

Changes in the biochemical composition of CSF could serve as a useful tool for investigations of pathological processes in the central nervous system (CNS). CSF is also in contact with blood plasma through the blood–brain barrier and thus resembles an ultra-filtrate of plasma in its protein constituents. CSF contains sugars, lipids, electrolytes and proteins. The concentration of proteins in CSF ranges from 0.2 to 0.8 mg/mL (0.3–1% of serum protein concentration) but more than 70% of the proteins in CSF are isoforms of albumin, transferrin and immunoglobulins (Ogata et al. 2005;

Wittke et al. 2005). The proteome of CSF contains proteins that are expressed in and secreted from circumventricular CNS structures. Therefore, the CSF proteome could provide unique biomarkers for early-stage diagnosis or the staging of a neuronal disease. This could offer potential insight into the biochemical characterization of affected neuronal populations and clarify the molecular basis of CNS pathologies (Yuan and Desiderio 2003; Yuan and Desiderio 2005).

Previous studies have used proteome comparisons to study neurological disorders such as Alzheimer's disease, Parkinson's disease, frontotemporal dementia, schizophrenia, and Creutzfeldt-Jacob disease. Some examples of utilizing proteomics approaches for discovery of biomarkers for neurological disorders in human CSF are given in Table 54.2.

Although insightful, the investigation of biomarkers in CSF has had some important limitations. Availability of larger volumes of CSF samples is limited by the need for invasive lumbar punctures. The large dynamic range of protein concentrations similar to this in plasma, which can be up to 12 orders of magnitude between the highest and the lowest expressed proteins, makes the analysis difficult (Maccarrone et al. 2004). Various schemes of sample pre-fractionation have been used to circumvent these problems. The widely used albumin removal method is affinity chromatography on various resins. However, this method is not specific only to albumin and it is known to bind numerous other proteins (Maccarrone et al. 2004; Gianazza and Arnaud 1982). A newer approach is to use immunoaffinity methods utilizing monoclonal or polyclonal antibodies to deplete not only albumin, but also other highly abundant proteins from biological samples. Resins coupled with antibodies could be packed in HPLC columns for depletion of the most abundant proteins for simultaneous depletion of 6, 12, 14 or more proteins (PMID: 17950469, 17929958). The application of HPLC columns for CSF preparation before 2D electrophoresis and shotgun mass spectrometry was compared with Cibacron Blue and protein G resins by Maccarrone et al. (Maccarrone et al. 2004). Immunoaffinity columns showed less nonspecific binding of CSF proteins. Another example of pre-treating CSF samples before proteomic analysis is the use of immunoglobulin Y (IgY) antibody microbeads and spin filters for depletion of the most abundant proteins (Seppro Mixed 6, GenWay, San Diego, CA). Comparison of IgY microbeads and immunoaffinity columns for pretreatment of CSF samples was performed by Ogata et al. (Ogata et al. 2005). The column method removed major proteins more effectively and approximately 50% more spots were visualized when compared to the 2D gel of CSF without protein depletion. Two other commercially available kits for removal of Human Serum Albumin (has) and HSA/IgG were used by Ramstrom et al. (Ramstrom et al. 2005) for CSF preparation prior to Liquid Chromatography Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (LC-FTICR MS). Both depletion methods provided a significant reduction of HSA, and the identification of lower abundant components was clearly facilitated.

Table 54.2 Summary of protein biomarkers of neurodegenerative disorders discovered using proteomics approach

Disease	Biomarker (protein)	Applied method	Lit. reference
Alzheimer's disease	Cystatin C, B-2 microglobulin isoforms, 4.8 kDa VGF polypeptide, unknown 7.7 kDa polypeptide	SELDI TOF and LC/MS	Carrette et al. (2003)
	Apolipoprotein A1, apolipoprotein E, apolipoprotein J, B-trace, retinol binding protein, kininogen, alpha-1 antitrypsin, cellcycle progression 8 protein, alpha 1B	2D electrophoresis and MALDI-TOF	Puchades et al. (2003)
	Glycoprotein, alpha-2—HS glycoprotein	MALDI-TOF	Wildsmith et al. (2014)
	Tau, hyperphosphorylated tau (p-tau), A β_{42}		
Frontotemporal Dementia	Transthyretin, fragment of VGF S-cysteinylated transthyretin, truncated cystatin C, fragment of chromogranin B	SELDI-TOF and MS/MS	Ruetschi et al. (2005)
Creutzfeldt-Jacob Disease	14-3-3 protein	2 D electrophoresis	Harrington et al. (1986)
	Cystatin C	SELDI-TOF, and LC-MS/MS	Sanchez et al. (2004)
	Ubiquitin	SELDI-TOF	Steinacker et al. (2010)
Schizophrenia	Apolipoprotein A-IV	2D electrophoresis and LC/MS	Jiang et al. (2003)
	Fibrinopeptide A	MALDI-TOF	Zhou et al. (2014)
	A-defensins	SELDI-TOF	Craddock et al. (2008)
Multiple Sclerosis	Cartilage acidic protein, tetranectin, SPARC-like protein, autotaxin t	2 D electrophoresis and LC -MS/MS	Hammack et al. (2004)
	Atg16L2	MALDI-TOF	Yin et al. (2014)
	Alpha-1-antichymotrypsin, contactin-1, apolipoprotein D, clusterin, kallikrein-6	ITRAQ	Kroksveen et al. (2013)

Immunodepletion of most abundant proteins, also called albuminome because albumin is most abundant protein in plasma, is based on interaction of proteinaceous antigen with immunoglobulin. Although it is a highly specific interaction, it still remains to be protein—protein interaction that might be non-specific to some extent. On the other hand, some proteins are partially removed from plasma samples because of their interactions with proteins that are being removed. Partial removal of other proteins may affect quantification and should be taken under consideration. More information about proteins removed along with albumin can be found in (Ciborowski 2013)

Every method of removing highly abundant proteins from CSF samples before proteomic analysis facilitates identification of discrete proteins, which could be important as a biomarker for classifying physiological stages of the CNS. However, the possibility of nonspecific removal of important peptides (through nonspecific binding to resins or forming complexes with target proteins) should be taken into account.

54.7 Neuroproteomics

Proteomic studies of the brain (central nervous system) pose significant challenges. Brain tissue collection, dissection, preservation, and maintenance of biochemical and molecular integrity are all critical aspects of neuroproteomics and

neurogenomics. Despite the fact that many proteins and nucleic acids are stable post-mortem (Yates et al. 1990) rapid degradation of other proteins may result in changes in overall protein composition (Choudhary and Grant 2004; Abbott 2003). Protein profile can change rapidly within minutes after death, making it very difficult to sort out changes related to disease from those related to death itself. In many studies done so far, protein extraction of the entire brain was used without distinguishing the specific region of origin (Wang et al. 2005). To address these issues, a variety of brain dissection techniques have been developed (Sanna et al. 2005). Manual dissection methods are still very useful and yield enough material for microarray analysis with somewhat limited “contamination” of the sample of interest with neighboring regions, which has a chance of affecting reproducibility of genomic and proteomic analyses. Ultimately, the laser dissection of brain tissues technique, which is a quickly emerging technique (He et al. 2013; Ly et al. 2011), further facilitated by increasing sensitivity of mass spectrometers, will be the method of choice for retrieving small regions, or even single cells of interest, from brain tissue to improve anatomical accuracy (Evans et al. 2003). Post-mortem collection of CSF has been shown to be a valuable source of information; however, it has to be analyzed with caution because of brain necrosis following death (Lescuyer et al. 2004). Lescuyer et al. found in post-mortem collected CSF samples three proteins that have been reported

as potential markers of various neurodegenerative disorders: prostaglandin D synthase, glial fibrillary acidic protein, and cathepsin D. Other proteins include ubiquitin C-terminal hydrolase L1, peroxiredoxin 5 (Lescuyer et al. 2004).

Some neurological disorders such as AD, PD, HAND, MS, schizophrenia or ALS are slowly developing diseases and will require extended longitudinal studies to search for biomarkers. In contrary, brain injury due to stroke, trauma, exposure to toxic substances, hypoxia or microbial infections are fast acting and require immediate intervention. Nevertheless, in all these cases the central nervous system is affected and damaged irreversibly to various extents. Thus, quick diagnosis and medical intervention is absolutely critical for the outcome of CNS diseases. Slowly developing neurodegenerative disorders are diagnosed by the observation of clinical symptoms after an already existing disease has been established. Thus, as much as biomarkers to measure disease progression are important, we should not stop in exploring prognostic biomarkers, which will inform us who might be highly susceptible to the development of neurodegenerative diseases. Although genetic tests help us in such prognosis, they are only applicable to a portion of cases. For example, in PD about 15 % of cases are correlated with a genetic predisposition due to having a first-degree relative with this disease. Therefore, when genetic tests cannot be used as predictors, proteomics appears to be an indispensable approach in the quest for predictive biomarkers.

Aggregated and modified proteins (α -synuclein in PD and tau in AD), along with deregulation of mitochondrial functions leading to overproduction of toxic ROS and glutamate, are factors responsible for neuronal death that are observed in many neurodegenerative disorders (Sultana et al. 2005). Nevertheless, specific triggers of neurotoxic mechanisms are vastly unknown and various proteomic techniques are employed to address these questions. High-throughput shotgun analysis used by Soreghan et al. (Soreghan et al. 2005) to identify targets of protein carbonylation in a PS1+AbPP transgenic mouse model pointed to iNOS-integrin signaling, CRE/CBP transcription regulation, and rab-lyst vesicular trafficking pathways as future research directions on neurodegeneration.

Significant progress has been made in CSF proteomic profiling in search of biomarkers for MS, which was reviewed by Kroksveen et al. (Kroksveen et al. 2013). Fourteen studies reviewed in this paper showed ten verified proteins, out of which six can be linked to immune response. Although neuroinflammation is a hallmark of MS, it is not specific for MS and its signatures have been shown in the CSF and plasma of individuals suffering from other neurodegenerative disorders. Haptoglobin, alpha-1-antichymotrypsin, Ig μ -chain C region, alpha-2-HS-glycoprotein/fetuin A, kallikrein-6, apolipoprotein D (ApoD) and chitinase 3-like protein 1 (CHI3L1) are almost uniformly detected in the CSF and plasma of individuals with all kinds of diseases, including

cancer. CHI3L1 is secreted by activated macrophages from viral infections (Ciborowski et al. 2007).

Another neurodegenerative disorder is HIV-1 Associated Neurocognitive Disorder (HAND). Despite the dramatic effect of antiretroviral treatment (ART) on slowing disease progression, HAND continues to be a major cause of HIV associated pathologies. This suggests that ART does not provide complete protection against neurological damage in HIV-infected brains. Laboratory measures of HIV-1 associated inflammation of the brain to determine HAND progression have been developed. Although valuable, these measures are not specific enough to be diagnostic at this time. Studies performed in non-human primate models with SIV infection did not lead to the discovery of much sought after biomarkers and only changes in relatively abundant proteins representing processes associated with many diseases have been observed (Wiederin et al. 2012). Taken together, results of this study provide an explanation as to why, despite convincing quantitative measures seen during biomarker discovery, protein candidates often fail during the subsequent validation phase. The authors propose that in chronic conditions, biological but not technical variance is a major obstacle in biomarker discoveries. Therefore significant changes of proteins with medium to high concentrations can be measured if such differences are high enough to exceed levels of natural fluctuations. The authors also envision that to overcome such a hurdle better correlates need to be made in improving experimental models, in system biologic statistical and computational approaches and in using better defined and more relevant clinical endpoints. It was encouraging to see that the same group showed changes in some of the same proteins such as geloslin and ceruloplasmin between humans and non-human primates (Pottiez et al. 2012).

Considering all obstacles related to neuroproteomic proteomic studies, questions arise as to which models are preferred. While there is no doubt that studies involving the intact nervous system are more relevant for elucidating mechanisms underlying neurodegenerative disorders, the use of proteomic profiling with in vitro culture models has many advantages. Ciborowski et al. proposed that proteomic profiling of secretome in in vitro HIV infected human macrophages may provide biomarker candidates to be measured directly in the CSF or plasma, omitting full unbiased profiling (Ciborowski et al. 2007).

In summary, the integration of proteomic profiling studies with in vitro, in vivo and ex vivo models can provide key insights on mechanisms of underlying pathologies.

54.8 Gene Arrays

Due to the established principle of making protein based on transcription of genomic DNA using mRNA as a messenger between chromosomes and ribosomes, gene arrays appear to

Table 54.3 Gene mutations associated with neurodegenerative diseases discovered using next generation sequencing approach

Disease	Gene	Mutation(s)	Effect on disease	References
Parkinson's disease	<i>VPS35</i>	Heterozygous p.Asp620Asn	Causative	Zimprich et al. (2011) and Vilarino-Guell et al. (2011)
Alzheimer's disease	<i>TREM2</i>	Heterozygous p.R47H	Increased risk (OR > 3)	Guerreiro et al. (2013) and Jonsson et al. (2013)
	<i>SORL1</i>	Heterozygous missense and nonsense	Potentially causative	Pottier et al. (2012)
Hereditary diffuse leukoencephalopathy with spheroids	<i>CSF1R</i>	Heterozygous missense, insertions and deletions all affecting the protein tyrosine kinase domain	Causative	Rademakers et al. (2012a)
Amyotrophic lateral sclerosis	<i>PFN1</i>	Heterozygous missense	Causative	Wu et al. (2012)
Autosomal-recessive cerebellar ataxia with spasticity	<i>GBA2</i>	Homozygous missense and nonsense	Causative	Hammer et al. (2013)

Source: Guerreiro R, Brás J, Hardy J, Singleton A. Next generation sequencing techniques in neurological diseases: redefining clinical and molecular associations. *Hum Mol Genet.* 2014, 23:R47–R53

be an indispensable link between genetic information and the functional product of genes—proteins. It was a surprise to discover that the human genome codes for only ~25,000 genes, that only approximately 75 % of the genome is transcribed into RNA, and that the majority of these RNA transcripts lack protein coding potential (Djebali et al. 2012), making them non-coding or ncRNAs. The relatively recent development of next-generation sequencing (Margulies et al. 2005; Shendure et al. 2005) revolutionized and advanced our knowledge about many diseases and allowed for the identification of new genes and genetic factors associated with diseases of the CNS. Data presented by Guerreiro et al. (Guerreiro et al. 2014) in Table 54.3 below shows examples of the impact next generation sequencing had on the identification of novel genes associated with neurodegenerative diseases.

Regardless of the fundamental importance of genomic experiments, this technology platform provides only initial and far from completed results. Proteomics, on the other hand, is a follow-up approach, and when results acquired from both technology platforms are combined, a more comprehensive picture of functional significance arises. Integration of these two experimental platforms is another challenge because of the complexity of systems biology. *First*, a bottom-up or a top-down strategy has to be chosen as an experimental strategy. *Second*, which part will be a driving force, genomics or proteomics? *Third*, an integrated bioinformatics platform has to be secured for complementary and coherent transformation of data into information. The ability to produce custom made DNA microarrays designed and manufactured by commercial entities and/or individual investigators to address specific biological question(s) would provide enormous support to such integrated strategies. Extensive literature can be found reviewing technical issues related to gene arrays including hybridization, post-hybridization quality control, normalization and data processing (Hartmann 2005; Boes and Neuhauser 2005; Reimers 2005). These specific tools allow for the performance of genomic experiments

based on results generated in initial proteomic studies (Soumelis et al. 2015) and our experience shows that experimental design and depth of data mining are critical.

Many more comprehensive or more focused studies have been performed to establish links between gene expression and neurodegenerative diseases in search of biomarkers. A thorough review of all these efforts would require a separate book, and therefore we will highlight here those of which we found to have an impact on our collective “-omics” knowledge. One such interesting study was performed by Tian et al. (Tian et al. 2014). The authors made very interesting comparisons between microarray data from patients with Sporadic Creutzfeldt-Jakob Disease (sCJD), Fatal Familial Insomnia (FFI), and Alzheimer's disease (AD). Based on principal component analysis, they identified commonalities between global gene expressions, thus supporting the idea that all neurodegenerative diseases have, to some extent, similar underlying mechanisms. Further bioinformatics analysis showed that signal transduction, synaptic transmission, and neuropeptide signaling pathways representing essential functions of the CNS are commonly affected in all three aforementioned diseases. A major weakness of this study was the limited number of samples; nevertheless, these data show the proof of principle that —omics technologies are indispensable in understanding the complexity of pathogenesis mechanisms and in searching for diagnostic and therapeutic biomarkers.

Recently, an interesting study of gene expression by microarray technology has been published by Durrenberger et al. (Durrenberger et al. 2015). The authors used 113 samples of post-mortem brains to create six study groups and controls of the following neurodegenerative disorders (NDs): Alzheimer's disease (AD), Huntington's disease (HD), Parkinson's disease (PD), multiple sclerosis (MS), and amyotrophic lateral sclerosis (ALS) and schizophrenia (SZ). The minimum number of samples in the diseased group was nine in the case of ALS. Bioinformatics data analysis showed that antigen

processing and presentation, cell adhesion, inflammatory response, regulation of cell proliferation, pattern specification process (referring to a developmental process), and response to drugs and nutrients and skeletal development were common for all six neurodegenerative disorders. The remaining genes, which were not included into these categories, were further grouped as signal transduction, angiogenesis, nervous system development, oxidation-reduction, apoptosis, and synaptic transmission ranging from 2 to 5 genes per category. Interestingly, the authors came to a conclusion that the molecular basis of the shared features in neurodegenerative diseases may not be as common as initially thought, which reinforced their view that each disease microenvironment is unique. Although the authors' assumption is experimentally substantiated, such a generalized conclusion should be taken with caution due to a lack of complementary proteomic studies.

In summary, it is now quite evident that all aspects of functional systems biology studies, including gene expression, mRNA and proteins with all PTMs, are essential for understanding molecular mechanisms underlying not only pathological processes, but developmental as well.

54.9 Proteomics and Tissue Profiling

With the current state of proteomic technology, tissue can be examined for global protein expression directly without time-consuming sample preparation. However, time required for data acquisition by scanning tissue section reminds significant. Can such profiling be used effectively in rapid clinical diagnostics to aid pathologists in their work? Can sections of tissue be placed on target, covered with matrix and profiled directly in mass spectrometers? Recent advancements indicate that regardless of limitations and challenges, this idea could lead to a breakthrough in modern clinical diagnosis in the near future (Jimenez and Verheul 2014; M'Koma et al. 2011).

Early attempts to develop patterns of specific compounds and proteins were based on tissue homogenates (Burns 1982; Jimenez et al. 1997; Mitchell et al. 1997). Tissue profiling, or more accurately called tissue imaging, based on direct mass spectrometry measurements is a younger area of research that began its development in the late 1990s when MALDI-MS measurements were performed on intact tissue sections (Chaurand et al. 1999). Techniques already well-established in proteomic workflows, such as microwave assisted and multi-enzyme digestion, have been adapted to tissue proteomics including FFPE and fresh tissue samples (Turiak et al. 2014).

MALDI-TOF mass spectrometers with high resolution and sensitivity reaching the attomolar range are the choice class of instrumentation for direct proteomic tissue analyses. In addition to proteins and peptides, this method allows for the detection of lipids, carbohydrates or glycoconjugates and

small molecules. Formalin-fixed paraffin-embedded (FFPE) tissue can also be investigated, making this approach an ideal tool for disease diagnostics as well as biomarker discovery. Since spectra are generated very fast, a wide range of masses are acquired. Hundreds and even thousands of spots can be analyzed using one tissue section, which is further processed by computers to create an image. Besides the high throughput of this type of analysis, a major advantage is that collected spectra can be linked to a location on the tissue section. Thus, molecules in question can be localized to tissue structures supplementing diagnosis based on histology, with immunohistology adding a molecular pathology component to histopathological diagnostics (Kriegsmann et al. 2014). This, in turn, is important for monitoring processes such as distribution of therapeutics, which can be small molecules as well as peptides and/or proteins. The remaining question to be addressed in tissue imaging is how important is structural analysis (peptide sequence, drug structure) of identified species since downstream processing of spectra is based on the presence, intensity, and signal-to-noise ratio data. Scattered presence of another molecule(s) with close molecular m/z (mass-to-charge ratio) can lead to misleading results. If the analyte's m/z is within 2000, identification based on sequencing can be performed in instruments equipped with post-source decay mode (Stoeckli et al. 2002). Another question deals with absolute quantitation, which is the weakness of MALDI-TOF comparing to other types of mass spectrometers. Nevertheless, meaningful information can be acquired if the system is properly validated. Despite the challenges discussed above, application of this advancing technology has resulted in reports on subjects such as classification of tumor samples using this technology platform (Chaurand et al. 1999) or single cell analysis (Li et al. 1999). More thorough reviews of this field that go beyond the scope of this chapter can be found on PubMed. Although certainly not limited to these, the following references give examples of such review papers published to date (Espina et al. 2009; Rodrigo et al. 2014; Lagarrigue et al. 2012).

54.10 Databases and Search Engines

Expression of proteins and genes on a global scale requires new and efficient tools for database searches and data analysis. Advancements in proteomics include the development of multiple search engines to determine how likely (or unlikely) a peptide sequence is represented by a particular mass list containing both precursor and fragment masses (Yates et al. 1995; Mann and Wilm 1994). Each search engine has inherent strengths and weaknesses and these must be considered when choosing which search engine(s) to use in processing data. We highly recommend using more than one search engine, particularly when data are search for PTMs. MASCOT, SEQUEST, Paragon used

by ProteinPilot™ and the more recently produced Andromeda, as part of MaxQuant, are the most widely used for database searches. Other search engines used less often include Protein Prospector, !XTandem or Spectrum Mill.

After an initial effort by many to create a universal protein database, an international consortium created the Universal Protein Resource (UniProt), which provides a comprehensive and freely accessible central resource of protein sequences and functional annotation (www.ebi.ac.uk/uni-prot/). UniProt consists of two sections: UniProtKB/Swiss-Prot, which is manually annotated and reviewed and UniProtKB/TrEMBL, which is automatically annotated and not reviewed. Despite this coordinated international effort, information included in protein databases is not complete and it is impossible to even estimate when, if ever, we will be able to claim victory of completeness.

Posttranslational modifications (PTM) occur in different biological contexts and therefore, complex protein mixtures extracted from biological samples invariably contain proteins carrying PTMs. The association of Biomolecular Resource Facilities lists 355 PTMs (<http://www.abrf.org/index.cfm/dm.home?AvgMass=all>). An additional level of complication is that PTMs can be heterogeneous, and therefore consist of various modifications present on the same peptide core. A good example of this are histones, which have a mosaic of PTMs dynamically changing in time as a result of their regulatory role (Burlingame et al. 2005). Variable modifications may or may not be present, e.g. phosphorylation of serine, threonine and tyrosine occurring in a percentage of the population of protein molecules. While searching for variable modifications is a powerful tool for identifying the PTMs, one needs to be cautious when specifying the number of variable modifications since adding even a single variable modification will generate more possible peptides to be searched against. If there are multiple modifiable residues within a single peptide, the workload for searching all the possible modification permutations could be exponentially increased.

Cells, their compartments and organelles (nucleus, mitochondria, endosomes etc.), as well as body fluids, are complex and dynamic systems comprising of multiple networks of interacting molecules: proteins, glycoproteins, glycolipids, nucleic acids, metabolites etc. Forming a better understanding of these systems and their mutual interactions and communications requires specific bioinformatics tools. This issue is further amplified by the amount of data/information accumulated in every experiment of high throughput analyses. A full understanding of interactions between different types of molecules such as DNA, RNA, and proteins in any biological system will require coordination of multiple experimental techniques at the same time, which will either require more sample or reduction of sample size for each individual test. Developing an application of micro fluidics in new analytical instrumentation will definitely facilitate miniaturization efforts in proteomics.

54.11 Review Questions/Problems

- Mathematical models of the molecular pathways in cells will facilitate:
 - (a) prediction of previously unknown interactions
 - (b) combining genomic and proteomic data
 - (c) discover novel proteins, cellular functions, and pathways
 - (d) *all of the above*
- Successful translation of results from laboratory to clinic depends on:
 - (a) exploratory research studies
 - (b) *validation*
 - (c) prospective screening studies on large-scale population
 - (d) *all of the above*
- Weakness of 2-dimensional SDS-PAGE is:
 - (a) *lack of superior reproducibility*
 - (b) lack of protection of proteins from structural de-stabilization
 - (c) inability of obtaining protein sequencing data
 - (d) lack of superior methods of protein labeling
- Major difficulty in proteomic studies of certain type of samples such as cerebrospinal fluid is:
 - (a) contamination with drugs penetrating through blood brain barrier
 - (b) *size and availability of the sample*
 - (c) lack of correlation with clinical diagnosis
 - (d) contamination with red blood cells during spinal tap
- Top-down approach in studies of systems biology is preferential over bottom-up approach because:
 - (a) it provides more global view
 - (b) it allows for faster conclusions which will lead to direct development of clinical tests
 - (c) requires less sophisticated technology and instrumentation
 - (d) *both approaches are equal*
- Major question to be addressed when considering application of genomics and proteomics to screening and testing include:
 - (a) selection of the mouse species
 - (b) selection of the non-radioactive reagents
 - (c) selection of the reputable provider of proteomics and genomics technologies
 - (d) *selection of conditions which are true reflections of in vivo biological function*
- Commercially available antibody arrays technology has several weaknesses. Major weakness is:
 - (a) problems associated with data analysis, interpretation, storage, and retrieval
 - (b) problems associated with high background created by not well developed reagents

- (c) problems associated with necessity of using radioactive materials
- (d) *problems associated with quality and standardization of antibodies*
- 8. What is the best approach to determine the sensitivity and specificity of the discussed methodologies, and to validate and standardize these technologies?
 - (a) to reduce “biological noise” in the samples and reduce number of replicates
 - (b) to link data obtained from database searches to biological effects via fast computers
 - (c) *to develop a standard approach to understanding and communicating variability in experimental data*
 - (d) none of the above
- 9. While planning proteomics experiments, a researcher should:
 - (a) have available all types of mass spectrometers
 - (b) mandatory access to protein microarrays
 - (c) *be aware of strength and weaknesses of each technology*
 - (d) always be an expert in statistics and computer programming for solving problems associated with bioinformatics
- 10. Neuroproteomics analysis is most conclusive when
 - (a) experiments are done using entire brain so that all cell types are used in one assay
 - (b) only in vitro models are conclusive
 - (c) *selected types of cell from brain are obtained and manipulated*
 - (d) two or more cell types are mixed together to facilitate interaction mimicking in vivo situation

Abstract

Pharmacogenomics is the study of the role of genetic variations in drug response. In the study of pharmacogenomics, one can relate variations in drug exposure and/or drug response (pharmacology) to the variations in genes (genomics). An administered drug may fail to work for one patient, but show the expected result for another. In some cases a drug may work well for a larger group of patients, while causing a subset of patients to experience unexpected or severe side effects. These adverse drug reactions can be harmful and sometimes deadly. Factors such as the environment, diet, age, lifestyle and co-morbid conditions all may influence the individual's response to drugs. Each is covered in this chapter with an eye towards how best to administer drug to individual patients.

Keywords

Gene variants • Metabolizers • Neurodegenerative • Pharmacogenomics

55.1 Introduction

Since the beginning of medical practice, different individuals respond differently to the same drug (Roden and George 2002). In line with this idea, several studies have shown that genetic variability clearly has implications for both drug safety and efficacy (Li et al. 2011). Neurodegenerative diseases are complex disorders of neurons, that include genetic, epigenetic, and environmental factors, and are characterized by the deterioration of higher activities of the central nervous system. Over 60 % of Alzheimer disease (AD) risk is estimated to be a result of genetic factors; several genes have been associated

with AD pathogenesis and neurodegeneration (Gatz et al. 2006; Eisenstein 2011). Studies have shown that patients with AD respond to drug treatment depending on which of the three genetic variants of the apolipoprotein E gene a person carries (Guerreiro et al. 2012; Cacabelos 2008; Choi et al. 2008). Genes involved in the absorption, distribution, metabolism and excretion of drugs, and various drug target genes make up the most important genetic determinants (Ma et al. 2002). The pharmacologic treatment of neurodegenerative diseases has seen some progress, but more effort needs to be made to understand the genetic components and the genome-drug interactions. In this chapter, we will review the roles of several defective genes involved in neurodegenerative diseases and correlate them with the clinical outcomes.

55.2 Classifications of Anti- Neurodegenerative Drugs in Various Disease Phenotypes

Neurodegenerative diseases include AD, multiple sclerosis (MS), Parkinson's disease (PD), Huntington's disease (HD), and amyotrophic lateral sclerosis (ALS).

55.2.1 Alzheimer's Disease

Alzheimer's disease (AD) is one of the most common causes of dementia among the aging population, and is characterized by declining cognitive failure, loss of communication and thinking capabilities. AD has become a major health challenge in both developed and developing countries (Gatz et al. 2006). Memory impairment is an integral feature of AD and is often the initial symptom. Deficits in other cognitive domains may occur with or after the onset of memory impairment. Language function and visual-spatial skills tend to be affected relatively early on, while loss of executive function and changes in personality and behavior generally occur later in the disease course. The pattern of memory impairment in AD is distinctive; deterioration in ability to remember facts and events is a cardinal feature. Neuropathologic findings include extracellular amyloid plaques, intracellular neurofibrillary tangles, synaptic deterioration, and neuronal death (Mathisen 2003). Amyloid plaques result from accumulation of β -amyloid peptides (A β). A β is an amino acid peptide formed by proteolytic cleavage of amyloid precursor protein (APP) by beta- and gamma—secretase (Mathisen 2003). Tau, a protein involved in microtubule assembly, is critical for normal axonal growth and neuronal development. Hyper-phosphorylated tau protein aggregates into helical filamentous neurofibrillary tangles that are deposited within neurons. Death of neurons in critical locations in the brain leads to a deficiency of acetylcholine, a neurotransmitter important for memory (Hellstrom-Lindahl 2000). Familial AD occurs earlier in life and involves mutations in genes involved in the processing of APP including *presenilin 1* and *presenilin 2*, whereas the risk for late onset AD is mostly influenced by apolipoprotein E (*APOE*) gene (Guerreiro et al. 2012). According to the Alzgene database, among hundreds of genes associated with AD, the top ten are *APOE* (19q13.2), *BINI* (2q14), *CLU* (8p21–p12), *ABCA7* (19p13.3), *CRI* (1q32), *PICALM* (11q14), *MS4A6A* (11q12.1), *CD33* (19q13.3), *MS4A4E* (11q12.2), and *CD2AP* (6p12) (Cacabelos et al. 2014). Other genes associated with AD are included in Table 55.1.

The US Food and Drug Administration (FDA) has approved four drugs for the treatment of AD: donepezil, rivastigmine, galantamine and memantine. Donepezil, rivastigmine and galantamine are cholinesterase inhibitors which are therapeutically active in ameliorating the clinical pathologies of mild to moderate AD (Loveman et al. 2006). Inhibition of acetylcholinesterase, the enzyme responsible for the destruction of acetylcholine, increases the availability of acetylcholine. Memantine is a noncompetitive N-methyl-D-aspartate receptor antagonist that is approved for the treatment of moderate to severe AD. Glutamate activation at the NMDA receptor is needed for learning and memory processes in the brain. Glutamate is the dominant excitatory amino acid in the brain, and stimulates NMDA receptors. This in turn leads to increased intraneuronal concentrations of calcium. Excessive

glutamate, and therefore calcium, in the CNS may cause neuronal damage. Blockade of NMDA receptors by memantine slows the intracellular calcium accumulation and helps to prevent further nerve damage (Danysz and Parsons 2003). A higher dose of donepezil, with or without memantine was approved to treat moderate to severe AD (Cummings et al. 2013). However, these drugs have different pharmacokinetic and pharmacodynamics profiles with donepezil having a relatively longer half-life ($t_{1/2}$) of 70 h than galantamine ($t_{1/2}$ =6–8 h) and rivastigmine ($t_{1/2}$ =1–2 h), whereas memantine has a ($t_{1/2}$ =60–70 h) (Noetzli and Eap 2013). Studies have shown that the combination therapy of memantine and acetylcholinesterase inhibitors in patients with AD may be associated with benefits of slowing cognitive impairment and preventing the onset of agitation and aggression (Shao 2015; Gareri et al. 2014). Hepatic CYP2D6 and CYP3A4 are

mainly responsible for the metabolism of donepezil and galantamine, whereas rivastigmine, a potent, selective inhibitor of brain acetylcholinesterase (AChE) and butylcholinesterase (BChE), is metabolized in liver and intestine independent of CYP450 system. Reports show that polymorphisms in genes involved in the cholinergic system including acetylcholinesterase, butylcholinesterase, choline acetyltransferase and paraoxonase are involved in the clinical response to AChE inhibitor (Noetzli and Eap 2013).

55.2.2 Multiple Sclerosis

Multiple Sclerosis (MS) is a common neurodegenerative disease that typically affects young adults to mid age group. It is a **demyelinating disease** in which the **insulating covers** of **nerve cells** of the **brain** and **spinal cord** are damaged. It is mediated by T-cell autoimmunity whereby these cells migrate across the blood brain barrier, and subsequently induce inflammatory responses resulting in myelin destruction, oligodendrocyte destruction, axonal breakdown, and gliosis in the central nervous system (Tsareva et al. 2016). MS is characterized by clinical features including fatigue, paralysis, visual field impairments, chronic pain and cognitive changes. Most MS patients experience a relapsing-remitting disease form characterized by varying periods of disease intensity and with time progress to a steady progression of symptoms known as secondary progressive MS. When disease is characterized by rapid increase in disability rate, it is known as primary progressive MS. Over 100 genetic risk factors have been associated to MS, but the class II region of the human leukocyte antigen (HLA)-DRB1*15:01, encoded within the major histocompatibility complex has been shown to be the largest contributing genetic risk component (Hollenbach and Oksenberg 2015). Both HLA and non-HLA genes have been associated to the genetic susceptibility of MS. Treatment options for MS are very wide because the FDA has approved several disease modifying therapies (DMTs) with proven efficacies compared with placebo in preventing relapses associated with MS (English and Aloï 2015). The list of DMTs include interferon beta (IFN β), glatiramer acetate, tumor necrosis factor inhibitors etanercept and adalimumab; fingolimod, mitoxantrone, natalizumab, teriflunomide, dimethyl fumarate, peginterferon- β -1a and alemtuzumab. Interferon injectables and glatiramer acetate were the first FDA approved DMTs that specifically decrease disease activity and are still considered first-line treatments for relapsing-remitting forms of MS due to their desired long term safety and efficacy profiles (English and Aloï 2015). Studies have identified some gene variants that are associated with therapy response. However, HLA class II genes which are the major MS susceptibility genes, showed associations with glatiramer acetate but not with IFN β . Some of those results for IFN β and glatiramer acetate are highlighted in Table 55.2.

55.2.3 Parkinson's Disease

Parkinson's disease (PD) is a neurodegenerative disorder that results in selective loss of dopamine neurons in the substantia nigra. Dopamine is a catecholamine formed in the body by the decarboxylation of dopa; it is an intermediate product in the synthesis of norepinephrine, and acts as a neurotransmitter in the central nervous system. PD is characterized by several clinical extrapyramidal features: resting tremor, rigidity, bradykinesia, postural instability, and freezing. PD has a low incidence among Asians and Africans as opposed to Caucasians. The various targets of anti-parkinson drugs are dopamine receptors (DR), dopamine transporter (DAT), catechol-O-methyltransferase (COMT) and monoamine oxidase B (Table 55.3). Levodopa (*L*-dopa) is the gold standard for Parkinson disease therapy and is highly effective when given in combination with a dopa-decarboxylase inhibitor (carbidopa). This combination reduces the decarboxylation of levodopa to dopamine outside of the blood-brain barrier, thereby allowing more efficient dosing of levodopa. Dopamine receptors are proteins on the surfaces of certain cells that bind specifically to the neurotransmitter dopamine. Stimulation of these receptors on vascular epithelial cells in the brain by dopamine cause the cerebral arteries to dilate, resulting in increased flow of blood. The dopaminergic system consists of the vital dopamine receptors (DR)

Table 55.3 Genes and their polymorphisms associated with Parkinson's disease. Table adapted from Drozdik et al. (2013)

Gene	Polymorphism
Levodopa	<i>DRD2</i> rs1800497(<i>TaqIA</i>)
	<i>DRD3</i> rs6280(<i>Ball</i>), rs4646996(<i>MspI</i>)

which are classified in five categories, namely D1–D5, which are co-expressed at various levels in the CNS and peripheral tissues and are located at chromosome 5, 11, 3, 11 and 4, respectively. The following polymorphisms may affect anti-parkinson drug therapy. *DRD1* genetic polymorphism includes −48 A>G (D1.1; B1/B2) and 1403 T>C (D1.7; C1/C2), *DRD2* with *TaqIA* located in kinase *ANKK1* (ankyrin repeat and kinase domain containing 1), *DRD3* associated with Ser9Gly (or *MscI* or *Ball*), which in turn is responsible for the insertion of *DRD3* receptor membrane and subsequent intracellular signal transduction. The different susceptible loci are the familial atypical forms of PD including *SNCA* (*PARK1*), *LRRK2*, *PRKN* (*PARK2*), *PINK1* (*PARK6*), *DJ-1* (*PARK7*), and recently *ATP13A2* (*PARK9*), *PLA2G6* (*PARK14*) and *FBX07* (*PARK15*). Sporadic PD is associated with common genetic variants such as N-acetyltransferase 2 (*NAT2*), monoamine oxidase B (*MAOB*), glutathione transferase (*GST*), mitochondrial tRNA, S18Y variant of ubiquitin carboxy-terminal hydrolase L1 (*UCHL1*), Rep variant of alpha-synuclein (*SNCA*) and tau (*MAPT*)H1 haplotype and leucine-rich repeat kinase-2 (*LRRK2*). Other newly recognized loci have been identified using GWAS namely; *BST1*, *GAK*, *HLA-DR*, *ACMSD*, *STK39*, *MCCC1/LAMP3*, *SYT11*, *PARK16*, *FGF20* and *GPNMB*. However, the anti-PD drugs targeting the motor systems lose their efficacy over time due to the emergence of side effects such as dyskinesias and psychosis. The genes and their SNPs that induced dyskinesias are *DRD2* with 9 polymorphisms (*TaqIA*, *TaqIB*, *TaqID*,

Table 55.4 Lists of some genes and their genomic locations associated with ALS. Table adapted from Cady et al. (2015) and Renton et al. (2014)

Gene name	Genomic location

<i>SQSTM1</i>	5q35
<i>VAPB</i>	20q13

Val96Ala, Leu141Leu, Pro310Ser, Ser311Cys, A>G231, −141C ins/del), *DRD3* with 2 (Ser9Gly, *MspI*), *DRD4* with 3 (48-bp VNTR, 13-bp repeat, 13-bp deletion) and 40-bp VNTR in *DET* gene. Among the *COMT* gene polymorphism Val158Met; (rs4680) is the most elaborately studied one and correlation with dyskinesia has been found (Payami and Factor 2014; Drozdik et al. 2013).

55.2.4 Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease, is a rapidly progressive, invariably fatal neurological disease that attacks the nerve cells responsible for controlling voluntary muscles, and belongs to a group of disorders known as motor neuron diseases, which are characterized by the gradual degeneration and death of motor neurons. In the vast majority of all ALS cases (more than 90%), the disease occurs apparently at random with no clearly associated risk factors. The remainder is hereditary. The familial form of ALS usually results from a pattern of inheritance that requires only one parent to carry the gene responsible for the disease. Mutations in superoxide dismutase 1(*SOD1*) have been identified as the highest genetic risk factor to cause familial ALS. Other genes that have been linked to familial cases of ALS include *TARDBP*, *VCP*, *C9ORF72*, and *FUS*. It is important to note that these genes are associated with familial ALS and also to a smaller degree to sporadic ALS (Renton et al. 2014). Other genes such as *IMPG2*, *TBK1*, *ANO9*, *LGALS1*, *CRLF3*, *DNMT3A*, *GPR158*, *GREB1L* with their coding variants are among the top ALS associated genes (Cirulli et al. 2015; Cady et al. 2015). Prevalence of variants in other ALS-associated genes are listed in Table 55.4.

Although more than 20 genes have been identified to be associated with ALS, effective treatment is still under inves-

tigation. The only licensed drug for ALS is riluzole. Riluzole has several pharmacological properties, but its precise mode of action is unclear. Riluzole seems to interfere with the damaging effects of excitatory amino acids, mainly glutamate, caused by excessive stimulation motor neurons nerve cells. Postulated mechanisms for this effect include the inhibition of glutamate release, blockade or inactivation of voltage-dependent sodium channels, and/or an inactivation of a G-protein mediated pathway (Cifra et al. 2013).

55.2.5 Huntington's Disease

Huntington's disease (HD) results from genetically programmed degeneration of neurons in certain areas of the brain. This degeneration causes uncontrolled movements, loss of intellectual faculties, and emotional disturbance. HD is a familial disease, passed from parents to children through a mutation in the huntingtin gene (*Htt*). Each child of an HD parent has a 50–50 chance of inheriting the HD gene. The involuntary movements associated with this disorder have been described as “chorea”. A 2006 systematic review of clinical studies evaluating pharmacologic treatments for HD concluded that the typical neuroleptics, haloperidol and fluphenazine, were possibly useful for treating chorea in patients with HD (Bonelli and Wenning 2006). Neuroleptics (anti-psychotic medications) act by blocking dopamine transmission. Tetrabenazine is a selective, reversible, centrally-acting dopamine depleting drug that works by inhibiting vesicular monoamine transporter 2 (VMAT2). Tetrabenazine depletes presynaptic dopamine, norepinephrine, and serotonin storage and antagonizes post-synaptic dopamine receptors. In vitro data indicate that tetrabenazine exhibits a weak binding affinity at the dopamine-2 receptor. Clinically, tetrabenazine improves the hyperkinetic movement disorder symptoms associated with HD (Chen et al. 2012). One of the earlier theories of the pathology of the disease is the formation of intracellular inclusion bodies due to the aggregation of mutant Huntington protein, which in turn binds and sequesters proteins and transcription factors that dysregulate the normal transcriptional activities (Fig. 55.1). Different pathways and the concerned genes such as neurotransmitter receptors, G-protein coupled receptor signaling, calcium signaling and homeostasis, neurotrophin receptor signaling, ubiquitin-proteasome system that are dysregulated in the HD has been listed in Table 55.5. Other systems that influence the genetic pathways of the disease are retinoid signaling, lipid metabolism, transcription and chromatin remodeling, and synaptic transmission. Genes of these pathways have altered expression levels that lead disease pathologies. Researchers have also found that histone deacetylase (HDAC) inhibitors might have a positive effect in the reversal of the Huntington-related gene (Chen et al. 2012; Seredenina and Luthi-Carter 2012).

55.3 Role of Genetic Variations in Cytochrome P450 Drug Metabolizing Enzymes

Most of the CNS drugs are metabolized by enzymes of the cytochrome P450 (CYP) family. The genes encoding *CYP2D6* and *CYP3A4* isoenzymes have a high degree of polymorphism leading to marked variability in the activity of the encoded enzymes. There is a high level of allelic variation in different ethnic groups that have been linked to inter-individual differences in drug response (Seripa et al. 2010).

55.3.1 CYP2D6

The *CYP2D6* gene (cytochrome P450, family 2, subfamily D, polypeptide 6) lies at locus 22q13.1 (Gough et al. 1993) and is involved in the metabolism of an estimated 25 % of all drugs (Wang et al. 2009). The CYP2D6 enzyme catalyzes the oxidative metabolism of over 100 clinically important and commonly prescribed drugs, such as cholinesterase inhibitors (tacrine, donepezil, galantamine), antidepressants, neuroleptics, opioids, class I anti-arrhythmics, analgesics and many other drug categories, acting as substrates, inhibitors or inducers with which cholinesterase inhibitors may potentially interact (Cacabelos 2008). Cholinesterase inhibitors are the first line symptomatic therapy for AD which increase active levels of acetylcholine in the synaptic cleft by inhibiting the enzymes that degrade acetylcholine (Mayeux 2010). Tetrabenazine, the first FDA-approved drug for the management of HD-associated chorea, is a monoamine storage inhibitor extensively metabolized by the hepatic CYP2D6 to its primary active metabolite, alpha-dihydroxytetrabenazine (Mehanna et al. 2013). More than 100 allelic variants of CYP2D6 have been identified with the enzyme activities ranging from deficient (poor metabolizers, PM), intermediate (intermediate metabolizers, IM), normal (extensive metabolizers, EM) to increased enzymatic activity (ultrarapid metabolizers, UM) with frequencies ranging from 5–10 %, 10–17 %, 70–80 %, 3–5 % respectively in Caucasian populations. PM have little or no CYP2D6 function because they have two null alleles and therefore unable to use the CYP2D6-dependent metabolic pathway for drug elimination. The most common variants associated with PM phenotype are *CYP2D6*3*, *CYP2D6*4*, *CYP2D6*5*, and *CYP2D6*6* in Caucasians, *CYP2D6*10* in Asian, and *CYP2D6*17* in Africans (Bradford 2002; Zhou 2009). The IMs metabolize drugs at a rate somewhere between the poor and extensive metabolizers whereas those classified as EMs have one or two alleles with normal CYP2D6 function. Expression of UM genes leads to greater than normal CYP2D6 function. Consequently, drugs are metabolized rapidly in UMs, causing decreased efficacy,

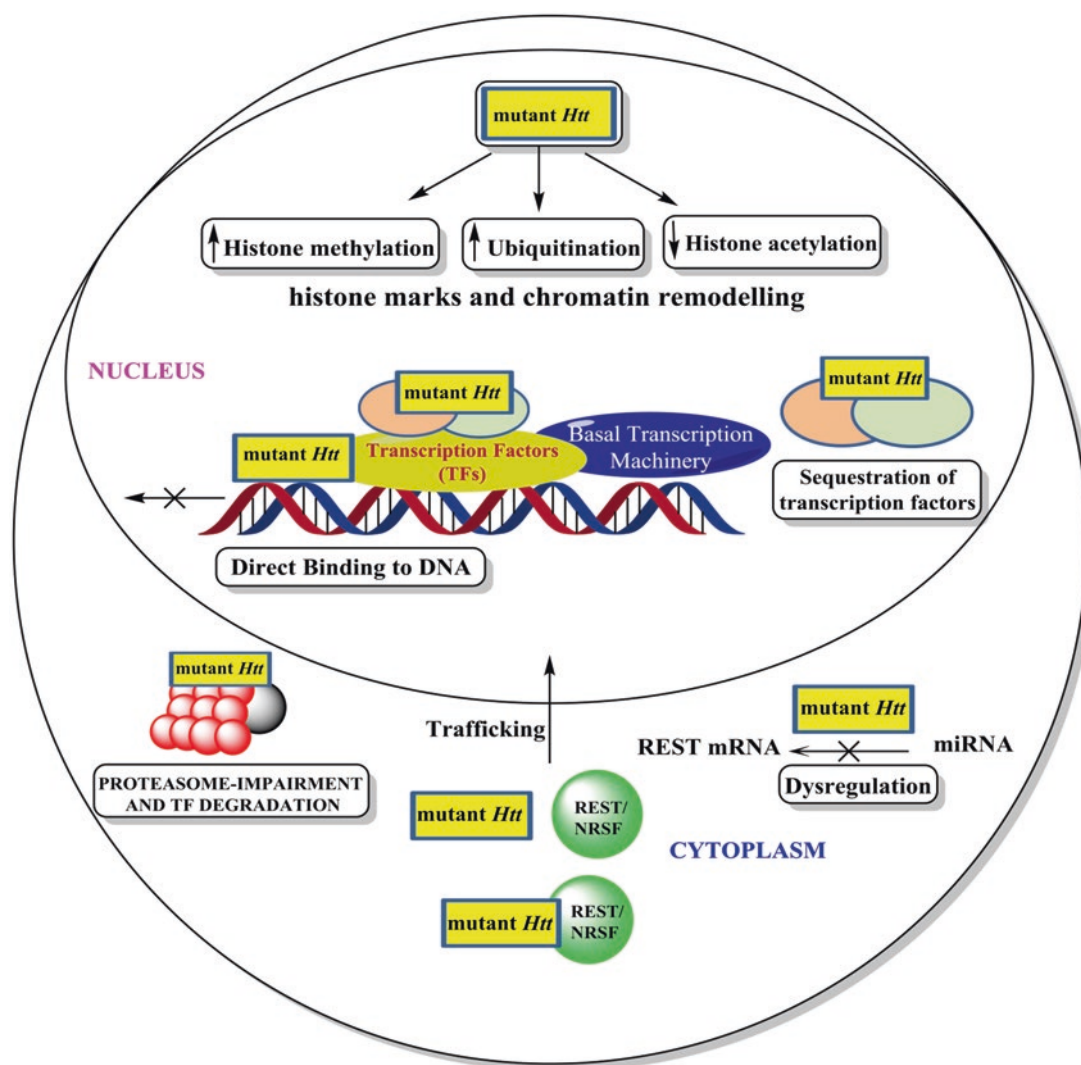

Fig. 55.1 Schematic representation of genetic dysregulation in Huntington's disease (Seredenina and Luthi-Carter 2012). *Htt* Huntingtin gene, *TFs* transcription factors, *REST/NRSF* RE1-silencing transcription factor/neural-restrictive silencer factor

Table 55.5 Lists of genes dysregulated in HD and their associated genetic pathways. Table adapted from Seredenina and Luthi-Carter (2012)

Genetic pathways	Genes dysregulated in HD

whereas slow metabolism of drugs in PMs causes toxicities owing to drug accumulation (Noetzli and Eap 2013).

The CYP2D6 enzyme is the major enzyme involved in the hepatic metabolism of donepezil to its active metabolite 6-O-desmethyldonepezil (Varsaldi et al. 2006). Donepezil is an inhibitor of acetyl cholinesterase, and is currently used for the symptomatic treatment of mild-to-moderate AD. Studies show that when administered with or without food, donepezil is well absorbed with a bioavailability of almost 100% (Cacabelos 2008; Seripa et al. 2011; Benjamin and Burns 2007; Varsaldi et al. 2006). Studies have also shown that functional polymorphisms in the CYP2D6 gene may affect enzyme activity and thus, the metabolism of donepezil, indicating that the plasma concentration of donepezil is dependent on CYP2D6 polymorphism (Pilotto et al. 2009; Varsaldi et al. 2006). In the general population, EMs account for 55.71%, IMs for 34.7%, PMs 2.28%, and UMs 7.31% whereas in AD, EMs, IMs, PMs, and UMs account for 56.38%, 27.66%, 7.45%, and 8.51%, respec-

Table 55.6 Summary of pharmacogenetic studies on anti-dementia drugs. Table adapted from Noetzli and Eap (2013)

Drug	Gene, variant	Number of patients	Results
Donepezil	CYP2D6	108	Significantly decreased clearance in PMs, increased clearance in UM compared with EMs
	Predicted phenotype		
	CYP2D6	94	EMs and IMs best responders in a combination therapy of donepezil with citicoline paracetamol and nicergoline
	Predicted phenotype		
	CYP2D6	127	Significant higher frequency of the G-allele, associated with a higher enzyme activity, in non-responders than in responders
	rs1080985 C>G		
	CYP2D6	57	Significant higher frequency of alleles conferring decreased or absent enzyme activity in responders than in non-responders
	16 functional SNPs		
	CYP3A	54	Genetic variants have no influence on plasma concentration and treatment outcome
	CYP3A4/CYP3A5 alleles		
	APOE	286	No significant influence of the APOE genotypes on treatment response
	ϵ 2, ϵ 3, ϵ 4		
	APOE	40	APOE ϵ 4 carriers demonstrated a poorer response on the AD Assessment Scale-Jcog score after 3 years of therapy
	ϵ 2, ϵ 3, ϵ 4		
	APOE	81	Better response in APOE ϵ 4 carriers in specific cognitive domains and on mini-mental state examination score
	ϵ 2, ϵ 3, ϵ 4		
Galantamine	CYP2D6	356	The population pharmacokinetic model indicates a reduced clearance in PMs compared with EMs
	Predicted phenotype		
	CYP2D6	27	Significantly increased plasma concentrations in PMs compared with EMs
	Predicted phenotype		
	APOE	202	No significant influence of the APOE genotypes on treatment response
	ϵ 2, ϵ 3, ϵ 4		
Rivastigmine	APOE	214	No significant influence of the APOE genotypes on treatment response
	ϵ 2, ϵ 3, ϵ 4		
Donepezil, rivastigmine	BCHE	114	Wild-type carriers showed better response to rivastigmine than to donepezil, whereas the treatment response was similar within carriers of the variant allele
	rs1803274		
Menantine	SNPs in SLC22A1/2/5,	108	NR1I2 rs1523130 significantly affected memantine clearance, with carriers of the CT/TT genotypes presenting a slower elimination than carriers of the CC genotype
	SLC47A1, ABCB1, NR1I2,		
	NR1I3, PPAR		

tively. The therapeutic response to conventional drugs in patients with AD is genotype-specific, with *CYP2D6*-PMs, and *CYP2D6*-UMs having the worst drug response (Cacabelos et al. 2012). Studies investigating the relation between clinical response to donepezil and a common variant (rs1080985) of *CYP2D6*, confirmed that rs1080985 is associated with poor response to the drug (Albani et al. 2012). Recently, studies have shown that *CYP2D6* is present in neurons in numerous human brain areas, including the thalamus, hypothalamus, hippocampus, substantia nigra, cerebellum, and in several layers of the frontal neocortex (Dutheil et al. 2009). The enzyme was implicated in metabolism of the endogenous compounds 5-methoxytryptamine, anandamide, progesterone and tyramine and in generation of serotonin and dopamine from trace amines; these findings raise questions about its potential role in the function of these neurons (Miksys and Tyndale 2013). The hypothesis that *CYP2D6* may have a role in the brain was strengthened by

a transgenic mouse model study: *CYP2D6* expression in the brain was associated with higher levels of serotonin measured in several brain regions, including the cerebellum and hippocampus (Cheng et al. 2013) (Table 55.6).

55.3.2 The Cytochrome P450 (CYP) 3A4 Gene

The *CYP 3A4* gene (cytochrome P450, family 3, subfamily A, polypeptide 4) lies at locus 7q21.1. The *CYP3A* gene includes a cluster of *CYP3A4*, *CYP3A5*, *CYP3A7*, *CYP3A43* and two pseudogenes named *CYP3A5P1* and *CYP3A5P2* (Seripa et al. 2010). These genes encode monooxygenases that catalyze many reactions involved in drug metabolism and synthesis of cholesterol, steroids and other lipids. The *CYP3A4* is the predominant hepatic form that demonstrates a large inter-individual variability in expression and activity,

and is involved in the metabolism of acetylcholinesterase inhibitors donepezil, and galantamine (Lamba et al. 2002; Noetzli et al. 2013). In a small study that evaluated the impact of CYP3A4 and CYP3A5 allele variants on donepezil plasma concentration and clinical outcome, there was no association.

55.4 Role of Defective Genes in Apolipoprotein E

Apolipoprotein E (*APOE*) gene mediates cholesterol metabolism in an isoform-dependent manner and is involved in lipid transport and injury repair in the brain involving beta-amyloid proteins (Eisenstein 2011). The human *APOE* gene is polymorphic, and has three allelic variants namely $\epsilon 2$, $\epsilon 3$ and $\epsilon 4$ at a frequency of 11 %, 72 % and 17 % respectively, and five common genotypes 2/3, 3/3, 2/4, 3/4, and 4/4 (Farrer et al. 1997; Guerreiro et al. 2012). The *APOE* gene has been shown to be the main genetic determinant of late-onset AD risk (Saunders et al. 1993; Bertram et al. 2007). Genome-wide association studies (GWAS) have repeatedly shown that the $\epsilon 4$ allele is the strongest known genetic risk factor for AD. Patients were found to respond to drug treatment depending on which of the $\epsilon 2$, $\epsilon 3$ or $\epsilon 4$ genetic variants of the *APOE* gene a person carried. Studies showed that individuals with the *APOE* $\epsilon 4$ allele relative to those without the *APOE* $\epsilon 4$ allele have at least a twofold risk for developing AD (Tang et al. 1998). Generally, those carrying the $\epsilon 4$ allele are at increased risk of AD compared with those carrying the more common $\epsilon 3$ allele, whereas the $\epsilon 2$ allele has been shown to decrease the risk (Liu et al. 2013; Eisenstein 2011). The *APOE* $\epsilon 4$ allele frequency was found to be significantly higher in the AD groups compared with the control group (Tsuang et al. 2013). Studies further indicate that *APOE* $\epsilon 4$ carriers preferentially benefit from receiving acetylcholinesterase inhibitors (tacrine, donepezil, galantamine, and rivastigmine) as AD treatment that improve their cholinergic deficit (Hanson et al. 2015). Other studies indicate that the presence of the *APOE* $\epsilon 4$ allele differentially affects the beneficial outcome and level of drug sensitivity in AD patients treated with neuroprotective compounds, nootropics (“smart drugs” or “memory enhancers”), endogenous nucleotides (CDP-choline), immunotrophins (such as Polypodium leucotomos: anapsos), neurotrophic factors (cerebrolysin), rosiglitazone, or combination therapies (Cacabelos et al. 2012; Cacabelos 2009). The presence or absence of *APOE* $\epsilon 4$ allele modifies treatment response to a wide variety of therapeutics therefore its role is very important and should be carefully considered when clinical studies are being conducted for future drug optimization.

AD is a complex disorder involving many different gene clusters. However several studies have shown that the *APOE*

gene seems to be a major risk factor for both degenerative and vascular dementia. *APOE*-4/4 carriers show a faster disease progression and a poorer therapeutic response to all available treatments than any other polymorphic variant. Studies analyzing the therapeutic response of AD patients with both the *APOE* and *CYP2D6* genes showed that it is genotype specific, with *CYP2D6*-PMs, *CYP2D6*-UMs, and *APOE*-4/4 carriers categorized as the worst responders. This indicates that *APOE* and *CYP2D6* may influence each other, as pleiotropic genes, in the metabolism of drugs and hepatic function. It has been observed that liver metabolism and transaminase activity were affected differently depending on whether patients were *APOE*-4/4 carriers or not. Therefore *APOE* may influence liver function and drug metabolism by modifying hepatic steatosis and transaminase activity (Cacabelos 2008, 2009).

55.5 Role of Acetylcholinesterase Inhibitors

Acetylcholinesterase (AChE) is an enzyme found mainly in neuromuscular junctions and cholinergic brain synapses that is involved in hydrolyzing the neurotransmitter acetylcholine into acetate and choline, thereby terminating neurotransmission. In humans, AChE and butyrylcholinesterase (BChE) are the two major forms of cholinesterase enzymes. Donepezil, galantamine, and rivastigmine are AChE inhibitors that prevent hydrolysis of acetylcholine, and are commonly used for the treatment of AD (Noetzli and Eap 2013). Donepezil is a potent non-competitive and reversible AChE inhibitor and functions by increasing the acetylcholine levels that are available for synaptic transmission in the central nervous system. Donepezil is the most widely used drug for mild to moderate to severe AD treatment. When donepezil is administered orally, over 90 % undergoes first-pass metabolism by the *CYP2D6* enzyme leading to one active metabolite, 6-O-desmethyldonepezil and several inactive metabolites. The active metabolite of donepezil 6-O-desmethyldonepezil has a half-life of about 70 h, easily crosses the blood brain barrier and is slowly excreted from the body (Noetzli and Eap 2013; Benjamin and Burns 2007; Seripa et al. 2011; Cummings et al. 2013). Studies analyzing an effect of *CYP2D6* gene variants on treatment response show that it is genotype specific, and patients with *CYP2D6*-PMs and *CYP2D6*-UMs were categorized as the worst responders. The pharmacokinetic profiles of these patients showed significantly decreased drug clearance in PMs and increased clearance in UM when compared with EMs (Noetzli and Eap 2013; Benjamin and Burns 2007; Seripa et al. 2011; Varsaldi et al. 2006; Pilotto et al. 2009). A study investigating the effect of *CYP2D6**10 and *APOE* polymorphisms on both steady state plasma concentrations and clinical response of donepezil in patients with mild-to-moderate AD found that patients with mutant allele (*10)

in *CYP2D6* gene may respond better to donepezil than those with wild allele (*1) (Zhong et al. 2013). However they did not find any relationship between *APOE* ϵ 4 status and the efficacy of donepezil. Recently, studies analyzing the influence of *CYP2D6* and *APOE* polymorphisms on the therapeutic effect of donepezil in patients with mild-to-moderate AD showed no significant differences between responders and nonresponders (Klimkowicz-Mrowiec et al. 2013; Liu et al. 2014). Other studies looking at the *APOE* gene variants showed that *APOE* ϵ 4 carriers displayed worst treatment response (Cacabelos et al. 2012), whereas the *CYP3A* genetic variants showed no influence on plasma concentration and treatment outcome (Noetzli and Eap 2013). These results encourage a continued evaluation of the role of various polymorphisms in response to donepezil treatment in different ethnic groups, and to assess other genetic variants of *CYP2D6*.

Galantamine is a competitive, rapidly-reversible AChE inhibitor that functions by increasing the acetylcholine levels at cholinergic synapses. It also interacts with the nicotinic acetylcholine receptor at binding sites separate from those for AChE, and may increase the levels of glutamate and serotonin. Galantamine is metabolized primarily by O-demethylation by *CYP2D6*, then O-oxidation by *CYP3A4* and glucuronidation. Studies investigating the clinical effectiveness and tolerability of galantamine with respect to plasma concentrations and *CYP2D6* polymorphisms showed that *CYP2D6* PMs displayed 45 % and 61 % higher dose-adjusted plasma concentrations than *CYP2D6* hetEMs and homEMs, respectively (Noetzli et al. 2013). However, other studies have failed to find any significant influence of the *CYP2D6* or *APOE* genotypes on galantamine treatment response (Clarke et al. 2011) (Noetzli and Eap 2013).

Rivastigmine is a non-competitive and very slowly reversible AChE inhibitor. The metabolism of rivastigmine is primarily by esterases in both the liver and the intestinal tract to an inactive and non-toxic metabolite NAP226-90. It is the only AChEI that inhibits both BuChE and AChE. This is an important aspect for selectivity since the activity of AChE is higher in the CNS, and the BChE activity is higher in the periphery; additional inhibition of BChE might be beneficial (Noetzli and Eap 2013). It has a bioavailability of 40 % and a half-life of about 2 h. In order to investigate the clinical efficacy and safety of rivastigmine for patients with AD, a database of double-blinded, randomized, controlled trials were analyzed and results point that rivastigmine improved the rate of decline of cognitive function, activities of daily living, and severity of dementia for people with mild to moderate AD in comparison with placebo (Birks and Grimley Evans 2015).

55.6 Personalized Medicine in Neurodegenerative Diseases

55.6.1 Potential Therapeutic Benefits

Personalized medicine in pharmacogenomics focuses on the ability to predict how a patient would respond when a drug is administered. In recent years, the US Food and Drug Administration (FDA) has aggressively pursued drug-label modification when studies have shown that excess risk can be convincingly linked to a genetic marker. Several examples are listed in the FDA's Table of Pharmacogenomic Biomarkers in Drug Labels <http://www.fda.gov/Drugs/ScienceResearch/ResearchAreas/Pharmacogenetics/ucm083378.htm>. The US FDA granted market approval for the first pharmacogenetic test known as The AmpliChip *CYP450* test that uses DNA microarray technology to identify genotypes in cytochrome P450 *CYP2D6* and *CYP2C19*. The test uses software to predict phenotypes, and tests for 27 *CYP2D6* alleles, including the deletions and duplications, and three *CYP2C19* alleles. The AmpliChip *CYP450* test classifies individuals into the EM and PM *CYP2C19* phenotypes by testing three alleles, and into four *CYP2D6* phenotypes namely UMs, EMs, IMs, and PMs (de Leon et al. 2006a, b). Most of the treatments so far have been symptomatic but with the understanding of genetic components to the disease, personalized therapeutics based on individual genomic profile will improve treatment and reduce adverse side effects. Examples of potential therapeutic benefits are shown in a study with pharmacogenomic testing whereby a patient who was highly sensitive to medications showed slow action of the Cytochrome P450 enzyme encoded by the *CYP2C19* gene, meaning the patient was a PM of most antidepressants. With these results, doctors were able to improve the therapeutic outcome by reducing her medication dose of venlafaxine (25 mg BID) and giving her a low-dose short-acting atypical antipsychotic (quetiapine IR, 25 mg/day). Another patient's pharmacogenomic profile showed increased function of enzymes encoded by *CYP2D6* and *CYP2C19* genes indicating an UM phenotype that called for adjusting treatment with escitalopram at 30 mg/day, higher than the recommended 20 mg/day (Dinama et al. 2014). As more genome wide association studies are performed, scientists will be able to assign specific genomic patterns to EM, IM, PM or UM leading to a more studies geared toward optimized drug therapy. This is very important for the future of personalized medicine as targeted therapies are designed for patients with specific gene variations (Pacanowski et al. 2014).

55.6.2 Current Clinical Trials of Neurodegenerative Diseases

In order to understand the preclinical and clinical course of AD, a multinational collaborative project also known as The Dominantly Inherited Alzheimer Network (DIAN) was initiated where cohorts who are at risk for autosomal dominant Alzheimer disease (ADAD) with mutations in either of the *APP*, *PSEN1* or *PSEN2* genes are studied. The outcome of the study concluded there was a difference in overall pattern among younger DIAN cohorts compared to late-onset AD population (Storandt et al. 2014). A study comparing changes in brain imaging and fluid biomarkers for *PSEN1* E280A mutation carriers versus non-carriers showed that mutation carriers had lower precuneus cerebral metabolic rates for glucose, smaller hippocampal volume, lower cerebrospinal fluid (CSF) A β 1-42, higher CSF total tau and phosphorylated tau, and significantly higher plasma A β 1-42 that was not affected by age (Fleisher et al. 2015). Other clinical trials investigated Bapineuzumab, a humanized anti-amyloid-beta monoclonal antibody against A β (1–6) to treat mild-to-moderate AD patients categorized as *APOE* ϵ 4 allele carriers and non-carriers. Results showed reduction in brain amyloid plaques and phosphorylated tau in CSF but no improvement in cognitive or functional outcome between the *APOE* ϵ 4 allele carriers compared to non-carriers was observed (Folch et al. 2016). These results are in agreement to the view that AD pathology begins before symptoms of dementia develop and largely influenced by amyloid plaques. However, more work needs to be done to incorporate the genetic aspect of neurodegenerative diseases.

55.6.3 Challenges to Overcome

Several challenges still need to be addressed for personalized medicine to become more effective. One is the use of combination therapy, which makes it difficult to study a large enough sample of patients treated with a single agent. In addition, the dosage of the drug may vary by regimen, further complicating efforts to study the pharmacogenomics of a specific drug of interest. Furthermore, replication of findings made in genome wide association studies from large randomized clinical trial is often difficult, because high costs and ethical considerations may mean that a second identical trial is not feasible. Other challenges to overcome involve environmental factors, the interactions between different genetic loci and between different genes. When data from multiple studies are combined, there is increased potential for confounding variables that may affect how results are interpreted. Influence of sex, race or inadequate sample size may lead to the lack of inclusion of a causal genetic variation leading to an erroneous interpretation.

55.7 Review Questions

1. What is pharmacogenomics?
2. Identify the four CYP2D6 phenotypes.
3. Explain the role of acetylcholine in the AD pathology.
4. What is the goal of personalized medicine?

55.8 Answers

1. Pharmacogenomics is the study of how specific genetic variations influence the therapeutic outcome.
2. Normal activity (extensive metabolizers, EM); low or no activity (poor metabolizers, PM); intermediate activity (intermediate metabolizers, IM); and high enzymatic activity (ultra-rapid metabolizers, UM).
3. Neuronal death in the brain at key locations leads to the deficiency of the neurotransmitter, acetylcholine thus causing memory impairment, hence leads to AD.
4. To combine clinical observations with information gotten from GWAS and candidate gene studies to predict how an individual will respond to a particular drug so that the problem of disease etiology is approached based on individual genomic profile. With this, clinicians can optimize drug dosage at beginning of treatment, find effective ways to diagnose, treat and prevent complex disorders with personalized therapeutics.

Abstract

Immunology, neuroscience and pharmacology are each independent broad multidisciplinary fields that are well developed for the biomedical sciences. The evolution of each at the molecular, biochemical and cellular levels have been, by any measure, enormous in impact by its collective abilities to change the world as we know for biomedical research. This book was fashioned to share with students and trained professionals a vision and integration for the discipline and to reach forward into its future.

Keywords

Adaptive immunity • Alzheimer's disease • Astrogliosis • HIV-associated neurocognitive disorders • Microglia • Neuroimmune pharmacology • Neuropharmacology • Parkinson's disease

Notably, like other disciplines of science, the fields of immunology, pharmacology and neuroscience intersect. How this has come about resides in history. Simply said, it did not begin in modern times but evolved over a century ago when Dr. Elie Metchnikoff discovered that an inflammatory cell type in starfish larvae could engulf foreign materials and as a consequence protect its host, birthing the field of immunology. It is from this field that some of the most significant medical advances have been realized. Indeed, immunology has become the most active and arguably the most prolific field of medicine. At its epicenter is the mononuclear phagocyte (MP; monocyte, tissue macrophage, dendritic cell and microglia) with its nonspecific ability to protect itself against pathogenic microbial and other injurious attacks. While the 1908 Nobel Prize in Medicine and Physiology was awarded

to Dr. Metchnikoff, even he was uncertain of the exceedingly broad implications of his discovery in appreciating how these cells could affect the well-being of the human race. This realization came only decades later through a plethora of new developments in immune-based diagnostics and therapeutics. For example, MP were subsequently found to induce intracellular killing of pathogenic microbes, process antigens for presentation, secrete biologically active factors and under certain circumstances, become instigators in pathological processes. It was considerably later when scientist discovered that MP phagocytic functions were central to normal tissue homeostasis (Gardai et al. 2005; Fadok et al. 1998). So how is MP function linked to disease? The obvious answer is through inflammation. On the one hand, inflammation is essential for life as it serves as the frontline defense against infection and tumor surveillance. Inflammation, for simplicity's sake, enriches the host's abilities to fend off disease-causing bacteria, viruses and parasites. It comprises the first-line of immune defense to eliminate invaders and plays a critical role in the repair of damaged tissue. On the other hand, when these highly regulated processes go awry, inflammation evolves into pathological processes that are disadvantageous to the host as is seen in cancer, infectious, cardiovascular diseases, autoimmunity and neurodegenerative disorders.

Neuroscience is defined broadly as the investigation of networks and models of neural communication in health and disease amongst hundreds of billions of neurons and supporting glia (microglia, oligodendrocytes and astrocytes). The intersection between the immune system and the nervous system is now considered significant. Indeed, within the central nervous system (CNS) immune activities abound. During disease, neuroinflammation perpetrated through the brain's MP has been linked to widespread neurodegeneration in adult diseases that include Parkinson's, Alzheimer's and Huntington's diseases (PD, AD, HD), HIV-1-associated neurocognitive disorders (HAND), stroke, multiple sclerosis and spongiform encephalopathies (prion-mediated neurodegeneration). We now understand that CNS injuries ranging from acute traumatic brain injury to the chronic neurodegenerative disease leads to the recruitment and activation of the adaptive immune system (Benner et al. 2008; Appel et al. 2010). The polarization of this adaptive immune response appears to have a significant impact on local CNS MP or microglial secretory functions with the capacity for both deleterious or beneficial outcomes. A range of microglial-derived products have been linked to neuronal injury including quinolinic acid, superoxide anions, matrix metalloproteinases, nitric oxide, arachidonic acid and its metabolites, chemokines, pro-inflammatory cytokines and excitotoxins. Activated microglia commonly speed disease progression while anti-inflammatory therapies appear to slow or halt it.

The ontogeny of the brain's immune system is still debated (Chan et al. 2007). However, recent lineage tracing experiments reveal that microglia begin as yolk sac-derived *Csflr*⁺ erythro-myeloid progenitor cells which enter the brain during early embryogenesis and differentiate into a mature microglial pool (Gomez Perdiguero et al. 2015). Microglia serve as the resident CNS phagocytes capable of reacting promptly to brain insults that range from pathogens to aggregated proteins. For the most part, resident microglia are equipt to detect and rapidly remove infected or damaged cells and thus are critical to brain's surveillance system. Both microglia and astrocytes were once thought of as simple support cells for neurons. However, new data suggest that these cells have a distinct and direct functions in shaping neuronal synapse formation suggesting a far more important roles in neural function (Lui et al. 2016; Singh et al. 2016). The newer discovery, in regards to microglial function show that they have evolved into cells with distinct identities as compared to peripheral myeloid cells and as such open new areas of studies of cell biology.

On balance, these glial cells serve neuroprotective functions. Astrocytes serve as a primary supporter of neuronal and microglial activities made possible by the cell's abilities to produce neurotrophins, eliminate excitotoxins, and control tissue functions. However, it is the microglia that is primarily responsible for the removal of debris and clearance of

microbes that have gained access to neural microenvironments. In particular and under a broad range of diseased states and infectious processes microglia serve with the astrocyte to promote neuronal survival. The activation of either cell type leads to profound morphological and functional changes. Activated microglia increase their numbers at the affected site and exhibit a "spider-like" ramified appearance with substantially enlarged cell bodies. Such cell signatures appear at the lesion close to injured or degenerating neurons. While such changes are clearly implicated in neurodegenerative processes the cells serve the nervous system through their abilities to affect tissue and cell function, molecular trafficking, regeneration and elimination of lipids and scavenging apoptotic cells. Such functions are coincident with innate cellular proliferation and surface expression of "activated" markers.

We can no longer propagate the perception that the CNS is an "immune privileged" site. Recent disclosures support the presence of an anatomical lymphatic system within the CNS (Louveau et al. 2015). Such a unique system serves to traffic cells and macromolecules into and out of the CNS. Brain-derived antigens drain to the deep cervical lymph nodes following injury (Benner et al. 2008) by way of this system, and CNS-derived dendritic cells function in perivascular regions that may serve to maintain immune tolerance through regulatory T cells (Treg). While naïve T cells are precluded from CNS entry, neuroinflammation aggressively recruits activated T cells to sites of active neurodegeneration (Karman et al. 2004). While the pathogenic role of T cell autoimmunity has been extensively studied, more recent studies have suggested a potential beneficial role in some settings. Nonetheless, a far more complex relationship between neurons and immunity exists than previously thought. For example, numerous interleukins and chemokines are readily expressed in neurons. Signaling between neurons, astrocytes and microglia during neural injury incite inflammatory responses and leukocyte migration. Yet another example, the major histocompatibility complex (MHC) class I and CD3 ζ molecules have a role in axonal guidance, activity-dependent remodeling, and plasticity in the developing nervous system (Huh et al. 2000). Within the neuronal synapse, MHC class I molecules may participate in synaptic connections. The cognate receptor for MHC class I peptide complexes is the $\alpha\beta$ T cell receptor (TCR) expressed on T cells. During neuroinflammatory responses MHC class I molecules are up-regulated on neurons without evidence of cytotoxic T lymphocyte (CTL) neural cell damage (Syken and Shatz 2003; Nishiyori et al. 2004). Altered peptide profiles at the neuronal synapse may affect neuronal plasticity and brain remodeling. Additionally, a myriad of animal model systems of human disease have shown that deficiencies in adaptive immunity lead to neuronal loss which are reversed following immune reconstitution. The relationship between T cell

responses following neural injury are now well known. However, the specific identity of T cell subpopulations and their divergent roles in neuroprotection and neurodegeneration are hotly debated.

How neurons are injured or die remains an important determinant in the ensuing microglial responses. This is of paramount importance as phagocytes clear cells undergoing programmed cell death and must do so in a manner that does not harm neighboring cells (Sastry and Rao 2000). The rapid clearance of such cells prevents the release of toxic or immunostimulatory molecules from dead neurons and is thought to play an important role in maintaining homeostatic functions (Magnus et al. 2001; Chan et al. 2001). Apoptosis leads to morphological and biochemical alterations at the cell surface making them suitable targets for resident phagocytes. Such changes include the reversal of membrane polarity, yielding a net anionic charge, and the surface expression of modified lipid (phosphatidylserine) and carbohydrate motifs. Apoptosis proceeds without an inflammatory response and phagocytosis of apoptotic cells inhibits innate immune activation (Savill et al. 2002). Actually this process leads to anti-inflammatory cytokine production that includes transforming growth factor beta (TGF- β) and interleukin-10 (IL-10). Alternatively, necrotic cell death alerts the immune system to danger through danger-associated molecular patterns (DAMP) and elicits significant inflammatory response (Krysko et al. 2011). Antigens from necrotic or stressed cells may trigger a class of pattern-recognition receptors (PRRs) designed to recognize evolutionarily distant microorganisms and includes Toll-like receptors (TLRs). While minimal evidence exists for any infection etiology parallel in neurodegenerative diseases, inflammation is nonetheless linked to neuronal loss. One example is the infusion of lipopolysaccharide (LPS), a pathogen-associated molecular pattern, into the brain, the eliciting of an inflammatory response and its association with neuronal loss. LPS signals through TLR4 and CD14 and results in a robust activation of microglial cells (Elward and Gasque 2003). Such immunostimulatory ligands include heat-shock proteins (HSP) (Asea et al. 2002), high mobility group 1 protein (HMG1) (Park et al. 2004), DNA (Collins et al. 2004), hyaluronan (Termeer et al. 2002), uric acid (Shi et al. 2003), and fibronectin (Okamura et al. 2001). Many of these target ligands are upregulated in stressed cells or liberated from the extracellular matrix during tissue damage. As such, they make excellent candidates for molecular triggers of immune activation following tissue injury and may therefore contribute to neurodegenerative process.

Interestingly, extracellular mitochondria, released during cell death, may also act as DAMPs to the innate immune system. Mitochondria likely evolved from a prokaryotic ancestor and have retained many phylogenetic characteristics including double membrane structures, primitive transcription and translation machinery, and stretches of unmethylated CpG

DNA motifs associated with microbial genomes. Both mitochondrial DNA (mtDNA) and DNA modified by oxidation (8-oxodG), strongly activate cells of the MP lineage (Collins et al. 2004). This has important implications for neurodegenerative disease where mitochondrial pathology and oxidative stress is associated with neuronal loss.

Aggregated proteins are also indicators of cellular stress and are potent activators of innate immunity. Most neurodegenerative diseases are associated with the accumulation of abnormal protein aggregates (proteopathies). Aggregated proteins can exert toxicity by disrupting intracellular transport, overwhelming the protein degradation machinery, or by sequestering normal proteins away from their physiological roles. In addition to direct toxicity, mounting evidence suggests that abnormal protein conformations can activate innate immune cells through scavenger receptors thus providing a mechanism for secondary tissue injury (Fischer et al. 2002; Yan et al. 1999; Bradt et al. 1998; Reynolds et al. 2008, 2009). Additionally, treatment of neurons with proteasome inhibitors and subsequent accumulation of ubiquitinated proteins elicits prostaglandin synthesis suggesting that intracellular accumulation of abnormal proteins can trigger the production of proinflammatory mediators (Rockwell et al. 2000). A major pathological hallmark of PD is the presence of eosinophilic, cytoplasmic inclusions of fibrillar, misfolded proteins called Lewy bodies (LB) suggesting derangements in proteostasis may be involved in disease pathogenesis (Dauer and Przedborski 2003). While LBs are intracellular, the fate of associated protein aggregates following cell death is unknown and can be released following cell death. Moreover, neurons go to great lengths during times of cellular stress to prevent such aggregation by upregulating ATP-dependent chaperones such as HSPs (Muchowski 2002). In addition to aggregated proteins, HSPs can be released during cell death and doing so may directly contribute to microglial activation (Kakimura et al. 2002).

Reactive oxygen species (ROS) include superoxide, hydrogen peroxide and hydroxyl free radicals as well as nitrogen intermediates (nitric oxide and peroxynitrite). These cause damage to neurons if produced in excess such as during prolonged neuroinflammatory responses. Much of the microglial-derived ROS such as superoxide cannot efficiently transverse cellular membranes, making it unlikely that these highly reactive molecules gain intracellular access to neurons and trigger intraneuronal toxic events (Ischiropoulos and Beckman 2003). However, superoxide can rapidly react with NO in the extracellular space to form a more stable oxidant, peroxynitrite (Wu et al. 2003). The stability of peroxynitrite facilitates its crossing of cell membranes where it can damage intracellular components in neighboring neurons. Its toxicity has been linked to the disruption of mitochondrial electron transport chain, lipid peroxidation, DNA damage, and the nitration of tyrosine

residues in cellular proteins. NO plays an important role in innate immunity and is associated with tumoricidal and bactericidal activities of macrophages. In addition to the physiological roles of NO, under pathological settings with excessive production it can act as a potent neurotoxin in a number of neurodegenerative models.

On a more general level, matrix metalloproteinases (MMPs) are a class of extracellular soluble or membrane bound cysteine proteases involved in remodeling of the extracellular matrix (ECM). MMPs have also been implicated in a range of neurodegenerative disease including, HAD, AD, PD and stroke. Gu et al. reported that S-nitrosylation of N-terminal cysteine residues within proMMP-9 leads to the subsequent activation of MMP-9 protease activity (Gu et al. 2002). These findings identify a potential extracellular proteolysis mechanism involved in neuronal cell death in which S-nitrosylation activates MMPs. An increase in MMP-9 expression has been determined in the MPTP model and pharmacological inhibition of MMP-9 was neuroprotective (Lorenzl et al. 2004).

The complex role of cellular and molecular inflammatory mediators, particularly within the CNS, makes it difficult to define their specific beneficial or deleterious roles in pathophysiological states (Gendelman 2002). Cytokines and chemokines are of particular importance in the initiation, maintenance, and resolution of inflammatory reactions within the CNS (Allan and Rothwell 2001). Moreover, cytokines and chemokines in particular, have important roles outside of inflammation including chemotactic axonal guidance during developmental stages of the CNS (Mennicken et al. 1999; Tran and Miller 2003a). With regards to the immune system, cytokines and chemokines act as potent survival cues and their tissue levels directly modulate the activity of inflammatory cell types. Therefore, the function of these molecules within the immune system is reminiscent of the function of neurotrophins within the nervous system (Tran and Miller 2003b). In fact, many neurotrophins are structurally related to molecules within cytokine families and these two classes of molecules appear to share functional overlap. IL-10 is a potent neuroprotective factor on purified cerebellar neurons and AD (Bachis et al. 2001; Kiyota et al. 2012) and NGF has emerged as a potent anti-inflammatory factor with beneficial effects in the mouse model of MS (Flugel et al. 2001). Indeed, neurons themselves can produce chemokines and express many of their receptors on their surface suggesting direct dialog between these two systems. Neuronal-immune communication is not restricted to soluble mediators. The CD200 receptor (CD200R) is expressed on myeloid cells including microglia and its ligand, CD200, is abundant on neuronal cell surfaces. Cognate CD200-CD200R interactions have potent inhibitory effects on cells of the myeloid lineage (Barclay et al. 2002; Hoek et al. 2000; Varnum et al. 2015). Cells of the adaptive immune system can also communicate with neurons. Activated T cells

express numerous neurotrophins in addition to the neurotrophic factor receptors, TrkB and TrkC, thus providing sufficient mechanistic means to establish direct T cell-neuron communications.

Functional cellular immune responses can provide conflicting studies. Virally or otherwise activated macrophages can have devastating consequences on neuronal function and survival. Depletion of peripheral monocyte/macrophage lineages in a spinal cord injury model can improve functional recovery (Popovich et al. 1999). Conversely, direct spinal injection of macrophages activated with damaged peripheral nerves *ex vivo* leads to enhanced functional recovery (Rapalino et al. 1998). Resident microglia, while contributing to noxious factors in CNS disease detailed above, also produce a plethora of neurotrophic factors upon activation. Local production of these factors can establish trophic gradients which stimulate and guide axonal sprouting following striatal injury (Batchelor et al. 1999, 2002). Thus, fine-tuning of cellular immune responses is critical for maximizing neuroprotection by immune cells.

The presence of T cells in CNS pathological settings has long been regarded as detrimental. One such case where T cells play a direct role in disease pathogenesis is multiple sclerosis (MS). MS is an inflammatory disease characterized by perivascular cuffs of mononuclear cells that include both lymphocyte and macrophage populations. Accumulation of these cells leads to significant damage to the myelin sheath and can involve the underlying axon (Kornek et al. 2000). However, provocative experimental data also implicate a role for adaptive immunity in otherwise non-autoimmune disorders of the CNS. Surprisingly, SCID and Rag2^{-/-} mice, both deficient in adaptive immunity, show enhanced motor neuron loss within the facial nucleus following transection of the facial nerve. Regulatory T cells such as CD4⁺CD25⁺, which comprise 10 % of the total CD4⁺ population, play a vital role in inhibiting autoreactive T cell activation and expansion and may be of paramount importance in maintaining peripheral tolerance against CNS antigens. Depletion of naturally occurring regulatory CD4⁺CD25⁺ T cells predisposes animals to development of organ-specific autoimmune diseases (Shevach 2000). Depletion of CD4⁺CD25⁺ regulatory T cells enhances T cell-dependent protective response and hence improves post-injury neuronal survival following disease (Kipnis et al. 2002). Alternatively, immunodeficient mice have improved dopaminergic neuronal survival (Benner et al. 2008) and Treg cells confers protection animal models of Parkinson's disease (Reynolds et al. 2010). Moreover, a recent study demonstrates that the influence of gut microbiomes on ischemic stroke outcomes is mediated through Treg regulation of $\gamma\delta$ T cells responses to injury (Benakis et al. 2016). In this study, Treg populations in the gut resulted in decreased $\gamma\delta$ T cell-derived IL-17 in the brain following stroke leading to improved outcomes. Thus, CD4⁺CD25⁺ regulatory T cells, at least for now are both agonistic and antagonistic and require further investigation.

How can we harness these complex immune responses within the nervous system for therapeutic gain? This has given rise to the development of neuro- and immuno-pharmacology. In the context of the immune system the drug acts on the biological system that augments cellular responses against disease or in maintaining host homeostasis. Such cellular responses can be utilized for therapeutic gain. The ensuing events that occur within the nervous system ultimately is the field of neuroimmune pharmacology. For example, an unexpected role of T cells in neuronal function is immune-mediated neuroregeneration, differentiation or protection. Surprisingly, for example, proinflammatory T_H1 cell responses generated through immunization with myelin-associated antigens can attenuate secondary neuronal loss following experimentally induced CNS injury (Weiner and Selkoe 2002; Schwartz 2001). It appears that such strategies can increase local production of proinflammatory cytokines as well as multiple neurotrophic factors within the injured tissue (Hammarberg et al. 2000; Moalem et al. 1999). These provocative observations have generated novel questions regarding neuro-immune interactions and it has been suggested that the observed neuroprotection can be directly linked to the proinflammatory nature of the infiltrating T cell population (Schwartz et al. 1999). However, detailed mechanistic data is lacking and the true mechanisms will likely prove as complicated as many other inflammatory mediators described above. Contrary to this, oral or nasal immunization that preferentially generates an anti-inflammatory T cell response (T_H2/T_H3) also has a demonstrated neuroprotective element and may prove more clinically feasible (Frenkel et al. 2003; Monson et al. 2003).

Neurodegenerative disorders are linked to innate immune activation comprised of an astonishing array of cellular and molecular players. There is little evidence for an infectious process in most neurodegenerative diseases however; multiple endogenous immune activators associated with cellular stress signals likely converge on resident glia leading to an inflammatory phenotype. The intended purpose of this response is beneficial to the host. However, when regulatory controls are breached and inflammation is allowed to persist, tissue damage ensues. The identification of individual activation pathways operative in disease and the subsequent response they elicit may prove beneficial in the development of novel therapeutics. In addition to innate immunity, the adaptive immune system may also play a role (beneficial or toxic) in neurodegeneration, even in the absence of overt autoimmune pathology. Moreover, the adaptive immune system may be manipulated through peripheral immunization and or immunotherapy in a way that modifies innate inflammatory mechanisms in the CNS. Strategies to maximize the benefit of protective innate and adaptive immunity against CNS disorders with emerging immunological, nanomedicinal, and molecular biological techniques is fundamental to these approaches. Careful pursuit of therapeutic strategies

with an emphasis on safety may lead to novel treatment means to combat a broad range of neuropsychiatric, developmental, infectious and degenerative disorders of the nervous system as highlighted in this 2nd edition of textbook. Here we humbly dedicate this new book for the field's future.

56.1 Review Questions

- Dr. Elie Metchnikoff's famous discovery that led to the birth of immunology was:
 - He discovered that an inflammatory cell type in starfish larvae could engulf foreign materials and as a consequence protect its host.
 - He discovered that cytotoxic T lymphocytes clear virus and cancerous cells from the body during disease.
 - He discovered that the gut is a central lymphoid organ and responsible for a plethora of immune responses in the host and during homeostasis and disease.
 - He discovered that macrophages and dendritic cells present antigens and mobilize adaptive immune responses.
 - All of the above.
- Neuroscience is defined as:
 - Cell to cell interactions and communication networks of neurons and glia.
 - The investigation of networks and models of neural communication in health and disease amongst hundreds of billions of neurons and supporting glia (microglia, oligodendrocytes and astrocytes).
 - The development of the nervous system.
 - The reaction of the brain and spinal cord to injury and infections.
 - All of the above
- The abilities to harness complex immune responses within the nervous system for therapeutic gain is defined by:
 - Neuroimmune Pharmacology
 - How a drug acts on a specific biological system and modulates cellular responses against disease
 - Finding the means to boost immune system to maintain host homeostasis.
 - Engaging cellular immune responses for therapeutic gain.
 - All of the above
- Astrocytes are NOT defined by:
 - Being the primary supporters of neuronal and microglial activities
 - The ability to produce neurotrophins, eliminate excitotoxins, and control tissue functions.
 - The removal of debris and clearance of microbes that have gained access to neural microenvironments.

- (d) The abilities to work in concert with microglia to promote neuronal survival.
 - (e) Activation leads to profound morphological and functional changes.
5. True or false.
While naïve T cells are precluded from the CNS entry, neuroinflammation recruits activated T cells to sites of active neurodegeneration.

56.2 Answers

1. A
2. E
3. E
4. C
5. True

Glossary¹

1.1

Δ⁹THC Tetrahydrocannabinol is the major psychoactive ingredient in the Cannabis plant. **Δ⁹THC** is responsible for both the psychiatric and therapeutic effects obtained from marijuana. Its receptor, the cannabinoid receptor, is located mainly in the presynaptic gap. The areas of the brain most affected are the basal ganglia, cerebellum, cerebral cortex, and the hippocampus. The acute effects consist of degradation in short term memory, changes in sensory perception, reduced concentration, disturbances in motor abilities, hypothermia, increased blood pressure and heart rate, and reduced pain perception.

2D electrophoresis A method for separation and analysis of macromolecules and their fragments and is commonly used to analyze proteins.

6-Hydroxydopamine A neurotransmitter analogue that depletes noradrenergic stores in nerve endings and reduces dopamine levels in brain. Its mechanism of action is linked to cytolytic free-radical production.

1.2 A

ACAID Anterior chamber-associated immune deviation—a unique form of immune tolerance. ACAID is a selective, systemic immune deficiency where Antigen-specific delayed hypersensitivity and complement-fixing antibody responses are impaired by lymphocyte responses while other immune effectors are left preserved.

Ach Acetylcholine is the chemical responsible for transmitting impulses between neurons in the central and peripheral (parasympathetic and somatic) nervous systems. It is the chemical that allows nerve cells to communicate with one another.

Acetylcholinesterase The enzyme responsible for the destruction of acetylcholine at the synaptic cleft (region

between nerve cells) after its neuronal release during neurotransmission.

AIDS Acquired Immunodeficiency Syndrome (AIDS) is an acquired defect of cellular immunity associated with infection by the human immunodeficiency virus (**HIV**), a CD4- positive T-lymphocyte count under 200 cells/ μ L or less than 14 % of total lymphocytes, and increased susceptibility to opportunistic infections and malignant neoplasms. Clinical manifestations also include emaciation (wasting) and dementia. These elements reflect criteria for **AIDS** as defined by the **CDC** in 1993.

Action potential Is a spike of electrical discharge that is propagated along the cell membrane. It is essential for information transmission amongst and from nerve cells to tissues throughout the body.

Active transport Movement of materials across cell membranes and epithelial layers against an electrochemical gradient, requiring the expenditure of metabolic energy. The process involves the use of cellular energy and commonly ATP to actively pump substances into or out of the cell.

Active vaccination The process of injecting a protein (an antigen) into a host, usually together with an adjuvant (a molecule to enhance immunity) for the purpose of preventing disease. In response, the host immune system generates an immune response that includes specific cells and antibodies against the antigen. Although most commonly used to prevent microbial infections, active vaccination has been used to ameliorate disease.

Active zone Specialized region of the cortical cytoplasm of the presynaptic nerve terminal that faces the synaptic cleft. It is the place for synaptic vesicle docking and neurotransmitter release.

ADEM Acute disseminated encephalomyelitis is an immune mediated disease of brain. It is brief but significant and results in direct myelin damage. It usually occurs following a viral infection or vaccination (commonly for measles, mumps or rubella), but it may also appear spontaneously.

¹Definitions provided by contributing authors, National Library of Medicine and/or Wikipedia unless otherwise noted.

- Acute flaccid paralysis** Loss of voluntary motion, due to temporary or permanent dysfunction of lower motor neurons or associated nerve fibres, neuromuscular junction, or muscle fibres. It is the most common sign of acute polio but is also associated with West Nile Virus infection. In chronic cases of permanent flaccid paralysis muscle tone is decreased and muscle atrophy may occur.
- Adamantiades-Behçet's disease** A rare form of systemic vasculitis through immune-mediated small vessels usually accompanied by mucous membrane ulceration and ocular problems.
- Adaptive immune system** The adaptive immune system evolved in early vertebrates and allows for a specific and targeted response based upon immunological memory of antigens or related antigens previously encountered by the host innate immune systems. This requires the recognition of specific "non-self" antigens. The effectors of the adaptive immune response include T cells and B cells.
- Adenoviruses** These are a family of non-enveloped medium-sized (90–100 nm), icosahedral double-stranded DNA viruses that infect various mammalian species, including humans. These viruses commonly cause mild respiratory infections. Adenovirus-based vectors have been used for gene delivery into the nervous system, as high vector titers can be generated, and these episomally maintained vectors efficiently infect and express transgenes in a variety of cell types including the non-dividing cells.
- AAV** Adeno-associated virus is a non-pathogenic member of the parvovirus family that harbors a single-stranded DNA viral genome. Vectors derived from AAV can carry up to a 4.5-kb transgene and stably express a transgene in vivo months to several years.
- Adjunctive** Something joined or added to another thing but not essentially a part of it, used in this context to refer to additional therapies for HIV-related neurological conditions.
- Adjuvant** A formulation of substances that is used to enhance/potentiate immune response to an antigen. Complete adjuvants are water in oil emulsions composed of inactivated or killed mycobacteria-usually *Mycobacterium tuberculosis*. Whereas incomplete adjuvants are the same adjuvants, but without the mycobacterial components.
- ACTH** Adrenocorticotrophic hormone is a peptide hormone released by anterior pituitary cells in response to stressful stimuli that causes the synthesis and release of cortisol (corticosteroid) from the adrenal cortex. It is an important component of the hypothalamic-pituitary-adrenal (HPA) axis. ACTH is released from pro-opiomelanocortin and secreted from corticotropes in response to corticotropin-releasing hormone (CRH) released by the hypothalamus.
- (Adsorptive) endocytosis** Cellular uptake of extracellular materials within membrane-limited vacuoles or microvesicles. **ENDOSOMES** play a central role in endocytosis.
- (Adsorptive) transcytosis** A mechanism for transcellular transport in which a cell encloses extracellular material in an invagination of the cell membrane to form a vesicle, then moves the vesicle across the cell to eject the material through the opposite cell membrane by the reverse process.
- Adult stem cell** A cell found in adult somatic tissue that can differentiate into the cells of the particular tissue in which it resides and can self-renew while maintaining its differential capability.
- Age related macular degeneration** A gradual worsening of vision that eventually leads to no vision in the center of the visual field. It is caused by damage to the macular of the retina.
- Akt** Serine/threonine protein kinase that is a cellular homologue of the viral oncogene v-Akt. There are three genes in the Akt family: Akt1, Akt2, and Akt3. Akt1 is involved in cell survival pathways by inhibiting apoptosis. Akt2 is an important signaling molecule in the Insulin signaling pathway, and is required to induce insulin transport. The role of Akt3 is unknown, but it is predominately expressed in the brain.
- Alkylosing spondylitis** Literally "stiff vertebra" is an autoimmune inflammatory disease that primarily affects the intervertebral joints (joints of the spine) and the sacroiliac joint.
- Allele** The name given to a specific polymorphic variation.
- Allele association** Association with a specific allele but not necessarily a genotype.
- Allograft** Tissue transplanted from the same species but of a different genotype.
- Alpha adrenergic receptor** One of two general classes of G protein-coupled receptors that can be further sub-classified and responds to the neurotransmitter norepinephrine.
- α-MSH** Alpha melanocyte stimulating hormone is a tripeptide derived from proopiomelanocortin that stimulates production of melanin and acts on melanocortin-1 receptors found on immune cells.
- Alpha synuclein** An abundant presynaptic neuronal protein found in the brain of uncertain function, but thought to act as a molecular chaperone involved in vesicular transport. Mutation and/or oxidation of alpha-synuclein increase its propensity to aggregate and is a major component of Lewy bodies that plays a role in neurodegeneration and neuroprotection.
- AD** Alzheimer's disease is the most common degenerative brain disease of unknown cause resulting in progressive mental deterioration with disorientation, memory disturbance and confusion. AD leads to progressive dementia, often accompanied by dysphasia and/or dyspraxia.

The condition may also give rise ultimately to spastic weakness and paralysis of the limbs, epilepsy and other variable neurological signs. Alzheimer disease is marked histologically by the degeneration of brain neurons especially in the cerebral cortex and by the presence of neurofibrillary tangles and plaques comprised of highly insoluble β -amyloid peptides in the CNS.

Amacrine cell Lateral inhibitory interneuron in the inner retina located at the inner plexiform layer where bipolar cells and ganglion cells synapse. Amacrine cells deliver the majority of the ganglion cells input, and also regulate the output of the cone bipolar cells. These cells are thus responsible for the complex processing of the retinal image by adjusting brightness as well as detecting motion.

Amphetamine A central nervous stimulant that increases neuronal activity by releasing norepinephrine, dopamine and/or serotonin from nerve endings.

Amygdala An almond-shaped mass of gray matter, one in each hemisphere of the brain, associated with feelings of fear and aggression and important for visual learning and memory.

A β Amyloid-beta is a peptide of 39–43 amino acids that is the main constituent of amyloid plaques in the brains of Alzheimer's disease patients. Similar plaques appear in some variants of Lewy body dementia and in inclusion body myositis, a muscle disease. A β also forms aggregates coating cerebral blood vessels in cerebral amyloid angiopathy.

APP Amyloid precursor protein is a single transmembrane molecule, a causative gene of FAD, and is acted upon by proteases to form the amyloid- β peptide.

ALS **Amyotrophic lateral sclerosis** is a rare fatal progressive degenerative disease of unknown cause that affects motor neurons, usually begins in middle age, and is characterized by muscular weakness; called also Lou Gehrig's disease.

Amyloid An abnormal aggregation of proteins or protein fragments with a beta-pleated sheet secondary structure.

Animal models Normal animals modified mechanically, genetically or chemically to create laboratory paradigms with infrahuman species (usually rodents) which study behavior, neurochemistry, or physiology to demonstrate all or part of the characteristics of a disease.

Antibodies repertoire Antibody genes are pieced together from widely scattered bits of DNA. The possible combinations are nearly endless. As this gene forms, it assembles segments that will determine the variable-V, diversity-D, joining-J, and constant-C segments of this antibody molecule. For example, variable-region and joining-region rearrangements of the immunoglobulin light chain called V_LJ_L rearrangements.

Antibody A protein used by the immune system to neutralize pathogens.

Antibody titer The concentration of a specific antibody in blood.

Antidepressant drugs Pharmacological agents used for ameliorating symptoms of depressive disorders, including monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, serotonin/norepinephrine reuptake inhibitors, and other agents.

Anti-ganglioside antibodies Circulating auto-antibodies directed against gangliosides. Anti-ganglioside antibodies are associated with axonal forms of GBS and can be induced experimentally in laboratory animals.

Antigen The molecule against which an immune response is raised.

Antigen presenting cells (APC) A cell that displays foreign antigens complexed with MHC on its surface. T-cells may recognize this complex using their T-cell receptor (TCR).

Anti-inflammatory cytokines A series of immunoregulatory molecules that suppress proinflammatory responses.

Antipsychotic drugs Pharmacological agents used to treat psychotic disorders, including schizophrenia, mania, and psychotic depression. These drugs are usually classified as "typical" or "atypical," depending on their affinity for the dopamine D₂ receptor, lack of extrapyramidal side effects, and action upon serotonin receptors.

Antiretroviral therapy Use of anti-HIV agents to treat disease by lowering viral titer and reducing viral replication, usually in combination of at least three drugs.

Antithymocyte globulin Purified gamma globulin from the serum of rabbits immunized with human thymocytes. It is used for induction of immunosuppression in the treatment of acute renal transplant rejection.

apoE Apolipoprotein E is a component of lipoprotein complex both in plasma and cerebrospinal fluid, responsible for cholesterol transport in the blood stream. One copy of the ApoE4 allele is an established risk factor of AD.

Apoptosis A genetically determined process resulting in cell self-destruction that is marked by the fragmentation of nuclear DNA, and is a normal physiological process eliminating DNA-damaged, superfluous, or unwanted cells (as immune cells targeted against the self in the development of self-tolerance). Apoptosis may occur prematurely in neurodegenerative conditions; also called programmed cell death.

Arbor Dendritic arbor, a single dendrite, the arbor density is called arborization.

Arboviruses (Arthropod-Borne virus) This type of virus is transmitted by arthropods.

Area postrema A structure in the brain that controls vomiting as well as other autonomic functions along with the central nervous system. It is located in the inferoposterior limit of the fourth ventricle.

Association Describes a relationship between a disease and a specific allele or haplotype of a polymorphism.

Astrocytes Major glial cells in the CNS (star-shaped cell as of the neuroglia). Astrocytes are characterized by histopathologically by glial fibrillary associated protein (GFAP). Astrocytes perform many functions including formation of the blood brain barrier, provide neurotrophic factors and metabolic support to the CNS, and have a role both in the repair and scarring process in the brain.

Atherosclerosis Characterized by the formation of plaques within the innermost layer of artery walls and narrowing of the vessel lumen. Vascular occlusion in the brain leads to stroke and in the coronary arteries leads to heart attack.

Atropine An alkaloid isolated from the belladonna plant that blocks the action of acetylcholine on muscarinic cholinergic receptors.

Autism spectrum disorders A section of neurodevelopmental disorders which include social deficits and communication problems.

Autoantibodies Immunoglobulins directed against self-antigens, representing an autoimmune process.

Autoimmune disease A condition in which a person's immune cells recognize self-produced molecules (self-antigens), leading to the inappropriate destruction of host tissue, e.g. rheumatoid arthritis, multiple sclerosis, and possibly Addison's disease.

Autoimmune T cells T cells that recognize self-antigens and are responsible for cell-mediated destruction of host tissue in an autoimmune disease.

Autoimmunity A condition in which an individual's immune system reacts against his or her own tissues, causing diseases such as lupus erythrocytes.

Autonomic nervous system The portion of the peripheral nervous system which acts autonomously through either of two divisions (parasympathetic and sympathetic) and regulates the action of smooth muscle, exocrine glands and the heart.

Axon The long extension of a neuron that carries nerve impulses away from the cell body.

Axonal damage Via inflammation not only the myelin sheath, but also the axon itself is destroyed.

Axon terminals The hair-like ends of the axon.

Axonal transport Bidirectional transport process, consisting of anterograde (transport of presynaptic molecules) and retrograde transport systems (neurotrophic signaling).

1.3 B

Bad A pro-apoptotic member of the Bcl-2 gene family involved in initiating apoptosis. BAD- Bcl-2-associated death promoter protein.

β -amyloid peptide (A β) A principal component of senile plaque, a pathological hallmark of AD, which is generated by β and γ -processing of APP.

Barbiturates A group of sedative-hypnotic agents that also have anti-anxiety effects. Barbiturates act on GABA-A receptors.

Basal ganglia Many subcortical nuclei at the base of the forebrain. They are involved in the control of motor movements, learning and routine behaviors.

Basiliximab Humanized monoclonal antibody directed against the IL-2 receptor on T cells. It is used for the prophylaxis of acute organ rejection in adult patients.

Bax A protein of the Bcl-2 gene family that promotes apoptosis by competing with Bcl-2.

B cell B lymphocytes; a white blood cell that specialize in the secretion of antibodies and cytokines.

Bcl2 The prototype for a family of mammalian proteins located in the membranes of the endoplasmic reticulum (ER), nuclear envelope, and in the outer membranes of the mitochondria. They can be either pro-apoptotic (Bax, BAD, Bak and Bok among others) or anti-apoptotic.

BCR B cell receptor is an antigen-specific receptor is a sample of the antibody it is prepared to manufacture; it recognizes antigen in its natural state.

Bcl11a C2H2 type zinc-finger protein. The corresponding mouse gene is a common site of retroviral integration in myeloid leukemia, and may function as a leukemia disease gene, in part, through its interaction with BCL6. During hematopoietic cell differentiation, this gene is down-regulated. It is possibly involved in lymphoma pathogenesis since translocations associated with B-cell malignancies also deregulate its expression.

BDNF Brain derived neurotrophic factor is a member of the nerve growth factor family of trophic factors. In the brain, BDNF has a trophic action on retinal, cholinergic, and dopaminergic neurons, and in the peripheral nervous system it acts on both motor and sensory neurons (From Kendrew, The Encyclopedia of Molecular Biology, 1994).

Belladonna alkaloid Any of several compounds that block the effect of acetylcholine on muscarinic cholinergic receptors.

Benzodiazepines A group of anti-anxiety agents that can also produce sedation, hypnosis and that have anti-convulsant effects. In the CNS, benzodiazepines act on GABA-A receptors. They also act on peripheral benzodiazepine receptors in the immune system.

Beta adrenergic receptor One of two general classes of G protein-coupled receptors that can be further sub-classified and responds to the neurotransmitter norepinephrine.

Beta-amyloid precursor protein converting enzyme (BACE) A single transmembrane aspartic proteinase, which processes APP at β -site; the β -secretase.

Beta-pleated sheet A molecular structure where proteins spontaneously fold into a layered shape, analogous to the accordion folds of a fan.

Bethanechol A derivative of acetylcholine with stimulant effects primarily on the smooth muscle of the gastrointestinal tract and the urinary bladder.

- Biogenic amine hypothesis** The hypothesis that major depressive disorder and bipolar disorder are functionally related to abnormal levels of catecholamines and/or serotonin.
- Bioinformatics** Field of science in which biology and computer science merge into a single discipline to create, manage and interpret massive sets of complex biological data.
- Biomarker** Distinctive biological indicator of biological state, process or condition.
- Bipolar cell** Retinal interneuron that transfers visual information from photoreceptors to ganglion cells.
- Bipolar disorder** A mental disorder characterized by cyclic episodes of mania or hypomania, usually accompanied by depressive episodes.
- BLIMP1** A protein that acts as a repressor of beta-interferon gene expression. The protein binds specifically to the PRDI (positive regulatory domain I element) of the β -IFN gene promoter. Transcription of this gene increases upon virus induction.
- Block copolymer** A polymer in which all of one type of monomer are grouped together and all of the other type are grouped together. A block copolymer can be thought of as two homopolymers joined together at the ends.
- Block ionomer complex** A complex between two oppositely charged block copolymers.
- Blood-brain barrier** Specialized non-fenestrated tightly-joined ENDOTHELIAL CELLS with TIGHT JUNCTIONS that form a transport barrier for certain substances between the cerebral capillaries and the BRAIN tissue.
- Botulinum toxin** A group of zinc proteases that can degrade one or more of the key proteins required for the process of exocytosis thus preventing the neuronal release of acetylcholine.
- Brain** The part of the central nervous system contained within the cranium, comprising the prosencephalon, mesencephalon, and rhombencephalon. It is derived from the anterior part of the embryonic neural tube.
- Brain endothelial cell** Highly specialized cells that form the blood-brain barrier.
- Butoxamine** An antagonist of norepinephrine action selective for the subtype two beta adrenergic receptor.
- to the cytoplasm in response to external stimuli. Elevation of intracellular Ca^{2+} activates a series of enzymes.
- CA1** Carbonic anhydrase 1; a gene containing an N-terminus active site, zinc binding site, and substrate-binding site.
- CAG repeats** Primary determinant of the onset of HD and other neurodegenerative disorders, including SBMA, DRPLA, SCA 1–3, 6, 7 and 17. CAG codes for the amino acid Glutamine, and extra repeats are thought to lead to a “toxic gain of function,” and increased propensity of the translated protein to form aggregates. Genetic testing of the HD CAG repeat is a useful tool for clinical diagnosis.
- Calcium excitability** Refers to the dynamics of calcium homeostasis.
- cAMP signaling** Signal transduction cascade initiated by the action of external stimuli on binding to a G-protein couple receptor (Gs) resulting in activation of adenylyl cyclase, production of cyclic AMP and activation of cyclic AMP-dependent protein kinase.
- Campylobacter jejuni* Gram-negative bacterium, which is one of the most frequent causes of bacterial gastroenteritis world-wide. *Campylobacter jejuni* gastroenteritis is the most frequently recognized preceding infection in GBS.
- Cannabinoids** Substances that bind to cannabinoid receptors.
- Case-control** Study describes an association study that compares allele frequencies using unrelated affected cases and matched controls.
- Caspase** Known as proteases, which play essential roles in apoptosis (cell death) and inflammation.
- CD1d** The sole group-2 member of the CD1 family of major histocompatibility (MHC)-like glycoproteins.
- CD3** Complex of delta, epsilon, gamma, zeta and eta chains of integral membrane glycoproteins that associates with T cell antigen receptor (TCR), and is required for TCR cell surface expression and signal transduction. CD3 is a universally expressed by T cells. Member of immunoglobulin superfamily.
- CD4** Nonpolymorphous glycoproteins belonging to immunoglobulin superfamily. Expressed on surface of T helper cells, accessory cells, macrophages and serves as co-receptor in MHC class II-restricted antigen induced T cell activation. Major receptor for HIV-1.
- CD5** Belongs to ancient scavenger receptor superfamily. CD5+ B cells, which may arise from B-1 cells (subset of B cells) produce “generalist antibodies”—polyreactive low affinity “natural” antibodies to exogenous antigens (tetanus toxoid, lipopolysaccharide) as well as autoreactive antibodies. CD5 may serve as a dual receptor, giving either stimulatory or inhibitory signals depending both on the cell type and the development stage. Key regulator of immune tolerance; abnormalities may produce autoimmunity.

1.4 C

- C5a** The 74-residue anaphylatoxin derived from C5 during complement activation that possesses inflammatory and immune stimulatory properties causing the accumulation of white blood cells at the site of complement activation.
- C5a agonist** A peptide mimetic of natural C5a that exhibits certain C5a-like activities.
- Ca^{2+} signaling** Signal transduction mechanism in which Ca^{2+} is recruited from extracellular or intracellular stores

- CD8** Cell surface glycoprotein, member of immunoglobulin superfamily. Heterodimer of an alpha and a beta chain linked by two disulfide bonds; heterodimer on thymocytes and homodimer on peripheral blood T cells MHC class I restricted receptor; binds to nonpolymorphic region of class I molecules; may increase avidity of interactions between cytotoxic T cell and target cell during antigen-specific activation. Can kill target cells by recognizing peptide-MHC complexes on them or by secreting cytokines capable of signaling through death receptors on target cell surface. CD8 alpha cells promote survival and differentiation of activated T cells into memory CD8+ T cells, which may become clonal (but not malignant) in the elderly.
- CD11b** Member of integrin receptor family; also called integrin alpha M, Mac-1. Mediates adhesion to substrates by opsonization with iC3b and subsequent phagocytosis, neutrophil aggregation, and chemotaxis. Ligands include fibrinogen, Factor X, ICAM1, iC3b, some bacteria. CD11b is a marker for both macrophages and microglia, and expression increases with cell-activation.
- CD11c** Member of b2 of integrin receptor family; also called integrin alpha X, CR4, LeuM5. Clears opsonized particles and immune complexes; also binds to fibrinogen and is involved in adhesion of monocytes and neutrophils to endothelium. Myeloid cell marker.
- CD19** Response regulator that plays a dominant role in establishing signaling thresholds for antigen receptors and other surface receptors on B cells; also regulates B cell development, activation and differentiation. Assembles with the antigen receptor of B lymphocytes in order to decrease the threshold for antigen receptor-dependent stimulation. Co-receptor with CD21. Earliest B cell antigen in fetal tissue. B cell marker.
- CD21** Complement component receptor-2 (CR2) that binds to C3d.
- CD25** IL-2 receptor alpha chain; exists in at least three forms. Limited expression may safeguard against catastrophic T-cell proliferation by immunogenic stimulus. Expressed, typically at high levels, on PHA-stimulated T cells, and is commonly used as a marker for activated T cells. Expressed on B cells stimulated with anti-IgM antibody. Expressed on monocytes/macrophages stimulated with LPS. Full signaling of IL-2 requires trimer with CD122 (IL-2R beta) and CD132 (IL-2R gamma) chains.
- CD27** Marker of T cell activation. CD27/CD70 interactions also regulate B cell proliferation and T cell differentiation. The protein is a member of the TNF-receptor superfamily. This receptor is required for generation and long-term maintenance of T cell immunity. It binds to ligand CD70, and plays a key role in regulating B-cell activation and immunoglobulin synthesis. This receptor transduces signals that lead to the activation of NF-kappaB and MAPK8/JNK. Adaptor proteins TRAF2 and TRAF5 have been shown to mediate the signaling process of this receptor. CD27-binding protein (SIVA), a pro-apoptotic protein, can bind to this receptor and is thought to play an important role in the apoptosis induced by this receptor.
- CD28** Cell adhesion molecule; co-receptor for B cell-T cell cooperation. Promotes T cell activation. Receptor for CD80 (B7.1) and CD86 (B7.2), found on activated B cells. Constitutive, high abundance, low affinity receptor; opposite signals are mediated by CTLA4 (CD152). Result of T cell antigen stimulation depends on sum of effects of T cell receptor, CD28 and its ligand, CTLA4 and its ligand. CD8+, CD28+ T cells mediate antigen specific cytotoxic T cells (class I restricted) (90% of CD8+ T cells). CD8+, CD28- T cells mediate suppressor T cells (10% of CD8+ T cells). CD28 costimulation is essential for CD4-positive T-cell proliferation, survival, interleukin-2 production, and T-helper type-2 (Th2) development.
- CD30** Tumor necrosis factor receptor superfamily, member 8, is a member of the TNF-receptor superfamily. This receptor is expressed by activated, but not by resting, T and B cells. TRAF2 and TRAF5 can interact with this receptor, and mediate the signal transduction that leads to the activation of NF-kappaB. This receptor is a positive regulator of apoptosis, and also has been shown to limit the proliferative potential of autoreactive CD8 effector T cells and protect the body against autoimmunity. Two alternatively spliced transcript variants of this gene encoding distinct isoforms have been reported.
- CD34** Cell-cell adhesion molecule and cell surface glycoprotein. May mediate attachment of stem cells to bone marrow extracellular matrix or directly to stromal cells. Constitutively expressed on endothelial cells.
- CD38** A multifunctional ectoenzyme widely expressed in cells and tissues especially in leukocytes and endothelial cells. CD38 also functions in cell adhesion, signal transduction and calcium signaling. Positive and negative regulator of cell activation and proliferation, depending on the cellular environment.
- CD40** Member of the TNF-receptor superfamily. This receptor has been found to be essential in mediating a broad variety of immune and inflammatory responses including T cell-dependent immunoglobulin class switching, memory B cell development, and germinal center formation. AT-hook transcription factor AKNA is reported to coordinately regulate the expression of this receptor and its ligand, which may be important for homotypic cell interactions. Adaptor protein TNFR2 interacts with this receptor and serves as a mediator of the signal transduction. The interaction of this receptor and its ligand is found to be necessary for amyloid-beta-induced microglial activation, and thus is thought to be an early event in Alzheimer disease pathogenesis. Two alternatively

spliced transcript variants of this gene encoding distinct isoforms have been reported.

CD44 Family of cell surface glycoproteins with isoforms generated by alternate splicing of mRNA. CD44 is important in epithelial cell adhesion (cell-cell and cell-matrix) to hyaluronate in basement membranes and in maintaining polar orientation of cells; also binds laminin, collagen, osteopontin, matrix metalloproteinases (MMPs) and fibronectin. Involved in leukocyte attachment and rolling on endothelial cells, homing to peripheral lymphoid organs and sites of inflammation and leukocyte aggregation, hematopoiesis, and tumor metastasis.

CD45 Leukocyte common antigen (LCA); a protein tyrosine phosphatase. Critical requirement for T and B cell antigen receptor-mediated activation. Expressed on all hematopoietic cells except erythrocytes and platelets at different levels. Some isoforms of CD45 are CD45RO, CD45RA, and CD45RB. Each CD45 isoform is distinguished from one another depending on the type of exon the CD45 has or the exons the CD45 does not have. The CD45RA isoform contains the A exon only and the CD45RB has the B exon only whereas the CD45RO has none of the exons: A, B, or C.

CD45RA CD45RA—expressed by naive/resting T cells, medullary thymocytes

CD45RO CD45RO—expressed by memory/activated T cells, cortical thymocytes

CD56 N-CAM (neuronal adhesion molecule). Regulates homophilic (like-like) interactions between neurons and between neurons and muscle. Also associates with fibroblast growth factor receptor and stimulates tyrosine kinase activity of receptor to induce neurite outgrowth. When neural crest cells stop making N-CAM and N-cadherin and start displaying integrin receptors, cells separate and migrate. Contributes to cell-cell or cell-matrix adhesion during development. Lymphocyte activated killer phenomenon mediated by IL-2 activated CD56+, CD3-, NK cells. Prototypic marker of NK cells, also present on subsets of CD4+ and CD8+ T cells.

CD62L L selectin; LECAM-1. Mediates lymphocyte homing to high endothelial venules of peripheral lymphoid tissue, leukocyte rolling on activated endothelium at inflammatory sites.

CD64 High affinity receptor binds to Fc region of IgG. CD64 is important in phagocytosis via receptor-mediated endocytosis of IgG-antigen complexes. Mediates antigen capture for presentation to T cells, antibody-dependent cellular cytotoxicity, release of cytokines and reactive oxygen intermediates.

CD68 A 110-kDa transmembrane glycoprotein that is highly expressed by human monocytes and tissue macrophages. It is a type I integral membrane protein with a heavily glycosylated extracellular domain. May have

a role in macrophage phagocytic activities. Specific to lysosomes, not cell lineage. Expressed by macrophage/monocytes, basophils, dendritic cells, mast cells, myeloid cells, CD34+ progenitor cells, neutrophils, osteoclasts, activated platelets, B and T cells.

CD117 (c-Kit) The tyrosine kinase type receptor. The c-Kit gene encodes a 145-kDa transmembrane protein that is a member of the receptor tyrosine kinase subclass III family that includes platelet-derived growth factor receptor (PDGF-R), macrophage colony-stimulating factor receptor (M-CSF-R or c-fms), and fms-like tyrosine kinase-3/fetal liver kinase-2 (Flt-3/Flt-2). The ligand for c-Kit, Steel factor (SF) or kit ligand, stem cell factor, and mast cell growth factor, exists both as a secreted and membrane-bound form where the latter appears to be most important for biologic activity in vivo. Important for development and survival of mast cells, hemopoietic stem cells, melanocytes, germ cells, and interstitial cells of Cajal.

CD122 IL-2 receptor beta chain.

CD123 Interleukin 3 receptor, alpha (low affinity). The receptor is comprised of a ligand specific alpha subunit and a signal transducing beta subunit shared by the receptors for interleukin 3 (IL-3), colony stimulating factor 2 (CSF2/GM-CSF), and interleukin 5 (IL-5). The binding of this protein to IL-3 depends on the beta subunit. The beta subunit is activated by the ligand binding, and is required for the biological activities of IL-3.

CD134 (OX40) Tumor necrosis factor receptor superfamily, member 4. This receptor has been shown to activate NF-kappaB through its interaction with adaptor proteins TRAF2 and TRAF5. Knockout studies in mice suggest that this receptor promotes the expression of apoptosis inhibitors BCL2 and BCL2L1/BCL2-XL, and thus suppresses apoptosis. The knockout studies also suggest the roles of this receptor in CD4+ T cell response, as well as in T cell-dependent B cell proliferation and differentiation.

CD154 CD40 ligand (TNF superfamily, member 5, hyper-IgM syndrome) is expressed on the surface of T cells. It regulates B cell function by engaging CD40 on the B cell surface. A defect in this gene results in an inability to undergo immunoglobulin class switch and is associated with hyper-IgM syndrome.

CD278 Inducible T-cell co-stimulator, belongs to the CD28 and CTLA-4 cell-surface receptor family. It forms homodimers and plays an important role in cell-cell signaling, immune responses, and regulation of cell proliferation.

Cell body The body of the neuron containing the nucleus (also called the soma or perikaryon).

Cell-mediated delivery Delivery of therapeutic agents to the site of action inside carrier cells.

Central memory t cells Memory T cells that express L-selectin and CC-chemokine receptor 7 (CCR7) and have the capacity to circulate from the blood to the

- secondary lymphoid organs. They have a non-polarized differentiation state in that they secrete IL-2 but not IFN- γ or IL-4; however, on restimulation, they rapidly differentiate into cytokine-producing effector cells.
- Central nervous system (CNS)** The main information-processing organs of the nervous system, consisting of the brain, spinal cord, and meninges that controls and coordinates most function of the body and mind.
- Centroblast** A proliferating germinal-centre B cell, which undergoes somatic hypermutation and immunoglobulin class switching.
- Centrocyte** The non-dividing progeny of a centroblast. These cells need to be selected on the basis of affinity for antigen, following interaction with immune complexes that are associated with follicular dendritic cells, and ability to elicit help from follicular B helper T (T_{FH}) cells.
- Ceramide** A sphingosine-based lipid molecule that regulates a wide spectrum of biological processes such as cellular differentiation, proliferation, apoptosis and senescence.
- Cerebellum** A part of the brain that specializes in motor control as well as attention, language, fear, and pleasure regulation.
- Cerebral amyloid angiopathy** The deposition of β -amyloid in brain blood vessels.
- CSF** Cerebrospinal fluids are fluid in the ventricles of the brain, between the arachnoid and pia mater, and surrounding the spinal cord that absorbs shocks and maintains uniform pressure.
- Chemoattractant-receptor homologous molecule expressed by t_H2 cells (crth2)** A cell-surface marker for human T helper 2 cells.
- Chemokines** A group of secreted proteins within the family of cytokines that by definition relate to the induction of migration. These “chemotactic cytokines” are produced by and target a wide variety of cells, but primarily address leukocyte chemoattraction and trafficking of immune cells to locations throughout the body via a concentration-dependent gradient. Chemokines are categorized on the basis of the protein structure according to the types of cysteine motifs (e.g., C-C, C-X-C)
- Chemotaxis** Attraction and trafficking of cells to locations via a gradient.
- Choline acetyltransferase** The enzyme present in nerve endings that is responsible for the esterification of choline yielding the neurotransmitter acetylcholine.
- Cholinergic receptors** One of two general classes of receptors (either G protein-coupled or ligand-gated) that can be further sub-classified and responds to the neurotransmitter acetylcholine.
- Chorea** An abnormal voluntary movement disorder, and subcategory of dyskinesias, which are caused by overactivity of the neurotransmitter dopamine in the areas of the brain that control movement. Chorea is a primary feature of HD and important diagnostic symptom.
- Chromogranin A** A type of chromogranin which was first isolated from chromaffin cells of the adrenal medulla but is also found in other tissues and in many species including human, bovine, rat, mouse, and others. It is an acidic protein with 431–445 amino acid residues. It contains fragments that inhibit vasoconstriction or release of hormones and neurotransmitter, while other fragments exert antimicrobial actions.
- Chronic inflammatory neuropathy** A chronic autoimmune neuritis, which involves demyelination of peripheral nerves and spinal roots. This disease is thought to be mediated by autoantibody production to peripheral myelin. The effector cell types include macrophages, B cells, and CD4+ T cells.
- Choroid** A layer of the eye adjacent to the RPE containing a dense bed of fenestrated capillaries (also called the choriocapillaris).
- Circumventricular organ** Brain structures that lack a normal blood brain barrier, which allows for a link between the central nervous system and peripheral blood flow of peptides and hormones. These include the area postrema, subfornical organ, vascular organ of lamina terminalis, subcommissural organ, posterior pituitary, pineal gland and median eminence.
- Clade** A group of biological taxa (as species) that includes all descendants of one common ancestor.
- Class-switch recombination** The process by which proliferating B cells rearrange their DNA to switch from expressing IgM (or another class of immunoglobulin) to expressing a different immunoglobulin heavy-chain constant region, thereby producing antibody with different effector functions.
- Clinical trials** An experiment to test quality, value, or usefulness of a therapeutic agent in human subjects.
- CNPase** Refers to 2',3'-cyclic nucleotide 3'-phosphodiesterase that is present in myelin.
- CNS homeostasis** Level of maintenance needed for normal central nervous system health and function.
- Cocaine** A compound present in the leaves of coca trees that is a central nervous stimulant, which increases neuronal activity by lengthening the duration of action of norepinephrine, dopamine and/or serotonin in the neuronal synapse.
- Combination antiretroviral therapy** Combination of several classes of antiretroviral drugs for the treatment of HIV infections. The major classes of combination antiretroviral therapy include nucleotide reverse transcriptase inhibitors, non-nucleotide reverse transcriptase inhibitors, protease inhibitors and integrase inhibitors.
- Combination therapy** The use of two or more therapies, especially drugs, to treat a disease or condition.
- Complement system** A host defense mechanism made up of a group of serum proteins involved in the control of inflammation, the activation of humoral and acquired immune responses, and the lytic attack on cell membranes.

Complex disease Is a disease due to the interaction of multiple susceptibility genes and/or environmental risk factors. Most common medical problems fall within this category

Cone Photo-sensitive retinal cell mediating color vision and responsive to higher light levels than rods.

Connexins (Cx) Connexins, or gap junction proteins, are a family of structurally-related transmembrane proteins that assemble to form vertebrate gap junctions.

Cornea A transparent part of the eye that covers the iris, pupil, and anterior chamber from the front. It refracts light and provides most of the eye's focusing power.

Corticosteroids A group of natural and synthetic hormones that are immunosuppressive agents and are used for treatment of transplant rejection and autoimmune disorders. Natural corticosteroids are synthesized from cholesterol in the adrenal cortex and are involved in the stress response and regulation of inflammation, carbohydrate metabolism, protein catabolism, blood electrolyte levels, and behavior. Corticosteroids are further classified as glucocorticoids and mineralocorticoids.

CRH Corticotropin releasing hormone is a peptide hormone produced by cells in the hypothalamus in response to stressful stimuli that causes the synthesis and release of ACTH from anterior pituitary cells.

Creutzfeldt-Jakob disease (CJD) The most common prion disease of humans and can have a sporadic, familial or acquired etiology.

Crohn's disease Is a chronic autoimmune disease affecting the gastrointestinal tract, and can affect any region from mouth to anus.

CXCR4 receptor The receptor for the chemokine stromal cell-derived factor (SDF-1).

Cyclic nucleotide 3' phosphohydrolase (CNPase) A component of myelin that demonstrates increased activity in active stages of MS:

Cyclooxygenase-2 (COX-2) An inducibly-expressed subtype of prostaglandin-endoperoxide synthase. It plays an important role in many cellular processes and inflammation. It is the target of cox2 inhibitors.

Cyclophosphamide Nitrogen mustard alkylating agent that is used as an anticancer agent and immunosuppressive agent mainly in the treatment of autoimmune diseases.

Cyclosporine A cyclic polypeptide that acts as a calcineurin inhibitor. It is an immunosuppressive agent that is used in organ transplantation and autoimmune diseases.

Cytokines Regulatory soluble glycoproteins (8–30 kDa), such as interleukins and lymphokines, secreted by inflammatory leukocytes and some non-leukocytic cells that act as intercellular mediators. They differ from classical hormones in that they are produced by a number of tissue or cell types rather than by specialized glands. They generally act locally in a paracrine or autocrine rather than

endocrine manner, and facilitate communication among immune system cells and between immune system cells and the rest of the body.

Cytotoxic T lymphocytes (CTL) T cells that can kill other cells. Most cytotoxic T cells are MHC class I-restricted CD8+ T cells. Cytotoxic T cells are important in host defense against cytosolic pathogens.

1.5 D

Daclizumab Humanized monoclonal antibody directed against the IL-2 receptor on T cells. It is used for the prophylaxis of acute organ rejection in adult patients.

Delusions Fixed false beliefs

Dementia A term describing memory loss and other cognitive impairments that result from a number of causes, including Alzheimer's disease; marked by the development of multiple cognitive deficits (including memory impairment, aphasia, and inability to plan and initiate complex behavior). Deteriorated mentality is often accompanied by emotional apathy.

Demyelination The act of demyelinating, or the loss of the myelin sheath insulating the nerves, and is the hallmark of some neurodegenerative autoimmune diseases, including: multiple sclerosis, transverse myelitis, chronic inflammatory demyelinating polyneuropathy, Guillain-Barre Syndrome, and adrenoleukodystrophy. When myelin degrades, conduction of signals along the nerve can be impaired or lost, and the nerve eventually withers.

Dendrites The branching structures projecting from the cell body of a neuron that receive messages from other neural cells and work to transmit these messages via electrical impulses to the cell body from which they project.

Dendritic cells Antigen-presenting cells that process material to the T cells of the immune system. They connect the innate and adaptive immune systems.

Dendritic spine A small protrusion from the dendrite comprised of a head that forms one half of a synapse and a thinner neck that connects the head to the dendrite. Responsible for the controlled diffusion of molecules from the synapse to the dendrite. They contain the highest concentrations of actin, which retains dynamic activity and can drive rapid changes in its shape and therefore its function.

Dentate granule cell layer Tiny neurons (10 μm in diameter) located in the dentate gyrus of the hippocampus, which contain glutamatergic projection axons, and are one of only two major types of adult neuronal populations to undergo neurogenesis.

Dentate gyrus A subfield in hippocampus.

Depression Mood disorder (clinically, major depressive disorder or a milder form referred to as dysthymia)

characterized by persistent sadness, hopelessness, cognitive impairment and other symptoms that interfere with work, sleep, etc. and in severe cases can lead to suicide.

Dexamethasone suppression test Measures cortisol levels in response to dexamethasone (synthetic cortisol) administration. Specifically, it tests the response of adrenal glands to ACTH (adrenocorticotrophic hormone which is secreted from the anterior pituitary gland of the brain). Cortisol levels should decrease following dexamethasone administration. Abnormally high cortisol levels are seen following dexamethasone administration in up to 50 % of patients with a major depressive disorder.

DICER (Endoribonuclease Dicer); An enzyme in humans that cleaves double-stranded RNA and pre-microRNA into small interfering RNA and microRNA.

Differentiation The ability of a pluripotent cell to become a specialized cell type by expressing distinct lineage specific genes and undergoing morphological changes.

Dobutamine A norepinephrine derivative that mimics norepinephrine action primarily at the subtype one beta adrenergic receptor.

Dopamine One of the catecholamine neurotransmitters in the brain. It is derived from tyrosine and is the precursor to norepinephrine and epinephrine. Dopamine is a major transmitter in the extrapyramidal system of the brain, and important in regulating movement. A family of receptors (receptors, dopamine) mediates its action.

Dopamine hypothesis The hypothesis that schizophrenia is functionally related to excessive dopamine activity. Evidence for this is the observation that many antipsychotics have DA-antagonistic effects.

Dopaminergic neurons Neurons that utilize dopamine as a neurotransmitter.

Doublecortin Binds to the microtubule cytoskeleton, stabilizing them and causing bundling of microtubules.

Drug delivery The transport of therapeutic agents to the site of action.

d-tubocurarine An alkaloid that blocks the action of acetylcholine on skeletal muscles causing paralysis

Dynorphins Endogenous opioid peptides, 17 amino acids in length, derived from prodynorphin.

Dysthymia Minor depression, with fewer and less intense symptoms as major depressive disorder.

Dystonia A neurological movement disorder consisting of repetitive muscle contracts and abnormal fixed postures. Over time, the symptoms may spread to nearby muscles.

EBF Early B-cell factor.

Effector memory t cells Cells that have an L-selectin⁻CCR7 phenotype. They have immediate effector functions, including rapid production of cytokines (IFN- γ or IL-4), and they migrate to sites of inflammation, such as the skin and the gut. They recognize foreign invaders with a faster and stronger immune response than the initial immune response.

Embryonic germ cell (EG) A totipotent cell that can differentiate into all the cells of the organism, self-renew while maintaining its differential capability, the precursor for adult germ cells, and can be isolated from primordial germ cells of 5–9 week human fetuses.

Embryonic stem cell (ES) A multipotent stem cell that can differentiate into all the cells of the organism except the trophoblast, self-renew while maintaining its differential capability, and is isolated from the inner cell mass of the blastocyst stage embryo.

Encephalopathy A disease of the brain; especially one involving alterations of brain function and/or structure.

Endocytosis Uptake of molecules that cannot readily pass through the cell membrane through engulfment by the membrane resulting in the formation of a vesicle. This process is employed for a variety of functions within the cell such as reloading of synaptic vesicles with vesicular components at the active site through receptor-mediated endocytosis.

Endorphins Endogenous opioid peptides, 31 amino acids in length, derived from proopiomelanocortin.

Endothelins 21-Amino-acid peptides produced by vascular endothelial cells and functioning as potent vasoconstrictors. The endothelin family consists of three members, ENDOTHELIN-1; ENDOTHELIN-2; and ENDOTHELIN-3. All three peptides contain 21 amino acids, but vary in amino acid composition. The three peptides produce vasoconstrictor and pressor responses in various parts of the body. However, the quantitative profiles of the pharmacological activities are considerably different among the three isopeptides.

Enkephalins Short endogenous opioid peptides derived from proenkephalin and proopiomelanocortin.

Epidemiology Science of the incidence, distribution, and control of disease in a population.

Epidermal growth factor (EGF) A 6-kDa polypeptide growth factor initially discovered in mouse submaxillary glands. Human epidermal growth factor was originally isolated from urine based on its ability to inhibit gastric secretion and called urogastrone. EGF exerts a wide variety of biological effects including the promotion of proliferation and differentiation of mesenchymal and epithelial cells.

Epinephrine An analog of norepinephrine that is formed in the adrenal medulla and acts primarily as a hormone on

1.6 E

E2A Immunoglobulin enhancer binding factors, also E12/E47. Binds the immunoglobulin k chain enhancer and is involved in promoter regulation.

either alpha or beta adrenergic receptors. Responsible for the “fight or flight” response to danger.

EPSC Excitatory postsynaptic currents are the flow of ions resulting in EPSP

EPSP Excitatory postsynaptic potentials are temporary increases in postsynaptic membrane potentials caused by the flow of positively charged ions into the postsynaptic cell. The influx of positively charged ions leads to an excitatory response therefore simplifying the neuron’s generation of an action potential.

Epstein Barr virus (EBV) A gamma human herpesvirus.

Exocytosis Vesicles carrying molecules to be secreted from the cell merge with the cell membrane resulting in the vesicular contents being released to the exterior of the cell. This is the method by which neurotransmitters are released at the active site.

EAE Experimental allergic/autoimmune encephalitis is an animal model for demyelinating diseases, such as multiple sclerosis. It is induced by injection of myelin basic protein or whole CNS tissue together with adjuvants.

Exosome A cell-derived vesicle present in many biological fluids.

Experimental allergic encephalomyelitis (EAE) An animal model of brain inflammation, used mostly with rodents, and serves as a model of the human disease multiple sclerosis.

Experimental allergic neuritis (EAN) Animal model of acute inflammatory demyelinating polyradiculoneuropathy that shares many features with human GBS. EAN can be induced in rodents, rabbits, and monkeys by immunization with peripheral nerve homogenate, myelin, and myelin proteins such as PO.

Each ferritin molecule consists of ferric iron in a hollow protein shell (apoferritins) made of 24 subunits of various sequences depending on the species and tissue types.

Fetal liver kinase (Flk)-2 A member of the tyrosine kinase receptor family, this 135–150 kDa molecule is expressed by multipotential progenitor cells including primitive B cell and myelomonocytic progenitors in fetal liver and adult bone marrow. Also called as Fms-like tyrosine kinase 3 (Flt3) and CD135 in human.

Fibroblast growth factor (FGF)-2 A single-chain polypeptide growth factor that plays a significant role in the process of wound healing and is a potent inducer of physiologic angiogenesis. Several different forms of the human protein exist ranging from 18 to 24 kDa in size due to the use of alternative start sites within the fgf-2 gene. It has a 55 % amino acid residue identity to fibroblast growth factor 1 and has potent heparin-binding activity. The growth factor is an extremely potent inducer of DNA synthesis in a variety of cell types from mesoderm and neuroectoderm lineages. It was originally named basic fibroblast growth factor based upon its chemical properties and to distinguish it from acidic fibroblast growth factor (Fibroblast Growth Factor 1).

Follicular dendritic cells (FDCs) Cells found in lymph follicles that present immune complexes to B cells, aiding in B cell maturation.

Fovea The high acuity region of the retina upon which the center of the visual image is focused. The fovea contains only cones.

Friedreich ataxia An autosomal recessive inherited disease, which causes damage to the nervous system and potentially scoliosis, heart disease, and diabetes.

1.7 F

Facilitated diffusion A process of passive transport where molecules move across membranes with the assistance of transport proteins

Family-based association study Is an association study that uses families as the source, where the parents are the controls and affected are their offspring.

Fas Fas/APO-1/CD95 (36 kDa) is a member of the tumor necrosis factor (TNF) receptor superfamily. Fas has been shown to be an important mediator of apoptotic cell death, as well as being involved in inflammation.

Fatal insomnia Rare prion disease of humans that is initially characterized by sleeplessness, later developing into hallucinations, followed by extreme weight loss, dementia and finally death

Ferritin Iron-containing proteins that are widely distributed in animals, plants, and microorganisms. Their major function is to store iron in a nontoxic bioavailable form.

1.8 G

Gadolinium A radio-opaque dye injected in conjunction with magnetic resonance imaging (MRI) to evaluate the brain parenchyma for breaches in the cerebrovascular system.

Ganglia A collection of cell bodies of the postganglionic motor neurons which join synapse with nerves from the central nervous system; they act as relay stations for CNS impulses to peripheral effector cells and as control loops for reflex actions.

Gangliosides Sialic acid-containing glycosphingolipids which are widely distributed in mammalian tissues but highly enriched in the nervous system, due to their incorporation into the myelin sheath. Gangliosides consist of a tetraose core to which variable numbers of sialic acids are attached; the ceramide or lipid portion of the molecule is attached to the internal glucose. GM1, GD1b, GD1a, and GT1b are the most abundant complex gangliosides in the nervous system.

- Gap junctions** Gap junction or nexus is a junction between certain animal cell-types that allows cell-to-cell passage of ions, hormones, and neurotransmitters. One gap junction is composed of two connexons (or hemichannels), which connect across the intercellular space, therefore connecting the cytoplasm of the cells. They are analogous to the plasmodesmata that join plant cells.
- GATA3** Binding protein 3. GATA-3 expression inhibits the differentiation of Th1 cells *in vivo*, induces Th2 cell differentiation, and increases functional capacity to secrete Th2 cytokines and enhance surface expression of markers for antigen-experienced Th2-committed cells. GATA-3 expression must be sustained to maintain the Th2 phenotype.
- Gene arrays** High throughput technique used to analyze different expression profiles using a collection of gene-specific nucleic acids.
- Gene modifiers** Are genes that affect the expression of the phenotype of a trait.
- General anesthetics** A group of diverse agents used in surgery to produce loss of pain perception and loss of consciousness. They depress most CNS modalities, including respiration.
- Genetic heterogeneity** Describes when a disorder has more than one genetic cause that causes the same clinical presentation.
- Genome** One haploid set of chromosomes with the genes they contain; *broadly*: the genetic material of an organism.
- Genomic convergence** A process in which multiple independent genomic research techniques are used to identify possible causal genes, with the overlap between the results in each technique converged to produce the genes with the highest likelihood of being involved in the disorder.
- Genomics** Field of science that combines genetics and molecular biology techniques to create genetic maps and DNA sequences; analyze and organize genetic information into databases.
- Genotype association** Association with a specific genotype but not necessarily an allele.
- Germinal centre** A lymphoid structure that arises within follicles after immunization with, or exposure to, a T-cell-dependent antigen. It is specialized for facilitating the development of high-affinity, long-lived plasma cells and memory B cells.
- Gerstmann-Straussler-Scheinker (GSS)** Syndrome is a prion disease linked to germline mutations or insertions in the human prion protein gene resulting in a neurodegenerative brain disorder.
- Glatiramer acetate** An FDA approved therapy for relapsing remitting multiple sclerosis that consists of acetate salts of polypeptides that are found in myelin and contains four naturally occurring amino acids randomly synthesized: L-glutamic acid, L-alanine, L-tyrosine, and L-lysine; available as Copaxone®, 20 mg of glatiramer acetate and 40 mg of mannitol for subcutaneous injection daily.
- Glaucoma** A group of eye diseases that include damage to the optic nerve and vision loss. Other symptoms can include severe eye pain, blurred vision, and nausea.
- Glia** Non-neural cellular element that has diverse functions in the nervous system including participation in innate immunity, myelin formation, signal transmission, and homeostasis maintenance.
- Glial activation** Refers to activation of glial cells (astrocytes and microglia) in response to proinflammatory stimuli triggered by injury or disease. This can usually be detected by the presence of glial fibrillary acidic protein (GFAP) in astrocytes.
- GDNF** Glial cell line-derived neurotrophic factor is the founding member of the glial cell line-derived neurotrophic factor family. It was originally characterized as a nerve growth factor promoting the survival of midbrain dopaminergic neurons, and it has been studied as a potential treatment for Parkinson's disease.
- GFAP** Glial fibrillary acidic proteins form the main intermediate filament in astrocytes and are therefore used as the marker protein of astrocytes.
- Glial scar** Scar formed due to insults to the CNS.
- Glucocorticoids** Steroid hormones (esp. cortisol in humans) produced by the adrenal cortex in response to stressful stimuli.
- Glutamate** The most important excitatory neurotransmitter in the CNS. Glutamate binds to either metabotropic, or ionotropic receptors. Ligation of glutamate at the NMDA receptor—one of the ionotropic receptors—induces calcium influx into the neuron. Astrocytes are crucially involved in glutamate metabolism, storage and re-uptake.
- Glutamine** An amino acid that is formed from glutamate. Glutamine in excess is toxic for the brain.
- Growth factor** Growth factors stimulate cell proliferation and/or differentiation during embryonic development, tissue growth and wound healing. The term “growth factors”, used in this chapter, also refers to a broad range of structurally diverse molecular families and individual proteins.
- Guanine nucleotide binding proteins (G-proteins)** Membrane-associated, heterotrimeric proteins composed of three subunits: alpha, beta and gamma subunits. G proteins and their receptors (GPCRs) form one of the most prevalent signaling systems in mammalian cells, regulating systems as diverse as sensory perception, cell growth and hormonal regulation. Binding of ligands such as hormones and neurotransmitters to a G-protein coupled receptors causes a conformational change, which in turn activates the bound G protein on the intracellular-side of the membrane. The activated receptor promotes the exchange of bound GDP for GTP on the G protein alpha subunit.

Guillain Barré syndrome An acute monophasic neuropathy characterized by an autoimmune response to peripheral myelin, and is the most common acquired demyelinating peripheral neuropathy. Pathogenesis involves mononuclear cell infiltration in the peripheral nerves, along with both B cells and CD4+ helper T cells. Symptoms begin as tingling sensations and weakness in the legs and in extreme cases can lead to the development of total paralysis. Current treatment includes high-dose intravenous Ig and plasma exchange.

1.9 H

Hallucinations Sensory misperceptions in which a person will experience an auditory, visual, or other sensory experience in the absence of observable stimuli

Haplogroup A haplotype of the mitochondrial genome.

Haplotype With two polymorphisms in linkage disequilibrium the alleles of those two polymorphisms travel together as a single combined allele or haplotype.

Hemorrhagic stroke Accounts for 15–20 % of all strokes. Rupture of a blood vessel into the brain parenchyma results in an intracerebral hemorrhage (ICH); this is commonly caused by hypertension-induced vascular disease of the small perforating intracranial arteries. Rupture of a vessel into the subarachnoid space results in a subarachnoid hemorrhage; this most commonly results from rupture of a brain aneurysm or an arteriovenous malformation.

Herpes simplex virus (HSV) A naturally neurotropic virus capable of establishing latent infection within neurons, but also possesses the ability to infect a wide range of cellular targets. Recombinant HSV vectors comprise a wild-type HSV genome rendered replication defective via disruption/deletion of an indispensable viral gene(s). Typically, the immediate-early gene loci, which encode for potent transactivation proteins that initiate the viral lytic cycle, are targeted for insertion of therapeutic transcription units via homologous recombination. The HSV-1 amplicon, another type of HSV vector, is a uniquely designed eukaryotic expression plasmid that harbors two non-protein encoding virus-derived elements: an HSV origin of DNA replication (OriS) and the cleavage/packaging sequence ("a" sequence). Both *cis* sequences are specifically recognized by HSV proteins to promote the replication and incorporation of the vector genome into viable viral particles, respectively. This highly versatile plasmid can be readily manipulated to contain desired promoters, enhancers, and transgenes of substantial size (~130 kb).

High endothelial venules (hevs) Specialized venules found in lymphoid tissues, which are the site of entry for lymphocytes from the bloodstream into lymph nodes and Peyer's patches.

Hippocampus Part of the brain located inside the temporal lobe. It forms a part of the limbic system and plays a part in memory and spatial navigation.

Histone acetyl transferase Enzymes that acetylate conserved lysine residues on histone proteins by transferring an acetyl group from acetyl CoA to form -N-acetyl lysine.

Histone deacetylase A class of enzymes that remove acetyl groups from an -N-acetyl lysine on histones.

HIV-1 associated dementia HIV-1 associated dementia is a cognitive disorder specific to HIV, HAD is the clinical consequence of HIV-1 infection in the CNS and chronic inflammatory response that ultimately causes neuronal damage.

Horizontal cell Lateral inhibitory interneuron in the outer retina.

HIV-associated neurocognitive disorders (HAND) These disorders can include AIDS dementia complex, HIV associated dementia, HIV encephalopathy, and Mild Neurocognitive Disorder. They share the features of cognitive impairment and motor dysfunction.

Homeostasis The property of a system to actively regulate a variable and maintain a constantly consistent level.

HTLV-I-associated myelopathy/tropical spastic paraparesis (HAM/TSP) A chronic progressive inflammatory disorder of the CNS caused by infection with HTLV-. This disorder affects 0.25–3 % of HTLV-I-infected individuals.

Human herpes virus 6 (HHV-6) A beta human herpesvirus, which is a common opportunistic viral infection for the immunosuppressed.

Human leukocyte antigen (HLA) The genetic designation for the human major histocompatibility complex (MHC). This group of genes resides on chromosome 6, and encodes cell-surface antigen-presenting proteins and many other genes. Individual loci are designated by upper-case letters, as in HAL-A, and alleles are designated by numbers, as in HLA-A0201. HLA-B27 is a genetic marker present in patients' ankylosing spondylitis and Reiter's syndrome

Human T cell lymphotropic virus type I (HTLV-I) An exogenous human retrovirus that infects 10–20 million people worldwide. Endemic areas of HTLV-I infection include southern Japan, certain regions of Africa and South American, and the Caribbean. HTLV-I is the etiologic agent of both an aggressive T cell leukemia and an inflammatory disorder of the CNS.

Huntingtin (htt) A causative gene of Huntington's Disease (HD), with its N-terminal CAG trinucleotide repeat expansion correlated with the onset of the disease. Predicted to function as a scaffolding molecule for multiple transporting/transcriptional molecules in cytoplasm and nucleus. Inclusion of htt and/or its N-terminal polyglutamine tract have been proposed as a potential mechanism of neurodegeneration in HD.

Huntington Disease A progressive neurodegenerative disorder that is inherited as an autosomal dominant trait, that usually begins in middle age, that is characterized by choreiform movements (involuntary, rapid, jerky movements) and mental deterioration leading to dementia. Histologically, Huntington disease shows atrophy of the caudate nucleus and the loss of brain cells with a decrease in the level of several neurotransmitters—called also Huntington's—abbreviation HD:

Hydrophilicity A physico-chemical characteristic of a compound attributed to its ability to dissolve in water solutions.

Hyphenated techniques Combination of individual techniques, such as liquid chromatography (LC) and mass spectrometry (MS), to create one encompassing method (LC-MS) capable of new analytical possibilities.

Hypomania A less severe and less persistent form of mania. Seen in such disorders as bipolar II and cyclothemia.

Hypothalamic-pituitary-adrenal (HPA) axis Neuroendocrine pathway that mediates the stress response by regulating systemic cortisol levels and brain CRH levels.

Hypothalamo-pituitary-adrenocortical (HPA) axis The major endocrine route in stress response. Activation of the HPA axis results in the secretion of corticotropin-releasing factor (CRF) from the hypothalamic paraventricular nucleus (PVN), adrenocorticotropin (ACTH) from the pituitary, and glucocorticosteroids (cortisol) from the adrenal cortex. Cytokines such as IL-1, IL-6, TNF- α are known to activate the HPA axis.

1.10 I

ID2 A helix-loop-helix protein that can inhibit transcription factors with a basic helix-loop-helix motif. Besides its role in lymphoid organogenesis, ID2 is required for the generation of natural killer cells.

IFN β -1a An FDA approved therapy for relapsing remitting multiple sclerosis. IFN β -a is available as Avonex[®] (Biogen-Idec) 33 μ g for intramuscular injection (IM) once a week and Rebif[®] (Serono) with doses of 22 μ g and 44 μ g for subcutaneous (SQ) injection 3X/week.

IFN β -1b An FDA approved therapy for relapsing remitting multiple sclerosis, available as Betaseron[®] for subcutaneous injection 22 μ g (6MIU) per dose for 66 μ g/week and 44 μ g (12 MIU) per dose for 132 μ g per week.

IKAROS This gene encodes a family of zinc-finger transcription factors that regulate transcription required for the development of all lymphoid lineages, as well as lymph nodes and Peyer's patches.

IL-7R A receptor for interleukine 7 (IL-7). The function of this receptor requires the interleukin 2 receptor, gamma

chain (IL2R γ), which is a common gamma chain shared by the receptors of various cytokines, including interleukines 2, 4, 7, 9, 15, 21. This protein has been shown to play a critical role in the V(D)J recombination during lymphocyte development. This protein is also found to control the accessibility of the TCR gamma locus by STAT5 and histone acetylation. Knockout studies in mice suggested that blocking apoptosis is an essential function of this protein during differentiation and activation of T lymphocytes. The functional defects in this protein may be associated with the pathogenesis of the severe combined immunodeficiency (SCID).

Imipramine An agent effective in the treatment of depression that acts to increase neuronal activity by lengthening the duration of action of norepinephrine and/or serotonin in the neuronal synapse.

Immune deviation Modification of cells having or producing antibodies or lymphocytes capable of an immune response to an antigen after prior exposure to that antigen.

Immune neuropathies Heterogeneous group of neuropathies with an assumed autoimmune pathogenesis. This includes acute forms such as Guillain-Barré Syndrome (GBS) and chronic conditions such as chronic inflammatory demyelinating polyneuropathy (CIDP) as well as polyradiculoneuropathies associated with monoclonal paraprotein.

Immune neuropathy Disease of the peripheral nerves that is mediated by autoimmune processes, either cellular or humoral autoimmunity

Immune privileged Organs or tissues where entry of effector lymphocytes is blocked by anatomic barriers and is not recognized by immune cells due to absence or low levels of expression of MHC class I and II antigens.

Immunoglobulins Natural immunomodulatory compounds that provide passive immunization and are used in a variety of diseases.

Immunomodulator A type of adjuvant that directly activates cells of the immune system, usually via cytokine release

Immunosuppression A decrease in any functional assay of immune competence from its baseline level in normal animals.

Immunotherapy The treatment of a disease by vaccination or by administering antibodies.

Induced pluripotent stem cells Stem cells which can be directly generated from adult cells.

Infliximab Chimeric anti-TNF- α monoclonal antibody. It is used in the treatment of rheumatoid arthritis and other autoimmune diseases.

Innate immune system The dominant system of host defense in most organisms. Innate immune defenses are non-specific, and do not confer long-lasting immunity against a pathogen.

Inflammation A local response to cellular injury that is marked by capillary dilatation, leukocytic infiltration, and often loss of function. Inflammation serves as a mechanism initiating the elimination of noxious agents and of damaged tissue:

Insulin degrading enzyme (IDE) Responsible for the degradation of the β -chain of insulin, expressed abundantly in microglia and also other neuronal cells in brain.

Insulin like growth factor Resembles insulin but is contained in part of a complex used to communicate with their physiologic environment, contributing to cell such processes as proliferation and inhibition of cell death. The complex consists of two cell-surface receptors, two ligands, and six high affinity binding proteins.

Intercellular adhesion molecule 1 (ICAM-1) Molecules that promote adhesion between cells.

Interferon-gamma The major interferon produced by mitogenically or antigenically stimulated lymphocytes. It is structurally different from type I interferon and its major activity is immunoregulation. It has been implicated in the expression of class II histocompatibility antigens in cells that do not normally produce them, leading to autoimmune disease.

Interferons (IFNs) Natural and recombinant compounds with important immunomodulatory activities, such as inflammation, antigen presentation, and antiviral activity. IFN type I binds to IFN- α receptor complex, and IFN type II binds to IFN- γ receptor complex.

Interleukin A group of cytokines (secreted signaling molecules) that mediate autocrine, paracrine and endocrine communication between cells of the immune system and other systems of the body. They enhance cell proliferation and differentiation, proteins **DNA** produced by the cells of the immune system of most vertebrates in response to challenges by foreign agents such as viruses, bacteria, parasites and tumor cells. They were first seen to be expressed by white blood cells (leukocytes, hence the -leukin) as a means of communication (inter-). The name is something of a relic though; it has since been found that interleukins are produced by a wide variety of bodily cells. The function of the immune system depends in a large part on interleukins. They are designated by IL and a number. IL-1 causes fever. IL-12 biases towards a Th1 response. IL-10 is anti-inflammatory. IL-8 is chemotactic. The interleukins are comprised of some of the cytokines and some of the chemokines.

Interleukin-2-recombinant form of IL-2 An immunostimulant used to treat adults with metastatic renal carcinoma and melanoma.

Intraocular pressure A measurement of the fluid pressure inside the eye. This fluid, or aqueous humor, nourishes the cornea, iris, and lens, and it helps the eye maintain its globular shape. Normal eye pressure, as measured by

an eye doctor, usually ranges between 10 and 21 mm of mercury, with an average of 16.

Ion channel Protein that mediates the transport of ions across membranes through the formation of a pore in the cell membrane, therefore allowing for the establishment of a voltage gradient across the cell membrane.

Ipratropium A derivative of atropine that blocks the action of acetylcholine on muscarinic cholinergic receptors.

IRF4 and IRF8 IFN regulatory factors (IRFs) are a family of transcription factors involved in the regulation of both innate and adaptive immunity. By gene knockout studies, IRF1, IRF4, and IRF8 have been found to be essential for the proper differentiation and functions of immune cells. Lymphocyte development requires IRF1 and IRF4, whereas IRF7 and IRF8 are needed for monocyte-to-macrophage differentiation, and together with IRF1, IRF8 orchestrates the development of Th1 immune responses by regulating the gene expression of IL-12, the major Th1 immune response-inducing cytokine. Recently, IRF4 and IRF8 have also been shown to participate in DC differentiation and functions. An interesting feature of IRF4 and IRF8 is their ability to function as transcriptional activators and repressors, depending on the promoter context.

Ischemic stroke Account for around 80–85% of all strokes and are nearly always caused by arterial vascular occlusions; rarely occlusion in the cerebral venous system may result in ischemic and/or hemorrhagic stroke.

Isoproterenol An analog of norepinephrine that mimics norepinephrine action primarily at the beta adrenergic receptors. It is used to treat asthma, chronic bronchitis, and emphysema; by relaxing the airways to allow for increased airflow.

Isotypes Classification of various immunoglobulins by the type of chain they are composed of. This classification varies between species.

1.11 J

JAK-STAT pathway A signaling pathway utilized by cells to respond to cytokines and growth factor stimuli. This pathway transduces the signals carried by cytokines to the cell nucleus, where activated STAT proteins modify gene expression. JAKs—Janus Kinases; STATs—Signal Transducers and Activators of Transcription.

1.12 K

Keratinocytes Epithelial cells dividing in the stratum basale of the epidermis, they accumulate keratin, undergo apoptosis and are sluffed off at the skin surface. In psoriasis, the cycle is accelerated from 30 days to 7–10 days.

KIRs Killer immunoglobulin like receptors are MHC-binding receptors on NK cells that triggers NK cell-mediated responses. KIRs diversify human natural killer cell populations and T cell subpopulations. Ly49, the analogous system in rodents.

Kinase A kinase is a type of phosphotransferase that catalyzes the transfer of a phosphate from ATP to specific substrates.

Kuru A prion disease of the Fore speaking tribes in the New Guinea highlands in which disease was transmitted via endocannibalism.

Kynurenic acid The only known endogenous NMDA receptor antagonist. Kynurenic acid is the end product of a side arm of the kynurenine pathway. Besides its neuroprotective NMDA binding properties, kynurenic acid also blocks the $\alpha 7$ nicotinic acetylcholine receptor.

Kynurenine pathway More than 95 % of tryptophan in the organism are metabolised through the kynurenine pathway, which is entitled by the first stable intermediate, kynurenine. The activity of one of the key enzymes, indoleamine 2,3-dioxygenase, is regulated by cytokines: IFN- γ and TNF- α are inducers, while IL-4 and IL-10 are inhibitors of IDO. Neuroactive kynurenine pathway intermediates include the free-radical generators 3-hydroxykynurenine, 3-hydroxyanthranilic acid, and quinolinic acid. The latter is also an excitotoxic NMDA receptor agonist. The major end product of the kynurenine pathway is nicotinamide adenine dinucleotide phosphate (NADP⁺/NADPH), a major source of electrons e.g. for reductive biosynthesis.

1.13 L

Learned helplessness A condition induced by inescapable, unavoidable, unpleasant stress, in which impaired coping and maladaptive behavior results.

Lectin Carbohydrate-binding proteins, macromolecules that are highly specific for sugar moieties.

LEF1 Lymphoid enhancer-binding factor 1 is a 48-kDa nuclear protein expressed in pre-B and T cells. LEF1 binds to a functionally important site in the T-cell receptor- α enhancer and confers maximal enhancer activity. LEF1 belongs to a family of regulatory proteins that share homology with high mobility group protein-1.

Lentivirus A member of the retrovirus family of enveloped RNA viruses associated with causing serious immunosuppressive diseases (i.e., AIDS). Vectors derived from lentiviruses can harbor a transgene up to 9 kb in size and express the transgene in vivo months to years.

Leucine-rich repeat kinase-2 (LRRK2) A complex protein with multiple domains, including a leucine-rich repeat (LRR), a ROC-COR GTPase, a mitogen-activated protein kinase kinase Kinase, and WD40 domains. Mutations have

been found in all domains in LRRK2 and have been identified as the cause of the late-onset, autosomal-dominant Park8 type of Parkinson's disease.

Lewy body Intracytoplasmic neuronal inclusions which are intensely eosinophilic under routine haematoxylin-eosin stain. Immunocytochemically, Lewy bodies share epitopes with phosphorylated and non-phosphorylated α -synuclein, neurofilament subunits, tubulin, microtubule-associated protein 1 and 2, and positively immunostain with ubiquitin. Lewy bodies are classically associated with Parkinson's disease, but also are present in a distinct form of dementia termed diffuse Lewy body disease, described recently in the elderly.

Limbic system An interconnected system of brain nuclei associated with basic needs and emotion, for example hunger, pain, pleasure, satisfaction and instinctive motivation.

Lin Lineage marker negative cells are those lacking distinctive antigen associated with lymphoid, myeloid, erythroid or natural killer cells.

Linkage Describes the relationship between two measurable traits that travel together through a pedigree more than expected by chance, suggesting the two lie physically near each other.

Linkage disequilibrium Two genetic variations that lie physically close to each other (linkage) and travel together through multiple generations in a population unchanged. This means the allele of one variation will be on the same piece of DNA as a specific allele of another variation, and thus they are correlated. This correlation can be measured and is referred to as linkage disequilibrium. The actual term comes from the fact that these variations do not follow the expectations of Hardy-Weinberg equilibrium and thus are in disequilibrium do to linkage.

Lipophilicity A physico-chemical characteristic of a non-polar compound attributed to its ability to dissolve in organic solvents.

Lipopolysaccharide (LPS) Large molecule consisting of a lipid and a polysaccharide (carbohydrate) joined by a covalent bond. LPS is a major component of the outer membrane of Gram-negative bacteria, contributing greatly to the structural integrity of the bacteria, and protecting the membrane from certain kinds of chemical attack. LPS is an endotoxin, and induces a strong response from normal animal immune systems. LPS acts as the prototypical endotoxin, because it binds the CD14/TLR4/MD2 receptor complex, which promotes the secretion of pro-inflammatory cytokines in many cell types, particularly in macrophages.

Liposome A spherical vesicle with a membrane composed of a phospholipid and cholesterol bilayer.

Liquid chromatography A method to separate mixtures using a liquid medium and high pressures.

Long terminal repeat A region of the retroviral genome principally involved in mediating insertion of the viral genome into the host chromosome.

Long-term potentiation A long-lasting enhancement of synaptic efficacy. Regarded as a primary mechanism in memory formation.

Ly49 Killer cell lectin-like receptor subfamily A, member 1. Analogous for human KIRs. A natural killer cell receptor.

Lymphocyte A subsection of white blood cells, which include natural killer cells, T cells, and B cells that are most commonly found in lymph.

Lymphoid chemokines (CCL-13, -21) These chemotactic cytokines are constitutively expressed in lymphoid tissues and mediate the formation and maintenance of micro-domains in lymphoid organs (See chemokines).

Lymphotoxin (It) Protein belongs to the tumour-necrosis factor family and can be produced as a secreted homotrimer, LT β , or as a membrane-bound heterotrimer, LT $\alpha_1\beta_2$. The heterotrimer LT $\alpha_1\beta_2$ binds to the lymphotoxin-receptor (LTR). LT β is an inducer of the inflammatory response system and involved in normal development of lymphoid tissue.

1.14 M

Macrophage A phagocytic cell of the reticuloendothelial system or mononuclear phagocyte system that may be fixed or freely motile. Myeloid-derived cell of the innate immune system matures from a monocyte, and functions in the protection of the body against infection and noxious substances.

Magnetic resonance imaging (MRI) The use of a nuclear magnetic resonance spectrometer to non-invasively produce electronic images of specific atoms and molecular structures in solids, especially human cells, tissues, and organs.

Magnetic resonance spectroscopy A method to determine physical and chemical properties of atoms and molecules through their magnetism.

Magnocellular ganglion cells Large retinal ganglion cells with low resolution but high sensitivity to intensity changes and motion.

Major depressive disorder A mental illness characterized by a persistent low mood and decreased interest and pleasure, as well as symptoms such as loss of energy and sleep and appetite disturbances

Major histocompatibility complex (MHC) A large genomic region with the primary immunological function to bind and "present" antigenic peptides on the surfaces of cells for recognition (binding) by the antigen-specific T cell receptors (TCRs) of lymphocytes. Differential structural properties of MHC class I and class II molecules account for their respective roles in activating different

populations of T lymphocytes. Class I molecules play a central role in the immune system by presenting peptides derived from the endoplasmic reticulum lumen. They are expressed in nearly all cells. The class II molecule plays a central role in the immune system by presenting peptides derived from extracellular proteins. Class II molecules are expressed in antigen presenting cells (APC: B lymphocytes, dendritic cells, macrophages).

Mania A phase of bipolar disorder characterized by elevated or irritable mood, as well as symptoms such as increased high risk behavior and decreased need for sleep.

Mantle zone The area of a secondary follicle that surrounds the germinal centre and contains IgD⁺ naive, resting B cells.

MAP kinase pathways Signaling pathway utilized by cells to respond to extracellular stimuli. Activation of this pathway regulates varied cellular activities including gene expression, mitosis, differentiation, and cell survival/apoptosis.

Mass spectrometry Technique used to measure the mass-to-charge ratio of ions to identify the components of a sample.

Mast cell A type of white blood cell derived from the myeloid stem cell and contains many granules with histamine and heparin.

MDR inhibitor A compound terminating multidrug resistance in cells.

Mecamylamine A synthetic compound which blocks the effect of acetylcholine at autonomic ganglia.

Medium spiny neurons (MSNs) The most numerous and principal projection neurons from the striatum. The death of GABAergic MSNs in the striatum is associated with Huntington's Disease.

Melanocortin-1 receptors G-protein-coupled receptors that are stimulated by α -MSH (melanocyte stimulation hormone). These receptors are found in pigmented cells as well as immune cells.

Melanopsin The photopigment found in intrinsically light-sensitive ganglion cells involved in setting circadian rhythms.

Mendelian disease A disease caused by a single gene mutation such as sickle-cell anemia.

Meningitis Inflammation of the meninges and especially of the pia mater and the arachnoid.

Metallothionein (MT)-I/II A family of Cys-rich, low molecular weight (MW ranging from 3500 to 14,000 Da) proteins. MTs have the capacity to bind both physiological (such as Zn, Cu, Se) and xenobiotic (such as Cd, Hg, Ag) heavy metals through the thiol group of its cysteine residues, which represents nearly the 30 % of its amino acid residues. Important to uptake, transport and retention of metals.

mGluR6 Type III metabotropic glutamate receptor that mediates responses of ON type bipolar cells in the vertebrate retina. mGluR6 couples to the G protein, G_o,

- stimulating a signaling cascade that causes the closing of cation channels.
- Micelle** An aggregate of surfactant molecules dispersed in a liquid colloid. A typical micelle in aqueous solution forms an aggregate with the hydrophilic “head” regions in contact with surrounding solvent, sequestering the hydrophobic tail regions in the micelle center.
- Microglia** Cells derived from myeloid progenitor cells (as are macrophages and dendritic cells) which come from the bone marrow and are key cellular mediators of neuroinflammatory processes in the CNS.
- microRNA** A small non-coding RNA molecule that functions in RNA silencing and post-transcriptional regulation of gene expression.
- Mitogen** A substance that induces cell division in lymphocytes in an antigen nonspecific way. Concanavalin A (Con A) is extracted from the Jack Bean plant and triggers T cell proliferation. Lipopolysaccharide (LPS) is part of the outer membrane of Gram-negative bacteria and triggers B cell proliferation.
- Mitoxantrone** FDA approval for use in progressive MS; available as (Novantron®) with recommended dosage of 5–12 mg/mL IV every 3 months. Because of cumulative cardiotoxicity, the drug can be used for only 2–3 years for a cumulative dose of 120–140 mg per m².
- Molecular adjuvant** An adjuvant comprised of a single molecular entity that targets antigens to and/or activates specific pathways of antigen processing and presentation.
- Molecular mimicry** Immunological mechanism, whereby epitopes incidentally shared by microbial antigens and target tissues elicit an autoreactive T- or B-cell response in the wake of an infective illness. This autoimmune response then injures the ‘self’ target tissues.
- Monoclonal antibody** A laboratory-produced antibody clone of one isotype that reacts to a single epitope.
- Mononuclear phagocytes (MP)** Phagocytic cells that typically initiate the host immune response. Mononuclear phagocytes include monocytes, mature macrophage, microglia and dendritic cells. These cells are widely distributed throughout the body in blood, tissue, and immune tissue identifying pathogens and steering the immune response, as well as clearing debris.
- Mood disorders** Mental disorders characterized by inappropriate or abnormal emotional states, such as depression and bipolar disorder.
- Mood stabilizers** Pharmacological agents used to treat bipolar disorder, including lithium, valproate, carbamazepine, and lamotrigine.
- Morphine** An alkaloid present in opium, an extract of the poppy plant, which binds principally to the mu opioid receptor and relieves pain.
- MPP+** A product of MPTP metabolism, capable of inducing a Parkinson like state through inhibition of complex I of the electron transport chain. (see MPTP)
- MPTP** 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, a lipophilic pro-neurotoxin that is metabolized by monoamine oxidase B to the active dopaminergic toxin, 1-methyl-4-phenylpyridinium (MPP+).
- Muller cell** A radial glial cell that is the predominant glial cell type in retina.
- Multidrug resistance** The ability of pathologic cells to withstand chemicals that are designed to aid in the eradication of such cells.
- Multiple Sclerosis** (Abbreviated MS, also known as disseminated sclerosis or encephalomyelitis disseminata) a chronic, inflammatory, demyelinating disease that affects the central nervous system (CNS). MS can cause a variety of symptoms, including changes in sensation, visual problems, muscle weakness, depression, difficulties with coordination and speech, severe fatigue, cognitive impairment, problems with balance, overheating, and pain.
- Muromonab-CD3** A monoclonal antibody directed at the epsilon chain of CD3 adjacent to the T cell receptor on human T lymphocytes, preventing T-cell activation. It is indicated for the treatment of acute organ transplant rejection.
- Muscarine** An alkaloid which blocks the effects of acetylcholine at G protein-coupled cholinergic receptors in the peripheral (parasympathetic) and central nervous systems.
- Mutation** Is a genetic change so severe that the disruption in the processing or gene function causes a disease by itself.
- Mycophenolate mofetil** A prodrug that is hydrolyzed to the active agent mycophenolate. Mycophenolate inhibits *de novo* purine synthesis and is indicated for prophylaxis of transplant rejection.
- Myelin** Ensheathes the axons of the nervous system
- Myelin associated glycoprotein (MAG)** A myelin protein that is a candidate autoantigen in multiple sclerosis.
- Myelin basic protein (MBP)** An abundant component of myelin that is a candidate autoantigen in MS.
- Myelin inhibitors** Adult mammalian central nervous system (CNS) lacks the ability to regenerate after injury. This is due in part to inhibitors within myelin. These inhibitors are myelin-Nogo, myelin-associated glycoprotein (Mag) and oligodendrocyte myelin glycoprotein (Omgp).
- MOG** Myelin oligodendrocyte glycoprotein is a glycoprotein believed to be important in the process of myelination of nerves in the central nervous system. The gene for MOG, found on chromosome 6, was first sequenced in 1995. It is a transmembrane protein expressed on the surface of oligodendrocyte cell and on the outermost surface of myelin sheaths. Interest in MOG has centered on its role in demyelinating diseases, particularly MS. Several studies have shown a role for antibodies against MOG in the pathogenesis of MS.

Myelin sheath The fatty substance that surrounds and protects some nerve fibers.

Myelination The formation of the myelin sheath around a nerve fiber.

1.15 N

nanoART Nanoformulated AntiRetroviral Therapy is a method of drug delivery using the patient's immunocytes as the transportation toward virus-targeted tissues.

Nanofiber A microscopic fiber whose diameter is measured in nanometres.

Nanogel A nanoscale size polymer network of cross-linked chains.

Nanoparticle A microscopic particle whose size is measured in nanometres.

Nanosphere A microscopic hollow particle whose size is measured in nanometres.

Nanosuspension A colloidal dispersion (mixture) in which a finely-divided species of a nanoscale size does not rapidly settle out.

Nanotube A microscopic tube whose diameter is measured in nanometres.

Natalizumab Tysabri® is a recombinant humanized monoclonal antibody that binds to the $\alpha 4$ subunits of $\alpha 4\beta 1$ and $\alpha 4\beta 7$ integrins that are expressed on the surface of all leukocytes except neutrophils and inhibit the $\alpha 4$ mediated adhesion to their receptors. Effective in phase I/II FDA trials for MS it was withdrawn due to deaths from progressive multifocal Leukoencephalopathy.

Natural killer cell A lymphocyte (white blood cell) that can kill target cells that express nonself proteins, such as viral antigens or tumor antigens.

Neostigmine An inhibitor of acetylcholinesterase which prolongs the actions of acetylcholine.

Neprilysin A neutral zinc metallopeptidases and important $A\beta$ degrading enzyme, which is involved in the clearance of $A\beta$ in the brain.

Nerve conduction Salutory propagation of nerve impulses along the axon

Nestin A large (200 kDa) intermediate filament protein found in developing rat brain. Often used as a specific marker of neuronal progenitor cells.

Neural progenitor cells (NPC) The term progenitor cell is used to refer to immature or undifferentiated cells, typically found in post-natal animals. While progenitor cells share many common features with stem cells, the term is far less restrictive.

Neuritis Inflammation of the peripheral nerve

Neurodegeneration A progressive loss of brain tissue structure or function due to a disease process; in the case of Alzheimer's and Parkinson's disease, due to accumulation of aggregated cellular products.

Neurodegenerative diseases The subset of neurological disorders that include neuron pathologies, but exclude diseases of the nervous system due to cancer, edema, hemorrhage, trauma, poisoning, hypoxia, etc.

Neurofibrillary tangle (NFT) Intraneuronal protein aggregates and a pathological hallmark of AD, composed of filamentous hyperphosphorylated tau (PHF-tau) and other ubiquitinated proteins.

Neurogenesis The formation of nervous tissue through a process that involves proliferation, migration, differentiation, and survival of neural stem cells.

Neuroimmune process The biochemical and electrophysiological interactions between the NERVOUS SYSTEM and IMMUNE SYSTEM that result in regulation of the immune system by the nervous system.

Neuroinflammation Chronic, CNS-specific, inflammation that is mediated predominantly by microglia that may engender neurodegenerative events.

Neuroinvasion The process by which prions enter the nervous system.

Neuromelanin A modified form of melanin pigment normally found in certain neurons of the nervous system, especially in the substantia nigra and locus ceruleus.

Neuromyelitis optica Also known as Devic's disease, is a severe variation of a demyelinating disease affecting the optic nerve and spinal cord.

Neuron Nerve cell that transmits nerve signals to and from the brain, consisting of a cell body, axon(s) and dendrite(s).

Neuronal apoptosis Death of neurons via programmed cell death.

Neuronal plasticity Refers to the changes that occur in the organization and/or function of the brain as a result of experience.

Neuropeptides Endogenous compounds made of amino acids that act upon receptors within the nervous system.

Neuroprotection Mechanisms that protect the brain from apoptosis (programmed cell death) or degeneration, following a brain injury or in the course of a neurodegenerative disorder.

Neuroproteomics Analysis of proteins and protein complexes of the nervous system (see Proteomics).

Neuropsychology The science of integrating psychological observations on behavior and the mind with neurological observations of the brain and nervous system.

Neuroregeneration The regrowth or repair of the nervous system or its components: tissues, cells or cell products.

Neurosphere A spherical group of neural progenitor cells growing in a suspension culture.

Neurotoxin A toxic complex typically of protein that acts preferentially on the nervous system.

Neurotransmitter Chemical that mediates information transfer between neurons.

- Neurotrophin** A small secretory molecule needed for growth, maintenance, or repair in the nervous system
- Neurovascular unit** A composition of endothelial cells, astrocytes, neurons, and a contractile apparatus of either smooth muscle cells or pericytes that form a functionally integrated network.
- NF- κ B** Transcription factor found in all cell types and is involved in cellular responses to stimuli such as stress, cytokines, free radicals, ultraviolet irradiation, and bacterial or viral antigens.
- NG2** Expressed by a variety of immature glia in the CNS including oligodendrocyte progenitor cells, paranodal astrocytes and perisynaptic glia. The protein has a large extracellular domain with two LNS/Lam G domains at the N-terminus and a short intracellular tail with a PDZ-recognition domain at the C-terminus.
- NADPH oxidase** Nicotinamide adenine dinucleotide phosphate oxidase, a primary producer of reactive oxygen species.
- Nicotine** An alkaloid that blocks the effects of acetylcholine at ligand-gated ion channels in the peripheral (parasympathetic and somatic) and central nervous systems.
- Nigrostriatal pathway** The neural pathway connecting the substantia nigra to the striatum.
- Nitric oxide** A free radical gas produced endogenously by a variety of mammalian cells, synthesized from arginine by nitric oxide synthase. Nitric oxide is one of the endothelium-dependent relaxing factors released by the vascular endothelium and mediates vasodilation. It also inhibits platelet aggregation, induces disaggregation of aggregated platelets, and inhibits platelet adhesion to the vascular endothelium. Nitric oxide activates cytosolic guanylate cyclase and thus elevates intracellular levels of cyclic gmp.
- Nitric oxide signaling** Nitric oxide is a gaseous molecule released from the vascular endothelium in response to a variety of chemical and physical stimuli. It triggers smooth muscle cells in the vessel wall to relax by activating soluble guanylate cyclases (sGC), increasing the cyclic guanosine monophosphate (cGMP) concentration and activating the protein kinase G.
- NMDA hypothesis** Based on the observation that NMDA receptor antagonists like phencyclidine frequently induce schizophrenia-like psychotic symptoms, the NMDA hypothesis of schizophrenia proposed an endogenous NMDA receptor antagonist that may be expressed in higher amounts in individuals suffering from schizophrenia. Because of the close functional relationship between glutamatergic neurotransmission via NMDA receptors and dopaminergic neurotransmission, the NMDA hypothesis includes the generally accepted disturbance of dopamine signaling in schizophrenia.
- NMDA receptor** *N*-methyl-D-aspartate receptor, named for the chemical agonist NMDA. The receptor is a heterodimer, forming an ionic channel that opens upon the binding of agonists, glutamate and glycine. NMDA receptors are permeable to a number of ions, but primarily sodium and calcium. NMDA function is fundamental to proper CNS function, but overstimulation is harmful resulting in excitotoxicity.
- Nociception** Pain perception.
- Nociception/orphanin FQ** An endogenous opioid peptide that acts on the nociceptin/Orphanin FQ receptor.
- Node of Ranvier** One of the many gaps in the myelin sheath—this is where the action potential occurs during saltatory conduction along the axon.
- Non-coding RNA** An RNA molecule that is not translated into a protein.
- Norepinephrine** The chemical responsible for transmitting impulses between neurons in the central and peripheral (sympathetic) nervous systems and acts on either alpha or beta adrenergic receptors.
- Notch** Family of evolutionarily conserved proteins that regulates a broad spectrum of cell-fate decisions and differentiation processes during fetal and post-natal development. The best characterized role of Notch signaling during mammalian hematopoiesis and lymphopoiesis is the essential function of the Notch1 receptor in T-cell lineage commitment. More recent studies have addressed the roles of other Notch receptors and ligands, as well as their downstream targets, revealing additional novel functions of Notch signaling in intra-thymic T-cell development, B-cell development and peripheral T-cell function.
- Nuclear hormone receptor** Receptor in which hormone binding is required to control the activity of the nuclear receptor.
- Nucleotide** Organic molecules that serve as the monomers, or subunits, of nucleic acids, composed of a nitrogenous base, a five-carbon sugar, and at least one phosphate group.
- Nucleus** The organelle in the cell body of the neuron that contains the genetic material of the cell.

1.16 O

- Obsessive compulsive disorder** (OCD) A mental disorder where people feel the need to check things, perform rituals, or think thoughts repeatedly.
- Ocular immunology** A branch of immunology studying immune processes in the eye
- Ocular inflammation** An inflammatory process affecting the eye:
- Olfactory bulb** Ovoid body resting on the cribriform plate of the ethmoid bone where the olfactory nerve terminates. The olfactory bulb contains several types of nerve cells

including the mitral cells, on whose dendrites the olfactory nerve synapses, forming the olfactory glomeruli. The accessory olfactory bulb, which receives the projection from the vomeronasal organ via the vomeronasal nerve, is also included here.

Oligoclonal bands (OCB) Bands of immunoglobulins that are seen when a patient's blood plasma or cerebrospinal fluid (CSF) is analyzed by protein electrophoresis:

Oligodendrocytes Are myelin-synthesizing cells of the CNS.

Olivopontocerebellar atrophy The degeneration of neurons in the cerebellum, pons, and inferior olives of the brain.

Opiate peptides Endogenous peptides with opiate-like activity. The three major classes currently recognized are the ENKEPHALINS, the DYNORPHINS, and the ENDORPHINS. Each of these families derives from different precursors, proenkephalin, prodynorphin, and PRO-OPIOMELANOCORTIN, respectively. There are also at least three classes of OPIOID RECEPTORS, but the peptide families do not map to the receptors in a simple way.

Opioids Substances typically used to relieve pain through the binding of opioid receptors.

Opioid receptors G-protein-coupled receptors that are the targets of the endogenous opioid peptides and of the opioid drugs, such as morphine.

Opiopeptides A general name for the whole class of endogenous peptides acting upon opioid receptors.

Opsin G-protein coupled receptor activated by light in photoreceptor outer segments. Cones have cone opsins and rods possess rhodopsin.

Optic nerve A paired nerve that sends visual information from the retina to the brain using ganglion cell axons and glial cells.

ORL-1 receptor Also known as the nociceptin/orphanin FQ receptor—a G-protein-coupled receptor for which the endogenous ligand is nociceptin.

Oxidative damage The oxidation of proteins, lipids, and DNA, which results in neuronal dysfunction. An important component of neuronal damage and aging, where neuroinflammation is significantly involved.

Oxidative stress An imbalance between formation and neutralization of reactive oxygen species.

Outer segment Photoreceptor cell structure that contains visual pigments and the enzymatic machinery for phototransduction.

p75^{NTR} signaling A member of the tumor necrosis factor receptor superfamily that facilitates apoptosis during development and after injury to the CNS. It activates Jun kinase (JNK), caspases 9, 6, and 3 and accumulates cytochrome c within the cytosol.

PASAT Paced auditory sequential addition test is a segment of the multiple sclerosis functional composite that tests one component of cognitive function.

Paraquat Trade name for the herbicide *N,N'*-dimethyl-4,4'-bipyridinium dichloride. Dangerously poisonous to humans as the compound is easily reduced resulting in superoxide generation.

Parasympathetic The division of the autonomic nervous system that regulates various body functions and is active primarily during periods of rest.

Parkin An E3 ligase in the ubiquitin-proteasome system. Parkin mutations have been associated with familial Parkinson's disease.

Parkinson's Disease (PD) A chronic progressive neurodegenerative disease chiefly of later life that is linked to decreased dopamine production due to loss of dopaminergic neurons in the substantia nigra. The clinical features are tremor of resting muscles, rigidity, slowness of movement, impaired balance, and a shuffling gait—called also paralysis agitans. Current therapies include L-DOPA and deep brain stimulation.

Parvocellular ganglion cells Small retinal ganglion cells that possess the high resolution and color sensitivity required for fine feature analysis and color vision.

Pax-5 Paired box gene 5 (B-cell lineage specific activator). The PAX proteins are important regulators in early development, and alterations in the expression of their genes are thought to contribute to neoplastic transformation. The PAX5 gene encodes the B-cell lineage specific activator protein (BSAP) that is expressed at early, but not late stages of B-cell differentiation. Its expression has also been detected in developing CNS and testis. Therefore, PAX5 gene product may not only play an important role in B-cell differentiation, but also in neural development and spermatogenesis.

Passive immunization Administering antibodies for temporary immune protection against an antigen. Immunity exists as long as the antibodies remain in the body.

Pathogen-associated molecular patterns (PAMPs) Small molecular motifs consistently found on pathogens; recognized by toll-like receptors and other pattern recognition receptors (PRRs) in plants and animals.

Pathogenesis The biological mechanism that leads to the diseased state.

Peripheral benzodiazepine receptor A G-protein-coupled receptor for benzodiazepines found primarily in the periphery, particularly in the immune system, such as microglia in brain.

1.17 P

p53 protein 53 (TP53) is a transcription factor critical factor to the prevention of mutation that regulates the cell cycle and hence functions as a tumor suppressor.

- Peripheral blood mononuclear cells (PBMC)** Lymphocytes and monocytes isolated from the peripheral blood, usually by Ficoll Hypaque density centrifugation.
- Peripheral nervous system** Part of the nervous system consisting of the nerves and neurons outside the central nervous system.
- Phagocytosis** The process in which a cell engulfs a solid particle to form an internal vesicle known as a phagosome.
- Pharmacogenomics** The study of the role of genetics in drug response.
- Phenotype** A notation of an organism's observable characteristics such as phenology, behavior, and products of behavior. It forms from the expression of genes as well as environmental stimuli.
- Phenylephrine** A norepinephrine analog that mimics norepinephrine action primarily at the alpha adrenergic receptors.
- Photoreceptor** Principle photo-sensitive cell in the retina
- Physostigmine** An inhibitor of acetylcholinesterase which acts to prolong the actions of acetylcholine.
- PI-3 kinase Phosphoinositide 3-kinases** A family of enzymes that are capable of phosphorylating the three position hydroxyl group of the inositol ring of phosphatidylinositol.
- PK11195** 1-(2-chlorophenyl-*N*-methylpropyl)-3-isoquinolinecarboxamide, a ligand for peripheral benzodiazepine receptors.
- PLP** Refers to proteolipid protein that is present in myelin.
- Polymorphism** A genetic variation in a base pair, repeat, deletion or duplication that is neutral or acts as a susceptibility allele
- Positron emission tomography (PET)** is a nuclear medicine, functional imaging technique used to observe metabolic processes within the body.
- Postsynaptic density** An electrondense region located opposite the active zone on the postsynaptic plasma membrane.
- Pralidoxime** A reactivator of acetylcholinesterase that has been inhibited by organophosphorus compounds.
- Prazosin** Synthetic compound that blocks the action of norepinephrine on alpha adrenergic receptors.
- Preproenkephalin** A precursor peptide for the enkephalins. It is processed into proenkephalin before being converted to multiple enkephalin molecules.
- Presenilin-1 (PS1)** A principal component of γ -secretase complex, processes APP at the γ -site, and a causative gene of the early onset of FAD. The γ -secretase complex is also critically involved in Notch processing and its signaling.
- Prion** Infectious protein agent that induces a fatal neurodegenerative disease in animals and humans that is characterized by the accumulation of the abnormal isoform of the prion protein.
- Prion disease** (Transmissible spongiform encephalopathies) are a group of progressive conditions that affect the brain and nervous system. The linking feature is a weakening of mental and physical capabilities as well as tiny holes appearing in the cortex.
- Prodrug** A medication that is metabolized within the body into a pharmacologically active drug.
- Progenitor/precursor cell** A cell that can differentiate into multiple cell types and has limited self-renewal capacities, so that the cell can proliferate while maintaining its differential capability for a short period of time but not for the entire life of the organism.
- Proinflammatory cytokines** Cytokines that induce an inflammatory response such as IFN- γ , IL-1(β), IL-18, and TNF- α . some authors also include IL-6, though this cytokine has an extremely broad range of actions.
- Proliferation** The ability to multiply cell population numbers by undergoing self-renewal or division.
- Proopiomelanocortin** A large precursor peptide that is the source of many active peptides, including some endorphins, enkephalins, alpha-MSH and others.
- Propranolol** A synthetic compound that blocks the action of norepinephrine on beta adrenergic receptors.
- Protein fingerprinting** Method of classifying new protein families based on conserved regions within alignments of related proteins.
- Protein microarrays** High throughput technology to detect differentially expressed proteins using protein-protein interactions.
- Protein-only hypothesis** Proposed by Dr. Stanley Prusiner to describe the novel properties of prions; prions are proteinaceous infectious particles that lack an agent-specific nucleic acid genome.
- Protein profiling** Identification of proteins in a sample.
- Proteolipid protein (PLP)** The most abundant myelin protein; a candidate autoantigen in MS.
- Proteomics** Field of science using high throughput techniques to analyze proteins expressed under a certain set of conditions within an individual cell or organism.
- PU.1** Spleen focus forming virus (SFFV) proviral integration oncogene *spi1*. The PU.1 plays indispensable and distinct roles in hematopoietic development through supporting HSC self-renewal as well as commitment and maturation of myeloid and lymphoid lineages.
- Pyroptosis** An inflammatory form of programmed cell death, occurs most frequently with infection of intracellular pathogens.

1.18 R

Radial glia Neuronal progenitor cells that arise from neuroepithelial cells after the onset of neurogenesis with more restricted differentiation abilities. In the developing nervous system, radial glia function both as neuronal progenitors and as a scaffold upon which newborn neurons

migrate. In the mature brain, the cerebellum and retina retain characteristic radial glial cells. In the cerebellum, these are Bergmann glia, which regulate synaptic plasticity. In the retina, the radial Müller cell is the principal glial cell, and participates in a bidirectional communication with neurons.

Randomized controlled trials An experiment in which investigators randomly allocate eligible people into (e.g. treatment and control) groups to receive or not to receive one or more interventions that are being compared. The results are assessed by comparing outcomes in the treatment and control groups. This form of trial is often used in performing scientific research due to its reliability in avoiding false causality.

Reactive oxygen species (ROS) Generally very small molecules that are highly reactive due to the presence of unpaired valence shell electrons. They include oxygen ions, free radicals and peroxides both inorganic and organic. ROS are formed as a natural byproduct of the normal metabolism of oxygen and have important beneficial roles in cell signaling and innate immunity. However, during times of environmental stress ROS levels can increase dramatically, potentially resulting in significant damage to cell structures. This culminates into what is known as oxidative stress and can lead to such results apoptosis or necrosis.

Redox signaling pathways Signal transduction pathways based on electron-transfer processes that play important messaging roles in biological systems. These pathways are activated by free radicals, reactive oxygen species (ROS), and other electronically-activated species and are turned off by reducing species.

Regulatory T cells Also called suppressor T cells, regulatory T cells are a small population of CD4⁺ T cells that have regulatory (that is, suppressor) activities towards other cells of the immune system and serve to limit immune responses, particularly those which may be against host tissue. These cells express the transcription factor forkhead box P3 (FOXP3) which is used as a specific marker for these cells. An absence of T_{Reg} cells or their dysfunction is associated with severe autoimmunity.

Relative risk A statistical tool used to measure the ratio of two conditional probabilities. For example, in genetic disease inheritance, relative risk can measure the degree of genetic contribution to a trait, defined as the risk of the disease in first degree offspring (sibs, parents, offspring) of an affected individual relative to the risk of the disease in the general population.

Reserpine An alkaloid that prevents the accumulation of catecholamines such as norepinephrine and dopamine in the synapses. Reserpine performs this action by irreversibly binding to these neurotransmitters and inhibiting their uptake into synaptic vesicles. The compound has been used as an antihypertensive as well as a sedative but

is rarely used any longer due to its risk of depression and the availability of better drug therapies.

Resting membrane potential Membrane potential prevailing in a resting unstimulated cell. The value is often negative, indicating an excess of negative potential inside the cell in comparison with the external environment. The difference in potential is based on the ion concentrations within and surrounding the cell membrane, as well as the ion transport proteins embedded in the cell membrane.

Retina A thin sheet of neural cells at the back of the eye that is continuous with the optic nerve. The retina is responsible for phototransduction and the initial stages of vision. The retina's photoreceptor cells, called rods and cones, produce neural signals in response to light that then undergo complex processing by ganglion cells of the retina. The resulting information is sent to the brain via the optic nerve to be interpreted into a visual image.

Retinal ganglion cell The output cell of the retina whose axons form the optic nerve and project to higher visual center. These cells process the signals produced by the photoreceptor cells of the retina and then send the resulting information to the brain via the optic nerve for interpretation.

Retinal pigment epithelium The pigmented epithelial cells forming the outermost layer of the retina. This layer of cells is attached to the choroid vascular tissue and provides nourishment to the cells of the retina.

Retinoid-related orphan receptor (ROR) An orphan nuclear hormone receptor that regulates the survival of CD4⁺CD8⁺ doublepositive (DP) thymocytes and is essential for the development of the lymph nodes and Peyer's patches.

Retrovirus Any of a family (Retroviridae) of enveloped RNA viruses (such as HIV and numerous tumorigenic viruses) that replicate in a host using a DNA intermediate produced using their RNA template and reverse transcriptase. Through the process, their viral genome is incorporated into the genome of infected cells. There are three common genes found in most retroviruses, the gag, pol, and env genes, which encode for the viral proteins, enzymes, and envelope of the viruses respectively.

Ribbon Structure in synaptic terminals of photoreceptors, retinal bipolar cells, and hair cells that is specialized for sustained neurotransmitter release.

RISC (RNA-induced silencing complex) is a multiprotein complex which contains one strand of a single-stranded RNA fragment.

Rivastigmine An inhibitor of acetylcholinesterase which prolongs the actions of acetylcholine with prominent effects in the central nervous system. The compound has been shown effective in treating the symptoms of dementia associated with Alzheimer's disease.

RNA binding proteins (RBP) bind to the double or single stranded RNA in cells and forms RNA complexes.

RNA interference A posttranscriptional genetic mechanism, which suppresses gene expression. In this mechanism, double-stranded RNA cleaved into small fragments initiates the degradation of a complementary messenger RNA. This pathway is thought to have developed as part of the innate immune system to protect against viruses, as in controlling development and genome preservation. This mechanism is used as a technique (as the introduction of double-stranded RNA into an organism) that artificially induces mRNA inhibition and is used for studying or regulating gene expression.

Rod A type of Photo-sensitive retinal cell mediating scotopic vision near visual threshold. These cylindrical-shaped photoreceptor cells are located primarily on the outer edges of the retina and are therefore used also for most peripheral vision.

Rostral migratory stream The route for neuronal precursors (periglomerular and granule cells) to migrate to the olfactory bulb where they differentiate into interneurons throughout the life of rodents. Overlying the rostral migratory stream is the anterior or olfactory limb of the anterior commissure (or commissura anterior pars bulbaris), which carries centrifugal fibers, including some from the medial forebrain bundle, to the region.

Rotenone A botanical insecticide that is an inhibitor of mitochondrial electron transport. Inhibition is achieved through the hindrance of the electron transfer chain preventing NADH from converting to ATP thus limiting usable cellular energy. The compound is considered moderately hazardous and mildly toxic to mammals, including humans.

1.19 S

Sca-1 A mouse member of the interferon-inducible Ly-6 family of genes that can conveniently be used as a marker for stem/early progenitor cells. Sca-1 is used to isolate many stem cells in the mouse. The density of this antigen declines with differentiation. Sca-1 belongs to a family of proteins bearing a UPAR (urokinase plasminogen activator receptor) domain. The UPAR protein plays a role in cellular adhesion and migration by modulating integrin function and degradation of the extracellular matrix.

Schaffer collaterals Axon collaterals given off by CA3 pyramidal cells in the hippocampus. They are part of memory formation and the emotional network of the Papez circuit.

Schizophrenia A mental illness characterized by cognitive dysfunction, hallucinations, delusions, thought disorder and poor social and vocational functioning. The term can also be used to describe a group of mental disorders characterized by the same or similar indicators.

Schwann's cells Cells that produce myelin in the peripheral nervous system. These cells are located between the axon and axon terminal of neurons and create the myelin sheath which aides in insulating axons and in increasing impulse speeds as they are propagated through the neuron (allowing for salutatory conduction).

Sclerosis A hardening of tissue as a result of scarring or plaques such as in the central nervous system when formed by inflammatory perivascular lesions.

SELDI-TOF Surface-enhanced laser desorption/ionization—time of flight is a soft ionization method used in mass spectrometry to analyze protein mixtures within tissue or clinical samples.

Senility A term once used to describe dementia.

Self-renewal The ability of a cell to divide into two daughter cells with identical properties and retaining equal differential capabilities as the parent cell.

Scavenger receptors Receptors that identify modified low-density lipoprotein by means of oxidation or acetylation.

SCID Severe combined immunodeficiency, a genetic disorder in which both “arms” (B cells and T cells) of the adaptive immune system are crippled. This disease is fatal if untreated due to extreme susceptibility to infectious diseases.

Sickness behaviour One of the immunological models of major depression. The cytokines IL-1, IL-6, and TNF- α have been identified to induce depression-like mood disturbance upon administration or during disease states that are accompanied by increased or over-production of these cytokines.

Signal serotonin Serotonin (5-hydroxytryptamine, 5-HT) is a biogenic indoleamine derived from the dietary amino acid tryptophan. Serotonergic neurons are located almost exclusively in the raphe nuclei of the brainstem, but their projections innervate virtually all other parts of the central nervous system. A reduced serotonergic neurotransmission is supposed to play a crucial role in the pathophysiology of major depression among other disorders.

Signal transduction Mechanism by which external stimuli are interpreted by cells. This transformation is often done through biochemical reactions involving secondary and cascade pathways within and between cells.

Simian virus 5 (SV-5) A paramyxovirus belonging to the family Paramyxoviridae. The genomes of these viruses are composed of negative-sense single-stranded RNA and this family of viruses is responsible for a number of human and animal diseases.

Single-chain antibodies Engineered antibodies composed of the minimal antibody-binding site formed by non-covalent association of the V_H and V_L variable domains joined by a flexible polypeptide linker. Sequences encoding eukaryotic secretion signals can be appended to the scFv

genes and subsequently be cloned into gene transfer vectors for prolonged *in vivo* expression. These antibodies are significantly smaller than natural antibodies but retain the same affinity as natural antibodies and can be produced in large quantities at relatively low costs using biotechnology.

Single nucleotide polymorphism The most common polymorphism in the human genome, a nucleotide polymorphism at a single base. The result of these differences creates alleles.

Single photon emission computed tomography By specifically using gamma rays, this imaging technique is able to provide true 3D information.

Sirolimus A macrolide antibiotic that inhibits T lymphocyte activation and proliferation. It is an immunosuppressive agent that is used mainly to prevent rejection during organ transplantation. The compound works to inhibit a response to interleukin-2 which is necessary to activate T cells.

Sjogren's syndrome An autoimmune disorder affecting the salivary and lacrimal glands. In this disorder, immune cells attack host exocrine glands that are responsible for the production of tears and saliva.

Smac/Diablo A mitochondrial protein that promotes some forms of apoptosis by neutralizing one or more members of the IAP family of apoptosis inhibitory proteins.

Substantia nigra pars compacta (SNpc) The portion of the substantia nigra within the midbrain that encompasses the dopaminergic neurons which innervate the caudate nucleus and putamen of the basal ganglia. This area of the brain plays an important role in the pleasure/reward system and in addiction. Additionally, degeneration of the neurons in this area of the brain is an indicator of Parkinson's disease.

Superoxide dismutase-1, copper-zinc superoxide dismutase (SOD1) A cytoplasmic enzyme that works as an antioxidant converting superoxide to oxygen and hydrogen peroxide. Mutations in the enzyme have been shown to be a factor in the motor neuron disease amyotrophic lateral sclerosis (ALS).

Suppressor of cytokine signaling (SOCS) proteins A family of proteins that inhibit the JAK-STAT signaling pathway by competitively binding to phosphotyrosine binding sites on cytokine receptors.

Soman An extremely toxic long acting organophosphorus compound with prominent inhibitory effects on acetylcholinesterase causing interference with nerve functioning

Somatic hypermutation Point mutations that occur in cycling centroblasts and are targeted to the immunoglobulin variable-region gene segments. Some mutations might generate a binding site with increased affinity for the specific antigen, but others can lead to loss of antigen recognition by the B-cell receptor and generation of

a self-reactive B-cell receptor. Each mutation occurs only within individual cells and the mutations are not passed on to offspring.

Sox4 A member of the SOX (SRY-related HMG-box) family of transcription factors involved in the regulation of embryonic development and in the determination of the cell fate. The encoded protein may act as a transcriptional regulator after forming a protein complex with other proteins, such as syndecan binding protein (syntenin). The protein may also function in the apoptosis pathway leading to cell death as well as to tumorigenesis and may mediate downstream effects of parathyroid hormone (PTH) and PTH-related protein (PTHrP) in bone development.

Spatial memory A type of memory responsible for recording information about one's environment and its spatial orientation. For example, a person's spatial memory is required in order to navigate around a familiar city, just as a rat's spatial memory is needed to learn the location of food at the end of a maze.

STAT4 A member of the STAT family of transcription factors. In response to cytokines and growth factors, STAT family members are phosphorylated by the receptor associated kinases, and then form homo- or heterodimers that translocate to the cell nucleus where they act as transcription activators. This protein is essential for mediating responses to IL-12 in lymphocytes, and regulating the differentiation of T helper cells.

STAT6 Protein that plays a central role in exerting IL-4 mediated biological responses. It is found to induce the expression of BCL2L1/BCL-X(L), which is responsible for the anti-apoptotic activity of IL-4. Knockout studies in mice suggested the roles of this gene in the differentiation of T helper 2 (Th2) cells, expression of cell surface markers, and class switching of immunoglobulins.

Stem cell A single cell that can differentiate along multiple lineages and can self-renew throughout the life of an organism while maintaining its differential capability. The three primary categories of stem cells are embryonic stem cells (originating from blastocysts), adult stem cells (derived from adult tissues), and cord blood stem cells (found in the umbilical cord).

Stem cell therapy Treatments and related research involving the use of undifferentiated cells which have self-renewal capacity and the unique potential to produce any kind of cell in the body.

Stress Any physical or psychological stimulus that disrupts homeostasis.

Stress granules Aggregations in the cytosol made of proteins and RNA which appear when the cell is under stress.

Striatum A continuous part of the basal ganglia comprised of the caudate nucleus and putamen. This portion of the

brain plays roles in modulating movement pathways as well as taking part in a variety of cognitive functions.

Stroke Brain injury caused by occlusion or rupture of blood vessels into or around the brain causing a subsequent loss of oxygen and glucose to the affected brain area. Stroke is commonly termed a “cerebrovascular accident” or a “brain attack” and can cause severe neurological damage or death.

Stromal cell-derived factor 1 (SDF-1) The ligand for CXCR4 receptor, this CXC chemokine (also designated CXCL12) is involved in chemotaxis, brain development, and immune cell recruitment.

Subgranular zone A brain region deep within the hippocampal parenchyma, at the interface between the granule cell layer and the hilus of the dentate gyrus, where adult neurogenesis occurs. It is one of the two major known adult neurogenesis sites of the brain, along with the subventricular zone.

Subluxation Partial dislocation of a joint or organ.

Substantia nigra A layer of large pigmented nerve cells in the midbrain that produce dopamine and whose destruction is associated with Parkinson’s disease.

Subventricular zone A paired brain structure situated throughout the lateral walls of the lateral ventricles. Along with the subgranular zone of dentate gyrus, this zone serves as a source of neural stem cells in the process of adult neurogenesis. It harbors the largest population of proliferating cells in the adult brain of rodents, monkeys and humans. Neurons generated in this zone travel to the olfactory bulb via the rostral migratory stream.

Susceptibility gene A gene with multiple polymorphic forms, of which one or more forms causes differences in the processing or function of the gene that makes an individual more susceptible to a specific disease, but only in the presence of other interacting or contributing susceptibility genes or environmental factors.

Sympathetic The division of the autonomic nervous system that regulates various body functions and is always active on a basal level, but becomes more active during periods of stress and/or exertion. It causes the “fight-or-flight” response during times of stress by promoting the release of adrenaline and noradrenaline which bind to adrenergic receptors in peripheral tissues and cause such reactions and increased heart rate and blood pressure and pupil dilation.

Symptomatic therapy Treatment or remedy for physical disturbance observed by the patient due to an underlying disease. Also called palliative care, this form of treatment does not address the basic cause or provide a cure for the underlying disease but rather focuses on preventing or easing suffering associated with the disease.

Synapse From the Greek meaning “to grasp”, a junction between two neural cells where the cell body (or dendrite) of one nerve is positioned across a small gap from the

axon of another nerve. Signal transmission occurs across these gaps via neurotransmitters, allowing the neurons to communicate with each other through the conversion of electrical impulses into chemical signals.

Systems biology A field of science that studies the interactions between the components of biological systems and how these interactions give rise to the function and behavior of that system.

1.20 T

Tacrolimus A macrolide antibiotic that acts as a calcineurin inhibitor to hinder T cell signal transduction and IL-2 transcription. It is an immunosuppressive agent that is used mainly to prevent rejection during allogeneic organ transplantation.

Tauopathies Neurodegenerative diseases featuring aggregation of tau proteins in neurofibrillary or gliofibrillary tangles.

T-bet T-box genes encode transcription factors involved in the regulation of developmental processes. This gene is the human ortholog of mouse Tbx21/Tbet gene. Studies in mouse show that Tbx21 protein is a Th1 cell-specific transcription factor that controls the expression of the hallmark Th1 cytokine, IFN γ . Expression of the human ortholog also correlates with IFN γ expression in Th1 and natural killer cells, suggesting a role for this gene in initiating Th1 lineage development from naive Th precursor cells.

T-cell receptor (TCR) A heterodimeric molecule found on the surface of T lymphocytes (T-cells) that is responsible for recognizing antigens bound to major histocompatibility complex (MHC) molecules. Upon antigen-receptor binding with MHC, a series of biochemical reactions occur which activate the associated T-cell.

T-cells T (thymus derived) cell. These white blood cells, known as T lymphocytes, mature in the thymus and have regulatory immune functions. As part of the adaptive (cell-mediated) immune system, these cells can recognize antigens processed by antigen-presenting cells in the context of specific receptors. The cell surface protein CD3 is a marker for these cells.

Temporal lobe Either of two lobes of the brain, located on either side of the cerebral hemisphere and part of the cerebrum. This portion of the brain is involved in auditory processing, semantics, and also contains the hippocampus which is responsible for learning and memory.

Terbutaline A norepinephrine derivative that mimics norepinephrine action primarily at the subtype two beta adrenergic receptor. This compound is used as a bronchodilator and tocolytic.

Th1 cells Also called inflammatory CD4 T cells, a subset of T cells that secrete the cytokines IL-2, IFN γ , and lym-

phototoxin and are most useful against intracellular pathogens that are best attacked by a cell-mediated response involving macrophage and granulocyte activation.

Th2 cells Also called helper CD4 T cells, a subset of T cells that secrete the cytokines IL-4, IL-5, and IL-10, and induce antibody and allergic responses that are useful for combating infections.

Th1/Th2 Subclasses of T helper cells that are distinguished by their cytokine profiles. Th1 cells are characterized by production of IFN- γ . Th1 cells are characterized by production of IL-4. Th2 cells polarize the immune response towards cellular immunity and Th2 cells polarize towards antibody formation.

Th1/Th2 balance According to the Th1/Th2 paradigm, naïve CD4⁺ T helper cells can be activated to differentiate into two types of effector cells: either Th1 or Th2 cells. In general, macrophages and dendritic cells tend to stimulate the Th1 differentiation, whereas extracellular antigens tend to stimulate Th2 cell differentiation. Th1 cells in turn stimulate macrophages and induce IgG production by B cells, while Th2 cells stimulate the humoral immune response including IgA, IgE, and certain IgG subtypes. An imbalance between Th1 and Th2 cells is observed in several immunological disease conditions; typical examples are Th1 predominance in rheumatoid arthritis and Th2 predominance in IgE-mediated allergy.

Thalidomide A drug originally used to treat morning sickness during pregnancy that caused severe limb deformities. This compound downregulates TNF α and is under investigation for treatment of severe Crohn's syndrome and other autoimmune disorders.

Therapeutics A branch of medical science dealing with the application of remedies to diseases.

Thymocyte Hematopoietic progenitor cells present in the thymus. They mainly generate T cells, but also respond to foreign pathogens.

Tissue profiling A tool for rapid detection of molecules, usually proteins and peptides, obtained directly from intact tissues to identify pathological changes.

T lymphocyte or T cell Please see "T cell".

Tolerance Refractoriness to physiological effects of a stimulus which develops with prolonged exposure, such as with drug tolerance. Alternatively, the failure of the immune system to react to an antigen, such as in the case of tolerance to self antigens

Toll-like receptors (TLR) A class of single membrane-spanning non-catalytic receptors that recognize structurally conserved molecules derived from microbes and activate immune cell responses. TLRs are believed to play a key role in the innate immune system. They are a type of pattern recognition receptors (PRRs) and recognize molecules that are broadly shared by pathogens but distinguishable from host molecules, collectively referred to as pathogen-associated molecular patterns (PAMPs). These

receptors are present in both vertebrates and invertebrates and have similarities with receptors found in bacteria and plants. Due to this, these receptors are thought to be one of the oldest and most conserved components of the immune system.

Tourette's syndrome Neuropsychiatric disorder consisting of motor and vocal tics.

Transcription nuclear factor-k-B A protein complex found in all cell types that is involved in cellular responses to stimuli such as stress, cytokines, and foreign antigens. This transcription factor plays a regulatory role in immune response to infection and has also been suggested to be involved in processes of synaptic plasticity and memory. When improperly regulated, this transcription factor has also been implicated in causing cancer, autoimmune diseases, and other immune system malfunctions.

Transducin G protein expressed in retinal photoreceptor cells that is activated upon absorption of a photon by opsin. Activation of this protein stimulates cGMP-specific phosphodiesterase which leads to the vertebrate phototransduction cascade.

Transgene A segment of DNA (generally coding DNA) which is taken from one cell or organism and is introduced into different cells or organisms to modify a phenotype.

Transmembrane protein transport (diffusion) The process of moving proteins from one cellular compartment (including extracellular) to another by various sorting and transport mechanisms such as gated transport, protein translocation, and vesicular transport. The tendency of a gas, solute or protein is to pass from a point of higher pressure or concentration to a point of lower pressure or concentration and to distribute itself throughout the available space:

Transport Movement or transference of biochemical substances that occurs in biological systems.

Traumatic brain injury A general term for an external force injuring the brain with subdivisions based on severity, mechanism, injury location, etc.

Trimethaphan A synthetic compound which blocks the effect of acetylcholine at autonomic ganglia thereby blocking the sympathetic and parasympathetic nervous system. This compound has been used to reduce bleeding during neurosurgery, as well as to treat such emergencies as pulmonary edema and hypertensive crisis.

Tropicamide An atropine derivative which blocks the action of acetylcholine on muscarinic cholinergic receptors. This compound is often used during eye examinations to dilate the pupil and may also be used before or after eye surgery.

Trk receptor Cell surface proteins that are involved in transducing the actions of neurotrophins to promote neuronal survival, proliferation, migration, axonal and dendritic outgrowth and patterning, synapse strength and plasticity,

injury protection, as well as controlling the activity of ion channels and neurotransmitter receptors.

Tryptophan L-tryptophan (TRP) is an essential amino acid, present in nearly all natural proteins. It is the precursor of the neurotransmitters serotonin and melatonin and of kynurenine, which is quantitatively the most important TRP metabolite.

Tumor necrosis factor Serum glycoprotein produced by activated macrophages and other mammalian mononuclear leukocytes that acts as a cytokine to help stimulate inflammation and the acute phase reaction of the immune system. It has necrotizing activity against tumor cell lines and increases ability to reject tumor transplants. Also known as TNF-alpha, it is only 30 % homologous to TNF-beta (lymphotoxin), but they share TNF receptors. Disregulation of this cytokine has been implicated in causing cancer, among other human diseases.

Tyramine The decarboxylated form of the amino acid tyrosine which is present in food (e.g., cheese, beer, wine) and promotes the release of norepinephrine from sympathetic nerve endings. Significant displacement of norepinephrine by this compound when ingested in large quantities or while taking monoamine oxidase inhibitor medication is thought to cause vasoconstriction and increased heart and blood pressure.

1.21 U

Urocortins Most recently discovered peptides belonging to the corticotropin-releasing factor family whose functions are generally unknown, but may play roles in immune function in addition to having anorexigenic and hypotensive effects, among other functions.

1.22 V

Vaccination The introduction of antigenic stimulants to the immune systems of humans or animals for the purpose of inducing the artificial development or regulation of immunity. Multiple kinds of vaccines exist to serve this

purpose including inactivated, live attenuated, subunit, and DNA vaccines.

Varicella zoster virus (VZV) An alpha human herpesvirus that causes the diseases chickenpox and, if later reactivated, shingles. A vaccine is currently available against the virus.

Vector A "vehicle", such as a modified virus or DNA molecule, used to deliver genetic material into the body for gene therapy. Alternatively, an organism that does not cause disease itself but can transmit infection through transferring pathogens among different hosts (such as a mosquito).

Vehicle A type of adjuvant that possesses no medicinal action of its own, but delivers or targets an antigen to cells of the immune system.

Vimentin A member of the intermediate filament family of proteins that is an important component of eukaryotic cell cytoskeletons. These proteins are responsible for cell flexibility and resilience under mechanical stress as well as the transport of low density lipoprotein intended to undergo esterification.

Viral vector Tools commonly used to deliver genetic material into cells.

Virus A small infectious agent that replicates only inside the living cells of another organism.

visual-evoked potential-(VEP) viruses Minute infectious agents whose genomes are composed of DNA or RNA, but not both. They are characterized by a lack of independent metabolism and the inability to replicate outside living host cells.

Vogt-Koyanagi-Harada disease A multisystem disease of presumed autoimmune cause, which affects pigmented tissues.

1.23 W

Withdrawal Signs and symptoms that occur as a result of a discontinuation of certain activities or drugs (such as opioids) and includes perturbations in various physiological systems that are indications of physical dependence.

- TYRO protein tyrosine kinase binding protein (TYROBP)
- pathway, 254–255
- Tyros3, 253

U

Urocortins

- CRHR2 receptors, 624
- mRNA expression, 623

US Food and Drug Administration (FDA), 960, 967

3'UTR, 331, 332, 334, 336

Uveitis

- intermediate, 564
- macular involvement, 564

V

Vaccine delivery vehicles, 820

Vaccines

- adjuvant properties, EP54 and EP67, 826
- humoral and cellular immune responses, 819
- polio, 819
- smallpox, 819

Valacyclovir, 443

Varicella zoster virus (VZV) induced encephalitis

- clinical features, 439–440
- epidemiology, 439
- infection and latency, 440
- neurological diseases, 440
- neuropathogenesis, 441

Varicella Zoster Virus infection, 731

Vascular endothelial growth factor (VEGF), 224

- angiogenic factor, 694
- intramuscular delivery, mSOD1 mice, 694

Vascular niche, 230

Vasoactive intestinal peptide (VIP), 781

 $\alpha\text{v}\beta 5$ integrin, 254

Vector genomes, 886

VEGF. *See* Vascular endothelial growth factor (VEGF)

Vertebrate CNS, 799

Very late antigen (VLA)-4 integrin, 360

Vesicular monoamine transporter 2 (VMAT2), 963

Vimentin, 124

Viral blipping

- clinical suppression, HIV replication, 741
- description, 740
- neuroinflammation pathway and development, HAND, 741
- virological failure, 741

Viral encephalitis

- biological properties, 437

Herpesviridae family, 437

JC virus, 437

Viral infection of brain

- clinical symptoms, 440
- encephalitis, 437
- oral bioavailability, 444

Viral infections, 319

Virchow-Robin Spaces, 26

VKH. *See* Vogt-Koyanagi-Harada (VKH) disease

VLJL rearrangements, 203

Vogt-Koyanagi-Harada (VKH) disease

- bilateral exudative panuveitis, 555
- clinical findings, 556
- description, 554
- diagnosis of, 556
- epidemiology, 554
- etiology and pathogenesis, 554–555
- fundus fluorescein angiography, 555
- ocular stages, 555
- RPE, 555

von Graefe's sign, 569

VX-765, 101

W

Wegener's granulomatosis, 565

Weighted-gene coexpression network analysis (WGCNA), 745

Welander Distal Myopathy (WDM), 305

West Nile virus (WNV) induced encephalitis

- animal models, 446
- antigenic variation, 445
- Flaviviridae family, 445
- mammalian cell lines, 445
- pathogenesis, 446

West syndrome, 400

WGCNA. *See* Weighted-gene coexpression network analysis (WGCNA)

Wnt signaling, 221

Wnt/ β -catenin pathway, 221

World Health Organization (WHO), 422

Y

Yamanaka factors, 228

Yolk sac blood islands, 207

Yolk-sac-derived erythro-myeloid, 203
