Human peripheral nerve myelin contains acidic glycosphingolipids such as sulfated glucuronyl paragloboside (SGPG) and sulfated glucuronyl lactosaminyl paragloboside (SGLPG) (Quarles 1997; Willison and Yuki 2002). One study found elevated IgM anti-SGPG antibody titers in six of nine patients (67 %) with CIDP (Yuki et al. 1996). In earlier studies, antibodies to a variety of glycolipid antigens were described, including LM1, GM1, GD1a (reviewed in (Willison and Yuki 2002)). Another candidate antigen is the HNK-1 carbohydrate epitope, which is common to some glycolipids and other cell adhesion molecules. More evidence for the role of GM1 as target has been given when rabbits were immunized with a ganglioside mixture (Yuki et al. 2001) : all of them developed high anti-GM1 IgG antibody titers, flaccid limb weakness of acute onset, and a monophasic illness course. Pathological findings for the peripheral nerves showed predominant Wallerian-like degeneration, with neither lymphocytic infiltration nor demyelination. IgG was deposited on the axons of the anterior roots, and GM1 was proved to be present on the axons of peripheral nerves. Sensitization with purified GM1 also induced axonal neuropathy, indicating that GM1 was the immunogen in the mixture and explaining the association of AMAN with anti-GM1 reactivity.

Over the last few years antibodies to complexes of two gangliosides were described forming new target epitopes in the cell membrane with higher avidity than single gangliosides. These autoantibodies may have profound pathogenic effects in GBS and MFS and may better correlate to clinical subtypes than those directed at single gangliosides (Kaida et al. 2004; Ogawa et al. 2013; Willison and Goodyear 2013).

EAN can be induced by immunization of an animal with myelin proteins such as P2 basic protein, P0 glycoprotein, and peripheral myelin protein 22 (PMP22) [see review in (Gold et al. 2005)]. Gabriel et al. (2000) investigated whether PMP22 may be important in inducing human inflammatory neuropathy. The sera of patients with GBS, CIDP, other neuropathies (ONP), and normal controls were evaluated for IgM and IgG antibodies against PMP22. Antibodies were detected in 52 % of patients with GBS, 35 % with CIDP, and 3 % with ONP; no antibodies were detected in normal controls (Gabriel et al. 2000). Furthermore, Ritz et al. (2000) reported PMP22 antibodies in three of six (50 %) CIDP patients. In contrast, Kwa et al. (2001) reported the absence of these antibodies in sera from 24 patients with CIDP. The discrepancy among the results of these studies may be due to differences in the PMP22 antigen used to test the sera. When linear peptide epitopes of PMP22 and purified PMP22 protein from overexpression in *E. coli* were used, a higher percentage of patient sera showed reactivity. However, when PMP22 protein was expressed in mammalian cells under native conditions, the sera failed to show any reactivity.

In any chronic autoimmune inflammatory condition, several antigens may be involved via epitope spreading (Lehmann et al. 1992), making it difficult to identify the culprit antigen in an individual patient. Moreover, antibodies display a variety of affinities and avidities and some may activate the complement cascade while others may not (Janeway et al. 2001). Therefore, it is not easy to define the pathogenic role of individual antigen binding specificities. Given the heterogeneity of GBS and CIDP, it is likely that different antibodies are sequentially or even collectively involved in the pathogenesis of this disease.

Recent evidence demonstrates that antibodies against myelin protein zero (P0), a major structural protein of myelin, may play a role in CIDP (Yan et al. 2001). There is indirect evidence that P0 may have immunologic relevance. In an experimental study of heterozygous P₀ knockout mice, an animal model of Charcot-Marie-Tooth disease, Schmid et al. (2000) showed that (1) myelin degeneration and impairment in nerve conduction were attenuated when the immune system was impaired, and (2) T cells isolated from these mutant mice demonstrated enhanced reactivity to myelin proteins such as P0 and P2. P0, an adhesive cell-surface molecule of the Ig superfamily and the most abundant protein of myelin on the peripheral nerves, has multiple functions in the development and maintenance of myelin (Martini et al. 1995). An increase in macrophages with a subsequent increase in T cells was observed within the nerves of heterozygous P0 knockout mice. It was hypothesized that a reduction in P₀ could result in an instability of myelin, which then could lead to an attraction of macrophages and a macrophage-mediated attraction of T lymphocytes because these were not tolerized due to lack of myelin protein P0 in thymus (Visan et al. 2004). Activation of autoimmune T cells by antigen-presenting macrophages could lead to cellular and humoral immune reactions, which ultimately could result in demyelination (Schmid et al. 2000).

Yan et al. (2001) studied the sera of 21 CIDP patients for antimyelin activity using immunofluorescence and for binding to myelin proteins using Western blot analysis. Results showed that the sera of six patients (29 %) contained anti-P0 IgG antibodies, and four of these caused conduction block and demyelination when injected intraneurally into experimental animals. These results suggest that P0 is an autoantigen in some patients with CIDP. More work is needed to ultimately define the precise nature of circulating antibodies and their pathogenic role in CIDP.

24.4 Summary

There are similarities in the importance of axonal damage in immune neuropathies and MS. Probably in both cases destructive immune responses are involved, presumably by a direct inflammatory assault. Recently new antigenic targets including nodal antigens and ganglioside complexes have been identified

that may exert a pathogenic role in GBS, MFS, and CIDP patients. The ultimate nerve damage, i.e. demyelination, axonal degeneration or both can experimentally be counteracted by endogenous survival factors. As yet only some of them have been identified, mostly belonging to the group of neurotrophins or neurotrophic factors. Their therapeutic application is limited because of their absorption in peripheral tissues such as liver, ultimately preventing them from access to the target organ. With the further progress in molecular and cellular gene therapy we may be able to overcome these obstacles. Currently available immune therapies such as plasmapheresis and intravenous immunoglobulins probably limit the damage by reducing the primary inflammatory assault, or by reducing titers of or neutralizing pathogenic autoantibodies.

24.5 Review Questions

- Describe clinical differences between GBS and CIDP
- Briefly summarize the different experimental neuritis models in relation to the human diseases
- Describe the key immunological factors contributing to axonal damage in GBS and CIDP
- Which factors contribute to chronification of the autoimmune inflammation in the animal model?
- Which potentially pathogenic humoral elements in CIDP patients have been identified?
- Which of the following myelin proteins is not involved in experimental neuritis?
 - MAG
 - P2 Protein
 - P0 Protein
 - MOG
 - PMP22
- Which neurotrophic cytokine has been identified as lesion factor in the PNS?
 - NGF
 - LIF
 - NT-3
 - CNTF
 - GMCSF
- Which is the correct explanation for “onion bulb” formation in CIDP?
 - Macrophages phagocytose myelin debris
 - Abundant T-cell apoptosis
 - Repetitive De- and Remyelination with Schwann cell proliferation*
 - Nitric oxide release
 - Genetic myelin deficiency
- Which of the following infectious agents is linked to axonal damage and GBS?
 - C. jejuni* Lior O4
 - Neisseria meningitidis*
 - Listeria monocytogenes*
 - Proteus mirabilis*
 - C. jejuni* serotype Penner 19
- The influence of the immune system on disease progression in genetic myelin disorders...
 - Has been excluded
 - Has been clearly shown in experimental models*
 - Has immediate therapeutic implications
 - Is merely speculative
 - Has been confirmed only in the Lewis rat

24.6 Answers

- Key Points: GBS is a monophasic disease of the PNS, mostly with preceding infection, 3% mortality, no response to steroids alone, fair to good response to plasmapheresis or polyvalent normal immunoglobulin G from healthy donors; CIDP is mostly chronic progressive or relapsing progressive, often responsive to corticosteroids alone, to plasmapheresis, immunoglobulin G from healthy donors, and to immunosuppressive drugs.
- EAN of Lewis rat—monophasic, predominantly demyelination upon immunization with crude myelin (dose-dependent), demyelination and axonal damage with cell transfer (cell-number dependent)—both types mimicking GBS; EAN of DA rat—relapsing remitting. EAN in SJL mice: mild disease, better mimicking relapsing CIDP.
- Multiple factors including cytokines like TNF alpha, free oxygen radicals, nitric oxide (NO); cytotoxic CD8 positive T cells, autoantibodies with complement.
- Autoimmunization with myelin proteins, genetic elements, epigenetic factors
- Autoantibodies (against P0 and other nerve antigens), Nitric oxide (NO)

Abstract

Autoimmunity is implicated in a small but important group of peripheral nerve diseases. These include the acute inflammatory neuropathies referred to as the Guillain-Barré (GBS) and Fisher syndromes. Early recognition and appropriate management of these neuropathies can prevent significant morbidity and mortality. Substantial evidence exists for an autoimmune pathogenesis in GBS and its subtypes. Although most current evidence supports an antibody driven pathogenesis triggered by infection, T-cell and other cellular immune components are crucial effectors of disease particularly in the demyelinating forms of GBS.

Keywords

Acute flaccid paralysis • Anti-ganglioside antibodies • *Campylobacter jejuni* • Experimental allergic/autoimmune neuritis (EAN) • Gangliosides • Immune neuropathies • Molecular mimicry • T-cells

25.1 Introduction

The term Guillain-Barré syndrome (GBS) is used to denote a group of clinically and pathophysiologically heterogeneous disorders of peripheral nerves that are characterized by acute onset, monophasic course, and potential for substantial recovery, which is expedited by two immunomodulatory therapies. After the near-eradication of polio, GBS is the commonest cause of acute flaccid paralysis worldwide. Current evidence supports the concept that GBS is likely of autoimmune origin. Postinfectious molecular mimicry (autoimmunity) is the currently favoured dominant theme in the pathogenesis of GBS. This concept implies antigens shared

between the infectious agents and peripheral nerves so that an infection results in an immune response to these cross-reactive antigens carried by the organism. The immune response triggered by infection then mediates injury to the peripheral nerves. The results from both clinical and experimental studies on some forms of GBS support this concept. This chapter outlines clinical and pathophysiological features of major variants of GBS and highlights the evidence that supports the hypothesis of postinfectious molecular mimicry in this group of disorders.

25.1.1 Historical Background

The history of Guillain Barré syndrome (GBS) is inseparably linked to the seminal paper of Georges Guillain (1876–1961), Jean-Alexandre Barré (1880–1967) and André Strohl (1887–1977) (Guillain et al. 1916). During the weekly meeting of the “*société médicale des hôpitaux de Paris*” in 1916, they presented the case history of two soldiers of the VI French army, who developed flaccid sensorimotor paralysis. Both patients, without any history of preceding infection, recovered

completely after a few weeks. The most important discovery of Guillain, Barré and Strohl was the pathological cerebrospinal fluid (CSF) examination. They performed a lumbar puncture in both patients and found the typical “*dissociation cytoalbuminique*”. Previously, the pathological condition of raised CSF protein and normal cell count was only described in cases of syphilis and compression of the spinal cord, but was never been associated with acute ascending paralysis.

The presentation of Guillain, Barré and Strohl was not the first clinical description of the disease. Half a century before, in 1859, Jean Baptiste Octave Landry (1826–1865) described the case of an 43 years old man, who developed an acute ascending paralysis and died within a few days (Landry 1859).

Landry noted a preceding pulmonary infection in his patient. He brought attention to a disease, which he called “*paralysie ascendante aigue*” by further reviewing four own and five other cases in the contemporary literature. In contrast to the description of Guillain and Barré, two patients of Landry’s case series died because of the disease. Therefore Landry’s acute ascending paralysis had been associated with poor prognosis, whereas Guillain-Barré syndrome was considered to have a mild clinical course with almost complete recovery. Landry noticed preceding infections in two cases of his series, however, on autopsy of his own case he was not able to detect any pathological changes of the nervous system. In the same year the German Adolph Kussmaul (1822–1902) (Kussmaul 1859) reported two cases of a deadly ascending paraplegia. Like, Landry he did not find a toxic or anatomical explanation on autopsy. The affection of the peripheral nerve as underlying cause for the disease, was not recognized before 1864 when L. Duménil described a case of “*paralysie ascendante aigue*”, in which he found an atrophy of peripheral nerve roots in autoptical material (Schott 1982). In the following decades, German physicians referred variously to the disease. In 1871 M. Bernhardt (Bernhardt 1871) described a lethal case of acute ascending paralysis followed by Carl Westphal (1833–1890) in 1876, who presented a similar case. He called the disease “*akute tödliche Spinallähmung*” (acute deadly spinal paralysis) (Westphal 1876). One has to consider that Landry’s ascending paralysis was a pure clinical diagnosis. It is likely that the early descriptions of Landry and others cover a range of different entities, including atypical forms of polio and infectious neuropathies. Therefore, the application of the lumbar puncture technique by Guillain, Barré and Strohl was a landmark for classifying and diagnosis of the disease, since it helped to distinguish it from other entities. In 1927 the term Guillain-Barré syndrome was introduced for the first time and become the preferred eponym in the following years (Draganesco and Claudian 1927). The name of Strohl, who was a medical student in 1916, disappeared unfairly from the original work, although he contributed substantially by doing electrophysiological examinations of the two patients.

A fundamental step towards an understanding the pathogenesis of GBS was made by observations of inflammatory

infiltrates and demyelination in peripheral nerves. These pathological studies on autopsy material lead to the assumption of GBS being a single pathophysiological entity synonymous with acute inflammatory demyelinating polyradiculoneuropathy (AIDP) (Haymaker and Kernohan 1949; Asbury et al. 1969). In the same time Waksman and Adams described the induction of an allergic neuritis in rabbits by immunization with peripheral nervous tissue (Waksman and Adams 1955). In the following years this model of an experimental allergic neuritis (EAN) was further expanded to other species, and was used as in-vivo model for GBS. The Fisher syndrome (FS) is named after Charles Miller Fisher, a Canadian neurologist. In 1956, Miller Fisher described three patients with acute external ophthalmoplegia, absent tendon reflexes, and ataxia, who recovered spontaneously (Fisher 1956). Some cases start as FS but subsequently develop weakness. Finally, work over last two decades indicates that some forms of GBS lack features of demyelination and have pathophysiology that is consistent with axonal injury; these cases are termed axonal GBS.

25.1.2 Classification of GBS Variants

Clinical features and/or electrodiagnostic examination provide a framework for classifying GBS into different variants. GBS can be broadly divided into major and minor variants. The major variants typically have muscle weakness or motor neuropathy as the dominant manifestation; they are further divided into demyelinating and axonal variants on the basis of the predominant pathophysiologic process of nerve fiber injury as determined by electrodiagnostic testing, namely, primary demyelination or primary axonal degeneration. Axonal variants are further subclassified according to the fiber type affected. Minor variants are classified based on the constellation of clinical symptoms and not by electrodiagnostic findings. The constellation of symptoms in minor variants is taken to imply regional localization of the pathophysiologic process. On the basis of this schema a simple classification of GBS is proposed in Table 25.1.

Table 25.1 Classification of GBS

Major variants
Demyelinating
AIDP
Axonal
AMAN
AMSAN
AIDP with secondary axonal degeneration
Minor variants
Fisher syndrome
Sensory ataxic variant
Acute idiopathic autonomic neuropathy

The demyelinating form of the disease is termed acute inflammatory demyelinating polyneuropathy (AIDP). Two axonal forms of GBS (Feasby et al. 1986; Yuki et al. 1990; McKhann et al. 1993), however, are now widely recognized on the basis of nerve fiber type affected: acute motor axonal neuropathy (AMAN), the more common form of axonal GBS, is distinguished by nearly pure motor axonal injury; the less common variant is acute motor-sensory axonal neuropathy (AMSAN), characterized by degeneration of both motor and sensory axons. It has been postulated that AMAN and AMSAN represent a pathologic spectrum and that AMSAN actually represents a more severe form of AMAN (Griffin et al. 1996a). Fisher syndrome (FS) is a minor GBS variant characterized by gait disturbance (ataxia), areflexia, and ophthalmoplegia. Other rarer forms without significant motor weakness that may be included under the term GBS include a predominantly sensory variant and acute idiopathic autonomic neuropathy or acute pandysautonomia.

25.1.3 Epidemiology

The incidence of GBS 0.35–1.34 per 100,000 is surprisingly similar throughout the world, despite different infection rates in various geographical regions (McGrogan et al. 2009; Sejvar et al. 2011; Hauck et al. 2008; Lehmann et al. 2007b; Govoni and Granieri 2001). Men are slightly more affected than women (Hughes and Cornblath 2005) and incidence rates increase with age (Hauck et al. 2008). The occurrence of GBS after influenza vaccination has increased the interest in establishing accurate background incidence rates for GBS in countries in which immunisation with seasonal influenza is recommended by health authorities (Destefano and Tokars 2010; Black et al. 2009; Adverse Effects of Vaccines 2011). Those age and gender specific background rates for GBS have been reported for the countries Brazil, Finland, UK and USA (Black et al. 2009).

Demyelinating forms of the disease are most prevalent in the United States, Europe (Hadden et al. 1998; A prospective study on the incidence and prognosis of Guillain-Barré syndrome in Emilia-Romagna region, Italy (1992–1993). Emilia-Romagna Study Group on Clinical and Epidemiological Problems in Neurology 1997), and most of the developed world, accounting for over 90% of patients. Compared to western world, the incidence of axonal forms of GBS is higher in northern China, Japan, Mexico, Bangladesh and other developing countries but are also, less frequently, seen in northern America and other developed countries (McKhann et al. 1993; Ramos-Alvarez et al. 1969; Ogawara et al. 2000; Islam et al. 2010). Notably, in northern China there is a clear seasonal pattern, with peak incidence in summer months, and a predilection of disease in children and villages (McKhann et al. 1991, 1993). The Fisher variant probably represents 5% of cases of GBS and has a similar incidence worldwide.

25.1.4 Clinical Features

The diagnosis of GBS is primarily clinical. In the AIDP variant the majority of cases have some sensory symptoms or paresthesias at the onset of the disease; however, abnormalities on sensory examination are less frequent. Pain, particularly low back, buttock, or thigh pain, is an early symptom in approximately 50% of patients (Ruts et al. 2007, 2008; van Doorn et al. 2008). Subsequently the clinical picture is dominated by weakness often progressing to paralysis. Muscle weakness may begin in the lower limbs and ascend upwards, characteristically involving both proximal and distal muscles. Respiratory muscles can be involved in up to one-third of the hospitalized patients. Complete or partial loss of reflexes is seen in almost all patients. Cranial nerve involvement is seen in two thirds of cases, most commonly causing facial weakness and difficulties of eye closure, ophthalmoplegia, difficulty swallowing or altered taste. Autonomic manifestations include reduced sinus arrhythmia, sinus tachycardia, arrhythmias, labile blood pressure, orthostatic hypotension, abnormal sweating, and pupillary abnormalities. Respiratory and bulbar weakness and autonomic instability are the major cause of morbidity and mortality in GBS.

Clinically, it is difficult to distinguish between axonal and demyelinating forms of GBS. Electrodiagnostic testing is essential to differentiate these variants. AMAN has exclusively motor findings, with weakness typically beginning in the legs, but in some individuals affecting arms or cranial muscles initially (McKhann et al. 1993). Tendon reflexes are preserved until weakness is severe enough to preclude phasic muscle contraction. This probably reflects sparing of muscle afferent fibers. The incidence of dysautonomia has not been systematically examined in axonal cases but it was seen in a small proportion of cases.

Minor variants without significant motor weakness include FS characterized by ataxia, areflexia, and internal and external ophthalmoplegia. Other rarer forms of the disease without significant muscle weakness include a pure sensory variant and acute autonomic neuropathy.

Differential diagnoses include structural lesions, such as myelopathy and infections including HIV, Lyme disease, *Cytomegalovirus* (CMV), rarely paralytic rabies (Sheikh et al. 2005), and, in endemic areas, polio. In children botulism should be considered. Toxic and metabolic conditions such as tick bite and porphyria can also mimic GBS (Derksen et al. 2014). In the intensive care setting, critical illness neuropathy and quadriplegic myopathy may be clinically indistinguishable from GBS.

25.1.4.1 Investigations

The main aim of the investigations is to exclude other conditions that can mimic GBS and to confirm the diagnosis. Electrodiagnostic testing is the most critical investigation in

the evaluation of patients with GBS; it can potentially provide support for the clinical diagnosis and useful prognostic information. Nerve conduction studies (NCS) are abnormal to some extent in most patients with GBS, but normal studies in the first week do not exclude this diagnosis. Gordon and Wilbourn reported the NCS changes seen in the first week (Gordon and Wilbourn 2001). Changes in F wave latencies are probably the most common abnormality early in disease. In AIDP, typical electrophysiological features of demyelination such as slow motor conduction velocities, prolonged distal motor latencies, and partial motor conduction block may not be present until the second or third week. Reduced or absent sensory nerve action potentials (SNAPs) and slowing of sensory conduction velocity are common. The pattern of preserved sural SNAP and abnormal ulnar/median SNAP (“sural nerve sparing pattern”) is more specific for AIDP than for GBS mimics at hospital admission (Derksen et al. 2014). In contrast to AIDP, conduction times like distal motor latencies and motor conduction velocities are relatively preserved in the axonal forms, but reduced compound motor action potential (CMAP) amplitudes are characteristic. Inexcitable motor nerves can be seen in more severe cases and in patients with the AMSAN variant. Sensory conduction studies are usually normal in AMAN, but SNAPs are decreased or absent in the AMSAN variant. Examination of CSF is most useful in excluding other differential diagnoses, particularly infections. Typically, CSF protein is increased in 80–90 % of GBS cases without significant pleocytosis. A mild increase in mononuclear cells can be seen in up to 10 % of patients. Significant pleocytosis raises the possibility of infection such as Lyme disease or HIV. Serological studies for anti-ganglioside antibodies can be considered for the diagnosis in incomplete forms and unusual variants of GBS, particularly when nerve conduction studies and CSF are normal. The role of anti-ganglioside serology in routine diagnosis and clinical decision-making remains to be established. Table 25.2 summarizes the common anti-glycolipid antibodies reported in association with various forms of GBS.

25.1.4.2 Clinical Course

GBS may progress up to 4 weeks with a nadir being reached within 2–3 weeks in a majority of patients. Recovery usually begins within 2–4 weeks of this nadir, but can be delayed for several months. About one-half of patients become chair- or

bed-bound, one-third require intensive care admission, and one-quarter mechanical ventilation (Winer et al. 1988; Rees 1998; Hughes and Cornblath 2005). Functional recovery is a rule and occurs in a majority of patients over 6–12 months; however 20–30 % of patients are left with significant disability and about 10 % require assistance with walking. Recent studies reported mortality rates for GBS between 2.58 and 3.8 % within 12 months, which is lower than those reported a decade earlier (van den Berg et al. 2013; Alshekhlee et al. 2008). Most deaths are attributed to cardiac arrest due to autonomic disturbance, respiratory failure or infection, or pulmonary embolism.

25.1.4.3 Prognosis

The extent and location of axonal injury are the two most important determinants of prognosis after an episode of GBS. Residual disability almost always indicates axonal degeneration. Axon regeneration is required for restoration of function. In GBS, there is characteristically significant pathology in spinal roots and proximal nerves and as peripheral axon regeneration advances at a rate of approximately 1 in./month, recovery is slow and often incomplete. Although peripheral axons have the capacity to regenerate, experimental evidence indicates that: (a) the efficiency of axonal regeneration decreases over time after injury (Fu and Gordon 1995a); (b) the denervated distal segment of peripheral nerves can optimally support axon regeneration only for a limited time (Fu and Gordon 1995b); and (c) the efficiency of reinnervation of original pathways and targets (pathfinding) decreases with advanced age (Le et al. 2001). Poor recovery after axonal GBS is not always the rule; exceptions include children with electrical features of acute denervation, cases with distal axonal degeneration where regeneration is needed over only a short distance, or patients with reversible axonal conduction failure. Poor prognostic factors include advanced age, ventilator dependence, preceding gastrointestinal infection, rapid progression from onset to nadir, severe motor involvement, and electrodiagnostic evidence of extensive axonal injury.

25.1.5 Pathology

Pathology of demyelinating and axonal forms presented below is well established. Pathological changes in minor variants of GBS are not well-characterized.

AIDP: The pathological changes in AIDP have been extensively characterized in postmortem studies. The most prominent feature in AIDP is marked segmental demyelination, which can be found throughout the length of all peripheral nerves including the mixed spinal roots and even the distal terminal nerves (Hall et al. 1992; Massaro et al. 1998). In areas of severe demyelination, signs of secondary axonal degeneration

Table 25.2 Anti-glycolipid antibodies in different GBS variants

Variants	Anti-glycolipid antibody
Fisher syndrome	GQ1b/GT1a
AMAN	GD1a, GM1, GM1b, GalNAc-GD1a
AIDP	GM1, Asialo-GM1, GD1b, GM2, LM1, GD2, GalC, Forssman antigen
Sensory ataxic variants	GD1b and structurally related gangliosides

can be observed. Another pathological hallmark is the presence of inflammatory infiltrates, especially in the spinal roots and proximal nerves, which contain T-lymphocytes and macrophages (Asbury et al. 1969; Prineas 1981). Macrophage-mediated myelin stripping (ingestion/breakdown) is characteristic. Lymphocytic infiltration can be minimal, however, sometimes it may not occur; moreover, localization may differ markedly (Cornblath et al. 1990; Honavar et al. 1991). Inflammatory infiltrates have also been detected in the spinal cord of GBS patients, indicating that there may be subclinical inflammation of CNS structures (Muller et al. 2003). In some cases of AIDP there is breakdown of blood-nerve barrier with deposition of activated complement products on Schwann cells, suggesting a role for antibody-mediated immune injury (Hafer-Macko et al. 1996b). These pathological observations implicate T-cells or autoimmune antibodies in inducing peripheral nerve demyelination in individual cases. Further, T-cell and antibody-mediated immune injury can predominate or act synergistically in an individual case.

Axonal variants: Unlike AIDP, axonal variants of GBS show primary axonal injury without substantial T-cell inflammation or demyelination (Griffin et al. 1995, 1996a). In AMAN, axonal degeneration predominantly involves the motor axons, whereas in AMSAN sensory axons are also involved. It has been postulated that AMAN and AMSAN represent a pathologic spectrum and that AMSAN actually represents a more severe form of AMAN.

In AMAN, deposition of IgG and complement can be detected on the nodal and internodal axolemma (Hafer-Macko et al. 1996a). Macrophages assume close association with the axons at the nodes and these cells then extend into inter-nodal regions where they surround axons, without disturbing/disrupting the overlying myelin, eventually leading to axon degeneration (Griffin et al. 1995, 1996a). The findings of IgG deposition on axolemma and periaxonal location of macrophages strongly imply that the potential target antigen(s) are expressed on the surface of (motor) axons. Current pathogenetic concepts assume that antibody binding to motor axolemma leads to activation of complement, recruitment of macrophages, and subsequent degeneration of axons.

Pathologic examination of early cases has shown that at the onset the pathological alterations in AMAN are mainly restricted to the nodes of Ranvier of motor fibers in the ventral roots (Griffin et al. 1996b). In these cases nerve fibers still appear normal except that the nodal gap is lengthened. It is believed that this nodal lengthening is sufficient to cause failure of transmission of nerve impulses and profound clinical weakness. Motor nerve terminals are another site susceptible to injury in AMAN, as indicated by degeneration of intramuscular nerves on muscle biopsy (Ho et al. 1997). These observations suggest that nodes of Ranvier and motor nerve terminals are two sites that are susceptible to injury in AMAN.

In summary, the pathological and immunopathological findings in AMAN suggest that antibody-mediated injury directed against axonal antigens plays a prominent role in the pathogenesis of this disorder.

25.1.6 Treatment

- (a) *Supportive care* is the mainstay of medical management in patients with GBS, despite the availability of immunomodulating therapies like plasma exchange and (PE) and intravenous immunoglobulins (IVIg). All patients with GBS should be admitted to a hospital with an ICU experienced in GBS care. The major risks are complications arising from weakness of respiratory and bulbar muscles and autonomic instability. The principles of supportive management include respiratory support in patients with respiratory failure, monitoring and management of dysautonomia, measures to prevent nosocomial infections and complications of immobility, and pain management.
- (b) Immunomodulatory therapies controlled clinical trials have shown that IVIg and PE are beneficial immunomodulatory treatments in GBS in populations where AIDP is the predominant form of the disease (Hughes et al. 2012; Hughes and van Doorn 2012). These trials indicate that treatment with PE or IVIg should be considered for all nonambulatory adult patients with AIDP. IVIg is now the first line of treatment for most patients because it can be administered easily and patient acceptance is high. Immunomodulatory treatments should begin as soon as possible after the onset of symptoms to obtain maximal benefit and limit the extent of nerve injury. There are no controlled studies of immunomodulatory therapy in the FS and primary axonal variants of GBS, but anecdotal reports indicate that both PE and IVIg are beneficial. There is no evidence that corticosteroids are beneficial for treatment of GBS (Hughes and van Doorn 2012). The current data indicate that the use of multiple immunomodulatory treatment modalities (PE followed by IVIg) is not superior to single therapy (PE or IVIg) for the treatment of GBS.

The precise mechanism(s) of action of PE and IVIg in GBS remain uncertain. PE removes a number of potentially pathogenic circulating factors including autoimmune antibodies, cytokines and complement, and can alter lymphocyte activation (Lehmann and Hartung 2011). IVIg is purported to neutralize and inhibit production of autoantibodies, suppress antibody dependent cellular cytotoxicity, decrease natural killer cell function, down-regulate proinflammatory cytokines, and interfere with complement activation (Dalakas 2002; Ritter et al. 2014). It is also proposed

that IVIg induces increased catabolism of immunoglobulins including autoantibodies by saturating FcRn transport receptors (Berger et al. 2013).

25.2 Acute Inflammatory Demyelinating Polyradiculoneuropathy (AIDP)

Most of our understandings about the cellular mechanisms in the pathogenesis of AIDP have been gained by studies of the experimental allergic/autoimmune neuritis (EAN). In particular, the important role of T-cells in the pathogenesis of EAN has paved the way for the development of hypothetical models for human AIDP (Fig. 25.1). EAN can be induced in different species with whole peripheral nerve tissues or neuritogenic epitopes of peripheral nerve proteins P0, P2, and PMP22 (Hughes et al. 1999). A modified model is the adoptive transfer EAN, where specific T-cell lines against P0 or P2 are passively transferred to the animals induce neuropathy. EAN is a monophasic disease; its severity is associated with cell or antigen dosage (Hartung et al. 1996b). Depletion of T-cells by thymectomy or antibodies against T-cells can protect against EAN, indicating that disease induction is dependent on the presence of T-cells (Holmdahl et al. 1985). Further, a normal function of T cells (Holmdahl et al. 1985; Hartung et al. 1987; Jung et al. 1992) and the presence of costimulatory molecules B7.1/CD80 or B7.2/CD86 and CTLA4/CD28 (Kiefer et al. 2000; Zhu et al. 2001a, b) are required for inducing and supporting EAN, which emphasizes the important role of T-cells as mediators for experimental neuritis.

T cell activation in EAN is accompanied by expression of inflammatory cytokines such as IFN- γ , TNF- α , TNF- β , IL-6 and IL-12 (Zhu et al. 1994, 1997). In sera and CSF of GBS, inflammatory cytokines detected include IFN- γ , TNF- α and IL-2, which are increased in patients and partially correlate with disease activity (Taylor and Hughes 1989; Hartung and Toyka 1990; Hartung et al. 1991; Exley et al. 1994; Creange et al. 1996; Sainaghi et al. 2010). In contrast, levels of TGF- β 1, a pleiotrophic cytokine, are lower in GBS patients than in controls (Creange et al. 1998).

Systemic immune activation in AIDP is reflected by an increased number of activated T-cells circulating in the peripheral blood during the early disease course (Taylor and Hughes 1989). Many studies to identify the putative antigen of a specific T cell response in AIDP provided conflicting results. Some studies postulated that peptides from P0 and P2 might be the epitope of specific T-cell lines in GBS, but most of them failed to obtain disease specific T-cell responses against neural antigens (Makowska et al. 2008; Csurhes et al. 2005; Pette et al. 1994). The CD4/CD8 ratios of T-cell populations detected in the peripheral nerves in AIDP closely resemble those in the peripheral blood. Of those, $\alpha\beta$ T-cells constitutes most of the nerve infiltrates (Cornblath et al. 1990). The usage of V β 15 T-cell receptor gene suggest the specific T-cell activation by a common antigen or superantigen (Khalili-Shirazi et al. 1997).

In the normal human immune repertoire there are far fewer T-cells that express the $\gamma\delta$ T-cell receptors than those expressing $\alpha\beta$ T-cell receptors. Unlike $\alpha\beta$ T-cells they do not recognize antigenic peptides in the context of MHC molecules and these cells are mainly localized in epithelial barrier

Fig. 25.1 Hypothetical scheme of the immune response in acute inflammatory demyelinating neuropathy (AIDP): Inflammatory cells migrate from the systemic immune compartment through the damaged blood-nerve barrier into the endoneurium. Inflammatory infiltrates, which contain T-lymphocytes and macrophages cause marked segmental demyelination and secondary axonal degeneration (*B* B-cell, *T* T-cell, *M ϕ* macrophage)

tissue. Interestingly, $\gamma\delta$ T-cells were isolated from sural nerve biopsies of GBS patients (Winer et al. 2002). A specific role of those $\gamma\delta$ T-cells has been postulated, as they may recognize non-protein antigens. Therefore, they could initiate an immune response to potential carbohydrate and glycolipid antigens (Winer et al. 2002). The proliferation of $\gamma\delta$ T-cells in response to *C. jejuni* lysates has been shown. Nonetheless, $\alpha\beta$ T-cells or stimulatory cytokines such as IL2 are required for expansion of $\gamma\delta$ T-cells (Van Rhijn et al. 2003). These studies suggest that T-cell subtypes with specificity for peptide and glycolipid antigens can invade the nerves in AIDP.

A crucial step during the process of inflammation is the migration of activated T-cells from the systemic immune compartment to the sites of inflammation. Like the CNS, the peripheral nerve represents an immunologically privileged environment, protected by an intact blood-nerve barrier. In EAN, the breakdown of the blood-nerve barrier is one of the earliest pathological changes that can be found. The upregulation of specific endothelium-binding molecules on T-cells and their specific ligands on vascular endothelium precedes the migration of T-cells through the blood-nerve barrier. E-Selectins binding sialyl Lewis antigens (Hartung et al. 2002) and VCAM-1/ICAM-1, are both upregulated in GBS and EAN (Enders et al. 1998; Creange et al. 2001). EAN can be partially inhibited by blocking VCAM-1 or its ligand VLA-4/a4b1 integrin (Enders et al. 1998). E-selectins are released into the blood and can be found in elevated levels in GBS patients. Chemokines, which exert chemotactic effects on leucocytes by binding to their specific receptor, contribute to the migration of inflammatory cells (Baggiolini 1998; Campbell et al. 1998). The differential expression of chemokines and their receptors has been studied in detail in sural nerves of patients with AIDP (Kieseier et al. 2002). Of those, specific upregulation of CCR-2 and CCR-4 were detected in invading T-cells, whereas endothelial cells expressing the chemokine IP-10 were identified (Kieseier et al. 2002).

Matrix metalloproteinases (MMPs), a heterogeneous group of zinc-dependent endopeptidases, are assumed to contribute to the structural breakdown of the blood-brain barrier, extravasation of leukocytes, and direct demyelination. In EAN, MMP9 and MMP7 are upregulated during early disease course and correlate with disease severity (Kieseier et al. 1998). Further, the administration of MMP inhibitors may attenuate the disease (Redford et al. 1997b). Human CSF samples from patients with GBS show increased gelatinase B activity (Creange et al. 1999). In sural nerve biopsies from GBS patients, augmented proteolytic activity for gelatinase B as well as increased mRNA expression for gelatinase B and matrilysin were detected (Kieseier et al. 1998). MMPs in the inflamed peripheral nervous system (PNS) appear not only to promote inflammation, but may also play a role in nerve repair. For example, in EAN, matrilysin remained upregulated throughout the clinical recovery

phase, implicating a possible role of this metalloproteinase in restoring the integrity of the PNS (Hughes et al. 1998). Schwann cell derived MMP-2 can also be found in the CSF of GBS patients and has been shown to promote myelination in vitro (Lehmann et al. 2009).

Because macrophages represent the major cell population in infiltrates of affected nerves, they are considered to be key mediators of injury to myelin, Schwann cells, and axons. This hypothesis is reinforced by experimental studies, where depletion of macrophages prevents the development of EAN. Although endoneurial macrophages are present in low frequency in the normal peripheral nerve, most of them migrate through the blood-nerve barrier during the process of inflammation (Hartung et al. 2002). Macrophages may exert their pathological effects by release of inflammatory mediators. Of those, MMPs, TNF α , nitric oxide, and others have been postulated to mediate neurotoxicity (Redford et al. 1997a, b; Hartung et al. 2002; Lehmann et al. 2007a). Besides direct harmful effects to nerve fibres, macrophages also perpetuate the inflammatory process by antigen-presenting to T-cells. It is assumed that macrophages also attack Schwann cells in AIDP (Prineas 1981; Hartung et al. 1996a; Hartung and Kieseier 1999) by antibody-mediated cytotoxicity and activation of complement (Hafer-Macko et al. 1996b). Another mechanism for Schwann cell injury/demyelination is via CD8+ T-cells, which are cytolytic T-cells that mediate cytotoxic effects by release of perforin and granzymes. CD8+ T-cells can be detected in postmortem tissue of GBS patients with prolonged disease course (Wanschitz et al. 2003). These results point to an additional direct role of T cell-mediated cytotoxicity in AIDP.

There is a growing interest in the role of humoral factor induced demyelination in AIDP. In demyelinating cases from China, complement activation markers were found on the abaxonal Schwann cell surface. They were associated with vesicular demyelination (Hafer-Macko et al. 1996b) and closely resemble the experimental nerve fiber demyelination induced by anti-galactocerebroside (a glycosphingolipid enriched in myelin) antibody in the presence of complement (Saida et al. 1979). It is likely that in these cases, the antibody and complement are directly involved in targeting the Schwann cell and myelin, and the role of T-cells may be to open the blood-nerve barrier (Spies et al. 1995a, b). This concept is supported by the observations that disease severity in models of adoptive transfer-EAN is enhanced by transferring antibodies that recognise myelin or Schwann cell epitopes (Spies et al. 1995a; Hahn et al. 1993). Several clinical and experimental observations also support a role for antibody-mediated mechanisms, including the response to plasmapheresis, the presence of anti-myelin and anti-glycoconjugate antibodies (reviewed in (Hughes et al. 1999)), and the ability of AIDP sera to induce demyelination after intraneural injection. Anti-ganglioside antibodies of

various specificities have been described in AIDP but their pathogenic role is not accepted because of lack of experimental models demonstrating their demyelinating activity. Antibodies against GM1, GD1b, asialo-GM1, the Gal(β 1–3)GalNAc epitope, GM2, LM2, and GT1b (reviewed in (Hughes et al. 1999; Willison and Yuki 2002) have been described, but antibodies to these individual gangliosides are not routinely detected. The observation that adjacent gangliosides in the plasma membrane can form conformational epitopes that are recognized by autoantibodies (anti ganglioside complex antibodies) has raised the possibility that newly formed complex epitopes may be targeted in AIDP as well. By use of glycoarrays the Willison lab could demonstrate that antibodies against various glycolipid complexes are present in more than 60 % of patients with AIDP (Rinaldi et al. 2013).

More recently antibodies against nodal proteins have been implicated to play a role in the pathogenesis of AIDP. In EAN, antibodies against two nodal proteins, gliomedin and neurofascin can be detected, supporting a role for those proteins as immune targets in this model (Lonigro and Devaux 2009). In about 5 % of patients with AIDP antibodies against neurofascin can be detected in the serum and monoclonal anti-neurofascin antibodies aggravate the disease course of EAN when passively transferred (Ng et al. 2012). Those studies testify substantial progress that has been made in understanding of the cellular and humoral mechanisms that might underlie nerve fibre injury in AIDP; however, definition of target antigens and how the undesirable processes of inflammation, myelin degradation, and subsequent axonal damage are initiated remain unclear.

25.2.1 Acute Motor Axonal Neuropathy (AMAN)

Unlike for AIDP there are almost no clinical or experimental data that have systematically examined the role of cellular immunity in AMAN. Clinical studies over the last 15 years show that patients with AMAN have specific antibodies against two major gangliosides, GM1 and GD1a, and two minor gangliosides, GalNAc-GD1a and GM1b in the peripheral nerves (Figs. 25.2 and 25.3a) (Rees et al. 1995a; Jacobs et al. 1996; Hadden et al. 1998; Ho et al. 1999; Ogawara et al. 2000; Yuki et al. 1993b; Kusunoki et al. 1994, 1996). Most of the data originates from Japan and northern China, where the AMAN form of the disease and preceding *C. jejuni* infections are frequent. Anti-GM1 antibodies have been reported in up to 50 % of Japanese patients with AMAN (Ogawara et al. 2000). Anti-GD1a antibodies are present in up to 60 % of patients with AMAN compared to 4 % in AIDP in northern China (Ho et al. 1999). The frequency of anti-GalNAc-GD1a and -GM1b in motor-predominant GBS is

about 10–15 % (Kusunoki et al. 1994, 1996; Yuki et al. 1999). Anti-ganglioside antibodies in AMAN are mostly IgG isotype and are commonly IgG1 and IgG3 (Willison and Veitch 1994; Ogino et al. 1995), which are complement-fixing subtypes in humans. These anti-ganglioside antibodies are oligoclonal or polyclonal and can have a broad range of crossreactivity. In AMAN, the differences of antibody specificity in different populations are not well understood. There are some data to suggest differences in immunogenetic repertoire, and geography may affect the specificity and isotype distribution of anti-ganglioside antibodies in various populations (Ogawara et al. 2000; Ang et al. 2001).

Apart from antibodies against individual gangliosides there is also evidence that in some GBS patients, antibodies are present that recognize conformational epitopes that are formed by two neighbouring gangliosides (ganglioside complexes). Around 8–17 % of GBS patients have antibodies that target epitopes on GD1a/GD1b, GM1/GD1a, GD1b/GT1b, GM1/GT1b, or GM1/GD1b complexes. Those patients can have predominant axonal or demyelinating damage but tend to have more often antecedent gastrointestinal infection and poorer prognosis than patients without those antibodies (Kusunoki and Kaida 2011; Kaida et al. 2004, 2007).

A brief discussion of peripheral nerve gangliosides is necessary for understanding the pathogenetic effects of anti-ganglioside antibodies. Gangliosides, the target antigens of anti-ganglioside antibodies, are sialic acid-containing glycolipids enriched in the mammalian nervous system. They contain one or more sialic acids linked to an oligosaccharide chain of variable length and complexity, which is attached to ceramide lipid anchor (Kolter et al. 2002). The ceramide portion of gangliosides anchors them in plasma membranes and glycan moieties are expressed on cellular/axonal surfaces. This organization allows anti-ganglioside antibodies to bind to glycan moieties on cell surfaces. The most abundant gangliosides in the adult mammalian nervous system are GM1, GD1a, GD1b, and GT1b; in peripheral nerves LM1 ganglioside is also enriched, particularly in myelin (Yu and Saito 1989; Svennerholm et al. 1992, 1994; Ogawa-Goto et al. 1990). Complex gangliosides are more concentrated in axolemmal fractions; GM1 is enriched in both axons and myelin (Yu and Saito 1989). Immunolocalization studies indicate that in normal rodents and humans, all complex gangliosides including GM1 and GD1a reside in axons, and GM1 is also found in paranodal Schwann cells, but compact myelin in internodal segments is difficult to stain with anti-ganglioside antibodies or toxins (Ganser et al. 1983; Sheikh et al. 1999; Gong et al. 2002). Minor gangliosides GalNAc-GD1a and GM1b are expressed in peripheral nerves and one study suggests that GalNAc-GD1a may only be expressed by motor neurons and nerve fibers (Ilyas et al. 1988; Yoshino 1997). In summary, it is important to emphasize that GM1 and GD1a gangliosides are present at the nodes of Ranvier and motor

Fig. 25.2 Proposed pathogenesis in acute motor axonal neuropathy (AMAN): In AMAN there is primary axonal injury without T-cell inflammation and demyelination. Deposition of autoantibodies and complement on the axolemma is followed by structural axonal injury or alteration of axon conduction. Macrophages within the periaxonal space contribute to the axonal damage (*B* B-cell, *Mφ* macrophage, *C5b-9* complement factors)

Fig. 25.3 (a) Schematic diagrams showing the glycan structures of gangliosides implicated as target antigens in AMAN and FS. (b) Teased nerve fibers showing GM1 staining at node of Ranvier (arrow) and paranodal Schwann cells. (c) GM1 is also localized to intramuscular

nerve (arrow) and motor nerve terminal (arrowhead); blue staining marks motor end plates (adapted with permission from Sheikh et al. 1999) (See color plates)

nerve terminals: two sites along the motor nerve fibres reported to be involved in patients with AMAN. Distribution of GM1 gangliosides at nodes of Ranvier and motor nerve terminals is shown as an example in Fig. 25.3b, c.

Several anatomical and physiological features make nodes of Ranvier and motor nerve terminals susceptible to antibody-mediated nerve injury: (1) most complex gangliosides are concentrated at the nodes and motor nerve terminals; (2) in myelinated fibers, axonal target antigens are exposed at these sites; (3) sodium and potassium ion channels are clustered at the nodes and disruption of their function can disrupt impulse conduction; (4) structural integrity of the node of Ranvier is critical for nerve fiber conduction; (5) motor nerve terminals are enriched in sodium and calcium channels and disruption of their functions can affect distal impulse conduction or neurotransmitter release at the neuromuscular junctions, respectively. Further, multiple studies indicate that gangliosides are concentrated in microdomains called lipid rafts that are specialized for cell signaling and that modulation of these lipid raft gangliosides can modulate receptor function, including ion channel function.

With this background information, we outline the experimental data that supports the notion that anti-ganglioside antibodies can induce nerve fiber injury in animal models and briefly review the effects of these antibodies on nodes of Ranvier and motor nerve terminals. There are several animal models that provide 'proof of concept' that anti-ganglioside antibodies with -GM1 and -GD1a specificities can induce neuropathy. First, Yuki and colleagues used GM1 ganglioside or *C. jejuni* lipopolysaccharide (LPS) with a mixture of keyhole limpet hemocyanin and complete Freund's adjuvant for repeated immunizations in rabbits to induce high titres of anti-GM1 antibodies, clinical paralysis, and electrophysiological and pathological evidence of motor axon injury (Yuki et al. 2001, 2004). The pathological and immunopathological studies in these animals showed features similar to that of human disease, i.e., deposition of IgG on motor axons and the presence of periaxonal macrophages. Further, analysis of animals shortly after the onset of clinical weakness showed only lengthening of the nodes of Ranvier without morphological features of axon degeneration (Susuki et al. 2003). We took an alternative approach to induce neuropathy in mice with anti-GD1a antibodies. This included generation of monoclonal anti-GD1a antibodies (Lunn et al. 2000) and implantation of antibody-secreting hybridoma in mice (Sheikh et al. 2004). Animals implanted with hybridoma develop high titres of anti-GD1a antibodies and axonal neuropathy in peripheral nerves and motor nerve terminals. Our studies showed that hybridoma implantation in transgenic mice lacking complex gangliosides (including GD1a) did not induce neuropathy despite high circulating levels of antibodies, confirming that gangliosides are indeed the target antigens of anti-ganglioside antibodies in this model (Sheikh

et al. 2004). Critical for anti-ganglioside antibody mediated injury to peripheral nerve fibers is the breakdown of the blood-nerve-barrier. In a recent study it was demonstrated that mechanical disruption of the blood-nerve-barrier by lumbar (L5) spinal nerve transection allowed sufficient access of systemically transferred anti-ganglioside antibodies to peripheral nerve endoneurial compartment (He et al. 2015). Moreover, transgenic mice that lack components of the innate immunity such as complement or FcγRs were used in this study to show that anti-ganglioside antibody-mediated injury to intact nerve fibers requires formation of immune complexes on the nerves and this then interact with activating FcγRs on macrophages to cause node of Ranvier and axonal injury (He et al. 2015).

Apart from direct nerve injury, antibodies against GD1a can also interfere with the regeneration of injured nerve fibres. Monoclonal mouse and polyclonal human anti-GD1a-antibodies were found to inhibit axonal regrowth after injury in vivo and in vitro, thereby interfering with the RhoA pathway (Lehmann et al. 2007c; Lopez et al. 2010; Zhang et al. 2011).

The pathophysiologic effects of anti-ganglioside antibodies on nodes of Ranvier have been examined both in vitro and in animal models. Most of the studies have used anti-GM1 antibodies derived from patients with acute and chronic immune neuropathies or produced experimentally. It has been reported that intraneural injections of sera containing anti-GM1 can induce acute conduction block (Santoro et al. 1992; Uncini et al. 1993). The immunization of rabbits with anti-GM1-antibodies can induce marked changes in the molecular structure of the nodes of Ranvier that include disruption of Na(v) channels clusters (Susuki et al. 2007). Deposition of IgG and complement suggest antibody mediated damage not only at the nodes itself, but also at the paranodal axoglial junctions and Schwann cell microvilli which are required for stabilization of Na(v) channel clusters (Susuki et al. 2007).

Takigawa and colleagues examined the effects of anti-GM1 sera on ion channel function at the nodes of Ranvier by using a voltage clamp technique on isolated myelinated fibers. They found that in the presence of complement these antibodies induced irreversible decreases in sodium currents and eventual blockade of the channels (Takigawa et al. 1995, 2000). Nonetheless, other investigators have been unable to reproduce these findings (Harvey et al. 1995; Hirota et al. 1997). Possible explanations include differences in experimental paradigms, including sources of antibodies, and affinity and fine specificity of these antibodies. Overall, these studies support the concept that anti-ganglioside antibodies can alter the nodal architecture and directly modulate ion channel function at the nodes of Ranvier. The effects of anti-ganglioside antibody-mediated injury on motor nerve terminals have been extensively examined by in vitro phrenic nerve-diaphragm preparations. Current concepts indicate that

anti-ganglioside antibodies can exert immunopharmacological effects on motor nerve terminal physiology and that they can also induce complement-dependent cytotoxic injury to motor nerve terminals. We have previously examined the effects of IgG anti-GM1 and -GD1a antibodies on motor nerve terminals by a perfused macro-patch clamp model with Buchwald's group. Our studies indicate that anti-GM1 and -GD1a antibodies depressed the evoked quantal release (Buchwald et al. 2007). This blockade was reversible or partially reversible after washout of these antibodies and did not require complement. Since calcium channels are critical in evoked quantal release, we examined the effects of these antibodies on depolarization-induced calcium influx by calcium imaging. These studies indicate that anti-GM1 and -GD1a antibodies significantly decrease depolarization-induced calcium influx, suggesting that antibody binding to gangliosides in the presynaptic motor terminals alters calcium channel function (Buchwald et al. 2007). Work done by others has characterized the complement-dependent pathophysiologic effects of anti-GD1a antibodies on motor nerve terminals in ex vivo hemidiaphragm preparations (Goodfellow et al. 2005). They showed that dense antibody and complement deposits develop over presynaptic motor axons, accompanied by severe ultrastructural damage and electrophysiological blockade of motor nerve terminal function. This pathophysiologic effect, however, required high density expression of GD1a ganglioside (Goodfellow et al. 2005).

In summary, experimental data indicate that active immunization with GM1 ganglioside or *C. jejuni* LPS can reproduce pathophysiological features of AMAN in a rabbit model. Passive transfer with an anti-GD1a monoclonal antibody (by hybridoma implantation) also reproduced axon and motor nerve terminal degeneration in a mouse model. Anti-GM1 and -GD1 antibodies can alter the nodal and motor nerve terminal function and architecture. Tissue and cell culture studies indicate that sodium and calcium ion channel function can be modulated by these antibodies at nodes of Ranvier and presynaptic motor nerve terminals, respectively. These antibodies have both complement-independent immunopharmacologic and complement-dependent cytotoxic effects. The detailed subcellular and molecular effects of these antibodies on motor axons remain to be elucidated. Preferential susceptibility of motor axons to anti-GM1 and -GD1a antibody-mediated injury in AMAN is another fundamental issue that remains unresolved, because biochemical studies indicate that both motor and sensory nerve fibres have similar levels of ganglioside expression (Gong et al. 2002). Despite these and other gaps in our knowledge about the pathogenetic sequence of this disorder, current data support the hypothesis that anti-ganglioside antibodies can induce pathophysiological effects on intact motor nerve fibres.

25.2.2 Fisher Syndrome

Several studies have indicated that anti-GQ1b antibodies are present in more than 80 % of the cases with FS (Chiba et al. 1992; Willison et al. 1993; Yuki et al. 1993a). Preceding *C. jejuni* infection is not uncommon in this disease. Anti-GQ1b antibodies in patients with FS can be IgA, IgM, or IgG isotype but the IgG response is most robust and persistent. These IgG antibodies are of complement-fixing isotypes, similar to those in AMAN. Studies indicate that anti-GQ1b antibodies commonly cross-react with a structurally related ganglioside GT1a (Fig. 25.3a) (Chiba et al. 1993; Ilyas et al. 1998). Biochemical and immunolocalization studies have mapped the distribution of GQ1b ganglioside in the peripheral nerves: anti-GQ1b antibodies bind to paranodal myelin and nodes of Ranvier, and neuromuscular junctions (NMJs) in extraocular and somatic muscles, and it has been shown that the GQ1b is twice as frequently expressed in the extraocular cranial nerves than in other cranial and somatic peripheral nerves (Chiba et al. 1993, 1997). Pathogenetic studies indicate that anti-GQ1b antibodies bind at the nodes of Ranvier but are unable to induce acute conduction failure (Paparonas et al. 1999). This experimental result has led to the notion that antibody-mediated conduction failure at the levels of the nodes of Ranvier may be less important in the pathogenesis of FS. Because extraocular muscles are paralyzed in FS, anti-GQ1b antibodies do not affect nodal function, and anti-GQ1b antibodies bind to NMJs, experimental approaches have focused on pathophysiologic effects of anti-GQ1b antibodies on NMJs to model ophthalmoplegia seen in FS. In this regard phrenic nerve hemi-diaphragm preparations have been used extensively to study the pathological effects of anti-GQ1b antibodies.

Investigators have examined the effects of FS sera, FS IgG, or human anti-GQ1b antibodies on NMJs and showed that these antibodies bind to NMJs, cause massive quantal release of acetylcholine from nerve terminals and eventually block neuromuscular transmission, primarily through pre-synaptic mechanisms. These pathophysiologic effects were complement-dependent and resembled the effects of paralytic neurotoxin alpha-latrotoxin (Plomp et al. 1999). Willison and colleagues have shown that these antibodies induce degeneration of preterminal motor axons both by direct cytotoxicity and indirectly through damage to peri-synaptic Schwann cells at NMJs (Halstead et al. 2004, 2005; O'Hanlon et al. 2001). In contrast, Buchwald et al. (1995, 1998, 2001), reported complement-independent immunopharmacological effects of IgG fractions from both GQ1b-positive and -negative FS on NMJs. They showed that these IgG fractions blocked release of evoked acetylcholine and depressed the amplitude of postsynaptic potentials, implicating both a pre- and postsynaptic blocking effect. This effect was reversible. That the antibody-mediated pathophysiological effects at

NMJs may be relevant to clinical disease is supported by an electrophysiological study suggesting that this site is affected in some cases with FS (Uncini and Lugaresi 1999). In a mouse model, the intraperitoneal injection of anti-GQ1b antibodies can cause complement-dependent respiratory paralysis due to transmission block at diaphragm NMJs. This effect can be reversed by application of complement-inhibiting compounds, including eculizumab (Halstead et al. 2008a, b).

25.3 Molecular Mimicry Hypothesis

In this section we consider microbial agents that commonly cause infections preceding GBS and are reported to carry antigens crossreactive with peripheral nerves. The demonstration of peripheral nerve-crossreactive epitopes in these microbes is the basis for the hypothesis of post-infectious molecular mimicry in GBS.

In this regard *Campylobacter jejuni* (*C. jejuni*) is the best characterized, and stringent data exist that demonstrate the presence of ganglioside-like antigens in these organisms. Recent studies have also implicated *Haemophilus influenzae* (*H. influenzae*), *Mycoplasma pneumoniae* (*M. pneumoniae*), and *Cytomegalovirus* (CMV) as microbes carrying peripheral nerve-crossreactive epitopes. A common theme with these microbes is that they express carbohydrate epitopes that mimic glycolipid antigens in peripheral nerves, and autoimmunity against these epitopes is manifested as anti-carbohydrate antibodies. Most of the discussion highlights molecular mimicry in *C. jejuni*. A brief discussion on *H. influenzae*, *M. pneumoniae*, and CMV is also included. Glycans mimicking peripheral nerve glycolipids expressed by these microbes are shown in Fig. 25.4.

25.3.1 *Campylobacter jejuni*

C. jejuni is a gram-negative rod that is one of the most common causes of bacterial gastroenteritis worldwide (Hughes and Rees 1997; Friedman et al. 2000; Oberhelman and Taylor 2000). *Campylobacter* infections in US are mostly sporadic and are associated with ingestion of improperly handled or cooked food, particularly poultry products. In northern China contaminated well water was reported as a mode of transmission (McKhann et al. 1993). *C. jejuni* gastroenteritis is reported to be the most frequently recognized event preceding AMAN and other variants of GBS (reviewed in (Hughes and Rees 1997)). In GBS cases, both stool culture and serologic methods are used to diagnose *Campylobacter* infection, because by the time neurological symptoms develop, the yield of *C. jejuni* from stool culture is relatively low (Nachamkin 1997). Association of GBS with preceding *C. jejuni* infection was noted in early 1980s

Campylobacter jejuni

Haemophilus Influenzae

Mycoplasma pneumoniae

CMV

Fig. 25.4 Glycan structures (mimics) expressed by different microbes that are invoked in molecular mimicry. The term “like” is used when glycan structure has been determined by biochemical/mass spectrometry studies and term “crossreactive” is used when evidence for glycan structure is indirect and based on antibody inhibition or binding studies

(Rhodes and Tattersfield 1982). Studies indicate that in patients with GBS, the incidence of preceding *C. jejuni* infection varies widely, ranging from 4% in North America to 74% in northern China (Hughes and Rees 1997; Ho et al. 1999), with an overall prevalence estimated around 30% (reviewed in (Moran et al. 2002)).

Ganglioside-like moieties in *Campylobacter* are contained in its lipopolysaccharide (LPS). *C. jejuni* LPS consists of three components: lipid A, the hydrophobic region inserted into the membrane, an oligosaccharide core divided into inner and outer parts, and capsular polysaccharides also called O-chains. Lipooligosaccharide (LOS) is differentiated from LPS by lack of O-chains. In *C. jejuni* it is the oligosaccharide core region that carries ganglioside-like moieties. Since 1990 a large number of studies have characterized the

core regions of LPS/LOS of GBS- and enteritis-associated *C. jejuni* strains. These studies demonstrate that different strains or serotypes of *C. jejuni* LPS/LOS contain several ganglioside-like molecules, including GM1-, GD1a-, GalNAc-GD1a-, GM1b-, GT1a-, GD2-, GD3-, and GM2-like structures (Yuki et al. 1992; Aspinall et al. 1993, 1994a, b; Sheikh et al. 1998; Nachamkin et al. 2002). Biochemical/structural studies with mass spectrometry have failed to demonstrate a GQ1b-like structure, target antigen for FS, but antibody binding assays with human or murine monoclonal antibodies did show the presence of GQ1b- and GT1a-cross-reactive moieties in *C. jejuni* LPS/LOS (Jacobs et al. 1995, 1997; Yuki et al. 1994). Figure 25.4 shows the ganglioside-like moieties in *C. jejuni* LOS that are implicated in AMAN and FS. Recent studies show that *Campylobacter* has genetic machinery for LOS biosynthesis with relevant genes clustering in a locus. It has been reported that specific polymorphisms in a sialyltransferase gene are associated with preferential expression of GM1- and GD1a- or GQ1b-like moieties. Based on this observation it has been postulated that these genetic polymorphisms determine the specificity of anti-ganglioside antibody response (anti-GM1 and -GD1a or -GQ1b) and clinical phenotype (AMAN or FS).

Despite the relationship of preceding *Campylobacter* infection, we emphasize that GBS is a very rare complication after *C. jejuni* infection: it is estimated that 1 in 1000 cases of *Campylobacter* infection is complicated by GBS (Allos 1997). Because GBS follows very rarely after *C. jejuni* infection, investigators have examined *Campylobacter* and host-factors that may lead to this complication. Thus, *Campylobacter* strains isolated from patients with GBS and enteritis have been characterized for ganglioside mimicry. It is known that both GBS- and diarrhea-associated isolates carry ganglioside-like moieties and associated synthetic genes, but GBS-related organisms are more likely to do so (Nachamkin et al. 1999, 2002). Notably, studies indicate that expression of ganglioside-like structures in LOS, even when accounting for increased probability of synthetic machinery for ganglioside-like moieties in GBS-associated isolates, is not sufficient by itself to explain the calculated rate of GBS after *Campylobacter* infection (1 in 1000). Some studies indicate that post-*Campylobacter* GBS cases preferentially associate with certain HLA alleles, the significance of these findings remains unclear because of lack of confirmatory studies (Yuki et al. 1991; Rees et al. 1995b). The host properties that could confer susceptibility to GBS after *C. jejuni* infection are not well established.

Clinical studies showing that GBS sera or purified anti-ganglioside antibodies from GBS sera bind to ganglioside-like moieties in the LPS/LOS (Wirguin et al. 1994; Oomes et al. 1995; Sheikh et al. 1998) promulgated the hypothesis that cross-reactive carbohydrate moieties in LOS incite production of these antibodies. This hypothesis has been

examined experimentally by immunization of laboratory animals with *C. jejuni* LPS/LOS to induce anti-ganglioside antibodies (Wirguin et al. 1997; Goodyear et al. 1999; Ang et al. 2000a). There is a high level of tolerance to self-gangliosides, and immunizations in experimental animals have generally induced low affinity non-T cell-dependent antibodies of IgM and IgG3 type (non-complement-fixing isotype in mice), despite the use of adjuvants to recruit T cell help (Wirguin et al. 1997; Goodyear et al. 1999; Bowes et al. 2002).

In contrast, serological studies in AMAN and FS indicate class switching to IgG and subclass restriction to IgG1 and IgG3 (complement-fixing isotypes in humans), both usually features of T-cell help. Transgenic mice lacking complex gangliosides are immune naïve to complex gangliosides such as GM1, GD1a, and GQ1b, and immunization with gangliosides or *C. jejuni* LPSs in these animals induces IgG anti-ganglioside antibodies with complement-fixing subclass isotypes, indicating recruitment of T cell help (Bowes et al. 2002; Lunn et al. 2000). These experimental observations suggest that break-down of tolerance to self-gangliosides might be critical in the pathogenesis of post-*Campylobacter* GBS. Despite these experimental advances the mechanism(s) of anti-ganglioside antibody induction in patients with *Campylobacter* infection remains unclear.

25.3.2 Haemophilus Influenzae

H. influenzae is a gram-negative bacterium that causes human respiratory tract infections. In GBS, preceding infection with *H. influenzae* is rare, ranging between 1 % in western Europe to 13 % in Japan (Jacobs et al. 1998; Mori et al. 2000; Koga et al. 2005b). In comparison to post-*Campylobacter* GBS, preceding infection with *H. influenzae* is associated with faster recovery, less cranial nerve involvement, and milder disease course (Kuwabara et al. 2001; Jacobs et al. 2008). Based on GBS or FS sera (antibody) binding to LOS/LPS it has been postulated that *H. influenzae* may carry ganglioside-like moieties such as GM1 and GT1a (Koga et al. 2001, 2005a; Mori et al. 1999). Structural/mass spectrometry studies demonstrating ganglioside-like moieties on *H. influenzae* are not yet available. Isolation of *H. influenzae* does not necessarily indicate that this infection is the trigger for induction of anti-ganglioside antibodies because a considerable number (15 %) of GBS patients with *H. influenzae* isolated by culture were seronegative for this bacterium, but seropositive for *Campylobacter*. Further, anti-ganglioside antibodies of seronegative patients did not show any crossreactivity with *H. influenzae* LOS (Koga et al. 2005b). Whether immunization with *H. influenzae* triggers induction of anti-ganglioside antibodies in experimental animals remains to be determined.

25.3.3 *Mycoplasma pneumoniae*

Antecedent infection with *M. pneumoniae* can be found in 2–12 % of patients with GBS (Hao et al. 1998; Jacobs et al. 1998; Ogawara et al. 2000). Studies indicate that some cases of demyelinating form of GBS are associated with *M. pneumoniae* (Hao et al. 1998; Ang et al. 2002). This infection is reported to trigger antibodies against galactocerebroside (GalC), a major glycolipid antigen in myelin, in some patients with GBS. Anti-GalC antibodies have been shown to induce demyelination in experimental animal models (Saida et al. 1979, 1981; Hahn et al. 1993). The hypothesis of molecular mimicry is supported by the findings that anti-Gal-C reactivity in GBS sera following *M. pneumoniae* infection was specifically inhibited by adding *M. pneumoniae* reagent (Kusunoki et al. 2001). According to a recent study GBS associated with anti-GalC antibodies have more frequent sensory deficits, autonomic involvements, and antecedent *M. pneumoniae* infection (Samukawa et al. 2014). One study has reported the AMAN form of GBS in association with anti-GM1 antibodies and preceding *M. pneumoniae* infections (Susuki et al. 2004). These investigators report that anti-GM1 antibodies bind to lipids extracted from *M. pneumoniae*, suggesting that GM1-like structures are also expressed by this microbe.

25.3.4 Cytomegalovirus (CMV)

In GBS, serological evidence for preceding infection with CMV ranges between 8 and 15 % (Dowling and Cook 1981; Visser et al. 1996; Ogawara et al. 2000; Hadden et al. 2001). Patients with CMV-associated GBS appear to have a different clinical phenotype: significantly younger patients are affected, the disease course is more severe, there is prominent cranial and sensory nerve involvement, and functional recovery is incomplete (Visser et al. 1996). With the availability of modern techniques, polymerase chain reaction (PCR) is more appropriate to demonstrate infection with CMV. A previous study failed to detect CMV genome in sural nerve biopsies from GBS patients (Hughes et al. 1992) but a recent study demonstrated the presence of CMV DNA in the CSF of about 30 % of GBS patients with positive CMV serology (Steininger et al. 2004). Several studies have reported an association of CMV infection with GM2 antibodies in patients with GBS (Irie et al. 1996; Yuki and Tagawa 1998; Khalili-Shirazi et al. 1999). It could be demonstrated that anti-GM2 reactivity in GBS sera was abrogated after incubation with fibroblasts infected with a GBS-associated CMV strain, indicating that CMV-infected fibroblasts express GM2-like epitopes recognized by anti-GM2 antibodies (Ang et al. 2000b). This intriguing finding raises the possibility that either CMV itself expresses GM2-like epitopes or it induces the expression of this ganglioside

in the host cells which renders them immunogenic. The later possibility would suggest that direct molecular mimicry by the infecting agent and target tissue antigens may not be necessary. Besides GM2, antibodies against GalNAc-GD1a and GM1 have also been reported in the setting of CMV infection and GBS (Khalili-Shirazi et al. 1999; Kaida et al. 2001).

25.3.5 Gaps in Molecular Mimicry Hypothesis

Despite the accumulation of significant data supporting the hypothesis of post-infectious molecular mimicry in GBS, clearly several fundamental questions remain unresolved: (1) Infectious agents invoked as triggers for anti-glycolipid antibodies in patients with GBS are microbes that induce gastrointestinal and upper respiratory tract infections in a large number of people but only rare individuals develop GBS after these common infections. (2) What are the mechanism(s) of anti-glycolipid antibody induction in patients with post-infectious GBS? The induction of these antibodies in GBS patients is likely to be substantially different from experimental approaches that involve repeated use of infectious organism and adjuvants or immune naïve animals to produce disease-associated anti-ganglioside antibodies. (3) Antibodies against GM1, GM2, and GalC can be seen in other neurological disorders or sometimes in normal controls. What are the antibody-related properties that can distinguish between disease-associated and non-disease-associated antibodies? These and other unresolved issues need further research to increase our understanding of post-infectious autoimmune disorders.

25.4 Review Questions

1. What is meant by the term molecular mimicry?
2. What is the basis of hypothesis of molecular mimicry in the pathogenesis of GBS?
3. What are the potential mechanisms of antibody-mediated peripheral nerve dysfunction/injury?
4. What are the potential mechanisms of T-cell mediated peripheral nerve dysfunction/injury?

25.5 Answers

1. The term molecular mimicry describes a mechanism whereby epitopes incidentally shared by microbial antigens and nerve structures elicit an autoreactive T- or B-cell response in the wake of an infective illness.
2. In GBS there is clinical and experimental evidence that molecular mimicry is an important mechanism how an autoimmune response against peripheral nerve tissue is induced. Several observations support this hypothesis: Epidemiological studies have established a relationship

between *Campylobacter jejuni* and the occurrence of Guillain-Barré Syndrome. GBS-patients with antecedent *C. jejuni* infection frequently associate with an axonal subtype of GBS called acute axonal motor neuropathy (AMAN). Cases of AMAN are significantly associated with the presence of antibodies against the gangliosides GD1a and GM1. *C. jejuni* strains isolated from patients with AMAN bear lipo-oligosaccharides on the cell-surface which share identical chemical structures like the tetrasaccharide structure of GD1a and GM1. The strongest evidence arises from animal models of AMAN in which immunization with relevant gangliosides or *C. jejuni* LPS reproduces clinical and pathological features of AMAN.

3. Experimental evidence suggests that a variety of effects are produced by antibodies on peripheral nerve. For example studies indicate that anti-GM1 antibodies may block or alter channel function. Alternatively, Willison and colleagues demonstrated on ex vivo phrenic nerve-diaphragm preparation, that anti-GQ1b and anti-GD1a antibodies bind to nerve terminals, cause complement-dependent quantal acetylcholine (ACh) release, which results in neuromuscular blockade. In patch-clamp experiments IgG GQ1b, GD1a, GD1b and GM1 antibodies have been shown to cause reversible complement independent pre- and post-synaptic blockade depending upon the antibody used.
4. Potential mechanisms of T-cell mediated peripheral nerve injury include direct mechanisms like release of toxic cytokines such as interferon-gamma and tumor necrosis factor-alpha. Both have proinflammatory effects and mediate myelin damage through activation of macrophages. Furthermore, blood-derived neural antigen-specific T-cells become reactivated in the PNS, expand clonally and release cytokines to orchestrate and perpetuate the immune response. The crucial role of T-cells is proven by the adoptive-transfer EAN, which means the transfer from lymph node cells from animals that had been immunized with myelin induces demyelinating peripheral nerve injury.

Abstract

The dogma of the immunological privilege of central nervous system (CNS) has been increasingly challenged by compelling evidence showing reciprocal communication pathways between the CNS and the immune system. Brain antigens may drain to the cervical lymph nodes and induce antibody production and T lymphocyte homing to the CNS. It is now clear that, besides classical autoimmune diseases of the CNS such as multiple sclerosis, many CNS diseases which were previously considered as purely neurodegenerative include inflammatory and autoimmune components. The present chapter critically summarizes available evidence concerning autoimmune neuroinflammation in classical neurodegenerative disease such as Alzheimer's disease and Parkinson's disease, and in amyotrophic lateral sclerosis. Attention will be paid also to the possible autoimmune basis of some forms of epilepsies, and the possible neuroprotective role of autoimmune T lymphocytes (neuroprotective autoimmunity) will be finally discussed.

Keywords

Alzheimer's disease • Amyloid β -protein peptide • Parkinson's disease • α -synuclein • SNCA1 • Amyotrophic lateral sclerosis • Autoimmune epilepsy • Rasmussen's encephalitis • Protective autoimmunity • CD4+CD25+ regulatory T cells

26.1 Introduction

An autoimmune response implies the immune response of an organism towards its own tissues and organs, possibly resulting in an autoimmune disease. Classical autoimmune diseases affecting the nervous system include central nervous system (CNS) demyelinating diseases, multiple sclerosis being the most prominent, and autoimmune diseases of the peripheral nervous system, ranging from acute inflammatory demyelinating polyneuropathy to chronic forms (Kieseier et al. 2012; Kamm and Zettl 2012).

The CNS has been considered for long an immunological privileged site (Streilein 1993), however compelling evidence exists for afferent and efferent pathways of communication between the CNS and the immune system (Weller et al. 1996). In particular, antigens may drain from the brain to induce antibody production in the cervical lymph nodes in the presence of activated lymphocytes. T lymphocytes in turn home to the CNS and are mainly recently activated/memory lymphocytes (Weller et al. 1996). Alpha 4-integrin among others plays a key role in lymphocyte recruitment across the blood-brain barrier, as demonstrated by the efficacy as well as by the side effects in the treatment of multiple sclerosis of natalizumab, a humanised monoclonal antibody that blocks alpha4beta1 integrin-mediated leukocyte migration (Rudick and Sandrock 2004).

Awareness of immune surveillance in the CNS paved the way to the identification and characterization of peculiar inflammatory responses in many CNS diseases which were previously considered as purely neurodegenerative

(Matyszak 1998). The CNS itself has an innate immune system which includes astrocytes and microglia regulating the initiation and progression of immune responses and interacting with inflammatory (e.g. Th1/Th17) and anti-inflammatory (e.g. Th2/Treg) subsets of peripheral T cells which in turn might regulate microglial fate towards neurodegenerative or neuroprotective phenotypes (González and Pacheco 2014).

Hereafter, evidence for autoimmune-mediated neuroinflammation will be discussed in classical neurodegenerative disease such as Alzheimer's disease and Parkinson's disease, and in amiotrophic lateral sclerosis, which etiopathogenesis remains so far controversial. Evidence for an autoimmune basis of some forms of epilepsies will be then discussed. Finally, the possibility that autoimmune T lymphocytes can contribute to repair, following an injury to the CNS (neuroprotective autoimmunity) will be examined.

The present chapter will not consider the multiple evidence supporting an association between schizophrenia and perturbations of autoimmunity (Goldsmith and Rogers 2008), since it is so far unclear whether autoimmunity actually contributes to abnormal signaling in multiple neurotransmitter systems and brain regions, or it is a consequence of the central and peripheral alterations which occur during such devastating disease. Anyway, the areas stringly calls for in-depth investigation of the neuroimmunological mechanisms actually involved.

26.2 Alzheimer's Disease

Alzheimer's disease (AD) accounts for the majority of cases of dementia. It has been estimated that AD affected between 21 and 35 million people worldwide in 2010. AD usually begins over 65 years of age, although 4–5 % of cases are early-onset AD which begin before this, and affects about 6 % of people 65 years and older (Querfurth and LaFerla 2010). Besides neurofibrillary tangles, dystrophic neurites and significant neuronal loss, a hallmark of AD is the presence of extracellular aggregates of the amyloid β -protein ($A\beta$) peptide, called $A\beta$ plaques, which seem to have proinflammatory properties. For instance, in the APPPS1 AD mouse model deposition of $A\beta$ peptide activates the NLRP3 inflammasome in microglia (Heneka et al. 2013), and it has been suggested that persistent $A\beta$ -driven release of p40 by microglia, could binds the IL-12R β 1 receptor in neighboring astrocytes and microglia, impairing their ability to attenuate AD pathology (Vom Berg et al. 2012).

The occurrence of chronic neuroinflammation in AD is now well established and it has been the subject of several reviews (Monsonogo et al. 2013; Heneka et al. 2015). It is however less certain to what extent autoimmune responses may contribute to AD. Immunoaging (i.e. immune changes occurring with age) often include increased inflammation and autoimmunity associated with a decline of T cell func-

tion and a decreased ration naive/memory T cells (Sardi et al. 2011). In search of putative autoantigens in AD, the hypothesis that novel macromolecules synthesized in the brain during the process of memory consolidation might be recognized by the immune system as “non-self” antigens has been also put forward (Arshavsky 2006). In 3xTg-AD mice, a well-established murine AD model, manifestations of systemic autoimmunity and inflammation, including splenomegaly, hepatomegaly, elevated serum levels of anti-nuclear/anti-dsDNA antibodies, low hematocrit, and increased number of double-negative T splenocytes, develop early, in parallel with behavioral deficits, in agreement with a causal association between autoimmunity and aberrant behavior (Marchese et al. 2014). Another murine AD model, the 5XFAD AD mice, develop an age-dependent increase in anti-ceramide antibodies, and ceramide administration may lead to increased amyloid plaque formation (Dinkins et al. 2015). The significance of autoantibodies in AD is however debated, as autoantibodies against $A\beta$ are found naturally in aging humans, however their pathological significance is far from clear (discussed in Kapadia and Sakic 2011).

It must be considered that, nearly two decades ago, AD was the first disease attempted to be cured through the elicitation of an immune response to a self peptide (Monsonogo et al. 2013). Based on evidence from animal models, the idea was that triggering an adaptive immune responses towards the $A\beta$ peptide would have considerably reduced its accumulation in the brain. A clinical trial of active $A\beta$ vaccine was however stopped because in the brains of some vaccinated AD patients developed severe inflammatory reactions, possibly attributed to the use of the full length of the $A\beta$ peptide together with a very strong adjuvant, thus leading to the induction of pathogenic T cells. Although itself a failure, the clinical trial had the merit to attract the attention on the occurrence of $A\beta$ -reactive T cells in AD as well as in healthy subjects. Stronger $A\beta$ -reactive T cell responses may occur in elderly healthy subjects and in AD patients in comparison to middle-aged subjects, and the immunodominant $A\beta$ epitopes in humans seem to reside in amino acids 16–33 (Monsonogo et al. 2003). The current hypothesis, depicted in Fig. 26.1, is that $A\beta$ -reactive T cells can promote pathogenic autoimmunity, but can also be used to enhance neuronal repair mechanisms (Monsonogo et al. 2013). See also below, 26.6 Neuroprotective autoimmunity.

26.3 Parkinson's Disease

Parkinson's disease (PD) is the second most common neurodegenerative disorder, with prevalence raising from 0.3 % of the whole population up to 1 % in those over 60 years of age and up to 4 % over 80, thus imposing an increasing social and economic burden on societies with increased aging of populations (de Lau and Breteler 2006). The pathogenesis of PD

Fig. 26.1 Migration of Aβ-specific T cells towards Aβ plaques in the brain parenchyma. (1) T cells may undergo activation following Aβ immunization or following drainage of Aβ or antigen-presenting cells (APCs) that carry Aβ to peripheral lymph nodes. Aβ-reactive helper T (Th) cells adhere and transmigrate into the perivascular space of Aβ-deposited vasculature in the brain (a, b). To cross the glia limitans, Th cells need to be re-stimulated by dendritic cells or, possibly, by other competent APCs located at the perivascular space and/or juxtavascular with processes sent into the perivascular space. Similar T-cell infiltration processes may occur at the choroid plexus (2), and/or the leptomeninges followed by their dissemination in the central nervous system subarachnoid space. Low levels of interferon-γ (IFN-γ) promote the infiltration process. Adhesion molecules such as P-selectin, vascular cell adhesion molecule-1 or intercellular adhesion molecule 1 (interacting with P-selectin glycoprotein ligand-1, integrin α4 and lymphocyte

function-associated antigen-1, respectively, on the T cells) and chemokine signalling (such as via CCR5 and CXCR3) play a key role in mediating the extravasation of the T cells through the blood-brain barrier (BBB) or the blood-cerebrospinal fluid barrier. (3) Leucocytes accumulate at the subarachnoid and perivascular spaces and may impact on the overall inflammatory reaction at both the vasculature and parenchyma. (4) Once Aβ Th cells cross the glia limitans they migrate and accumulate around Aβ plaques, possibly interacting with APCs (i.e. microglia, or peripheral monocytes or dendritic cells recruited towards CCL2) that present Aβ T-cell epitopes. Cytokines such as IFN-γ are secreted by the T cells and facilitate Aβ clearance either by brain endogenous microglia or by infiltrating microglia-like cells. (5) T cells secreting IFN-γ and/or neurotrophic factors stimulate neural precursor cell proliferation and differentiation (reproduced with permission from Monsonego et al. 2013)

remains elusive, and the mechanisms underlying the selective dopaminergic cell loss in the brain are still far from being understood. Mitochondrial dysfunction, oxidative stress, and protein mishandling have a central role in PD pathogenesis, however more than 90% of PD cases are sporadic, and it is likely that all these processes are induced by non-genetic factors, probably in interaction with susceptibility genes.

Neuroinflammation and the adaptive immune system in PD are increasingly seen as key players in triggering and maintaining the pathogenic processes leading to neurodegeneration, although these processes are still poorly understood. Microglial cells are main contributors to chronic inflammation in PD brains. Their toxicity towards dopaminergic neurons occurs in vitro and in animal models of PD

(McGeer and McGeer 2008). Reactive microglia expressing human leukocyte antigen (HLA)-DR and CD11b can be found in the substantia nigra of PD patients (McGeer et al. 1988). Less is known about the role of astrocytes, but they are known to secrete both inflammatory and anti-inflammatory molecules and may play a role in modulating microglial activity (McGeer and McGeer 2008). Besides microglial activation, several lines of evidence suggest the occurrence of dysregulated peripheral immunity in PD patients. Baba and coworkers (2005) showed in PD patients reduction of total numbers of lymphocytes, of CD4+ T cells, as well as of the ratio CD4+/CD8+ T cells, while the ratio IFN- γ /IL-4 producing cells was increased. Saunders and coworkers (2012) showed increased percentages of CD45RO+ and FAS+ cells, while the percentages of CD45RA+ and CD31+ were decreased. In addition they reported decreased α 4 β 7+CD4+ T cells and increased α 4 β 1+CD4+ T cells. Low expression of α 4 β 7 and high expression of α 4 β 1 are characteristic of T cells that are in charge for immune surveillance of the brain (Denucci et al. 2009).

CD4+ T cells are attracting increasing attention as key players in PD. CD4+ T lymphocytes infiltrate postmortem human PD specimens and mediate dopaminergic toxicity in murine models of PD (Benner et al. 2008; Brochard et al. 2009). In recent years, evidence accumulated regarding a dysregulation of the CD4+ T cell compartment in PD. Baba et al. (2005) already reported the occurrence of decreased CD4+/CD8+ T-cell ratios, fewer CD4+CD25+ T cells and significantly increased ratios of IFN- γ -producing to IL-4-producing T cells in peripheral blood of PD subjects. In murine models, CD4+ T cells isolated from lymph nodes and spleens of animals protect the nigrostriatal system from neurodegeneration (Laurie et al. 2007); in particular, adoptive transfer of CD3-activated CD4+CD25+ regulatory T cells to MPTP-intoxicated mice provides greater than 90% protection of the nigrostriatal system (Reynolds et al. 2007). Recently, CD4+CD25+ regulatory T cells were shown to suppress microglial activation. In contrast, CD4+CD25- effector T cells exacerbated microglial inflammation and induced putative neurotoxic responses (Reynolds et al. 2009). In human peripheral blood, CD4+ T cells include CD4+CD25- effector T cells as well as CD4+CD25+ regulatory T lymphocytes (Treg), the latter being a specialized subset of T cells which are crucial for the control of immune homeostasis. Besides PD, Treg seem to be key neuroprotective immunomodulators in acute experimental stroke (Liesz et al. 2009) possibly through modulation of microglial oxidative stress and inflammation (Reynolds et al. 2007) and preliminary evidence in patients with neurodegenerative disease indicates the occurrence of specific functional alterations affecting the Treg subset (Rosenkranz et al. 2007). A recently published report also shows that in PD patients, peripheral CD4+ T cells have an increased susceptibility to apoptosis with Fas involve-

ment, which may explain the decreases number of CD4+ T-cell subsets in PD patients, possibly in relationship with the neurodegenerative process (Calopa et al. 2010).

Several lines of evidence suggest that α -synuclein (α -syn) may represent the connection between central microglia, the peripheral immune system and neuroinflammation (Sanchez-Guajardo et al. 2013). Alpha-syn is a protein which is abundant in the human brain but which can be found also in periphery. Although its function is not well understood, it may help regulate the release of several neurotransmitters such as dopamine. Alpha-syn is crucial in PD pathogenesis: mutations in SNCA1, the gene encoding α -syn, cause autosomal dominant forms of PD, while aggregated and post-translationally modified forms of α -syn are present in Lewy bodies in both sporadic and familial PD. Accumulation of abnormal forms of α -syn is a trigger for PD, and recent evidence suggests that much of the downstream neurodegeneration may result from inflammatory responses which raise from an interplay between central microglia and peripheral lymphocytes which migrate to the brain following peripheral activation (Allen Reish and Standaert 2015). Three missense mutations, A53T, A30P and E46K have been linked so far to familial PD, as well as multiple copies of the wild-type (wt) α -syn gene to a sporadic form of PD (Kruger et al. 1998; Polymeropoulos et al. 1997; Zarranz et al. 2004). Of potential relevance for PD pathogenesis, α -syn can self-assemble to form ordered fibrillar aggregates, characterized by a cross β -sheet structure (Chiti and Dobson 2006), and it has been hypothesized that aggregated α -syn may become (neuro) toxic (Bennett 2005). While typically considered as an intracellular protein, α -syn is also found in human CSF and plasma. Indeed, in PD patients α -syn levels may be elevated in plasma (Lee et al. 2010), and decreased in CSF (Tokuda et al. 2006). Plasma α -syn in PD could be predominantly oligomeric (El-Agnaf et al. 2006).

Abnormal species of α -syn are linked to microglial activation, oxidative stress, neuroinflammation, and hence loss of dopaminergic neurons in affected brain regions (Zhang et al. 2005; Reynolds et al. 2008), however various α -syn forms occur also in periphery. Nitrated (N)- α -syn, has been found in cervical lymph nodes of MPTP-treated mice (Benner et al. 2008), and modified forms of α -syn are also present in gut tissue of PD patients (Lebouvier et al. 2010; Forsyth et al. 2011; Hilton et al. 2014). Aggregated α -syn is one of the main proteins recognized by autoantibodies in PD patients (Benner et al. 2008; Spillantini et al. 1998), and 90% of patients with familial PD are positive for antibodies against α -syn (Papachroni et al. 2007).

It has been proposed that α -syn could stimulate TLRs resulting in microglial activation. Thereby, inflammatory cytokines produced by M1-like microglia would promote an immunogenic microenvironment for the presentation of neoantigens by APCs, thus triggering an inflammatory T-cell

response against cells expressing α -syn (Ohmori and Kanayama 2005). In particular, N- α -syn induces a neurotoxic microglial phenotype (M1) (Thomas et al. 2007; Zhang et al. 2005; Zhang et al. 2007; Zhou et al. 2005), while extracellular, non-aggregated α -syn produces a moderate proinflammatory response in glia, and a moderate stimulation of Th1 chemokine secretion (Roodveldt et al. 2008).

Also circulating lymphocytes express α -syn, which is increased in cells from idiopathic PD patients, and its expression is correlated to glucocorticoid-sensitive apoptosis, possibly caused by the enhanced expression of glucocorticoid receptor, caspase activation, CD95 (Fas) up-regulation, and ROS production (Kim et al. 2004). Expression of α -syn also occurs in human macrophages and its levels are increased by stimulation with IL-1 β or LPS (Tanji et al. 2002). Antibodies against all the three forms of α -syn (monomeric, oligomeric, and fibrillar) have been shown in the serum of 65 % of all PD patients (Papachroni et al. 2007), apparently reaching the highest values after 5 years of disease duration, and decreasing after 10-year duration (Gruden et al. 2011).

Several α -syn-targeting active vaccine are currently going to be introduced into the phase of clinical development, on the hypothesis that a reduction of α -syn in the brain has the potential to modify the pathophysiology underlying the disease. Companies developing immunotherapies against α -synuclein include, besides Prothena and AFFiRiS, AstraZeneca, BioArctic, Biogen, Genentech, and Lundbeck (Anonymous 2015).

26.4 Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease and Charcot disease, or motor neuron disease, has a global incidence about 1–2 per 100,000 and risk of ALS is estimated to be 1/600–1/2000. ALS is characterized by muscle stiffness and twitching and muscle wasting due to the death of spinal motor neurons (Eisen 2009). Besides 5–10 % familial cases due to Superoxide Dismutase I mutations, the pathogenesis of sporadic ALS is still a matter of debate, and etiopathogenic hypotheses include autoimmunity, neurofilament, and glutamate toxicity (Silani et al. 2001).

Preliminary evidence obtained mainly in animal models strongly suggests that immune-mediated neuroprotection may be relevant in ALS (Schwartz and Ziv 2008) (see also below: 2.3.1.5. Neuroprotective autoimmunity). For instance, in the (SOD1)(G93A) transgenic mouse model of ALS, T cells seem to play an endogenous neuroprotective role by modulating a beneficial inflammatory response to neuronal injury (Chiu et al. 2008; Banerjee et al. 2008). The involvement of immune mechanisms was recently suggested on the basis of decreased CD4+ T cells and increased CD8+ T cells, as well as diminished CD45RA/CD45RO (naive/memory)

ratio among CD4+ T cells, due to reduction in CD45RA+ cells and concomitant increase in CD45RO+ cells (Banerjee et al. 2008). The increase in CD8+ cytotoxic T cells in ALS was recently confirmed and findings were extended to increased natural killer (NK) T cells reduced regulatory T lymphocytes. Interestingly, regulatory T cells were also negatively correlated with progression of the disease (Rentzos et al. 2012). Significantly reduced regulatory T cells have been reported in ALS patients at a less severe stage of disease, suggesting their early recruitment towards the CNS area of primary neurodegeneration (Mantovani et al. 2009). Available evidence thus suggests a systemic immune activation in ALS patients, possibly to some so far undetected endogenous proteins or viruses. A dysfunction of regulatory T cells likely contributes to disease development and progression (He and Balling 2013).

26.5 Autoimmune Epilepsy

Humoral and cell-mediated immune responses against the glutamate receptor subunit GluR3 was first identified less than 20 years ago in Rasmussen's encephalitis, a rare progressive pediatric epileptic syndrome (Andrews and McNamara 1996). Soon data began to accrue suggesting the involvement of immune mechanisms in the pathogenesis of intractable childhood epilepsies. For instance, epilepsy is more common in patients with systemic lupus erythematosus with antiphospholipid antibodies, raising the possibility that such antibodies are also responsible of immune-mediated cortical damage (Aarli 2000). Besides antibodies to glutamate receptors, over the years antibodies to voltage-gated calcium and potassium channels have been detected in serum and liquor of patients with ataxia, limbic encephalitis and certain forms of epilepsy, and some patients also have antibodies to glutamic acid decarboxylase or specific ribonuclear proteins. Some patients respond to immunotherapies, although the pathogenicity of such antibodies has been questioned and in only a few cases IgG derived from patients produced pathogenic effects in vivo or in vitro (Lang et al. 2003; Billiau et al. 2005).

In 2007, Dalmau et al. reported a series of 12 patients with teratoma of the ovary (11) and of mediastinum (1) who developed prominent psychiatric symptoms, amnesia, seizures, frequent dyskinesias, autonomic dysfunction, and decreased level of consciousness often requiring ventilatory support (Dalmau et al. 2007). Psychosis may be linked to both abnormalities in autoimmunity and glutamatergic signaling in the context of an anti-N-methyl-D-aspartate receptor (NMDAR) encephalitis. The syndrome was originally described in young women but it is now established that also children and males can be affected, either as a paraneoplastic manifestation of a teratoma or without a tumor. Reversible internalization of NMDAR due to binding of IgG antibodies

is thought to be the main cellular mechanisms (Hughes et al. 2010). Current knowledge about anti-NMDAR encephalitis has been recently revised (Kayser and Dalmau 2014).

From a general point of view, neuroinflammation may occur in epilepsy, and brain inflammatory reactions may result in enhanced neuronal excitability, impairing cell survival, and increasing blood-brain barrier permeability, while some antiinflammatory treatments reduce seizures in experimental models and, in some instances, in clinical cases of epilepsy (Vezzani and Granata 2005). In 2002, for the first time a session with the “autoimmune epilepsy” concept took place in at the International Congress of Autoimmunity in Geneva, Switzerland (Levite 2002). Levite and Ganor (2008) reported AMPA GluR3 autoantibodies in 27% of patients with different epilepsies, and NMDA NR2A or NR2B autoantibodies in 30% of systemic lupus erythematosus patients, with or without neuropsychiatric impairments. NR2 autoantibodies were also found in patients with epilepsy (33%), encephalitis and stroke. Glutamate receptor autoantibodies can damage the brain in both human and animal models. GluR3 autoantibodies cause neuronal death either by receptor activation and excitotoxicity or by complement fixation independent of receptor activation, resulting in multiple brain damage and neurobehavioral/cognitive impairments (Levite and Ganor 2008). Auto-antibodies which have been found over the years in patients with seizures include antibodies against to the NMDA, GABAB and AMPA receptors and to LGI1, CASPR2 and Contactin-2, components of the voltage-gated potassium channel complex, which are all important elements controlling the brain electrical activity. Patients with temporal lobe epilepsy may have antibodies to glutamic acid decarboxylase (GAD) (Errichiello et al. 2011), while around 90% of patients with the newly described faciobrachial dystonic seizures syndrome may have antibodies to LGI1. All of these antibodies bind to the extracellular domains of their targets and their pathogenicity is very often supported by the effectiveness of immunotherapies (Irani et al. 2011).

Besides auto-antibodies, evidence from several types of epilepsy (including Rasmussen’s encephalitis, West syndrome, Landau-Kleffner syndrome and continuous spikewaves during sleep, limbic encephalitis, hemiconvulsion–hemiplegia syndrome, Batten disease), suggest the contribution of both adaptive and innate immunity (Granata et al. 2011). For instance, in Rasmussen’s encephalitis is brain inflammation dominated by cytotoxic CD8+ T cells and microglial activation, followed by neuronal loss and astrogliosis restricted to the affected hemisphere (Granata et al. 2011). Data supporting the involvement of IL-1 β , TNF- α and toll-like receptor 4 in seizure generation and the process of epileptogenesis have also been recently summarized (Friedman and Dingledine 2011).

Immune mechanisms may also be a factor in a number of epilepsies such as Rasmussen’s encephalitis, Lennox-Gastaut syndrome, Landau-Kleffner syndrome, and tempo-

ral lobe epilepsy. Immunologic abnormalities are found in routine epilepsy surgical specimens, suggesting a broader role of immunopathology in the etiology of epilepsy. The prevalence and impact of immunopathology in epilepsy syndromes remains to be determined by future research (Najjar et al. 2008). In any case, the identification of autoimmune encephalitis has changed the diagnosis and management of several syndromes that occur with seizures and status epilepticus previously attributed to viral or idiopathic etiologies (Davis and Dalmau 2013). Awareness of autoimmune encephalitis in addition is bringing to increased recognition of autoimmunity as a cause of neurologic presentations in the pediatric intensive care unit (ICU) setting. Autoimmunity is now routinely suspected in *N*-Methyl-D-aspartate (NMDA) receptor encephalitis, CNS vasculitis, demyelinating disorders, neurologic involvement of systemic autoimmune disorders, febrile infection-related epilepsy syndrome (FIRES) and rapid-onset obesity, hypoventilation, hypothalamic dysfunction, and autonomic dysregulation (ROHHAD) syndrome (Benson et al. 2014).

The contribution of immune mechanisms in epileptic disorders of unknown etiology has opened up the way for new immunosuppressive and immunomodulatory treatments. The benefits of corticosteroids in certain epileptic encephalopathies, such as West syndrome and continuous spike waves during sleep (CSWS), suggest a role of inflammation in these syndromes. This hypothesis is further supported by the efficacy of ketogenic diet, which also has an antiinflammatory effect, in some epileptic encephalopathies and in severe epilepsies (Nabbout 2012).

Finally, immunological mechanisms (possibly leading to ischemia and neuronal damage) may also underlie the occurrence of seizures in well-established autoimmune disorders, including multiple sclerosis (MS), diabetes mellitus, celiac disease, thyroid disease, and systemic lupus erythematosus (SLE) (Vincent and Crino 2011).

26.6 Neuroprotective Autoimmunity

Neuroprotective autoimmunity is a condition in which cells of the adaptive immune system promote or restore the functional integrity of the nervous system, or facilitate its repair following any damage. According to the theory of “protective autoimmunity”, CNS-specific T cells, along with circulating and local innate immune cells, can enhance CNS healing processes following non-infectious injuries, or any deviation from homeostasis, including chronic pathological conditions (reviewed in Schwartz and Raposo 2014; Graber and Dhib-Jalbut 2009). Brain-specific T cells have been shown to play beneficial roles in several experimental models of disease of the nervous system, including brain injury (Hauben et al. 2000; Moalem et al. 1999), amyotrophic lateral sclerosis

Table 26.1 Diseases, animal models and therapies with evidence for protective immunity (modified with permission from Graber and Dhib-Jalbut 2009)

Disease	Model	Therapeutics
MS	EAE	Oral myelin, statins, vaccination, hormonal therapy, IVIg
	Theiler's virus	Anti-CD154
	Lysolecithin	GA
	Cuprizone	IFN-beta
Stroke	Ischemic infarct	Vaccination, IFN-beta, FK506, minocycline, poly-YE
CNS trauma	Optic nerve injury	Vaccination
	Spinal cord injury	IFN-beta, Anti-Nogo-A, MMP-3
	Head trauma	GA
Parkinson's disease	MPTP rat	GA
	6-OHDA rat	VIP
ALS	SOD1 mouse	GA
HIV encephalitis	HIV encephalitis	GA
Peripheral nerve injury	Facial nerve injury	GA
	Nerve root avulsion	GA

(Holmoy 2008) and stroke (Frenkel et al. 2003) (Table 26.1). For example, in a rodent model of neurodegeneration, neuronal loss caused by intraocular injection of aggregated A β was significantly greater in immunodeficient mice than in normal mice, neurodegeneration was respectively attenuated or augmented by elimination or addition of CD4+CD25+ regulatory T cells, and in hippocampal slices, microglia encountering activated T cells overcame the cytotoxicity of aggregated A β (Avidan et al. 2004). Such kind of results were interpreted suggesting that locally activated T cells induce a microglial phenotype that helps neurons withstand the insult irrespective of toxicity type, concluding that possibly both acute and chronic neural damage might be arrested or retarded by immune strategies that increase T cell effector activity and/or weaken regulatory T cell-dependent immunosuppression.

According to the theory of “protective autoimmunity”, autoimmune mechanisms help maintaining life-long plasticity of the adult CNS and loss of immunity to self contributes to the emergence of chronic neurodegenerative conditions (Schwartz et al. 2009). As a prominent example, Ziv and co-workers (2006) showed that in mice hippocampal neurogenesis is associated with T cell recruitment and microglia activation, while in immune-deficient mice hippocampal neurogenesis was markedly impaired (Fig. 26.2), but was restored by T cells recognizing myelin basic protein. Spatial learning and memory and the expression of brain-derived neurotrophic factor in the dentate gyrus required the presence of CNS-specific T cells (Ziv et al. 2006). Other types of immune cells can contribute to CNS neurogenesis, as in the case of macrophages in the olfactory bulb (Borders et al. 2007). Likely mechanisms for immune cell-induced CNS plasticity are the production of growth factors like BDNF and IGF-I, the ability to locally buffer excess glutamate, and to activate the local microglial response in manners that result

in benefits to the CNS (reviewed in Schwartz et al. 2009). Despite the impressive amount of evidence in animal models, translation of “protective autoimmunity” to the clinics still requires the identification of adequate conditions, which results in augmentation of autoimmunity, without the risk of induction of an autoimmune disease (Fig. 26.3).

26.7 Other Neurologic Disease with an Autoimmune Component

Obsessive-compulsive disorder (OCD) and related conditions are chronic, relapsing disorders of unknown etiology associated with impairment and disability, which affect as many as 0.3–3 % of the pediatric population. They include Tourette syndrome (also called Tourette's syndrome), a neuropsychiatric disorder with onset in childhood, characterized by multiple physical (motor) and vocal (phonic) tics. Immune contribution in the development of such movement disorders began to be considered following the description of Sydenham chorea (SC), a classical poststreptococcal movement and psychiatric disorder, often associated with other features of rheumatic fever. When sudden onset of neuropsychiatric symptoms is temporally associated with Group A Streptococcus infection, the presentation is termed pediatric autoimmune neuropsychiatric disorders associated with Streptococcus (PANDAS). The immunobiology of such movement disorders remains unestablished, however the predominating theory, based on the clinical evidence of the presence of several types of antineuronal antibodies, is molecular mimicry whereby antibodies intended to target Group A Streptococcus target brain proteins instead. Preliminary evidence exists also for a possible role of T and B lymphocytes (Murphy et al. 2010; Dale 2013; Williams and Swedo 2014).

Fig. 26.2 Impaired neurogenesis in T cell-deficient mice. (a) Quantification of BrdU+ cells and BrdU+ DCX+ cells in the dentate gyrus of nude and wild-type mice 7 days after the first BrdU injection. *** $P < 0.001$, t -test; $n = 4$ per group. (b) Number of BrdU+ DCX+ cells as a percentage of the total number of BrdU+ cells in the dentate gyrus. *** $P < 0.001$, t -test; $n = 4$ per group. (c) Dendritic arborization examined by DCX staining in wild-type and nude mice. (d) Number of BrdU+ DCX+ cells as a percentage of the total number of BrdU+ cells in the dentate gyrus of wild-type, nude and splenocyte-replenished nude mice, 7 days after the first BrdU injection. * $P < 0.05$, ANOVA; $n = 5$ per group. (e) Total numbers of PCNA+ cells in the dentate gyrus of wild-type, nude and splenocyte-replenished nude mice. * $P < 0.05$, ANOVA; $n = 4$ per group. (f) T cells (CD3+) in the brain of a replenished nude mouse. (g) Higher magnification of the marked area in (f). (h) CD3+ cells lining the wall of the third ventricle in the brain of a wild-type mouse. (i) CD3+ cells in the parenchyma adjacent to a blood vessel in the brain of a replenished nude mouse. Data are expressed as mean plusminus s.e.m. LV, lateral ventricle; CA3, CA3 of the hippocampus. Scale bar 20 μm in (c), 50 μm in (g) and 25 μm in (h) and (i) (reproduced with permission from Ziv et al. 2006)

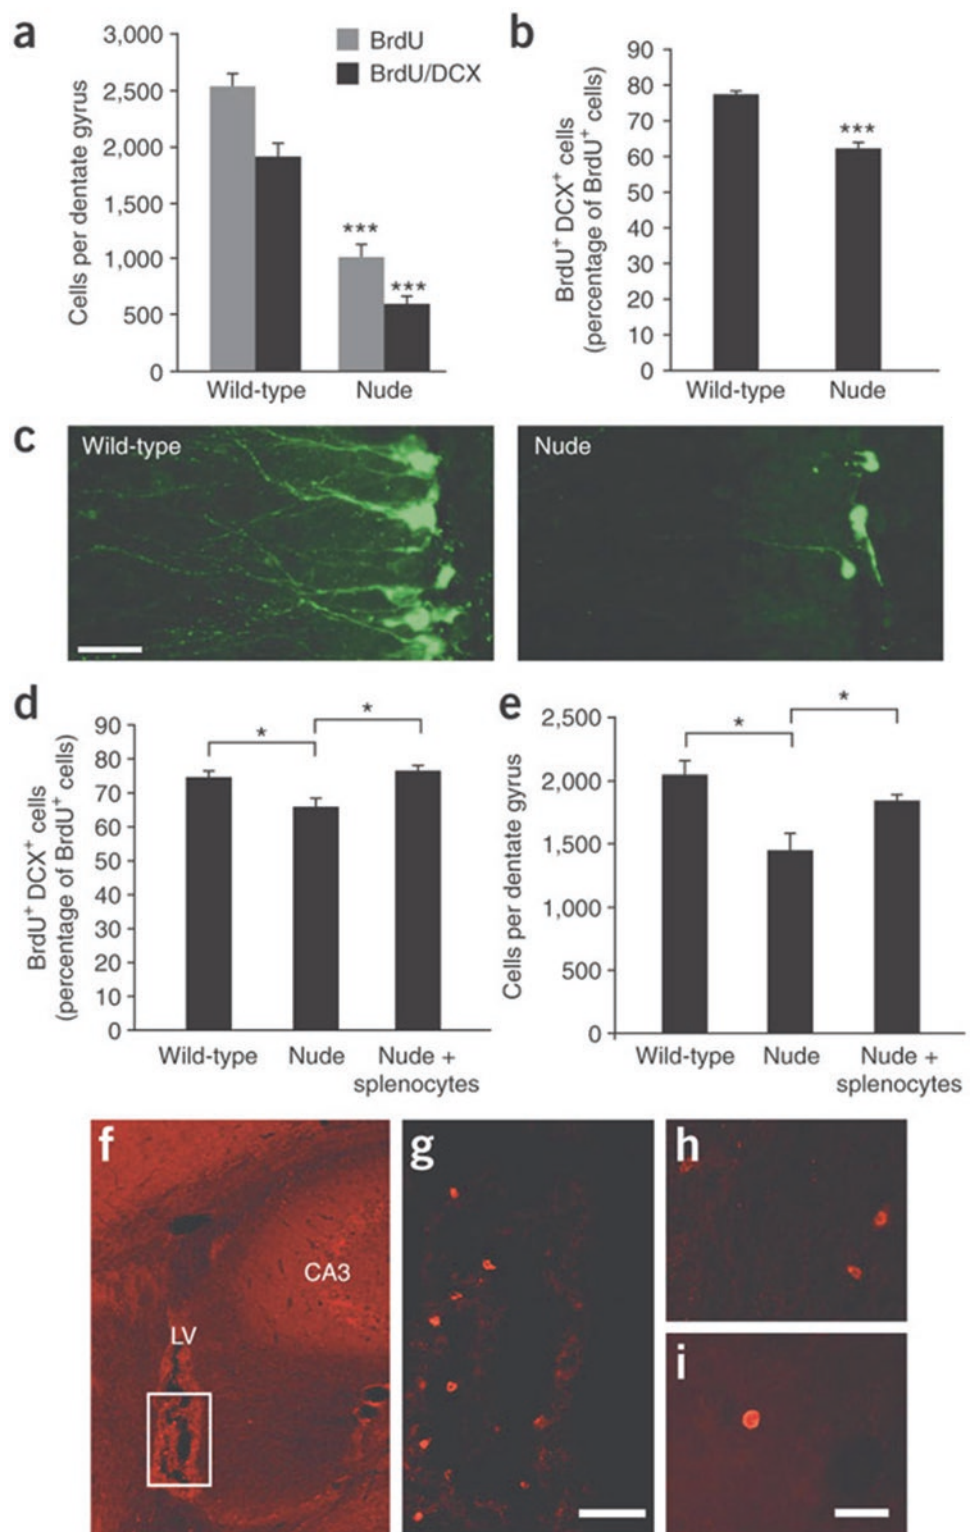

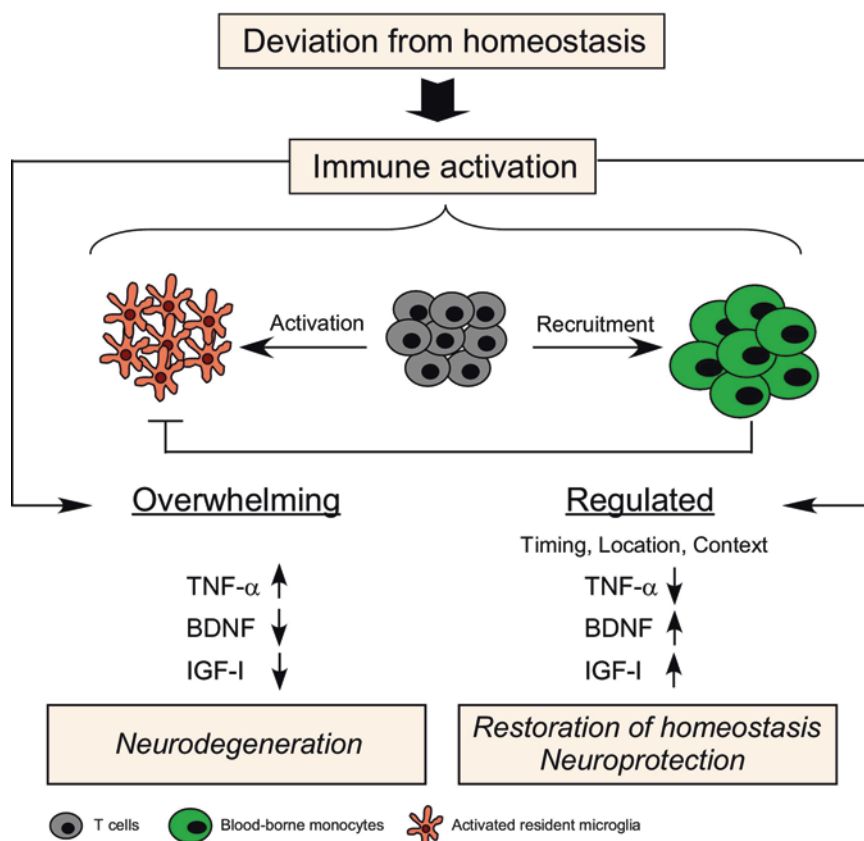

Fig. 26.3 Adaptive immunity, in concert with innate local and peripheral immunity, contributes to CNS maintenance and repair.

Under healthy conditions the resident microglia are capable of containing small deviations from homeostasis, assisted by peripheral immunity, that presumably act at the perivascular spaces. Under injurious conditions or chronic diseases, the assistance of the T cells is local and is manifested in part by the recruitment of blood-borne monocytes to the damaged parenchyma. The T cells together with the monocytes provide a mechanism of amplifying a regulated immune response, which alleviates the risk of cytotoxic factors (e.g. TNF- α) and provides the growth factors that are needed for survival, repair and regrowth (IGF-1, BDNF) (reproduced with permission from Schwartz et al. 2009)

26.8 Review Questions

1. How does the immune surveillance awareness of the CNS pave the way to the identification and characterization of peculiar inflammatory responses?
2. List 4 hallmarks of Alzheimer's disease discussed within this chapter.
3. What was the hypothesized adaptive immune response used in animal models of Alzheimer's Disease discussed in this chapter?
4. Why are CD4+ T cells being used more and more in treatments of Parkinson's disease?
5. What evidence suggests that α -synuclein may represent the connection between central microglia, the peripheral immune system and neuroinflammation?
6. Why are immune mechanisms becoming a hypothesized factor in a number of epilepsies?

26.9 Answers

1. The CNS itself has an innate immune system which includes astrocytes and microglia regulating the initiation and progression of immune responses and interacting with inflammatory and anti-inflammatory subsets of peripheral T cells which in turn might regulate microglial fate towards neurodegenerative or neuroprotective phenotypes.
2. Neurofibrillary tangles, dystrophic neurites, significant neuronal loss, and the presence of extracellular aggregates of the amyloid β -protein (A β) peptide, called A β plaques.
3. By triggering an adaptive immune response towards the A β peptide, it would have considerably reduced its accumulation in the brain.
4. CD4+ T lymphocytes can infiltrate postmortem human Parkinson's disease specimens and mediate dopaminergic toxicity in murine models.
5. α -synuclein is crucial in PD pathogenesis: mutations in SNCA1, the gene encoding α -syn, cause autosomal dominant forms of PD, while aggregated and post-translationally modified forms of α -syn are present in Lewy bodies in both sporadic and familial PD. Accumulation of abnormal forms of α -syn is a trigger for PD, and recent evidence suggests that much of the downstream neurodegeneration may result from inflammatory responses which raise from an interplay between central microglia and peripheral lymphocytes which migrate to the brain following peripheral activation.
6. Immunologic abnormalities are found in routine epilepsy surgical specimens, suggesting a broader role of

immunopathology in the etiology of epilepsy. In any case, the identification of autoimmune encephalitis has changed the diagnosis and management of several syndromes that occur with seizures and status epilepticus previously attributed to viral or idiopathic etiologies.

Howard Fox and Phillip Purnell

Abstract

HIV infection in the central nervous system (CNS) is responsible for a spectrum of neurocognitive and behavioral disorders. The wide use of appropriate combination antiretroviral therapy (cART) has decreased the severity of cognitive dysfunction. Viral loads are reduced and CD4+ T cell counts are increased. In addition, patients are living longer with improved quality of life. However, cART does not completely eliminate CNS dysfunction in HIV infected patients. There is an increase in milder forms of HIV-associated neurocognitive disorders (HAND), which are the result of a complex interplay between many factors including: aging, vascular disease, Alzheimer's disease, and psychiatric disease. The underlying biochemical and molecular changes that underlie these changes and the underlying mechanisms of HAND pathogenesis continue to be an area of ongoing research. New advances in imaging and biomarker discovery will continue to advance clinical diagnosis and management. Treatments that can perturb the viral reservoirs and decrease chronic inflammatory response, in addition to continuing cART, may give the clinician additional tools to prevent HAND.

Keywords

cART • HIV-associated neurocognitive dysfunction (HAND) • HIV pathogenesis

27.1 Introduction

Human Immunodeficiency virus (HIV), the cause of the acquired immunodeficiency syndrome (AIDS), was identified over 30 years ago and continues to infect, and affect, many. It is estimated that more than one million people are living with HIV infection in the United States with 15% unaware of their HIV status (CDC 2014). Worldwide, 35 million people are living with HIV (WHO 2014). HIV is a lentivirus that predominately infects CD4+ T cells and macrophages expressing CD4. In addition to CD4, HIV requires the expression of a co-receptor, utilizing the chemokine

receptors CCR5 and/or CXCR4 to target susceptible cells. The incidence of new HIV infection is approximately 50,000 per year in the U.S. and has been constant over the past several years, although the incidence has spiked in certain areas of the U.S. The wide use of combination antiretroviral therapy (cART, previously referred to as highly active antiretroviral therapy, HAART) began in the 1990s and has dramatically increased the life span of patients living with HIV. These therapies (including nucleoside and non-nucleoside reverse transcriptase inhibitors, protease inhibitors, integrase inhibitors, entry/fusion inhibitors) have decreased HIV related mortality by effectively reducing viral loads and improving immune cell function, which can be decimated by the infection. The use of cART, which prevents HIV-mediated loss of CD4+ T cells, (and leads to degrees of recovery in those with CD4+ T cell loss) has decreased the incidence of opportunistic infections, which afflicted those with immunodeficiencies. cART has turned HIV infection from a fatal diagnosis into a treatable, chronic condition.

In addition to effects on the immune system, HIV infects and perturbs the brain. Before the onset of effective treatment 8–15 % of HIV infected individuals developed a severe cognitive disorder, HIV-associated dementia (HAD) (Janssen et al. 1992; McArthur et al. 1993). HAD, in the post-cART era, has now been reduced to 2 % (Heaton et al. 2010). Unfortunately, cART does not completely shield the brain from HIV. Effectively treated patients with undetectable plasma viral levels, continue to have chronic immune activation in the central nervous system (CNS), along with morbidities more commonly associated with aging including atherosclerosis, metabolic syndrome, cancer and neurodegenerative disease (Alzheimer's). Furthermore, many of the widely used antiretrovirals are poorly CNS penetrable, perhaps facilitating pathogenic effects as well as HIV reservoirs in the CNS. Therefore, despite a drastic decline in HAD, there continues to be a large number of patients with mild neurocognitive disorders (MND) and asymptomatic neurocognitive impairment. Nearly half of patients in the CNS HIV Antiretroviral Therapy Effects Research (CHARTER) study, which categorized neurocognitive impairment in over 1500 patients with HIV at six large research universities in the U.S., have either mild neurocognitive disorders or asymptomatic neurocognitive impairment (Heaton et al. 2010). Similar findings were reported in a study of 400 members of the ANRS (Agence Nationale de Recherche sur le Sida) CO3 Aquitaine cohort in France (Bonnet et al. 2013). Another study selected a cohort of 200 patients in Switzerland because of undetectable plasma HIV-1 RNA, no history of major opportunistic infections of the CNS in the past 3 years, no current use of intravenous drugs, and no major depression and they continued to have neurocognitive impairment (Simioni et al. 2010).

With the onset of cART, the clinical aspects of HIV-induced CNS disease evolved. The National Institute of Mental Health and the National Institute of Neurological Diseases and Stroke convened a panel of experts to design consensus criteria for HIV-associated neurocognitive disorders (HAND). These are outlined and discussed below. Now that neurocognitive impairment is less severe than in the pre-cART era many investigators have turned their attention to the milder forms of impairment which continue to lead to significant issues with memory, motor and behavioral abnormalities that may require clinical assessment.

27.2 Diagnostic Criteria

HAND encompasses a number of disorders previously referred to as HIV encephalitis (HIVE), HIV encephalopathy, minor cognitive motor disorder, and HIV or AIDS dementia complex (ADC). The 2007 HAND classifications were intended to revise and update the 1991 American

Academy of Neurology AIDS taskforce descriptions of HIV CNS manifestations (AAN 1991). The 1991 descriptions focused largely on HAD, differentiating between HAD with motor symptoms, with behavioral/psychosocial symptoms, and HAD with both motor and behavioral/psychosocial symptoms. There was also a less severe condition classified as minor cognitive motor disorder (MCMD). The 2007 classification, known as the Frascati criteria, describes three separate clinic entities of increasing severity under the collective umbrella of HAND (Antinori et al. 2007):

- **Asymptomatic neurocognitive impairment (ANI)** is the least severe form and does not interfere with normal daily functioning. It is defined as greater than one standard deviation deficit in at least two areas of standardized neuropsychological testing that includes language, concentration, abstraction, memory, mental speed, perception and motor skills.
- **Mild neurocognitive disorder (MND)** has the same neuropsychological testing criteria (>1 SD deficit in two areas) with impairment in daily functioning defined as patient or family reported changes in mental acuity, inefficiency at home or work, or social functioning.
- **HIV associated dementia (HAD)** is the most severe form of HAND demonstrated by impairment greater than two standard deviations in at least two of the same areas described above. In addition, this impairment causes marked dysfunction at work, home or social situations.

All three HAND diagnoses assume that there are no pre-existing causes for these disorders. If patients meet criteria for major depressive episodes or substance abuse disorders, HAND diagnoses are deferred. Another important caveat is to rule out delirium, which is especially prevalent in hospitalized patients (European Delirium Association and American Delirium Society 2014; Watkins and Treisman 2015). Unfortunately, this classification system does not extensively deal with psychiatric manifestations of HIV infection including depression, mania, or anxiety. Although this classification system has been clinically validated and widely used, it requires the need of multiple hours of testing by practitioners with expertise in clinical neuropsychology to identify at least five of the following abilities: attention/information processing, verbal/language, abstraction/executive functioning, memory including learning/recall, simple motor skills, complex perceptual motor skills, or sensory perceptual abilities. Several groups have developed screening tools that may be less clinically cumbersome (Cysique et al. 2006; Munoz-Moreno et al. 2013; Koski et al. 2011; Zipursky et al. 2013; Carey et al. 2004; Brouillette et al. 2015; Power et al. 1995; Morgan et al. 2008; Sacktor et al. 2005) and may be used for clinical monitoring (Kamminga et al. 2013). Even with these tools, a major complicating

factor is the lack of a linear relationship between ANI, MND and HAD and the unpredictable time course of HAND progression. Patients with ANI and MND treated with cART rarely progress to HAD; therefore, there is no predestined progression with neurocognitive decline as in other neurodegenerative diseases. To further confuse the situation, the course of neurocognitive decline can differ dramatically along the spectrum from decline to improvement (Heaton et al. 2015). Since neurocognitive status can change, the need to diagnose the high prevalence of ANI (although by definition it does not interfere with daily function) is extremely important because the presence of ANI carries a twofold to fivefold increased risk for development of symptomatic impairment at some point in time. Specific and accurate diagnosis of ANI enables optimal clinical and pharmacologic treatment (Grant et al. 2014).

27.3 Clinical Manifestations

As described, the clinical features of HAND impairment are variable. HAND has been classically characterized as subcortical impairment or dementia with the triad of cognitive, behavior and motor dysfunction (Ances and Ellis 2007). Generally, the cognitive changes are observed long before any identifiable motor dysfunction. While many of the abnormalities are attributed to subcortical processes, deficits in learning and executive function imply the likely presence of other regional brain abnormalities (Cysique and Brew 2011; Heaton et al. 2011). Other prominent clinical manifestations include mood disturbance, psychomotor retardation and impaired memory. Motor problems are generally mild and include weakness, bradykinesia and tremor. Severe cases of HAD display features such as incontinence, paraplegia and global dementia, although these cases are now extremely rare (Glass et al. 1993). As severe HAD cases have decreased, MND and ANI continue to affect the daily lives of patients and continue to be a clinical dilemma for healthcare providers (Joska et al. 2010). Rates of MND and ANI remain high even in patients with optimal cART treatment and low HIV viral loads (Cysique and Brew 2011; Robertson et al. 2007). In the post cART era, the observed neurocognitive dysfunction seems to be independent of current CD4+ T cell counts and history of HIV-related CNS disease (Cysique and Brew 2011). Overall, the incidence of any type of HAND has increased in the post cART era, with mild disorders now accounting for the vast majority of cases (Heaton et al. 2011). The overall increased incidence of HAND is likely due to both chronic HIV infection and an aging population with HIV.

The best predictor for future HAND symptoms is CD4+ T-cell nadir (Ellis et al. 2011). Patients who receive cART before their T-cell level fall are much less likely to develop HAND, emphasizing the need for early antiviral treatment

(Heaton et al. 2010). This also points to the importance of early detection of HIV infection. Unfortunately, many infected individuals are not being identified at an early stage and more than 30% of U.S. HIV patients present to their initial clinical evaluation with a CD4+ T cell count of less than 200/mm³ (Spudich and Ances 2012). This will improve as new clinical guidelines, which encourage routine HIV screening, are widely implemented. While cART treatment has lowered viral load and reduced immune abnormalities, it is likely that the extended lifespan in combination with low viral CNS levels and chronic immune activation is driving neurocognitive changes. The changes, although mild in comparison to HAD, continue to affect the lives of those with HIV in important areas such as medication adherence (Hinkin et al. 2002), driving (Marcotte et al. 1999), work disability (Albert et al. 1995) and risky decision making (Iudicello et al. 2013). Post-cART era patients have a higher prevalence of dysfunction in both executive function and learning/memory (Heaton et al. 2011), differing from the classic triad of cognitive, behavior and motor dysfunction that dominated the clinical picture before cART. Data suggest that optimal cART does not preclude HAND but does change the clinical picture of neuropsychiatric dysfunction. Fortunately, cART significantly delays the onset and lowers the incidence of HAD. In individuals taking and adhering to cART, HIV has now turned into a chronic disease; and infected individuals are aging with HIV. Differentiating between normal aging, HIV-mediated chronic inflammation, antiretroviral effects and medical comorbidities make causative characterization of cognitive impairment very difficult but for optimal patient management, accurate diagnosis is ultimately required.

27.4 Comorbidities

There is significant overlap between the risk factors for HIV infection and risk factors for other conditions that can result in neurocognitive impairment, most notably substance abuse and psychiatric illness. The prevalence of both substance abuse and mental illness are higher in HIV positive patients (Byrd et al. 2011). There are reports that HIV-infected drug abusers have more severe neurological disease, along with higher overall viral loads (Bell et al. 1998); however, this report was in the setting of HIV encephalitis before the use of cART. In addition, such studies are difficult in this population as the reliability of drug histories is often suspect and whether effective treatment for HIV is both given and taken appropriately is often unclear (Kim and Hill 2003). In animal models, the effects of cocaine, methamphetamine and opioids in the background of HIV infection have been widely studied (Gill and Kolson 2014; Chang et al. 2014; Dutta and Roy 2012; Buch et al. 2012; Persidsky et al. 2011; Nath 2010; Loftis and Janowsky 2014). In a 2011, a large well-controlled study

(from CHARTER) comparing rates of neurocognitive impairment in HIV-infected individuals (approximately 50% with HAND) with no substance abuse, nonsyndromic substance abuse, and syndromic substance abuse revealed no effect of substance abuse on neurocognitive impairment (Byrd et al. 2011). However, in this study, most subjects were currently abstinent, so the effects of ongoing substance abuse remain unclear. Further investigations in this area may be more ethically studied in animal models. The other confounding factor in substance abuse studies is the increased non-adherence to antiretroviral treatment (Reback et al. 2003; Moore et al. 2012; Hinkin et al. 2004), thus removing that protective effect against HAND. Co-infection with other viruses such as hepatitis C (HCV) has also been proposed as a risk factor for neurocognitive dysfunction (Forton et al. 2002). The prevalence of HCV coinfection is quite high in HIV positive patients with some studies suggesting up to 80% in high-risk intravenous drug users (Gupta 2013; Sulkowski 2007). Again, the 2015 CHARTER study found that, in the absence of substantial liver damage, HCV did not contribute to neurocognitive impairment (Clifford et al. 2015).

Among the psychiatric conditions, depression is frequent in HIV infected individuals, as it is in many patients living with chronic diseases. Patients with symptomatic HIV infection are at higher risk of depression than those with asymptomatic infection and uninfected patients (Atkinson et al. 2008); viral infection itself does not appear to predispose to depression. The presence of depression in combination with HIV does appear to increase mortality rates and the level of neurocognitive impairment (Ickovics et al. 2001; Gibbie et al. 2006). Therefore, it is important for clinicians to be prudent with screening for depression, schizophrenia and bipolar disorder, which can all predispose to difficulty with medication adherence especially without adequate social support (Durvasula and Hinkin 2006).

27.5 Pathophysiology of Hand

The pathophysiology of HAND is multifactorial with contributions from viral infection, inflammatory cytokines, neuronal dysfunction and comorbid factors. HIV penetrance into the CNS is an early event after HIV transmission. Both cerebrospinal fluid studies and brain imaging have demonstrated signs of inflammation in acute HIV infection as soon as eight days after HIV exposure (Valcour et al. 2012). It is speculated that the initial inflammatory and vascular insults may lead to lifelong residual changes even with effective and prompt initiation of cART. Interestingly, a 2015 study found evidence for different states of virus and inflammation within the cerebrospinal fluid (CSF) early after infection, including a subset of cases with compartmentalization of virus and/or episodes of inflammation (Sturdevant et al. 2015). Whether

this results in an increased risk for HAND is not known but is provocative. Most of the studies on pathophysiological mechanisms of CNS disease due to HIV infection arose from the changes observed in the pre-cART era and are highly relevant for HIVE and HAD. However, the causes of the more common mild manifestations of HAND in the setting of cART are currently unknown. The unknown causes are likely still dependent upon the interplay of the virus and the immune response, including other host and exogenous factors in the now chronic condition.

The virus is dependent on hematogenous spread to enter the CNS. This is achieved by viral interaction with the CNS vascular endothelium or by passage of virally infected immune cells beyond the blood-brain barrier (BBB) (Nottet et al. 1996; Persidsky et al. 1997). A number of studies have revealed that free virus can enter the CNS. One mechanism is through a transcytosis-mediated process utilizing the viral gp120 envelope glycoprotein (Banks et al. 2001); a second is through the virus binding to the mannose-6 phosphate receptor (Dohgu et al. 2012); and a third possibility is through endothelial surface proteoglycans acting as electrostatic contacts for HIV (Bobardt et al. 2004; Moses et al. 1993). Additionally, viral proteins such as gp120 and Tat directly increase BBB permeability (Strazza et al. 2011). Increased permeability of the BBB, caused by this HIV-induced inflammation and common comorbid conditions such as substance abuse, can also facilitate HIV entry to the CNS (Shiu et al. 2007; Banks et al. 2005; Davidson et al. 2012; Mahajan et al. 2008). For example, expression of tumor necrosis factor- α (TNF- α) after acute or chronic HIV infection has been shown to increase free viral passage into the CNS (Fiala et al. 1997). In addition, illicit drugs such as cocaine can promote an additional cytokine release from resident brain monocytes, further affecting the BBB (Zhang et al. 1998). Both initial inflammatory cytokine release and chronic inflammation may permanently disrupt the BBB easing future viral entry.

Although it is possible that free virus infects the CNS, the lentivirus "Trojan horse" hypothesis was put forth to explain how cell-associated virus can be responsible for HIV infection of the brain (Peluso et al. 1985; Haase 1986; Gendelman et al. 1985, 1986). Infected monocyte derived macrophages and CD4+ T cells can migrate into the brain from the peripheral circulation to initiate and propagate infection within the CNS (Haase 1986; Wiley et al. 1986; Fischer-Smith et al. 2004). In the brain, microglia and macrophages are infected; and these long-lived cells are thought to be the reservoir and source of chronic infection (Kaul et al. 2001). Interestingly, neurons are spared from direct damage from primary HIV infection; however, products of infected cells, including viral proteins and inflammatory mediators such as cytokines have been shown to lead to neuronal damage and death. Many molecules have been implicated and well-studied in neuropathogenesis and neurotoxicity including the HIV proteins

gp120 and Tat, numerous cytokines including TNF- α , chemokines, small molecules such as arachidonic acid, nitric oxide, glutamate, and various free radicals (Kaul et al. 2001; Gonzalez-Scarano and Martin-Garcia 2005; Kraft-Terry et al. 2009; Gendelman et al. 1994; Ellis et al. 2007). While many of these molecules can be produced by infected microglia/macrophages, non-infected macrophage/microglia as well as astrocytes are activated and can contribute to local CNS damage. Astrocytes may also be susceptible to HIV infection. Although they do not support efficient and productive replication, astrocytes can still express certain neurotoxic HIV proteins (Ranki et al. 1995; Gorry et al. 1999).

Brain macrophages and microglia are the key cells infected by the HIV in the brain. SIV (simian immunodeficiency virus) infected rhesus macaques have been key to elucidating the underlying pathophysiology of HIV virus. SIV models have shown peripherally infected monocytes entering the CNS to become perivascular macrophages. The virus is thought to specifically invade the CNS in CD14+CD16+ mature monocytes that are more susceptible to HIV infection and may have preferential access to the CNS (Ellery et al. 2007; Zhu et al. 2002; Buckner et al. 2011). This is in part due to the high expression of the CCR5 coreceptor on this subset of mature monocytes (Ellery et al. 2007). HIV strains found in the CNS also have particular tropism for CCR5 (He et al. 1997). These CNS macrophages then release virus and infect surrounding cells including resident microglia (Kim et al. 2006; Soulas et al. 2009). Infected monocytes are attracted to the CNS by chemokines including monocyte chemoattractant protein type 1 (MCP-1) (Monteiro de Almeida et al. 2005) and migrate through the BBB in parallel with increased endothelial expression of adhesion molecules for monocytes. In addition to serving as a reservoir for HIV in the brain, monocytes can lead directly to neuronal dysfunction and death. Interestingly, CD16+ circulating monocytes are higher in patients with HIV (Ellery and Crowe 2005); and they may be elevated in HAND (Fischer-Smith et al. 2001). This cell population is also specifically increased in other primarily inflammatory diseases (Aguilar-Ruiz et al. 2011). In vitro HIV infected monocytes and monocyte derived macrophages have decreased ability to emigrate from the brain back out into blood vessels suggesting that these cells are confined to the CNS acting as another reservoir (Westhorpe et al. 2009).

As noted above, astrocytes may also harbor HIV infection, while the number of infected cells is generally very low (Wiley et al. 1986; Tornatore et al. 1994; Takahashi et al. 1996), extensive infection has been reported in a study on HAD (Churchill et al. 2009). In the brain, astrocytes act as an integral part of the BBB and are in direct communication with the CNS vascular endothelial cells. HIV infected astrocytes disrupt the BBB and can cause endothelial cell death

even in low numbers facilitating increased monocyte and lymphocyte migration (Eugenin et al. 2011). Both macrophages and astrocytes are implicated in the release of neurotoxic factors including inflammatory cytokines and viral proteins, and they are both likely responsible for prolonged CNS inflammation. Furthermore, a role for CD8+ T cells in pathogenesis, indicated by earlier studies in HIV infected people (Jassey et al. 1993) and SIV infected monkeys (Marcondes et al. 2001, 2015), was found in cART treated individuals with HAND (Schrier et al. 2015).

While most studies on pathophysiology of HAND have focused on virally infected macrophages, activated glia, and the production of neuroinjurious molecules in the brain, non-CNS sources are also possible. Given the effects of HIV infection on the BBB, blood-borne neurotoxic molecules, including many of those mentioned above, may enter the brain through the BBB with increased permeability. In addition, the role of the gut in HIV pathogenesis has received considerable attention, including aspects relevant for CNS pathogenesis. Bacterial products from the gastrointestinal tract, specifically LPS (lipopolysaccharide), can activate the immune system and affect the brain. The gut barrier also becomes more permeable in HIV infection, and elevated levels of LPS can contribute to a cascade of effects correlated with HAND (Ancuta et al. 2008; Ryan et al. 2001). In addition, although not studied in relationship to HAND, the gut microbiome is significantly different in those with HIV infection and correlates with immune activation (Mutlu et al. 2014). Another potential source of neuropathogenesis is iatrogenic, in the form of the antiretrovirals themselves. While potent in inhibiting the virus, the long-term effects on the CNS and other end organs is unknown, and for some, such as efavirenz, both clinical and experimental data indicate significant effects on cognition and neurotoxicity (Funes et al. 2014; Ciccirelli et al. 2011; Tovar-y-Romo et al. 2012). While many studies of candidate pathogenic molecules demonstrate frank toxic effects on neurons, changes in biochemical and cell biologic pathways have been proposed to explain the pathogenesis of HAND. As opposed to neuronal death, these changes can be reversible, perhaps correlating with the fluctuating course of neurocognitive abnormalities in some individuals and the response to antiviral treatment. These mechanisms include alterations in sphingolipid metabolism (Bandaru et al. 2013), changes in the glutamergic system (Potter et al. 2013), deficiencies in detoxifying enzymes (Gill et al. 2014) and defects in the two systems mediating protein turnover, the ubiquitin-proteasome system and autophagy (Zhou et al. 2011; Alirezai et al. 2008; Nguyen et al. 2010). While beyond the scope of this chapter, the interested reader is encouraged to reference the review articles cited above in regards to these specific topics.

27.6 Study of HIV Induced Neuropathology

The combination of viral entry and infected macrophages in the CNS leads to the mounting of a defensive neuroinflammatory host response. This macrophage mediated inflammatory response leads to CNS disease. The hallmark neuropathologic findings in HIV infection are HIV infected macrophages (Koenig et al. 1986), which lead to microglial activation, formation of multinucleated giant cells, and diffuse astrogliosis (Michaels et al. 1988). This combination of factors contributes to the development of HIV encephalitis. Additional findings in the pre-cART era showed at the time of autopsy, the severity of HAD correlated with the total number of macrophages accumulated in the basal ganglia and the total number of perivascular macrophages (Glass et al. 1995; Fischer-Smith et al. 2001). HIV patient brains also have neuronal loss with both cortical and subcortical neurodegeneration (Moore et al. 2006; Everall et al. 1991).

Morbidity from HIV infection, including HAD, has declined with the use of cART, and studies directly on the brains of individuals with HAND are limited due to the reduced mortality and difficulty in procurement. To meet the need for research on the brain, the National NeuroAIDS Tissue Consortium (NNTC) was organized to obtain, properly store, and distribute samples of central and peripheral

nervous system tissue, other organs, biologic fluids such as CSF and plasma, from well-characterized HIV positive and negative patients, in order to support researchers studying HIV-related nervous system disorders (Morgello et al. 2001). This is ongoing at four sites in the U.S., which have already enrolled almost 3000 participants and has CNS materials from over 2000 individuals (NNTC 2015). These specimens have already been valuable, revealing the presence of synaptic and dendritic damage in HAND (Everall et al. 1999). NNTC specimens have revealed a range of brain pathology present in HAND, of which HIV related brain pathology was found to be associated with a low CD4+ T cell nadir and a higher plasma viral load within 6 months of death (Everall et al. 2009). Immunohistochemical analyses of brains from the NNTC brains indicated persistent signs of inflammation even with the use of cART and absence of overt HIVE, but the relationship between inflammation and the presence or absence of HAND was not determined (Fig. 27.1) (Tavazzi et al. 2014). Molecular studies on NNTC specimens have revealed additional possible causes of the damage in HAND, such as changes in the CNS neurovascular unit (Gelman 2015; Gelman et al. 2012). The effect of treatment was addressed in another study on NNTC specimens, with significant changes in brain gene expression found when comparing those with HAND who had a history of recent cART usage versus those naïve to treatment (Borjabad et al. 2011).

Fig. 27.1 HLA-DR expression in HIVE was seen by MΦs/microglia that accumulated perivascularly (*Panel F*) and within nodular lesions (*Panel G*). In the parenchyma, HLA-DR was expressed by activated microglia, with thickened and retracted processes, most often observed in areas of pathology (*Panel C*). In the CNS of subjects with HIV+/no E, HLA-DR was, for the most part, not expressed by cells in the parenchyma (not shown). Interestingly, when parenchymal HLA-DR was observed, it was seen on aggregates of cells, or “soft nodules” (*Panels A and B*). Rare HLA-DR expression was seen on perivascular MΦs in HIV+/no E (*Panel D*), with the exception of five subjects, who demonstrated some degree of HLA-DR+ MΦ accumulation perivascularly, that appeared to develop into cuffs in one subject (*Panel E*). A nodule also appears to have formed in the region of the cuff shown in *Panel E* (arrow). All panels shown at $\times 40$ magnification under oil (Figure 4 and legend from (Tavazzi et al. 2014) “Copyright 2014 Betham Sciences”)

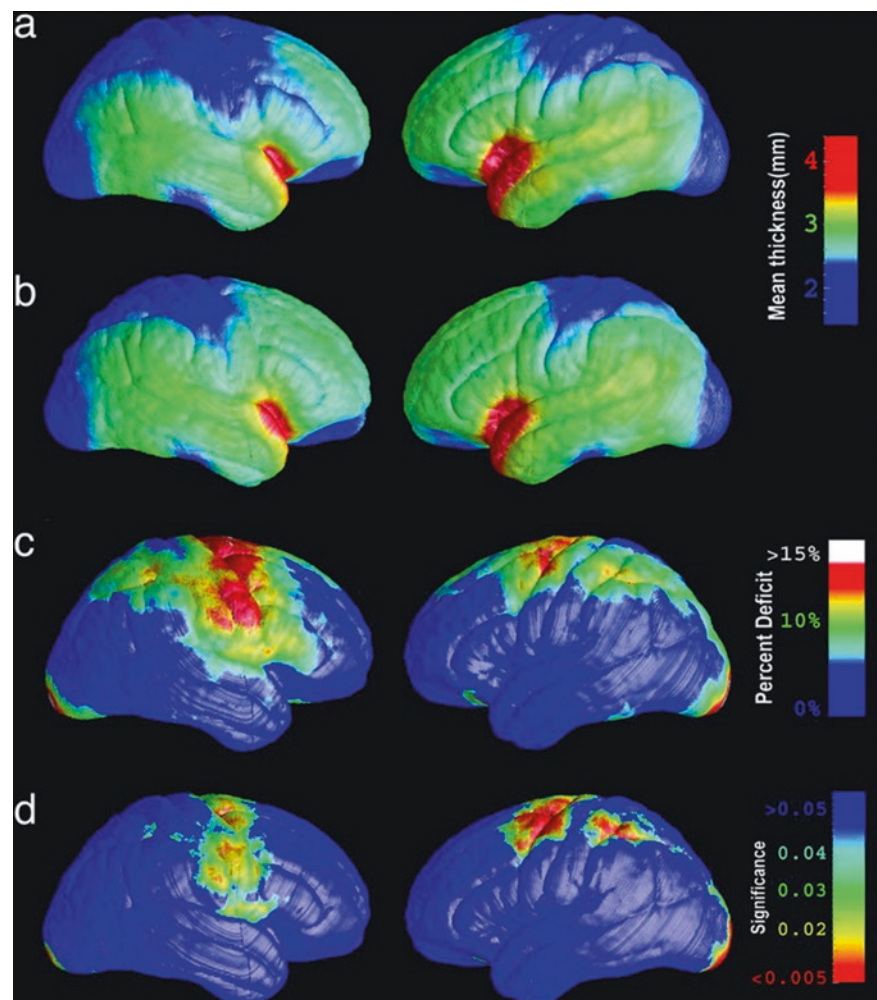

However, the exact history of antiretroviral usage, such as regimens, dosage, compliance, and how often/if they were taken in the time period before death, is often difficult to ascertain. This complicates the determination of the true nature of CNS pathology in individuals with HAND in the setting of cART.

27.7 Imaging and Biomarkers of Hand

Neuroimaging has had several recent advances that may aid in the diagnosis, treatment and investigations into the pathogenesis of HAND. Magnetic resonance spectroscopy (MRS) technology quantifies specific metabolites in regions of the brain and has revealed a number of changes within the brains of HIV infected individuals. Altered metabolites correlating with inflammation, gliosis, and injury or loss of neurons are associated with neurocognitive status (Harezlak et al. 2011; Mohamed et al. 2010). MRS alterations are still present with cART treatment (Harezlak et al. 2011; Cardenas et al. 2009). Treatment with cART can improve, but not totally reverse,

these changes (Chang et al. 1999). Magnetic resonance imaging (MRI) has revealed decrease in volume of brain structures, again most severe in HAD (Aylward et al. 1993; Stout et al. 1998). While studies on individuals before and after cART have not been reported, MRI abnormalities are still present in the post-cART era Fig. 27.2 (Ances et al. 2012; Thompson et al. 2005; Cardenas et al. 2009). Diffusion Tensor Imaging (DTI), examining fiber tracts through measurements of the diffusion process of water molecules, has revealed white matter abnormalities that correlate with HAD (Chen et al. 2009). Treatment with cART may be able to improve abnormalities found by DTI (Gongvatana et al. 2011; Wright et al. 2012). Finally, Positron Emission Tomography (PET) measures metabolic activity in the brain by monitoring glucose consumption (using fluorodeoxyglucose). Regions of altered metabolism have been identified in relationship to cognitive status specifically in HAD (von Giesen et al. 2000). In the cART era, hypometabolism is found in a high proportion of HIV infected individuals, but the link to HAND by PET is not clear (Towgood et al. 2013; Andersen et al. 2006). The role of imaging in the diagnosis

Fig. 27.2 Cortical thinning on the lateral brain surface in HIV/AIDS. (a) Average profile of cortical thickness in AIDS patients. Right hemisphere is on the left. (b) Mean cortical thickness for matched healthy controls. (c) Average percentage thinning of the cortex in AIDS relative to healthy controls. (d) Color-coded map that shows the significance of the group difference, at each cortical point (reds indicate significant cortical thinning). The band of thinner cortex encompasses the primary sensorimotor, premotor, and parietal cortices (Figure 1 and legend from (Thompson et al. 2005). Copyright (2005) National Academy of Sciences, U.S.A.)

of HAND is thus largely to rule out other disorders of the CNS and will have an ever-increasing role in studies unraveling the changes in the brain now occurring in chronic, treated HIV infection. Someday imaging may change the diagnostic criteria for HAND by better characterizing individual neurocognitive changes.

Much effort has also gone into investigating CSF and blood biomarkers that may aid in the diagnosis and study of HAND. As stated above, there have been a plethora of viral and host molecules associated with HAND; however, many were found associated with HIVE and HAD and not the less severe pathological and clinical states (MND and ASNI). While the presence of HIVE has declined, soluble markers of inflammation within the CSF persist even in treated individuals and correlate with imaging markers of CNS damage (Anderson et al. 2015). However while a number of markers in the CSF, including inflammatory molecules (neopterin, MCP-1), signs of neuronal injury (neurofilament) as well as viral escape (HIV in the CSF in the absence of detectable plasma HIV) have been studied, their utility as biomarkers is still unclear (Marcotte et al. 2013; Peluso et al. 2012; Hagberg et al. 2010; Canestri et al. 2010; Gisslen et al. 2007; Abdulle et al. 2007).

Peripheral markers would be a distinct clinical advantage, requiring a blood draw instead of neuroimaging or CSF. Before the advent of cART, an increased plasma viral load and decreased blood CD4+ T cell count correlated with the risk of HAND, similar to other HIV-induced pathologies; however, this is no longer the case (Robertson et al. 2007; Heaton et al. 2011). As indicated above, CD4+ T cell nadir, perhaps relating to the amount of maximal legacy damage HIV has caused, correlates both with risk of developing HAND and eventual neuropathology (Ellis et al. 2011; Everall et al. 2009). A 2014 study discovered that in patients with undetectable viral loads due to effective cART had an increase in CCR2 (the receptor for MCP-1, a frequently studied pathogenic marker attracting monocytes to the CSF) expression on CD14+CD16+ monocytes. Indeed this correlated with increased transmigration across an in vitro BBB model (Williams et al. 2014). Still, neuroimaging, CSF and plasma biomarkers remain in the research realm.

27.8 Treatment

The most effective treatment for any individual with HAND, as well as essential for HIV infection in general, is to suppress viral production through the use of cART. Many of the components of cART do not penetrate the brain to yield effective drug concentrations; thus, it is thought that the use of drugs with increased ability to reach the CNS and hence control virus in the brain would be useful. To accomplish this, a CNS penetration-effectiveness index (CPE) has been constructed (Letendre 2011; Letendre et al. 2008). However, it is unclear if use of a cART regimen with an increased CPE

is useful for preventing or treating HAND, due to issues inherent in the studies, characteristics of specific drugs used, differences in viral susceptibility, and possible neurotoxic effects of the drugs themselves (Libertone et al. 2014; Ciccarelli et al. 2013; Vassallo et al. 2014; Fabbiani et al. 2015; Smurzynski et al. 2011; Cysique et al. 2011). While it has been recommended that changing to a high CPE regimen may be useful in those with symptomatic HAND (Mind Exchange Working Group 2013), a 2014 randomized clinical trial found no benefit (Ellis et al. 2014).

Adjunctive (non-antiretroviral) treatments have also been studied, based on potential pathogenic mechanisms of neuronal damage. Valproic acid and lithium (targeting glycogen synthase kinase-3 β), rivastigmine (cholinesterase inhibitor), memantine (NMDA receptor antagonist), minocycline (anti-inflammatory antibiotic), thiocetic acid (anti-oxidant) deprenyl and selegiline (monoamine oxidase inhibitor), peptide T (a gp120-derived peptide), and nimodipine (calcium channel blocker) have all been studied clinically; however, no significant effects on HAND were found (Uthman and Abdulmalik 2008; Ances et al. 2008; Simioni et al. 2013; Zhao et al. 2010; Sacktor et al. 2011; Nakasujja et al. 2013; Dana Consortium 1998). Current clinical trials include studies on a number of antiretrovirals as well as paroxetine (selective serotonin reuptake inhibitor), fluconazole (antifungal), atorvastatin (HMG-CoA reductase inhibitor), and non-drug treatments (cognitive rehabilitation) (NIH 2015). While results of trials of non-drug treatments have not been reported for HAND, it is intriguing that exercise and fitness appear to be protective for HAND (Mapstone et al. 2013; Dufour et al. 2013; Fazeli et al. 2014). Indeed cognitive training and exercise have been frequently investigated for non-HIV mild cognitive impairment and early stage dementia. While some positive effects are found for such interventions, limitations to the studies make determination of benefits problematic (Rodakowski et al. 2015).

27.9 Review Questions

1. Since the wide use of cART the more severe forms of HAND are less prevalent, now the two most common clinical classifications of CNS HIV infection are
 - (a) Asymptomatic Neurocognitive Impairment and HIV-associated dementia
 - (b) Mild Neurocognitive Disorder and HIV-associated dementia
 - (c) HIV-associated dementia and HIV encephalitis
 - (d) *Asymptomatic Neurocognitive Impairment and Mild Neurocognitive Disorder*
2. The factors that may be responsible for development of HAND include
 - (a) Poor CNS penetrability of antiretrovirals
 - (b) HIV reservoirs in the CNS

- (c) Infection of neurons with HIV virus
 - (d) Production of inflammatory molecules by astrocytes
 - (e) *a, b, and d*
 - (f) All of the above
3. This is generally NOT considered one of the main clinical manifestations of HAND
- (a) Cognitive impairment
 - (b) Behavioral changes
 - (c) *Cardiovascular disease*
 - (d) Dysfunction in learning and memory
 - (e) Motor disturbances
4. Treatment for HAND
- (a) Requires treating virus in the brain with cART that penetrates the BBB
 - (b) Can be done with single drug regimens
 - (c) Requires neuroimaging confirmation and follow-up
 - (d) *Is basically the same as treatment of HIV infection*

Neuroimmunomodulation of Human T-Lymphotropic Virus Type I/II Infection

28

Akinari Yamano, Yoshihisa Yamano,
and Steven Jacobson

Abstract

Human T-Lymphotropic Virus type I (HTLV-1) is an oncogenic retrovirus. Infection is associated with a variety of human diseases including HTLV-1 associated myelopathy/tropical spastic paraparesis (HAM/TSP). Large numbers of epidemiological, virological, immunological, and clinical studies on HTLV-1 and HTLV-1 associated diseases have been published, although the pathogenesis of HAM/TSP is not yet fully understood. In the last several years, researchers have shown that several key factors are important in HTLV-1 associated neurological diseases including high HTLV-1 proviral load (PVL) and a strong immune response to the virus. In this review, we summarize the pathophysiological findings on HAM/TSP and focus on the viral-host immune responses such as virus specific CD8+ T cell responses in infected individuals.

28.1 Introduction

28.1.1 HTLV-1-Associated Myelopathy/Tropic Spastic Paraparesis

Human T-lymphotropic virus type 1 (HTLV-I) is the first human oncogenic retrovirus to be identified and infects approximately 10–20 million people worldwide (Poiesz

et al. 1980; de The and Bomford 1993). Endemic areas for HTLV-1 are known in the world such as southern Japan, the Caribbean, Central and South America, the Middle-East, Central and West Africa, and Melanesia. In addition, there are smaller foci in the aboriginal populations of Australia, Papua New Guinea and northern Japan (Gessain 1996). HTLV-1 has been demonstrated to be the etiological agent of both adult T cell leukemia (ATL) and a progressive neurological disease termed HTLV-1-associated myelopathy/tropic spastic paraparesis (HAM/TSP) (Hinuma et al. 1981; Gessain et al. 1985; Osame et al. 1986). 1985, Gessain first reported the high prevalence of anti-HTLV-1 antibodies in the sera of the patients with tropic spastic paraparesis (TSP) in Martinique of the French West Indies. Subsequently, Rogers-Johnson reported similar findings in Jamaica and Colombia. In 1986, Osame reported the association between HTLV-1 infection and spastic paraparesis in Kagoshima prefecture in southern Japan, where the climate is not tropical but temperate, and he proposed the diagnostic term HTLV-1-associated myelopathy (HAM). The official name of the

disease, HTLV-1-associated myelopathy/tropic spastic paraparesis (HAM/TSP), and the clinical and laboratory guidelines for the diagnosis of HAM/TSP were formulated based on the World Health Organization (WHO) guidelines in 1987 (WHO 1989; Osame 1990). HAM/TSP is characterized by spastic paraparesis, persistent lower back pain, bladder dysfunction and mild sensory disturbances in the limbs. These features are typically symmetrical in most patients with HAM/TSP, while there are some patients whose disease progression and symptoms vary from the norm, and some patients present with atypical neurological feature like mononeuropathy (Leite et al. 2004), amyotrophic lateral sclerosis (Matsuzaki et al. 2000), or spinocerebellar degeneration (Kira et al. 1993). Interestingly, the majority of infected individuals remain lifelong asymptomatic carriers. In endemic areas, the seroprevalence varies from 1 to 20 %. Approximately 0.25 % (Kaplan et al. 1990) to 5 % of infected individuals develop HAM/TSP while 2–5 % develop ATL. The reason why only a subset of HTLV-1 infected individuals develop a clinical disease while the vast majority remain as asymptomatic carriers (ACs) are not known but it is believed to be related to genetic susceptibility associated with a deregulated immune response that results in neuropathology. Most people who go on to develop HAM/TSP have been infected with HTLV-1 for months, years or even longer.

28.1.2 Human T-Lymphotropic Virus Type-1

HTLV-1 is an exogenous, human retrovirus, which varies little in sequence. Thus is highly divergent in structure and function from the human immunodeficiency virus type-1 (HIV-1). It is classified in the genus deltaretrovirus of the subfamily Orthoretrovirinae. The HTLV-1 genome contains three open reading frames that encode four viral proteins. The three typical structural and enzymatic genes (Gag, Pol, and Env) are flanked by two long terminal repeats as seen in other retroviruses. In addition, a region called pX contains at least four partially overlapping reading frames (ORFs) encoding accessory proteins (p12, p13, p30), the post-transcriptional regulator REX (ORF3), and the TAX transactivator (ORF4).

Transmission of HTLV-1 occurs through three main routes that includes breast-feeding, sexual contact and blood transfusion. For all these routes, infected cells pass from infected individuals since HTLV-1 transmits by cell-cell contact. HTLV-1 infected cells produce and transiently store virions in extracellular adhesive structures rich in extracellular matrix components and linker proteins that are crucial for HTLV-1 cell-to-cell transmission (Pais-Correia et al. 2010). When an infected cell contacts an uninfected cell, a microtubule-organizing center is polarized at the cell-cell-

junction, and a virological synapse forms at the interface (Igakura et al. 2003). HTLV-1 integrates randomly into the host genome (Doi et al. 2005). Analyses of integration sites verify that the proliferation of HTLV-1-infected cells is clonal and persistent (Furukawa et al. 1992; Wattel et al. 1995; Etoh et al. 1997; Cavois et al. 1998). Unlike the amplification of HIV-1 proviral genomes that is associated with *de novo* infection of new cells (Miyazato et al. 2006; Taylor et al. 2006; Feuer and Chen 1992), clonal proliferation of HTLV-1 infected cells contribute to the increased number of infected cells in PBMCs.

28.2 HTLV-1 Immunity and Gene Expression in Infected Cell Populations

28.2.1 HTLV-1 in the CNS of HAM/TSP Patients

There is a strong antibody response to HTLV-1 with high titers of HTLV-1-specific IgM, IgA and IgG, which are correlated with proviral load (PVL) (Kira et al. 1992; Manns et al. 1999). Increased numbers of HTLV-1-specific HLA class I restricted CD8+ CTLs is also a noteworthy feature of HAM/TSP (Jacobson et al. 1990; Pique et al. 2000). These observations suggest that there must be persistent HTLV-1 proviral expression *in vivo*. Although HTLV-1 can infect a wide range of human and non-human cells *in vitro*, HTLV-1 has been thought preferentially to infect CD4+ cells (Richardson et al. 1990; Trejo and Ratner 2000). High HTLV-1 proviral loads are in PBMCs of patients with HAM/TSP and were higher than in asymptomatic carriers (Kubota et al. 1993; Hashimoto et al. 1998; Nagai et al. 1998), although HTLV-1 Tax-expressing cells were difficult to detect. HTLV-1 Tax encodes a transactivator protein for virus expression and plays important roles in activating cellular genes including inflammatory cytokines. Tax also has a dominant epitope recognized by HTLV-1-specific CD8+ cytotoxic T lymphocytes (Niewiesk et al. 1995). Therefore it has been suggested that strong HTLV-1 Tax expression, somewhere, is needed to drive these elevated CTL numbers. HTLV-1 proviral load and HTLV-1 Tax expression were found more frequently in the CSF than in the PBMCs of the patients with HAM/TSP (Nagai et al. 2001c; Moritoyo et al. 1999). The ratio of HTLV-1 PVL in the CSF cells to that in the PBMCs was significantly associated with clinically progressive disease and with recent onset of HAM/TSP (Takenouchi et al. 2003). In addition, HTLV-1-infected lymphocytes shared the same HTLV-1 integration site in the cellular DNA of both the CSF cells and PBMCs of the HAM/TSP patients (Cavois et al. 2000). These findings suggest that HTLV-1-infected lymphocytes migrate from the periphery into the CNS and that expression of HTLV-1 Tax in the

CNS may induce a significant immune-response prior to the development of HAM/TSP.

28.2.2 HAM/TSP Pathology

All patients with HAM/TSP have symptoms of a myelopathy but not meningitis; the brain is grossly unremarkable except for diffuse thickening of the leptomeninges (Izumo et al. 1992). The spinal cord shows mild to severe atrophy with a thickening of the leptomeninges. MRI/CT scans often detect atrophy of the spinal cord at thoracic lesions. Histochemically, chronic inflammation is mainly seen in the mid-to lower spinal cord, especially at the thoracic region and is consistent with clinical features of the patients with HAM/TSP. A number of lymphocytic infiltrates and foamy macrophages are seen in the thickened meninges, parenchyma and perivascular area of the mid-to lower spinal cords. Not only T cells but also B cells are sparse in the parenchyma and thickened meninges (Akizuki et al. 1989). NK cells are rarely observed in the lesion (Umehara et al. 1994a). Smaller numbers of infiltrating cells are also found in the midbrain, pons, medulla oblongata, cerebellum and cerebral white matter (Akizuki et al. 1988). MRI scans have detected abnormal signals of white matter in the cerebrum and these have been associated with inflammation (Kira et al. 1991). These lesions detected by MRI are usually small, less than 5 mm wide, and in the white matter. Almost all the patients with HAM/TSP do not show symptoms associated with those lesions in the cerebrum. The reasons why lesions are scattered in the CNS or why the thoracic spinal cord is mainly affected is not known. Importantly, the neuropathology of the spinal cord appears to change gradually during the progression of HAM/TSP (Umehara et al. 1993).

In cases with clinical history up to 3 years, parenchymal lesions with marked inflammation and those with degeneration rather than inflammatory changes co-exist in the spinal cord. Lymphocyte exudation occurs at random in both grey and white matter but is more frequently seen in the deeper portion of the cord than in the surface areas. Inflammation involves both the white and grey matter, but the white matter is preferentially degenerated in the lesions. Interestingly, the lateral column is commonly symmetrically and most extensively involved with inflammation, while the anterior and posterior columns are usually less affected. These lesions are associated with the presence of a number of CD4+ and CD8+ cells, foamy macrophages, and fibrillary gliosis. They are commonly seen along the course of the small vessels running from the grey matter to the white matter. B cells are also found in the lesions but mainly located in perivascular spaces of larger vessels (Iwasaki 1993). A number of infiltrating macrophages and microglia are activated with the expression of MRP14 and MRP8 (Abe et al. 1999). Neurons in the ante-

rior horn are relatively well preserved despite the presence of inflammatory cells. Immunoreactivity for HLA class I is present on endothelial cells and infiltrating mononuclear cells (Wu et al. 1993). Up-regulation of HLA class II expression is also found on endothelial cells, microglia, and infiltrating mononuclear cells in the lesions (Umehara et al. 1993). High expression of vascular cell adhesion molecule-1 (VCAM-1) on the endothelium has been demonstrated (Umehara et al. 1996). Expression of very late antigen-4 (VLA-4) and monocyte chemoattractant protein-1 (MCP-1) is also up-regulated in the infiltrating cells in active-chronic lesions of affected spinal cord. Intracellular adhesion molecules-1 (ICAM-1) and its counterpart molecule lymphocytes function-associated antigen-1 (LFA-1) are also suggested to be involved in the lymphocyte infiltration into the spinal cord (Cabre et al. 1999). Proinflammatory cytokines such as TNF- α , IFN- γ and IL-1 β were detected in perivascular infiltrating cells (Umehara et al. 1994a), while IL-1 β was predominantly expressed on the infiltrating macrophages and parenchymal astrocytes. IFN- γ is also expressed in glial cells.

In cases with disease duration of 4–6 years, smaller numbers of inflammatory cells are located in the meninges and perivascular spaces. CD8+ cell are predominantly seen in the parenchyma relative to CD4+ cells. Activated macrophages and microglia expressing MRP-8 are also present. The white matter is uniformly degenerated.

In HAM/TSP cases of longer disease duration show equal myelin and axon degeneration. Notably, tissue is largely replaced by glial scar formation with foamy cells, microglial cells and a small numbers of lymphocytes, mostly CD8+ cells with concomitant down-regulation of pro-inflammatory cytokine expression with the exception of IFN- γ (Umehara et al. 1993; Iwasaki 1990). Although a number of macrophages are detectable in the lesions, the markers of activated macrophages and microglia such as MRP-14 or 8 are down-regulated (Abe et al. 1999). Fibrous thickening of adventitia and hyalinized changes of the small vessels (hyalinous thickening of their wall) are conspicuous in both the grey and white matter in the lesion of the patients with long history. Myelin staining revealed symmetrical myelin pallor of the lateral column that is most conspicuous the entire length of the lateral pyramidal tract even cases with mild changes of the lateral column. Myelin pallor of the anterior or posterior funiculi is less involved and milder. Wallerian degeneration of ascending tracts in the posterior funiculi is less conspicuous than that of the pyramidal tract in the lumbar and sacral funiculi (Iwasaki 1990). In some cases, when the patient has had the disease for more than 20 years, a number of infiltrating CD8+ cells have been observed in the spinal cord (Iwasaki et al. 2004). The rate of progression of disease depends on the individual.

Aye et al. reported that perivascular inflammatory infiltration in HAM/TSP cerebrum was seen in deep white matter

and in the marginal area of cortex and white matter. The types of the infiltrating cells were similar both in the spinal cord and cerebrum. In addition to infiltrating cells, demyelination and axonal damage were also seen in the lesion. Therefore, they suggested that HAM/TSP inflammatory process progressed and diminished in the entire area of the CNS simultaneously and that the lesions had a correlation with the site of slow blood flow in the spinal cord of the brain (Aye et al. 2000).

28.2.3 Localization of CNS HTLV-1 and HTLV-I Tax Expression

Does HTLV-1 exist in the CNS? Pathological studies using in situ PCR techniques showed HTLV-1 DNA localized to inflammatory T lymphocyte infiltrates (UCHL-1: CD45RO positive cells) but not CD68+ cells in the affected area of spinal cords of HAM/TSP patients (Matsuoka et al. 1998). Another study using in situ hybridization showed that HTLV-1 Tax mRNA was found in infiltrating CD4+ T lymphocytes in active lesions of the affected areas of spinal cords (Moritoyo et al. 1996). Kubota et al. reported that quantitative PCR analysis showed that the amount of HTLV-1 DNA decreased concomitantly with the number of infiltrating CD4+ cells but with neither CD8+ cells nor macrophages in spinal cord lesions (Kubota et al. 1994). These findings suggest a preferential viral reservoir in the CNS in infiltrating CD4+ T lymphocytes that express HTLV-1 Tax. However, other cells may also harbor HTLV-1 in the CNS. For example, HTLV-1 RNA has been shown to localize to astrocytes (Lehky et al. 1995; Ozden et al. 2002). Recently, Afonso et al. reported the alterations in BBB function caused by HTLV-1-infected endothelial cells that may be associated with increased migration of inflammatory cells into the CNS (Afonso et al. 2008).

The proliferation and HTLV-1 Tax expression of HTLV-1 infected cells has not been determined in the CNS parenchyma and other tissues/organs of patients with HAM/TSP. In contrast, semi-quantitative studies on the distribution of HTLV-1 proviral DNA in situ suggested that strong HTLV-1 provirus signals could be detected by PCR in the spinal cord, peripheral nerves, muscles, lungs, and liver, and that weak HTLV-1 provirus signals were detected in the medulla oblongata, optic nerve, and lymph nodes (Sueyoshi et al. 1994).

28.2.4 HTLV-1 in PBMC

CD8+ cells including HTLV-1 specific CD8+ CTLs have been shown to be infected with HTLV-1 in PBMC (Hanon et al. 2000; Nagai et al. 2001a). Interestingly, HTLV-1 tax

expression in these infected CD8+ T cells rendered them susceptible to cytolysis mediated by autologous HTLV-1 specific CD8+ CTLs (Hanon et al. 2000). HTLV-1 specific CTLs may serve a dual function as both target and effector cells while HTLV-1 infected CD8+ cells have not been demonstrated in the CNS parenchyma of HAM/TSP patients.

Previous studies have shown that mononuclear phagocytes (MPs) including monocytes, macrophages and dendritic cells (DCs), are susceptible to HTLV in vivo, while the frequency of these infected MPs was determined to be 0.5–5% of the total MP population (Macatonia et al. 1992; Koyanagi et al. 1993; Makino et al. 1999). Although HTLV-1 PVL in DCs is positively correlated with that of PBMCs (Azakami et al. 2009), HTLV-1 tax expression of the MPs including CD14+ cells and macrophages was barely detectable compared with that of CD4+ or CD8+ cells in the PBMCs even after culture. More recent studies demonstrated that DCs can be efficiently infected by cell-free HTLV-1 virions in vitro (Jones et al. 2008) although this seems unlikely to contribute to maintaining the high HTLV-1 PVL in infected individuals since HTLV-1 cell-free virions have not been reported in the periphery and are known to be poorly infectious to CD4+ cells. Recently, CD14+ cells are reported to have cell surface expression of IL-15, inducing degranulation and IFN- γ production from CD8+ T cells in HAM/TSP patients. Also, it is reported that PVL in the CD14+ cells are higher in HAM/TSP patients than in ACs, suggesting HTLV-1 infection in CD14+ cells may be a major determinant of spontaneous degranulation in HAM/TSP patients (Enose-Akahata et al. 2008).

Yamano et al. has reported that CD4+ CD25+ cells are the predominant viral reservoir in HAM/TSP PBMCs and that the decreased Foxp3 expression in this subset was associated with a loss of suppressor function (Yamano et al. 2004; Oh et al. 2006; Michaelsson et al. 2008; Hayashi et al. 2008). It was suggested that this decrease of Foxp3 expression (loss of T-regulatory cell function) maybe involved in persistent T cell activation in lesions of HAM/TSP patients. In HAM/TSP patients, decreased demethylation in the FoxP3 Treg-specific demethylated region was also observed which may lead to reduced Treg function (Anderson et al. 2014). In contrast, Toulza et al. have reported that FoxP3+ cells in CD4+ T cell subset was increased in HAM/TSP patients (Toulza et al. 2008). In the report, the frequency of tax negative Foxp3+CD4+ cells was negatively correlated with the HTLV-1 specific CTL frequency, while the frequency of Tax-positive Foxp3+CD4+ cells was not. Yamano et al. reported the CD4+CD25+ CCR4+ T cell subset was increased in HAM/TSP patients and also highly infected with HTLV-1 compared with CD4+ CD25+ CCR4- cells (Yamano et al. 2009). The Foxp3-negative population in CD4+CD25+CCR4+ T-cells was significantly increased in HAM/TSP patients. In this study, purified CD4+ CD25+ CCR4+ T cells subset

proliferated independently, while CD4+CD25-CCR4- subset did not. Moreover, the HTLV-1 Tax protein increased expression of the T box transcription factor, the Th1 master regulator, and promote production of IFN- γ . Abundant CD4+CCR4+ T cells were observed to coexpress the Th1 marker CXCR3 and produce T-bet and IFN- γ in CSF and spinal cord lesions in HAM/TSP (Araya et al. 2014). In addition, immunostimulatory T cells (CD39+CD25-CD4+) were increased in HAM/TSP patients compared to those in ACs. Reduced number of Th17 cells and conversion of CD39+CD25+CD4+ T cells (suppressive phenotype) to those with increased IFN- γ , TNF- α , and IL-2 production is also demonstrated in HAM/TSP (Leal et al. 2013). Asquith et al. has also shown that CD4+ CD45RO+ T cell proliferation, which are also susceptible to HTLV-1 infection, was elevated in the PBMCs of HTLV-1-infected individuals. In this study, the increased proliferation *in vivo* was correlated with *ex vivo* HTLV-1 Tax expression (Asquith et al. 2007). Collectively, these observations suggest that the strong immune response to HTLV-1 seen in HTLV-1 infected individuals may be due to increased proliferation of HTLV-1-infected CD4+ cells and their HTLV-1 Tax expression.

28.3 Risk Factors for Acquiring HAM/TSP

Less than 5% of HTLV-1-infected individuals develop HAM/TSP while the majority remain lifelong asymptomatic carriers. It is therefore obvious that infection with HTLV-1 is necessary but not sufficient to cause HAM/TSP. The crucial risk factors that determine the outcome of an HTLV-1 infection is still unclear but include HTLV-1 proviral load, host genetic factors, variants of HTLV-1, age, and gender. Since the majority of HTLV-1 infected individuals remain lifelong asymptomatic carriers and each HAM/TSP patients greatly vary in progression, investigation of risk factors and prognosis biomarkers is important.

28.3.1 HTLV-1 Proviral Load (PVL) Is an Important Risk Factor for HAM/TSP

Higher HTLV-1 proviral loads (PVL) have been demonstrated in PBMCs of patients with HAM/TSP compared to asymptomatic carriers. Previous studies have shown that HTLV-1 PVL of HAM/TSP patients was about 5–16-fold higher than those of asymptomatic carriers (Kubota et al. 1993; Hashimoto et al. 1998; Nagai et al. 1998). The study in Kagoshima, southern Japan, is one of the largest endemic areas in the world for HTLV-1 showed that the prevalence of HAM/TSP rose steeply as the proviral load exceeded 1% of PBMCs (Nagai et al. 1998). Moreover, HTLV-1 PVL was also increased in the CSF of the patients with HAM/TSP

compared with that in the PBMCs (Nagai et al. 2001c). Importantly, the ratio of PVL in the CSF cells to that in the PBMCs was significantly associated with clinical progress and recent onset of HAM/TSP (Takenouchi et al. 2003). In a small prospective cohort study performed in the UK, Taylor et al. have validated these observations and suggests that high PVL predispose to a high risk of onset of HAM/TSP (Taylor et al. 1999). Collectively, these results demonstrate that an increased HTLV-1 PVL is a strong risk factor for HAM/TSP and is associated with clinical progression in this disorder.

28.3.2 HTLV-1 Integration and Proviral Load

HTLV-1 Tax expression in cultured PBMCs without CD8+ cells is more frequently detectable in HAM/TSP patients than in asymptomatic carriers at a given proviral load (Yamano et al. 2002; Asquith et al. 2005b). Asquith et al. reported that HTLV-1 Tax expressing rate in CD4+ cells after 18 h culture without CD8+ cells was positively correlated with HTLV-1 PVL in PBMCs (Asquith et al. 2005b). In this study, it was the rate of HTLV-1 Tax expression *ex vivo* in CD4+ cells that was thought to be a strong predictor for HAM/TSP independent of HTLV-1 PVL. The authors suggested the positive correlation between the HTLV-1 Tax expressing rate and HTLV-1 PVL was attributed to the infected cell proliferation by Tax-induced up-regulation of cellular genes involved in proliferation and deregulating cell cycle checkpoint (Bex and Gaynor 1998; Hollsberg 1999; Mesnard and Devaux 1999). They went on to demonstrate that CD4+CD45RO+ T lymphocyte proliferation was increased in HTLV-1-infected individuals *in vivo* and that the proliferation rate correlated with *ex vivo* HTLV-1 viral expression, suggesting that persistent viral gene expression *in vivo* was necessary for the maintenance of HTLV-1 PVL (Asquith et al. 2007). Recently, Meekings et al. reported that genomic integration in transcriptionally active genomic regions determines the rate of HTLV-1 proviral expression (Meekings et al. 2008). The genomic integration of HTLV-1 to certain regions may induce high HTLV-1 tax expression and subsequent Tax-induced proliferation that define HTLV-1 PVL and that may drive the expansion of HTLV-1-specific CTLs (Bangham et al. 2009). More recently, Melamed showed that HTLV-1 preferentially integrates within 1 kb of a host transcription start site and is strongly biased to specific transcription factor binding sites, in particular STAT1, p53, HDACs, and HATs. Relative position of the HTLV-1 integration site and the transcriptional orientation of the nearest host gene influence both clonal abundance and spontaneous Tax expression of the infected cells (Melamed et al. 2013). Furthermore, Niederer et al. demonstrated that AC clones

were more frequently integrated in transcriptionally active areas than clones from HAM/TSP patients or individuals who have HLA class I alleles that were able to effectively present HBZ peptides to CTL (Niederer et al. 2014).

28.3.3 Genetic Factors and HTLV-1 Tax Subtypes

While HTLV-1 PVL is an important risk factor for HAM/TSP, the range of HTLV-1 PVL seen in both groups of HAM/TSP patients and asymptomatic carriers is large with extensive overlap (Nagai et al. 1998). Of importance, HTLV-1 PVL in asymptomatic carriers of families with HAM/TSP patients was higher than those of unrelated asymptomatic carriers. In addition, since HTLV-1 varies little in sequence other than tax gene either within or between hosts (Daenke et al. 1990), the variation in proviral load among HTLV-1 infected individuals is thought to be caused by differences in the host rather than in the virus. There are wide variations (over 1000-fold) in PVL among infected individuals, although within an individual, the HTLV-1 PVL is stable over time (Takenouchi et al. 2003; Matsuzaki et al. 2001). These findings suggest that the genetic factors as well as HTLV-1 PVL and rates of HTLV-1 Tax expression in CD4⁺ cells play an important role in the development of HAM/TSP. Some HLA genotypes were found to influence HTLV-1 PVL and the risk for HAM/TSP. In a case-control studies, candidate gene association studies in the HTLV-1 endemic area of Kagoshima in Kyushu Island, Japan (Jeffery et al. 1999, 2000; Vine et al. 2002), it was reported that HLA-A*02 or Cw*08 were independently associated with a lower risk (absence or presence) for HAM/TSP. The association between these two class I alleles and PVL was found in only the group of asymptomatic carriers (Vine et al. 2002). HLA-B*5401 was also associated with higher HTLV-1 PVL and high risk for HAM/TSP. Furthermore, individuals who are heterozygous at all three HLA class I loci have a lower PVL than those who were homozygous at one or more loci (Jeffery et al. 2000). HLA class II alleles such as HLA-DRB1*0101 was also associated with high risk for HAM/TSP (Jeffery et al. 1999; Usuku et al. 1988). Other genetic factors not associated with HLA have also been reported to be associated with HAM/TSP. Vine et al. reported that a promoter polymorphism in the cytokine gene TNF- α -863A, stromal cell-derived factor-1 (SDF-1) and IL-15 also influenced the outcome of the HTLV-1 infection (Vine et al. 2002). Clearly, a wide range of genes both within and outside the HLA region will be shown to influence susceptibility to HTLV-1 and the clinical outcome of an HTLV-1 infection.

28.3.4 Cytokines and Chemokines as Risk Factors for HAM/TSP

Several cytokines and chemokines are known to be elevated in the peripheral blood and/or CSF of HAM/TSP patients, such as soluble interleukin-2 IL-1 β , granulocyte-macrophage colony-stimulating factor, IFN- γ , TNF- α , chemokine (C-X-C motif) ligand 9 (CXCL9), CXCL10, chemokine (C-C motif) ligand 5 (CCL5), and neopterin (Yamaguchi et al. 1989; Nomoto et al. 1991; Kuroda and Matsui 1993; Kuroda et al. 1993; Nakamura et al. 1993; Umehara et al. 1994a; Narikawa et al. 2005; Guerreiro et al. 2006; Tanaka et al. 2008; Tattermusch et al. 2012). In the spinal cords of HAM/TSP patients, astrocytes produce CXCL10 by IFN- γ secreted (Sato et al. 2013) by infected T cells. Subsequently, CXCL10 attracts CXC motif receptor 3⁺ T cells which include HTLV-1 infected T cells leading to further IFN- γ secretion in a positive feedback loop (Ando et al. 2013). Retrospective study demonstrated that elevated neopterin concentration, high levels of CXCL9 and CXCL10, were well-correlated with the disease progression over a 4-year-period and was better in predicting disease progression than HTLV-1 PVL in PBMCs (Sato et al. 2013).

28.4 Immune Response Against HTLV-1

28.4.1 Increased Tax-Specific CD8⁺ CTLs Have a Strong Association with the Pathogenesis of HAM/TSP

One of the most striking features of the cellular immune response in HTLV-1-infected individuals is the increased numbers of HTLV-1-specific HLA class I restricted CD8⁺ CTLs in PBL and CSF cells (Jacobson et al. 1990; Elovaara et al. 1993; Parker et al. 1994; Greten et al. 1998; Nagai et al. 2001b; Kubota et al. 2002). Cytotoxic T cells (CTLs) are an important component of the adaptive mammalian immune response to viruses and act by killing autologous cells that express viral antigen in association with MHC class-I and by suppressing viral replication by secretion of IFN- γ . While HTLV-1-specific CTLs are also detectable in PBMCs of asymptomatic carriers (Parker et al. 1992), the magnitude and frequency of these responses are clearly higher in patients with HAM/TSP, particularly in the CSF (Nagai et al. 2001c; Elovaara et al. 1993). In HAM/TSP, most of these cells express IFN- γ and TNF- α , were CD8⁺ cells and were HTLV-1-specific CTLs. The frequency of IFN- γ +CD8⁺ cells was significantly higher in the PBMCs of HAM/TSP patients than in that of asymptomatic carriers or healthy controls and was correlated with HTLV-1 PVL in PBMCs (Kubota et al. 1998, 2000), although positive correlations between CTLs frequency and HTLV-1 PVL was not always seen in other

studies. HTLV-1 PVLs were also increased in CSF cells compared with that in the PBMCs of HAM/TSP patients, and those were proportional to the frequency of HTLV-1-specific CTLs in the CSF (Nagai et al. 2001c). These observations coupled with pathological findings that infiltrating TIA-1+ cells (CTL) appear to correlate with the presence of apoptotic CD4+ T cells in inflammatory lesion in HAM/TSP (Umehara et al. 1994b), suggests that the increased HTLV-1 specific CTLs in the CNS are strongly associated with the pathogenesis of HAM/TSP.

Tax specific CD8+ CTL clones have also been demonstrated to secrete various inflammatory cytokines, chemokines and matrix metalloproteinase (MMP) such as IFN- γ , TNF- α , monocyte inflammatory protein (MIP)-1 α , MIP-1 β , interleukin(IL)-16, and MMP-9 (Biddison et al. 1997). TNF- α induces cytotoxic damage to endothelial cells, thus decreasing the integrity of the BBB. It can also directly injure oligodendrocytes. MIP-1 α and 1 β can enhance transendothelial migration of lymphocytes into the CNS. IL-16 is a chemoattractant for CD4+ cells, and CD4+ T cells are the major source of IL-2 that is required by IL-2 non-producer CD8+ cells for proliferation. Therefore, HTLV-1-specific CD8+ CTLs are an important source of proinflammatory soluble mediators that may contribute significantly to the pathogenesis of HAM/TSP.

28.4.2 Why Does the High Frequency of HTLV-1-Specific CTL Not Decrease HTLV-1 PVL?

HTLV-1 PVL and Tax mRNA positively correlated with the frequency of HTLV-1-specific CTLs in PBMCs (Yamano et al. 2002; Nagai et al. 2001b; Kubota et al. 2000). Why does the high frequency of HTLV-1-specific CTLs therefore not contribute to a decrease in HTLV-1 infected cells and PVL in the periphery of infected individuals? One possibility is that HTLV-1-specific CTLs are functionally dysregulated. Sabouri et al. reported that the frequency of intracellular perforin-positive CD8+ T cells was significantly lower in both HAM/TSP and ACs than in healthy controls (HCs) (Sabouri et al. 2008). In this paper, an inverse correlation between HTLV-1 PVL and the percent perforin-positive CD8+ T cells were observed only in HLA-A*02+ HCs but not in HAM/TSP patients. In this context, there may be differences in CTL function rather than CTL frequency. The CTL-mediated lysis effect (killing ability per CTL) of CTLs could be evaluated by measuring the effect of varying the frequency of CD8+ cells (not HTLV-1 Tax specific CTLs) on the rate of disappearance of HTLV-1 Tax-expressing cells ex-vivo (Asquith et al. 2005a). Asquith et al. reported that the CTL lysis effect of HAM/TSP patients was not different from that of ACs. In addition, the variation in HTLV-1 PVL

among HTLV-1 infected people was explained by differences in CTL lysis effect. The CTL lysis effect was negatively correlated with HTLV-1 PVL in both HAM/TSP patients and ACs groups. Interestingly, HTLV-1 PVL of HAM/TSP patients were significantly higher than ACs at any given lytic effect of CTLs. These results suggest that CTLs do contribute to decrease HTLV-1 PVL, and high HTLV-1 PVL in HAM/TSP patients is not a consequence of weak CTL lysis. Again, additional factors must also be associated with high level HTLV-1-specific CTLs that may be associated with the pathogenesis of HAM/TSP.

28.4.3 CD8+ CTL Activity and CD244-SAP Signaling

The ability of CD8+ T cells to degranulate (CD107 α) has been directly correlated with cytolytic activity of effector CD8+ T cell and has been used as a useful tool to characterize total CD8+ T cell lytic activity in various diseases (Rubio et al. 2003; Betts et al. 2003, 2006; Kozako et al. 2006; Gehring et al. 2007). Enose-Akahata et al. recently reported an increased spontaneous degranulation with IFN- γ expression (CD107 α /IFN- γ) in CD8+ cells of HAM/TSP patients but not in ACs (Enose-Akahata et al. 2008). These authors have extended these observations and have shown that the CD244/SAP pathway in CD8+ cell is involved in the active regulation of CTL of patients with HAM/TSP (Enose-Akahata et al. 2009). In this study, while the expression of CD244, a signaling lymphocyte activation molecule (SLAM) family receptor, was significantly higher on CD8+ T cells in both HAM/TSP patients and ACs than those on healthy normal donors (NDs), SLAM-related adapter protein (SAP) was over expressed only in HAM/TSP patients compared to ACs and NDs. Blockade of CD244 inhibited the degranulation and IFN- γ production (CD107 α /IFN- γ) and SAP knockdown by siRNA also inhibited IFN- γ production in CD8+ T cells of HAM/TSP patients. The results suggested that differential expression of SAP in the CD8+ cells results in a higher frequency of degranulation in HTLV-1 infected individuals, thereby contributing to the higher CTL activity observed in patients with HAM/TSP.

28.4.4 Interaction Between HTLV-1-Specific CD8+ CTL and Mononuclear Phagocytes (MPs)

While high SAP expression of CD8+ cells in HAM/TSP patients was shown to influence CTL activity, additional factors are also important. Recently, there has been a greater appreciation for the role of MPs including CD14+ cells, macrophages and dendritic cells. These populations have

been shown to play a role in the spontaneous cell proliferation that is seen in cultured PBMCs of HTLV-1 infected individuals and is inhibited by blocking with antibodies against IL-2, IL2R α , IL-15 and IL15R (Macatonia et al. 1992; Makino et al. 1999; Tendler et al. 1990; Ali et al. 1993; Azimi et al. 1999). Azimi et al. reported the role of MPs in proliferation of CTL in HAM/TSP patients (Azimi et al. 2001). Enose-Akahata et al. reported CTL degranulation to be mediated by HTLV-1 infection of MPs with the concomitant expression of IL-15 (Enose-Akahata et al. 2008). In this study, the frequency of CD107 α /IFN- γ cells in the CD8+ cells was reduced in purified CD8+ cells compared with total PBMCs in HAM/TSP patients and then restored by the addition of autologous CD14+ cells but not CD4+ cells of HAM/TSP patients. They showed that cell-to-cell interaction with CD14+ cells was necessary for degranulation and that the frequency of CD107 α /IFN- γ cells in CD8+ cells was increased by the addition of rhIL-15 or CD14+ cells and decreased by addition of both CD14+ cells and anti-IL-15 antibodies. Lastly, IL-15 expression on CD14+ cells was increased in PBMC of HAM/TSP patients compared with ACs. These findings suggested that MPs play an important role in exacerbating CTLs degranulation in HAM/TSP patients.

28.4.5 Tax-Specific CD8+ CTLs in the Brain

The phenotype of inflammatory cells in the CNS of HAM/TSP patients has been extensively studied. Significantly, later in disease, there is a predominance of CD8+ T cells in the lesions of affected spinal cord in areas that express HLA class I antigens and from which functional HTLV-1-specific CD8+ CTLs have been demonstrated (Levin et al. 1997). In addition, the infiltration of CD8+ CTLs in the affected spinal cord was characterized as TIA-1 positive (Umehara et al. 1994b; Anderson et al. 1990). TIA-1 is a monoclonal antibody that recognizes a 15-kDa granule-associated protein contained in CTLs and NK cells. Double staining for anti-CD8 and TIA revealed that 80 % of TIA-1+ infiltrating cells throughout the parenchyma and perivascular area were positive for CD8. TIA-1+ cells were scarcely observed in inactive-chronic lesions, though CD8+ cells dominated in the parenchyma and perivascular area. The number of TIA-1+ cells was clearly related to the amount of the proviral DNA in situ and the number of infiltrating CD8+ cells appeared to correlate with the presence of apoptotic cells. More recently, HTLV-1 Tax-specific CD8+ CTLs in parenchyma and meninges were directly detected in the spinal cord of the patients with HAM/TSP by using HLA-A2 HTLV-1 Tax peptide pentamers. Of importance, about 30 % of the infiltrating CD8+ cells were found to be

HTLV-1-specific CTLs (Matsuura et al. 2015). These observations continue to support a role for HTLV-1-specific CTLs as a major contributing factor in HTLV-1 associated neurologic disease.

28.4.6 Antibody Responses Against HTLV-1

As mentioned, HAM/TSP patients have significantly higher titers of anti-HTLV-1 antibodies (Abs) than ACs, suggesting the existence of a humoral immune response against HTLV-1 (Kira et al. 1992). Abs for all three HTLV-1 proteins (Gag, Env, and Tax) had higher immunoreactivity in HTLV-1 infected patients compared to NDs. Furthermore, HAM/TSP patients had higher Ab response for Gag and Env, but not for Tax, compared with ACs, but Ab responses for all 3 HTLV-1 proteins was higher compared with ATL patients. By using luciferase immunoprecipitation system, measurement of Ab response to HTLV-1 makes it possible to distinguish HAM/TSP patients from ACs at a positive rate of 85.42 % and from ATL patients at a positive rate of 75.00 % (Enose-Akahata et al. 2012). In addition, Enose-Akahata et al. reported that Abs against HBZ was detected in HTLV-1 infected individuals. Although this was not able to discriminate between AC, ATL patients, and HAM/TSP patients. Antibody responses against HBZ was also observed in CSF of HAM/TSP patients (Enose-Akahata et al. 2013). Further studies are needed to determine if these Ab responses will be of clinical use, to either predict disease risk of developing HAM/TSP, or to be able to monitor HAM/TSP progression.

28.5 Natural Killer (NK) Cell, NKT Cell and GDT Cell in Patients with HAM/ TSP

NK cell activity and frequency of this subset was reported to be significantly decreased in HAM/TSP compared with healthy controls (Azakami et al. 2009; Fujihara et al. 1991; Yu et al. 1991; Wu et al. 2000). Cytotoxic activity and antibody-dependent cell-mediated cytotoxicity (ADCC) were also lower in NK cells from HAM/TSP patients than those of controls (Yu et al. 1991). The study revealed NK cell activity was significantly increased after 4 weeks of oral administration of LcS preparation with improvements in spasticity (Modified Ashworth Scale Scores) and urinary symptoms, while HTLV-1 PVL was not changed (Matsuzaki et al. 2005). These results suggested that low NK activity may be an additional risk factor for HAM/TSP.

Human natural killer-cell receptors are expressed by NK cells and some T cells, primarily TCR+ CD8+ cytotoxic T lymphocytes. Inhibitory NK cell receptors (iNKR) can

down-regulate antigen-mediated T-cell effector functions including cytotoxic activity and cytokine release (Mingari et al. 1998; Biassoni et al. 2001). It is reported that CD8+ T cells that express the HLA-E ligand including an iNKR were significantly decreased in association with HAM/TSP but not in asymptomatic carriers (Saito et al. 2003). It was therefore suggested that the decrease in these iNKR cells in HAM/TSP patients contributes to the excessive antiviral immune response.

NKT subset was also significantly decreased in HAM/TSP compared with healthy controls (Azakami et al. 2009; Wu et al. 2000). iNKT cells are unique T cells that regulate the immune response to microbes, cancers, and autoimmunity. Frequency of iNKT, NK, and dendritic cells has been shown decreased in the peripheral blood of HAM/TSP and ATL patients (Azakami et al. 2009). In this study, an inverse correlation between the iNKT cell frequency and the HTLV-1 proviral load was found in the peripheral blood of infected individuals. In vitro stimulation of PBMCs with alpha-galactosylceramide increased iNKT cells and subsequently decreased HTLV-1-infected T cells in samples from asymptomatic carriers but not HAM/TSP or ATL patients. These authors suggested that iNKT cells contribute to the immune defense against HTLV-1 and iNKT cell depletion plays an important role in the pathogenesis of HAM/TSP and ATL.

28.5.1 Co-morbid Conditions

HTLV-1 has been known to be associated with not only HAM/TSP and ATL but also uveitis, alveolitis, myositis, arthritis, dermatitis, mononeuropathy, inclusion body myositis, hearing loss, Sjogren syndrome, Bechet disease, pseudohypoparathyroidism, and SLE (Leite et al. 2004; Morgan et al. 1989; Higuchi et al. 1992; Sugimoto et al. 1987; Vernant et al. 1988; Nakao et al. 1991; Nishioka et al. 1989; LaGrenade et al. 1990; Cupler et al. 1996; Ozden et al. 2001; Matsuura et al. 2008; Bakhshaei et al. 2015). Although HAM/TSP patients with HCV hepatitis are sometimes seen, there appears to be no epidemiological link (Taylor et al. 1999; Ijichi et al. 1993). Retrospective studies show stronger associations of HTLV-1 with HAM/TSP, uveitis, myositis and peripheral neuropathy (Gessain et al. 1985; Morgan et al. 1989; Higuchi et al. 1992; Nakao et al. 1991; Gilbert et al. 2001; Leite et al. 2003), but less clear associations are for alveolitis, arthritis and the other suggested diseases. While there is no epidemiological study for pulmonary diseases associated HTLV-1, some radiological studies suggest that there may be significantly higher radiological abnormalities in HTLV-1-infected subjects (Kohno et al. 1992; Okada et al. 2006). HTLV-1-associated myopathy, dermatitis and peripheral

neuropathy may be less frequent in southern regions of Japan than in the Caribbean and South America. Again, host genetic factors must clearly influence these conditions. Because monoclonal T cell expansion of HTLV-1 is not seen in these HTLV-1 related disorders except ATL, the immune responses in these conditions are thought to be similar to that of HAM/TSP. However, unlike HAM/TSP, there are much less reports on the pathogenesis of these other HTLV-1-associated diseases. In this context, HTLV-1 associated myositis has been studied. Pathological studies have demonstrated HTLV-1 proviral DNA and HTLV-1 Tax expression in the infiltrating cells in perimysium but not muscle fibers by in situ hybridization and in situ PCR, respectively (Higuchi et al. 1992, 1995). HTLV-1 DNA and Tax mRNA were also detected in the infiltrating cells in perimysium (Matsuura et al. 2008). These reports suggest that immunopathogenic CTLs may also be playing a similar role in these other conditions associated with HTLV-1 infection as has been suggested in HAM/TSP. Therefore, a better understanding the pathophysiology of HAM/TSP may lead to therapies that may ameliorate a number of disorders in which HTLV-1 is thought to play a role.

28.6 HAM/TSP Therapies

To date, various treatments have been used to HAM/TSP patient, such as corticosteroids (Nakagawa et al. 1996), and INF- α (Izumo et al. 1996). However, strong therapeutic efficacy of previous treatments has not been demonstrated. Although not the focus of this review, the following are select examples of treatment that are currently in clinical trials.

28.6.1 Mogamulizumab

As mentioned previously, CD4+ CD25+ CCR4+ T cell subset being a main reservoir in HAM/TSP patients (Yamano et al. 2009), Mogamulizumab, a defucosylated humanized anti-CCR4 immunoglobulin G1 monoclonal antibody, targets infected cells by marking CCR4+ T cells for elimination and reduce the number of infected cells. Using Mogamulizumab, Yamauchi et al. demonstrated the significant reduction of HTLV-1 proviral load in PBMCs from patient with HAM/TSP in vitro. As HTLV-1 is known to infect CD8+ cells as well in HAM/TSP patient (Nagai et al. 2001a), they also revealed that the majority of infected CD8+ cells are also CCR4+ (Yamauchi et al. 2015). The evidence suggests that Mogamulizumab would reduce HTLV-1 PVL by eliminating both CD4+ CCR4+ cells and CD8+ CCR4+ cells, subsequently improve chronic inflammation in HAM/TSP patients.

28.6.2 Raltegravir

Raltegravir, integrase inhibitor, have been in use for the treatment for human immunodeficiency virus type 1, same retrovirus as HTLV-1. Seegulam et al. found that Raltegravir also prevent integration of HTLV-1 in vitro for both cell-free and cell-to-cell modes of infection (Seegulam and Ratner 2011). In vivo study, HTLV-1 PVL showed transient decline in HAM/TSP patient, but it returned to a baseline level after the therapy, with no improvement in clinical manifestations. Also, there were no significant HTLV-1 PVL decreases observed in ACs (Trevino et al. 2012). However, larger cohorts are needed to assess the efficacy of this treatment.

28.6.3 Hu MiK β 1

IL-15 is one of the proinflammatory cytokines over expressed in PBMCs of HAM/TSP patients (Azimi et al. 1999), and IL-15 promoter activity have positive correlation with HTLV-1 Tax protein expression (Azimi et al. 1998). It is known that IL-15 plays a role in survival and function in HAM/TSP patients ex vivo (Azimi et al. 2001), suggesting a relation between the pathogenesis of HAM/TSP. Azimi et al. demonstrated that Antibodies against IL-15 or its receptor inhibit HAM/TSP PBMC spontaneous proliferation (Azimi et al. 1999). Therefore, Hu MiK β 1, a monoclonal antibody which block IL-15, is hypothesized to inhibit spontaneous proliferation and immune overreaction in HAM/TSP, leading to an improvement of chronic inflammation.

28.7 Concluding Remarks

In HAM/TSP, localization of HTLV-1 in CD4+ cells in the CNS may lead to the production of cytokines/chemokines that are thought to adversely effect resident cells in the CNS (bystander hypothesis) resulting in neurodegeneration of the long tract. Histological studies in HAM/TSP patients have demonstrated that although CD4+ cells are predominantly infected with HTLV-1, other cells may also harbor HTLV-1 including astrocytes and glia. All of these cells could potentially express HTLV-1 antigens (processed HTLV-1 peptides in association with HLA class I molecules) and be seen as targets by inflammatory, HTLV-1 specific CTLs. Recognition by CTLs could lead to a cascade of events that produce toxic products within the CNS associated with death or dysfunction of important neuronal components leading to clinical symptoms of HAM/TSP.

Although it has been known for over 30 years that HTLV-1 induces a chronic central nervous system dysfunction, the mechanisms associated with HTLV-1 infection still

remains unclear. New factors for the development of HAM/TSP have recently been demonstrated. Differences between HAM/TSP patients and ACs include host HLA, HTLV-1 genomic integration site, HTLV-1 Tax subtype, HTLV-1 PVL, HTLV-1 gene expression rate, adhesion or migration ability of infected CD4+ cells, and CTL activating factors (SAP in CD8+ cells and IL-15 in MPs). While high levels of HTLV-1 Tax expression has not been demonstrated to explain the strong virus-specific immune response seen in affected tissue, elevated proliferation of CD4+ and CD8+ cells in vivo may explain the continuous Tax expression that may serve to drive strong T cell responses. While HTLV-1-specific CTLs have been thought to play a role in decreasing HTLV-1 PVL, these same cells may be activated by MPs and cause immunopathology in the CNS. It is clear that further information regarding the frequency, distribution, activity and function of CTLs in the CNS of HAM/TSP as well as that of other HTLV-1 associated disorders will be needed to better understand the role that this virus plays in these diseases.

28.8 Review Questions

- Which level of spinal cord is predominantly affected in patients with HAM/TSP?
 - Cervical level
 - Thoracic level*
 - Lumbar level
- Which cells are infiltrated in the chronic phase of HAM/TSP?
 - CD4 positive T cells*
 - CD8 positive T cells
 - B cells
- Which part is mostly degenerated in spinal cord in patients with HAM/TSP?
 - Anterior column
 - Lateral column*
 - Posterior column
- Which is most unusual symptom in patients with HAM/TSP?
 - Spastic paralysis
 - Higher brain dysfunction*
 - Bladder and rectal disturbance
- Which is most endemic area of HTLV-I?
 - North America
 - Caribbean*
 - Europe
- Which is inappropriate infection route of the HTLV-I?
 - Transmission through breast milk
 - Sexual contact
 - Droplet infection*

7. Which inflammatory disease is shown to be associated with HAM/TSP?
 - (a) *Sjogren syndrome*
 - (b) Atopic dermatitis
 - (c) Crohn's disease
8. Which adhesion molecules is mostly detected in the spinal cord of HAM/TSP?
 - (a) ICAM-1
 - (b) VCAM-1
 - (c) *ICAM-1 and VCAM-1*
9. How much is the frequency of the development of HAM/TSP in HTLV-I carrier?
 - (a) *Less than 5 %*
 - (b) 10–20 %
 - (c) More than 50 %
10. Which cytokine is mostly detected at degenerated spinal cord in HAM/TSP?
 - (a) TNF-alpha
 - (b) IL-1 beta
 - (c) *IFN-gamma*

Abstract

Viral encephalitis is a rare disorder by caused by numerous viruses. Herpes simplex virus 1 causes more cases of encephalitis than other viruses. Additional viruses that can cause encephalitis are Varicella zoster virus, human cytomegalovirus, and several RNA viruses, including West Nile virus. These viruses have novel properties with respect to epidemiology, pathogenesis, clinical features and therapeutic approaches. All viruses that cause encephalitis have the ability to induce inflammation in brain tissue (cerebral edema). Encephalitis, in general, destroys neurons, causes bleeding in the brain (intracerebral hemorrhage), and brain damage. This chapter discusses the clinical features, productive infection, latent infection, epidemiology, pathogenesis, and animal models used to examine encephalitis. Furthermore, therapeutic strategies used to treat encephalitis for many of the viruses that can cause encephalitis are discussed. The major antiviral agents used to treat herpes encephalitis are acyclovir, valacyclovir, ganciclovir, cidofovir and foscarnet. For each of these drugs, we discuss the pharmacology, mechanism of action and adverse effects.

Keywords

Arboviruses • Herpesviruses • Inflammation • Viral infection of brain

29.1 Introduction

Encephalitis is an acute inflammation of the brain that can be caused by several viruses. Members of the Herpesviridae family cause most cases of encephalitis: for example, herpes simplex virus 1, varicella zoster virus, human cytomegalovirus, human herpesvirus 6, and Epstein Barr virus. In addition, several arboviruses, including West Nile virus, Saint Louis encephalitis, Eastern encephalitic virus,

Western equine encephalitic virus, La Crosse virus, and Colorado Tick Fever can cause encephalitis. Arboviruses are RNA viruses transmitted by arthropod vectors: mosquitoes, ticks, and sandflies for example. Additional RNA viruses that are not arboviruses can cause encephalitis, and these include Mumps virus, Measles, Rubella, Henipah, and Enteroviruses. The only other DNA virus known to cause encephalitis is the JC virus, which belongs to the Polymavirinae subfamily. Although these viruses have very different biological properties, they can all enter the central nervous system, replicate in neurons, promote inflammation in the brain, and consequently cause encephalitis. In general, patients with encephalitis suffer from fever, headache, seizures, and photophobia. Less commonly, stiffness of the neck can occur with rare cases of patients also suffering from stiffness of the limbs, slowness in movement and clumsiness depending on which part of the brain is involved. Encephalitis is not a typical outcome of viral infections, but it is life threatening and

difficult to treat. This chapter discusses the properties of viruses that cause encephalitis, how they cause clinical disease, and available therapeutic that are available.

29.2 Herpesvirus Mediated Encephalitis

The Herpesviridae family is divided into three subfamilies: α -herpesvirinae, β -herpesvirinae, and γ -herpesvirinae. Each subfamily member contains a human virus that can cause encephalitis and these viruses are discussed below.

29.2.1 Herpes Simplex Virus 1 (HSV-1) Mediated Encephalitis

29.2.1.1 Epidemiology of HSV-1

Approximately 90 % of the population is infected with herpes simplex virus 1 (HSV-1), and at least 10 % with HSV-2 (Whitley 1997; Nahmias and Roizman 1973). Humans are the only natural reservoir for this infection and no vector is needed for virus transmission (Stanberry 2004). HSV-1 primary infection occurs mainly in childhood and HSV-2 infection occurs predominantly in sexually active adolescents and young adults. HSV encephalitis (HSE) is the most common causative agent of encephalitis of the herpesviruses.

29.2.1.2 Pathogenesis and Clinical Symptoms of HSE

HSV is the most commonly identified cause of acute, sporadic viral encephalitis in the U.S. accounting for 10–20 % of all cases (Corey 2005). It is estimated that there are approximately 2000 new diagnosed HSE cases per year in the U.S. There are peaks at 5–30 years of age, and at more than 50 years of age. Since the 1940s, HSV-1 and HSV-2 have been implicated in the causation of acute necrotizing encephalitis in infants, children and adults. Encephalitis due to HSV 2 in newborn infants is a widespread disease in the brain and commonly involves a variety of other organs in the body including the skin, eyes and lungs (Stanberry et al. 2004). HSE is typically associated with necrotic cell death resulting from virus replication and inflammatory changes secondary to virus-induced immune response (DeBiasi et al. 2002). However, there is not a perfect correlation between virus burden in the brain and the severity of histological changes and neurological symptoms. Deficiency of a cellular gene, UNC-93B, was identified in a family that had a high incidence of encephalitis (Casrouge et al. 2006). The UNC-93B gene apparently plays a role in interferon signaling indicating the importance of controlling virus replication in the CNS of infected individuals.

Two recognizable groups of symptoms are seen in most patients. There are nonspecific clinical symptoms that include fever, headache, meningeal irritation, nausea, vomiting,

confusion, generalized seizures, and alteration of consciousness. The second group of changes is referred to as focal necrosis of the orbitofrontal and temporal cortexes and the limbic system, and includes anosmia, memory loss, peculiar behavior, speech defects, hallucinations (particularly olfactory and gustatory) and focal seizures. There is rapid progression in some cases with the appearance of reflex asymmetry, focal paralysis, hemiparesis and coma. Cerebral edema contributes to these symptoms and plays an important role in the outcome (Stanberry et al. 2004).

HSE is characterized by severe destruction of temporal and frontal lobe structures, including limbic mesocortexes, amygdala, and hippocampus. Without antiviral therapy, the mortality rate is as high as 70 %; but even after antiviral therapy 20 % of these patients die. Despite early treatment, chronic progressive tissue damage in magnetic resonance imaging (MRI) can be found up to 6 months following the onset of symptoms. Approximately 2/3 of HSE cases occur because of reactivation from latency (Yamada et al. 2002), which explains why there is high morbidity and long-term complications despite antiviral treatment (Lahat et al. 1999; McGrath et al. 1997; Skoldenberg 1991).

29.2.1.3 Summary of Productive Infection

HSV-1 and HSV-2 are double stranded DNA viruses with a genome size of 152 kb, and they encode at least 84 proteins. Binding and entry of HSV-1 into permissive cells is mediated by viral proteins interacting with cellular receptors (Spear 1993). After uncoating, the viral genome is present in the nucleus and viral gene expression ensues. HSV gene expression is temporally regulated in three distinct phases: immediate early (IE), early (E), or late (L) (Honess and Roizman 1974). IE gene expression does not require protein synthesis and is stimulated by VP16 (O'Hare 1993). In general, proteins encoded by IE genes regulate viral gene expression, and as such are important for productive infection. E gene expression is dependent on at least one IE protein, and generally E genes encode nonstructural proteins that control viral DNA synthesis. L gene expression is maximal after viral DNA replication, requires IE protein expression, and L proteins comprise the virion particle.

29.2.1.4 Summary of Latent Infection

Acute infection is typically initiated in mucosal epithelium, and then HSV-1 establishes latency in sensory neurons located in trigeminal ganglia (TG) or sacral dorsal root ganglia. Despite a vigorous immune response during acute infection, latency is established. As many as 20–30 % of sensory neurons are latently infected [reviewed in (Jones 2003; 1998)]. As a consequence of primary infection, HSV-1 genomic DNA is also present in the central nervous system (CNS) of a significant proportion of the adult human population (Fraser et al. 1981).

The latency associated transcript (LAT) is abundantly transcribed in latently infected neurons [reviewed in (Jones 2003; 1998)]. Mice, rabbits, or humans latently infected with HSV-1 express LAT. In productively infected cells or latently infected rabbits, an 8.3 kb transcript is expressed that has the same sense as LAT. Splicing of the 8.3 kb transcript yields an abundant 2 kb LAT and an unstable 6.3 kb LAT. The majority of LAT is not capped, is poly A-, appears to be circular, and is designated as a stable intron. In small animal models, LAT is important but not required for the latency-reactivation cycle [reviewed in (Jones 2003; 1998)]. The first 1.5 kb of LAT coding sequences are important for reactivation from latency. A study by (Umbach et al. 2008) concluded LAT is a micro-RNA (miRNA) precursor that encodes four miRNAs plus two within LAT promoter sequences. The various LAT encoded micro-RNAs inhibit expression of key viral transcriptional regulatory proteins (ICP4 and ICP0) and the neurovirulence protein ICP34.5 (Tang et al. 2008; 2009). The miRNAs that are abundantly expressed during latency do not appear to be essential for latency using a mouse model of infection (Kramer et al. 2011).

LAT interferes with apoptosis in transiently transfected cells, and in TG of infected rabbits or mice (Jones 2003). Inhibiting apoptosis may be the most important function of LAT because two anti-apoptosis genes, the bovine herpesvirus 1 LAT homologue (Mott et al. 2003; Perng et al. 2002) and the baculovirus IAP gene (Jin et al. 2005) restores wild-type levels of spontaneous reactivation to a LAT null mutant. Two additional small RNAs (s-RNAs) encoded within the first 1.5 kb of LAT coding sequences (Peng et al. 2008) inhibit apoptosis as well as productive infection (Shen et al. 2009). These LAT s-RNAs are not miRNAs because they lack Dicer cleavage sites and a mature miRNA band that migrates between 21–23 nucleotides is not detected.

29.2.1.5 Animal Models for Studying HSE

HSE occurs in a certain percentage of mice or rabbits following infection. The frequency of HSE in experimental infections is dependent on the pathogenic potential of HSV-1, and the mouse strain used for experimental infection. For HSE to occur after ocular infection, the virus must enter the TG, and then spread to the CNS, or the virus directly gains access into the brain via the optic nerve. Models have also been developed in which HSV is directly inoculated into the brain. In this model, transport from the peripheral tissue → peripheral nervous system → CNS is not important. Thus, viral genes necessary for neuronal transport and spread are not as important if the brain is inoculated.

Viral genes necessary for productive infection, inhibiting apoptosis, or inhibiting immune recognition play a significant role in the potential of HSV to initiate encephalitis. Innate immune responses play a significant role in lethal encephalitis because HSV-1 interactions with toll-like receptor 2 contributes

to HSE (Kurt-Jones et al. 2004). LAT, although not important for productive infection, enhances the frequency of encephalitis in male Balb/C mice (Jones et al. 2005). These studies add support to the concept that viral and host factors regulate the frequency of HSE.

29.2.2 Varicella Zoster Virus (VZV) Induced Encephalitis

29.2.2.1 Epidemiology of VZV

Humans are the only known reservoir for VZV, and VZV is a ubiquitous human pathogen. A serologic study of 1201 US military trainees indicated that 95.8 % of the population has been exposed to virus (Jerant et al. 1998). Chickenpox is common in childhood and affects both genders equally as well as people of all races. VSV is spread by droplet or airborne transmission and is highly contagious. Primary infection produces varicella (chickenpox), after which VZV becomes latent in neurons of TG, cranial nerve, dorsal root, and autonomic ganglia along the entire neuro-axis. Reactivation can occur decades later resulting in zoster (shingles). The details of latency and neuropathogenesis are presented below.

29.2.2.2 Clinical Features of VZV

Acute VZV infection leads to chickenpox, which results in an extensive vesicular rash (Abendorth and Arvin 2000). Chickenpox in the immunocompetent child is mostly benign and associated with lassitude and a temperature of 100–103 °F for 1–2 days. Other symptoms include malaise, itching, anorexia, weakness and exhaustion, which gradually resolve as the illness improves. The hallmark of chickenpox is the skin manifestations that consist of maculopapules, vesicles and scabs in varying stages. In general, immunocompromised children have more lesions. Although chickenpox is usually a mild disease, there are exceptions. For example, an epidemic of 292 cases of chickenpox occurred in rural India resulting in 3 deaths (Balraj and John 1994). In the United Kingdom, about 25 people die from chickenpox every year, in part because VZV vaccination is not mandatory (Rawson et al. 2001). VZV vaccine effectively prevents varicella; however breakthrough varicella and virus reactivation can still occur [reviewed by (Arvin and Gershon 1996)].

With chickenpox, the most frequent organ affected other than the skin is the CNS (Liesegang 1999). The neurologic abnormalities are often seen as acute cerebellar ataxia or encephalitis. Encephalitis is the most serious complication of chickenpox and it can be life threatening in adults. It occurs in 0.1–0.2 % of patients with chickenpox (Johnson and Milbourn 1970).

Herpes zoster is characterized by a unilateral vesicular eruption with a dermatome distribution and affects up to one mil-

lion people in the United States each year, reviewed in (Gilden et al. 2007). Since VZV is latent in most ganglia, herpes zoster can occur nearly anywhere on the body. The most common sites are the thoracic and in the cutaneous distribution of the ophthalmic branch of the trigeminal nerve. Postherpetic neuralgia (pain that persists more than 30 days after the onset of rash or after cutaneous healing) is the most serious complication in immunocompetent patients and generally occurs in patients more than 60 years old. Acute retinal necrosis caused by VZV occurs occasionally in immunocompetent patients although more recent reports have focused on ocular disease in HIV-infected patients. In HIV-infected patients, the lesions rapidly increase in size and coalesce. These lesions respond poorly to antiviral therapy and almost inevitably cause blindness in the involved eye. Retinitis is less aggressive in immunocompetent patients and can often be treated with antiviral therapy such as acyclovir. Neurologic complications associated with zoster are diverse, including motor neuropathies of the cranial and peripheral nervous system, encephalitis, meningoencephalitis, myelitis and Guillain-Barre syndrome (Liesegang 1999). Extracutaneous sites of involvement include the CNS as shown by meningoencephalitis or encephalitis. The clinical symptoms are similar to those of other viral infections of the brain. Involvement of the CNS with cutaneous herpes zoster is probably more common than recognized clinically. Classically, VZV infection involves dorsal root ganglia. Motor paralysis can occur as a consequence of the involvement of the anterior horn cells, in a manner similar to that encountered with polio. These patients may have severe pain. Herpes zoster in the immunocompromised patient is more severe than in the normal person but even in these patients disseminated herpes zoster is rarely fatal. Following a zoster outbreak, VZV can spread to blood vessels of the brain, leading to vasculopathy, particularly in immunocompromised patients.

Therapy for herpes zoster is aimed at accelerating healing, limiting the severity and duration of acute or chronic pain, and reducing complications associated with the infection. In patients who are immunocompromised, therapy should be aimed at reducing the risk of viral dissemination. Acyclovir, valacyclovir and famciclovir are all used in the U.S. for the treatment of herpes zoster. Acyclovir is approved in the U.S. for the treatment of both chickenpox and herpes zoster in the normal host. Oral acyclovir therapy in normal children, adolescents and adults shortens the duration of lesion formation by about a day, reduces the total number of new lesions by about 25 % and reduces many of the symptoms in about one-third of patients (Snoeck et al. 1999; Gnann and Whitley 2002).

29.2.2.3 Summary of Productive Infection and Latency

VZV contains many genes similar to HSV-1 suggesting they are functional homologues. Thus, the general steps during productive infection are similar for VZV and HSV-1, and

will not be discussed in detail. In contrast to HSV-1, VZV infectious virus produced during productive infection is tightly cell associated making it difficult to obtain high yields of virus.

VZV appears to be latent only in ganglia and viral genomes are primarily found in sensory neurons. Analysis of latent VZV is restricted to human ganglia obtained at autopsy. Based on *in situ* hybridization (ISH) studies combined with sequencing, four transcripts corresponding to VZV genes 21, 29, 62, and 63 have been identified in latently infected human ganglia (Gilden et al. 2007). A monospecific polyclonal antiserum directed against VZV ORF 63 protein detected this protein in the cytoplasm of neurons [reviewed in (Mitchell et al. 2003)]. These VZV proteins are primarily in the nucleus during productive infection (zoster), suggesting that the cytoplasmic location might maintain VZV in a latent state. In contrast to HSV-1, VZV does not appear to encode a LAT that is abundantly expressed during latency. Several independent studies have demonstrated that T cells, CD8⁺ T lymphocytes in particular, are crucial for controlling HSV infection in sensory ganglia (Nash et al. 1987; Simmons et al. 1992). A persistent cell-mediated immune response occurs in TG during HSV-1 latency, and that CD8⁺ as well as CD4⁺ T lymphocytes reside in TG and inhibit reactivation from latency long after acute infection is over (Nash et al. 1987; Simmons and Tschärke 1992; Simmons et al. 1992; Khanna et al. 2003; Liu et al. 1996, 2000a, b, 2001; Prbhakaran et al. 2005). In sharp contrast, persistent infiltration of lymphocytes in human or macaque TG latently infected with human VZV (Verjans et al. 2007) or simian VZV (Ouwendijk et al. 2013) does not occur. However, infiltration of lymphocytes does occur in TG when simian VZV reactivates from latency (Ouwendijk et al. 2013).

29.2.2.4 Neurological Disorders Associated with VZV

In general, neurological diseases occur as a result of reactivation from latency. The neurological complications after VZV reactivation are serious and can be life-threatening. VZV is the causal agent in 29 % of 3231 cases of encephalitis, meningitis, and myelitis, and the most common cause of encephalitis in patients over the age 65 (Rantalaiho et al. 2001). More than 500,000 Americans develop zoster (severe dermatomal distribution pain and rash) every year. Zoster is frequently followed by postherpetic neuralgia (pain that persists for months and often years after the rash disappears), myelitis, or unifocal or multifocal vasculopathy. Many cases of VZV vasculopathy, myelitis, and polyneuropathy occur in the absence of rash. Since VZV causes a wide spectrum of neurological disorders, testing for VZV DNA and antibody in cerebrospinal fluid (CSF) should be routinely performed. Proper diagnosis is critical because antiviral treatment can be curative, even after weeks to months of chronic VZV infection.

Reactivation of latent VZV in dorsal root ganglia results in a localized cutaneous eruption termed “herpes zoster” (or shingles). The annual incidence is about 1.5–3.0 cases per 1000. Zoster occurs during the lifetime of 10–20 % of all persons (Liesegang 1999). The epidemiology of herpes zoster differs from that of chickenpox. Decreasing virus-specific cell-mediated immune responses, which occur naturally as a result of aging or from immunosuppressive illness or medical treatments, increase the risk of shingles (Gnann and Whitley 2002). Most patients who develop herpes zoster have no history of exposure to other persons with VZV infection at the time of the appearance of lesions. Over 90 % of adults in the U.S. have serologic evidence of VZV infection and are at risk for herpes zoster. Patients with cancer, those receiving immunosuppressive agents and organ-transplant recipients are thus at an increased risk of shingles. Furthermore, individuals who are positive for human immunodeficiency virus also develop herpes zoster at a higher frequency than those who are negative (Liesegang 1999).

29.2.2.5 Potential Models to Study VZV Neuropathogenesis

Unlike HSV-1, VZV does not reactivate from ganglia after experimental infection of primates or rodents. However, after footpad inoculation of rats with VZV, the protein encoded by gene 63 can be detected in lumbar ganglia 1 month after infection (Debrus et al. 1995). Viral protein is also detected in neurons, both in the nuclei and cytoplasm of infected cells. An independent study using the same rat model detected VZV gene 63 DNA in 5–10 % of neurons and VZV RNA in neurons and non-neuronal cells (Kennedy et al. 1999). Simian varicella virus may also be a valuable model to study the pathogenesis of varicella virus-host interactions. Finally, VZV infection of humanized immuno-deficient mice (SCID-hu) has provided new information about viral genes that regulate viral growth and pathogenesis (Ku et al. 2005).

29.2.3 Human Cytomegalovirus (HCMV) Induced Encephalitis

29.2.3.1 Epidemiology of HCMV

HCMV is widely distributed among humans from developed and industrial nations as well as isolated aboriginal groups (Pass 1995). The prevalence of HCMV increases with age in every group that has been studied. In general, prevalence is greater and acquired earlier in life in developing countries, and in lower socioeconomic sections of developed countries (Pass 2001).

29.2.3.2 Clinical Features of HCMV

Although HCMV acute infection is usually asymptomatic in patients with intact immune systems, it is a common opportunistic pathogen in immunocompromised patients.

In HIV-infected individuals, HCMV disease appears to be due to reactivation of the latent virus. The clinical manifestations of HCMV disease are generally seen when the CD4⁺ T-lymphocyte count falls below 100 cells/ml. Retinitis is perhaps the most well known disease associated with this infection. Other features associated with infection include gastro-intestinal disease, pneumonitis and neurologic disease. HCMV is associated with various neurologic infections in persons infected with HIV, particularly inflammation of the ventricle accompanied by encephalitis (ventriculoencephalitis) and ascending polyradiculopathy (disease or injury involving multiple nerve roots). Ventriculoencephalitis usually occurs in advanced HIV infection of patients with a prior HCMV diagnosis. Polyradiculopathy is the most common CNS infection caused by HCMV and is characterized by urinary retention and progressive bilateral leg weakness. Clinical symptoms generally progress over several weeks to include loss of bowel and bladder control, and paralysis. A spastic myelopathy has been reported and sacral paresthesias may also occur. The CSF often shows a greater than normal number of cells, less than normal content of glucose, and elevated protein levels (Cheung and Teich 1999; Cheeseman et al. 2004).

29.2.3.3 Summary of Virus Lifecycle

HCMV is a β -herpesvirinae subfamily member that is an important causative agent of congenital disease, and a significant opportunistic infection (Knipe and Howley 2001). Like other herpesviruses, HCMV is a large DNA virus that is estimated to encode approximately 165 genes. In contrast to HSV-1, HCMV exhibits a restricted host range in cell culture. Primary differentiated fibroblasts show the greatest susceptibility to infection. As with other herpesvirus members, HCMV immediate early genes regulate viral transcription, and inhibit cellular responses to infection (apoptosis and interferon induction for example).

29.2.3.4 Pathogenesis and Persistence of HCMV

Unlike HSV-1 and VZV, HCMV does not establish latency in the nervous system. Myeloid-lineage hematopoietic cells (granulocytes, macrophages, and dendritic cells for example) are important targets for lifelong latency. It is now well established that one site of HCMV latency in vivo is cells of the myeloid lineage including CD14⁺ monocytes and their CD34⁺ progenitors, reviewed in (Poole et al. 2014). Low passage HCMV strains (Toledo and FIX for example) can efficiently establish latency in CD34⁺ cells whereas strains extensively passaged in cell culture (AD169 and Towne) do not because the low passage strains contain additional genes (UL133–UL138). The UL138 ORF is required for HCMV to establish and maintain a latent infection in CD34⁺ hematopoietic progenitor cells infected in vitro (Goodrum et al. 2007).

The UL138 protein localizes to the Golgi apparatus and a mutant that expresses the UL138 transcripts, but not the protein, has an impaired loss of latency phenotype (Petrucelli et al. 2012), which raises the possibility that additional viral genes located between UL133-UL138 are important for latency.

29.2.3.5 HCMV Induced Encephalitis

Approximately, two out three newborn children that have symptomatic congenital CMV infection have CNS involvement (Bopanna et al. 1992). CNS pathology includes microcephaly, elevation of cerebrospinal fluid protein, and neurologic abnormalities (poor feeding, lethargy, or generalized hypotonia for example). Cranial computed tomography scans are abnormal in 75% of symptomatic newborns, with the most common abnormality being periventricular calcification (Bopanna et al. 1997). Fortunately, only 5–10% of newborns with congenital HCMV infection are symptomatic.

29.2.4 Human Herpesvirus 6 (HHV-6) Induced Encephalitis

Like HCMV, HHV-6 is a β -herpesvirinae subfamily member. HHV-6 was originally isolated from peripheral blood leukocytes of patients with lymphoproliferative disease (Salahuddin et al. 1986) and is now recognized as the causative agent of exanthem subitum, also referred to as roseola, (Yamanishi et al. 1988). Following acute infection, HHV-6 can persist in several different cell types, including peripheral lymphocytes. Since the receptor for HHV-6 (complement-regulatory trans membrane protein CD46), is widely expressed in humans, HHV-6 has the potential to infect many cell types (Santoro et al. 1999).

HHV-6 DNA and certain viral transcripts, but not viral antigens, have been detected in brains of healthy immunocompetent humans suggesting the virus is latent, reviewed in (Reynaud and Horvat 2013). Several studies have concluded that HHV-6 can cause encephalitis (Reynaud and Horvat 2013; Yoshikawa and Asano 2000; Nagasawa et al. 2007). The clinical symptoms associated with HHV-6 induced encephalitis appear to be distinct relative to other herpesviruses because there is a cluster of convulsions during the eruptive stage. The features of HHV-6 induced encephalitis are summarized below (Nagasawa et al. 2007). First, primary infection occurs in a normally developing infant followed by the initial convulsion with the onset of encephalopathy occurring on the second day of febrile illness. Following the first convulsion, consciousness is disturbed. Frequent convulsions occur within one day after fever is resolved, which is associated with the onset of exanthem subitum (eruptive stage). Conversely, “typical” encephalitis that features convulsions and severe disturbance of consciousness has been described following initial stages of disease: then a slow recovery ensues.

29.2.5 γ -Herpesvirus Induced Encephalitis

Although Epstein Barr Virus (EBV) can cause encephalitis (Fujimoto et al. 2003; Hussain and Hussain 2013; Bhatti et al. 1990), it is a relatively rare event when compared to HSV-1 or CMV. Since EBV acute infection is primarily initiated in pharyngeal tonsils (infectious mononucleosis) and then establishes a latent infection in B cells, reviewed by (Young and Rickinson 2004; Cohen 2000), it is not surprising that encephalitis occurs only rarely.

29.2.6 Therapeutic Agents Available to Treat Herpesvirus Infections and Encephalitis

29.2.6.1 Acyclovir

Acyclovir is an acyclic guanine nucleoside analog that lacks a 3'-hydroxyl on the side chain. Acyclovir was the first drug clearly demonstrated to be effective against herpes simplex virus infections (Wagstaff et al. 1994). Acyclovir selectively inhibits viral DNA synthesis because it is preferentially activated in virally infected cells. Cellular uptake and initial phosphorylation are facilitated by the herpes virus thymidine kinase. The affinity of acyclovir for HSV thymidine kinase is about 200-fold greater than for the mammalian enzyme. Cellular enzymes subsequently convert the monophosphate to acyclovir triphosphate. Acyclovir triphosphate is present in 40- to 100-fold higher concentrations in HSV-infected than in uninfected cells, and competes for endogenous deoxyguanosine triphosphate. The triphosphate competitively inhibits viral DNA polymerases to a much greater extent than cellular DNA polymerases. The triphosphate is also incorporated into viral DNA where it acts as a chain terminator as a result of the lack of the 3'-hydroxyl group. The terminated DNA template containing acyclovir binds the enzyme and leads to irreversible inactivation of the DNA polymerase (Wagstaff et al. 1994; Scholar 2000). The oral bioavailability of acyclovir is poor and ranges from 10–30%. The drug is poorly protein bound but is widely distributed throughout body fluids and tissues including the cerebrovascular fluid. It is primarily excreted unchanged in the urine (Wagstaff et al. 1994).

Acyclovir is useful for treating infections caused by HSV, herpes zoster and for VZV infections (Whitley and Roizman 2001). Acyclovir is the major therapy used for HSV encephalitis. It should be given intravenously at a dose of 10 mg/kg every 8 h for 14–21 days. It is usually well tolerated with few side effects. Although HCMV is relatively resistant to acyclovir, some cytomegalovirus infections have responded marginally to large doses of acyclovir and it seems to be effective for the prophylaxis of cytomegalovirus infections in immunocompromised patients. Epstein-Barr virus is not sensitive to acyclovir and clinical infections do not respond to the drug.

Oral acyclovir is recommended for the treatment of VZV infection (chickenpox) in patients over 13 years-of-age who are otherwise healthy, children over 12 months of age with a chronic cutaneous or pulmonary condition, or receiving long-term salicylate therapy, and in children receiving short or intermittent courses of aerosolized corticosteroids. Intravenous acyclovir should be used for treatment of varicella infection in immunocompromised children, including those receiving high doses of corticosteroids. In general, acyclovir is the most effective agent for the treatment of infections caused by VZV (Snoeck et al. 1999).

Parenteral acyclovir is the drug of choice for the treatment of initial and recurrent mucosal or cutaneous herpes simplex infections in immunocompromised patients and for the treatment of disseminated, neonatal, encephalitic, and severe first episodes of genital herpes simplex infections in immunocompetent patients (Whitley 1997). Intravenous acyclovir should also be used for severe diseases such as encephalitis (Brady and Bernstein 2004). Acyclovir is generally well tolerated whether administered topically, orally or by the intravenous route. Gastrointestinal disturbances, headache, and rash may occur. Renal dysfunction due to crystalline nephropathy is more likely with IV administration, rapid infusion, and in patients in the dehydrated state and with underlying renal disease and large doses. CNS effects are rare but include encephalopathy, tremors, hallucinations, seizures, and coma. Due to an elevated pH, intravenous administration may also cause phlebitis and inflammation at sites of extravasation (Wagstaff et al. 1994).

29.2.6.2 Valacyclovir

Valacyclovir is an ester prodrug of acyclovir. It provides significantly better oral bioavailability compared to acyclovir. This advantage results in substantially higher serum concentrations than is possible with oral acyclovir. In addition, fewer daily doses are required with valacyclovir (Curran and Noble 2001). Valacyclovir and famciclovir are alternative drugs used for the treatment of HSV encephalitis (Griffiths 1995; Stanberry et al. 2004; Stanberry et al. 2002).

After oral administration and absorption, valacyclovir is converted to acyclovir which is the active antiviral component of valacyclovir. The antiviral activity and mechanism of action of valacyclovir is identical to that of acyclovir (Perry and Faulds 1996). The oral bioavailability of valacyclovir is significantly greater than that of acyclovir. Oral administration of valacyclovir results in plasma acyclovir concentrations comparable to those observed with intravenous acyclovir.

Valacyclovir is effective for the treatment of herpes zoster (shingles), for the treatment of initial and recurrent episodes of genital herpes, and for suppression of recurrent genital herpes in immunocompetent and HIV-infected patients. It is also indicated for the reduction of transmission of genital herpes in immunocompetent individuals, and for the treatment of cold

sores. Valacyclovir appears to be equally effective in treating herpes zoster and recurrent genital herpes in immunocompetent adults. Valacyclovir has shown efficacy in the prophylaxis of cytomegalovirus infections in transplant patients (Perry and Faulds 1996).

Like acyclovir, valacyclovir is a well-tolerated drug. The most common adverse effects of valacyclovir are headache and nausea. Other adverse effects associated with valacyclovir administration include vomiting, weakness, dizziness, and abdominal pain. Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome has also been reported in a few patients after high doses of valacyclovir as has confusion, hallucinations and nephrotoxicity (Perry and Faulds 1996; Curran and Noble 2001).

29.2.6.3 Famciclovir

Famciclovir is an oral prodrug of the antiviral agent penciclovir. Famciclovir lacks intrinsic viral activity and this drug owes its activity to formation of penciclovir. Penciclovir is an acyclic guanine nucleoside analog. Penciclovir and its prodrug famciclovir are chemically similar to acyclovir. Penciclovir differs structurally from acyclovir only by the presence of an additional hydroxyl group. Famciclovir is the diacetyl 6-deoxy analogue of penciclovir. The mechanism of antiviral activity of penciclovir is similar to acyclovir. Both drugs inhibit viral DNA synthesis (Scholar 2000). Penciclovir is rapidly and selectively phosphorylated in virus-infected cells by viral thymidine kinase to the monophosphate and this is followed by further phosphorylation to the triphosphate, which is the active form of the drug. Over 90% of penciclovir triphosphate in virus cells is the (S)-enantiomer, a competitive inhibitor of DNA polymerases with respect to the natural substrate deoxyguanosine triphosphate (dGTP). Inhibition of the polymerase results in prevention of viral replication by inhibition of viral DNA synthesis. The R-enantiomer of penciclovir triphosphate has only minimal activity on viral DNA polymerases (Scholar 2000). In contrast to acyclovir triphosphate, which is an obligate DNA chain terminator, penciclovir triphosphate allows DNA chain extension owing to its free hydroxyl group; however, penciclovir appears at least as effective as acyclovir as an inhibitor of herpes virus DNA synthesis.

Famciclovir is rapidly converted to penciclovir in intestinal and liver tissue after oral administration. More than half of an oral dose of famciclovir is excreted in the urine as unchanged penciclovir. The plasma elimination half-life of penciclovir is about 2 h, similar to that of acyclovir; however, the intracellular half-life of penciclovir in herpes virus-infected cells is considerably longer than that of acyclovir.

Oral famciclovir is used for the treatment of immunocompetent patients with herpes zoster infections and for the treatment and suppression of recurrent genital HSV. It is also effective for the treatment of recurrent mucocutaneous her-

pes simplex in both immunocompetent and immunocompromised patients. Famciclovir is fairly well tolerated. Adverse effects include headache, dizziness, nausea, and diarrhea (Scholar 2000).

29.2.6.4 Ganciclovir

Ganciclovir is an acyclic guanine nucleotide analog with a structure similar to acyclovir but with an additional hydroxymethyl group on the acyclic side chain. It is inhibitory to all herpes viruses but is especially active against cytomegalovirus. Like acyclovir and penciclovir, ganciclovir inhibits viral DNA synthesis. Also like these other agents, the virus-induced enzyme to the monophosphate form first phosphorylates it intracellularly. Cellular enzymes catalyze further phosphorylation to the di and tri phosphates. Intracellular ganciclovir triphosphate concentrations are tenfold higher than those of acyclovir triphosphate and decrease much more slowly with an intracellular half-life of elimination greater than 24 h. These differences probably explain at least in part the greater activity of ganciclovir against HCMV and provide a rationale for single daily doses in suppressing HCMV infections. (Scholar 2000; Markham and Faulds 1994). Ganciclovir-triphosphate acts as an inhibitor and substrate for the cytomegalovirus DNA polymerase. Ganciclovir-triphosphate competitively inhibits the binding of deoxyguanosine triphosphate to DNA polymerase that results in the inhibition of DNA synthesis and termination of DNA elongation. Ganciclovir is incorporated into both viral and cellular DNA. It appears to limit viral DNA synthesis and packaging of viral DNA into infectious units.

The bioavailability of orally administered ganciclovir is quite low. In patients with normal renal function, the plasma half-life is about 2–4 h. Concentrations of ganciclovir in cerebrospinal fluid are lower than those in serum after intravenous administration (Markham and Faulds 1994). More than 90% of the drug is eliminated unchanged in the urine. The plasma half-life increases as creatinine clearance declines and may reach 28–40 h in patients with severe renal insufficiency. Ganciclovir is an effective antiviral agent for the treatment of serious life threatening or sight-threatening HCMV infections in immunocompromised patients. Intravenous ganciclovir, foscarnet or the combination of both are recommended for the treatment of HCMV neurological syndromes (Markham and Faulds 1994).

The dose limiting and most common adverse effects with intravenous and oral ganciclovir is bone marrow suppression (anemia, leukopenia, neutropenia and thrombocytopenia). These effects are usually reversible upon withdrawal of the drug. CNS side effects are less common and range in severity from headache to behavioral changes to convulsions and coma. Fever, edema, phlebitis, disorientation, nausea, anorexia, rash, and myalgias have also been reported with ganciclovir therapy (Markham and Faulds 1994).

29.2.6.5 Foscarnet

Foscarnet is an inorganic pyrophosphate analog that has antiviral activity against all herpes viruses and the human immunodeficiency virus. Foscarnet is a pyrophosphate analogue that acts as a noncompetitive inhibitor of many viral RNA and DNA polymerases as well as HIV reverse transcriptase (Chrisp and Clissold 1991). It is approximately 100 fold more effective against the herpes virus DNA polymerase than the cellular DNA polymerase- α ; however, some human cell growth suppression has been observed with high concentrations in vitro. Inhibition of DNA polymerase results in inhibition of pyrophosphate exchange which prevents elongation of the DNA chain (Scholar 2000). Similar to ganciclovir, foscarnet is a virostatic agent. Foscarnet is not a nucleoside and thus is not phosphorylated. It reversibly blocks the pyrophosphate-binding site of the viral DNA polymerase in a noncompetitive manner and inhibits cleavage of pyrophosphate from deoxynucleotide triphosphates.

The oral bioavailability of foscarnet is poor so intravenous therapy is needed to treat viral infections. It is fairly well distributed throughout the body with CSF levels averaging two-thirds of those in plasma. Foscarnet is taken up slowly by cells, and biotransformation of foscarnet does not occur. The drug is excreted mainly unchanged in the urine (Chrisp and Clissold 1991). Foscarnet is frequently used for treatment of HCMV retinitis and mucocutaneous acyclovir-resistant HSV infections. It may also be beneficial in other types of CMV or HSV infections (Wagstaff and Bryson 1994).

In contrast to ganciclovir, foscarnet is not associated with dose-limiting neutropenia, enabling it to be used in combination with zidovudine and other bone marrow suppressant drugs. Nephrotoxicity and hypocalcemia are the major dose-limiting toxicities. Renal toxicity can be minimized with adequate hydration. Changes in serum calcium and phosphate levels may be related to incorporation of the drug into bone. Other adverse effects of the drug include tremor, headache, fatigue, nausea, and vomiting. Some cases of penile and vaginal ulceration have also been reported.

29.2.6.6 Cidofovir

Cidofovir is an antiviral cytidine nucleotide analog with inhibitory activity against HCMV and other herpes viruses. Cidofovir is first converted to an active diphosphate form by cellular enzymes. Antiviral effects of cidofovir are due to inhibition of viral DNA polymerase by the diphosphate metabolite (Scholar 2000; Neyts and De Clercq 1994; Plosker and Noble 1999). The diphosphate probably interacts with DNA polymerase either as an alternate substrate (incorporation at the 3'-end or within interior of DNA chain) or as a competitive inhibitor (with respect to the normal substrate dCTP). Cidofovir inhibits HCMV DNA synthesis at intracellular concentrations 1000-fold lower than are

required to inhibit cellular DNA synthesis (Neyts and De Clercq 1994). For HSV-1 and HSV-2, corresponding concentrations are at least 50-fold lower.

Cidofovir has poor oral bioavailability (<5%) and is therefore administered intravenously. It has a long intracellular half-life that allows for a prolonged interval between maintenance doses. Cidofovir is excreted extensively by the kidneys and is eliminated almost entirely as unchanged drug in the urine (Plosker and Noble 1999). Intravenous cidofovir is well tolerated. The major treatment limiting toxicity of this drug is irreversible nephrotoxicity (Plosker and Noble 1999). Intravenous pre-hydration with normal saline and administration of oral probenecid must be used with each cidofovir infusion to lessen the effects on the kidney. Serum creatinine and urine protein must be monitored with each infusion and adjusted accordingly. Other adverse effects associated with its use are neutropenia and peripheral neuropathy (Plosker and Noble 1999).

Cidofovir, ganciclovir, and foscarnet are effective at treating HCMV disease, and are approved for use in the U.S. (Cheeseman et al. 2004; Cheung and Teich 1999). Antiviral therapy for esophagitis, enterocolitis, encephalitis, peripheral neuropathy, polyradiculoneuropathy and pneumonitis is usually treated with intravenous ganciclovir or foscarnet regimens similar to those used for retinitis. Patients with CNS or neurologic disease often respond best to combination therapy (Arribas et al. 1996).

29.3 Arboviruses

Arboviruses are a group of RNA viruses transmitted by arthropod vectors. Clinical symptoms occur between 3–15 days after exposure and typically consist of fever, headache, and malaise, reviewed in (Kuno and Chang 2005). Less frequently, life-threatening encephalitis and hemorrhagic fever can occur. Arboviruses are maintained in nature by cycling between a vector, (mosquitoes, ticks, sandflies, as well as other arthropods) that consumes the blood of vertebrates. Vertebrates that have their blood consumed act as the hosts, with each vector usually preferring the blood of a specific species, making those species the host. Transmission between the vector and the host occurs when the vector feeds on the blood of the vertebrate, consequently the virus establishes

infection in the salivary glands of the vector. High levels of infectious virus must be present in the blood of the host to allow transmission to the vector. If high levels of virus are not present in the host, viremia is not achieved and this infection is referred to as a “dead end host”, which cannot be transmitted back to the vector. Below is a discussion of the major arboviruses that pose a health threat to humans.

29.3.1 West Nile Virus (WNV) Induced Encephalitis

29.3.1.1 Summary of Virus Lifecycle and Virus Transmission

West Nile virus (WNV) is a member of the Flaviviridae family (Lindenback and Rice 2001), and is a small positive strand RNA virus that is approximately 11,000 bases long. Genomic RNA serves as a messenger RNA that is translated into a single polypeptide. This polypeptide is then cleaved into at least 10 discrete proteins by cellular proteases and a virally encoded serine protease. Three structural proteins (C, prM, and E) are produced from the polypeptide (Fig. 29.1). Seven non-structural proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5) are generated from the polypeptide. NS5 is the most conserved protein in the Flaviviridae family because this protein is the viral encoded RNA dependent RNA polymerase. The other non-structural proteins are not as well conserved suggesting they have virus-specific functions.

WNV has a broad range of antigenic variation and restriction-length polymorphisms indicating WNV has a highly variable genome. Strains from Africa, Europe, and the Middle East form a distinct group relative to strains isolated in India and the Far East (Price and O’Leary 1967). WNV is widely disseminated throughout Africa, Europe, the Middle East, and the Far East. During the summer of 1999, WNV was introduced to the east coast in the United States, and has since spread westward.

WNV can be readily grown in a variety of mammalian cell lines, and *Drosophila* cells (Lindenback and Rice 2001). In the wild, WNV is vectored by female mosquitoes of the genus *Culex*, and can infect a variety of small rodents and birds. In addition, WNV can infect soft and hard ticks under natural and experimental conditions. Almost all species of birds tested (wild species, chickens, and pigeons) develop viremia. During the recent US outbreak, a number of crows have been killed by

Fig. 29.1 Schematic of West Nile Virus genome. The various genes of the WNV genome are presented, and those comprising the non-structural proteins are denoted. For details, see text

the virus, which has been used to track virus spread (Anderson et al. 1999). Sporadic cases of naturally acquired infections can occur in horses, and these infections can lead to encephalitis. Bovine species do not develop viremia, but antibodies in cattle are prevalent. Finally, dogs are susceptible to infection, but low viremia levels preclude a significant role in virus transmission. Humans are a dead end host and human to human transmission is rare, but as described below infections can be serious.

29.3.1.2 Pathogenesis of encephalitis

The incubation period is 1–6 days, and the typical case is mild. Typical clinical features are fever, headache, backache, generalized myalgia, and anorexia. Rash occurs in about 1/2 of the cases, the rash is usually roseolar or maculopapular, and usually involves the chest, back, and upper extremities. The disease usually runs its course in 3–6 days, and is usually milder in children. WNV can also cause severe, potentially fatal neurological disease, including encephalitis, meningitis, paralysis, and anterior myelitis. Although neurons are the primary target of WNV infection, a hallmark of WNV encephalitis is the accumulation of inflammatory infiltrates extending from the meninges in the brain parenchyma. These infiltrates are primarily comprised of lymphocytes and macrophages (Kelley et al. 2003). Most cases of WNV induced encephalitis generally occur in older individuals.

29.3.1.3 Animal Models for Studying WNV Induced Encephalitis

Mice have been used extensively to examine virus host interactions, and to examine virus induced encephalitis. The adaptive immune response plays a crucial role in controlling WNV infections in mice, including encephalitis (Diamond et al. 2003; Shresta and Diamond 2004; Wang et al. 2003). WNV infection leads to a toll-like receptor 3 dependent inflammatory response, which promotes brain penetration of the virus, neuronal injury, and enhanced encephalitis (Wang et al. 2004). Since toll-like receptor 3 recognizes double stranded RNA and promotes innate immune responses, this was somewhat surprising. The innate immune response also protects against WNV induced encephalitis because when mice lacking the alpha/beta interferon receptor are infected with WNV an increase in the frequency of encephalitis is seen in mice (Samuel and Diamond 2005). With the availability of a number of knockout mice, future studies should lead to identification of additional cellular factors that regulate WNV induced encephalitis.

29.3.2 Other Arboviruses Associated with Encephalitis

In addition to WNV, there are several additional encephalitic viruses that are transmitted via an insect vector, reviewed in (Stahl et al. 2011). With respect to North and South America,

the notable arboviruses that cause encephalitis include Saint Louis encephalitis, Eastern encephalitic virus, Western equine encephalitic virus, La Crosse virus, and Colorado Tick Fever virus. In addition, there are several arboviruses that can cause encephalitis in other parts of the world, and these include Japanese encephalitis virus, Tick-borne encephalitis virus, and Toscana virus. Like WNV, these are RNA viruses.

29.3.3 Therapy

Currently there is no specific treatment for arboviruses. Treatment consists only of supportive and symptomatic care, including support of respiration, intravenous fluids and prevention of secondary infections. In addition, insect repellents and other antivectorial measures are used to reduce the incidence of human transmission.

29.4 Other Encephalitic Viruses

The final category of encephalitic viruses are non-herpesviruses that are not arbovirus members, reviewed in (Stahl et al. 2011). All viruses included in this category are transmitted via human to human and have no intermediate vector. The RNA viruses included in this category are Mumps virus, Measles, Rubella, Hendrix, and Enteroviruses. The only other DNA virus known to cause encephalitis is the JC virus, which belongs to the Polymavirinae subfamily.

29.5 Review Questions

1. What are the common non-specific symptoms of a patient in the early stages of encephalitis?
2. If you are a physician and you diagnose a patient with encephalitis, which virus family would you first expect and how would you treat these patients?
3. A patient who has been on vacation in a tropical setting exhibits signs of encephalitis, what family of viruses would you suspect to cause this disease? What is the logic for your choice?
4. What are the major differences between herpesviruses and arboviruses?
5. Can West Nile Virus be spread from human to human?
6. If you develop shingles and then develop headaches and other symptoms consistent with encephalitis, what virus might be the culprit?
7. There are three subfamily of herpesviruses? Which one would you suspect is the most common causative agent of encephalitis and why?

29.6 Answers

1. Patients in the early stages of encephalitis suffer from fever, headache, seizures, and photophobia. Less frequently, patients can also experience stiffness of the neck, stiffness of the limbs, slowness in movement, and clumsiness.
2. A member of the herpesviridae family would be expected. In particular, HSV-1, would be a reasonable guess because it causes encephalitis more frequently than other herpesviruses. Acyclovir or derivatives of acyclovir would be effective because this family of drugs inhibits the viral encoded thymidine kinase.
3. I would suspect arboviruses because they are frequently spread by insect bites, in particular mosquitoes.
4. Herpesviruses are large double stranded DNA viruses (>130,000 base pairs) that encode more than 80 viral proteins. Conversely, arboviruses are all RNA viruses that have a genome of approximately 10,000 bases that encode approximately 10 viral proteins. Transmission of arboviruses to humans is usually via an insect vector. In contrast, herpesviruses are spread via human to human spread; most common mechanism of spread is by aerosol and to a lesser extent by sexual transmission.
5. No. Human to human spread does not normally occur. Humans are considered to be a dead-end host. Birds commonly develop viremia and virus replication is high in birds.
6. Varicella Zoster Virus (VZV), the "Chicken Pox Virus". The rationale for this suspicion is many elderly suffer from VZV reactivation from latency, which frequently leads to chicken pox. When VZV reactivates from latency in the elderly, the virus may also enter the central nervous system where it can cause encephalitis.
7. ANSWER: Since α -herpesvirinae subfamily members establish a latent infection in sensory neurons, there ability to infect neurons is why they cause encephalitis more frequently. β - or γ -herpesvirinae subfamily members typically have a more restricted cell tropism and establish a latent infection in non-neural cells. Thus, they do not cause encephalitis as frequently as members of the α -herpesvirinae subfamily.

Abstract

AD is the most common form of elderly dementia and has no effective therapy. Clinical diagnosis is based on the evaluation of cognitive function and lab tests. Pathological diagnosis is based on post-mortem neuropathology, defined by three hallmarks: senile plaque, NFT, and neuronal cell loss. Senile plaque mainly consists of A β aggregates and serves as a focal point of astrocyte and microglial activation, while NFT contains hyperphosphorylated tau. A β is produced during the processing of APP by BACE and the γ -secretase complex that includes PS1. Both APP and PS1 are causative genes of AD, while apoE4 is a risk factor allele. The A β load in CNS is maintained by balancing its production and clearance, which is mediated by passive diffusion to blood stream, degradation by A β degrading enzymes (IDE and neprilysin), and microglial phagocytosis. A β production, deposition, and neurodegeneration are significantly regulated by astroglial and microglial activation via direct contact as well as secretion of a number of neurotoxins. Specific pro-inflammatory cytokines, chemokines, and excitotoxins have been characterized as mediators of neuroinflammation and neurotoxicity. Currently their specific roles in mediating the pathogenesis in AD are being explored. Those diverse studies are generating a large number of potential therapeutic targets for treating AD. Beneficial effects have been reported for anti-inflammatory drugs, such as NSAIDs, to treat glial inflammation and disease progression.

Keywords

Amyloid precursor protein (APP) • Apolipoprotein E (apoE) • β -amyloid peptide (A β) • β -amyloid precursor protein converting enzyme (BACE) • Insulin degrading enzyme (IDE) • Neurofibrillary tangle (NFT) • Oxidative damage • Presenilin-1 (PS1)

30.1 Introduction

Alzheimer's disease (AD) is the most frequent neurodegenerative disease and the most common cause of dementia. While AD affects multiple systems of the central nervous system (CNS), the classic and most frequent initial symptom is the loss of short-term memory that progresses to profound

cognitive failure. As initially observed by Alzheimer, brains of AD patients exhibit two hallmark neuropathological features: (1) senile plaques containing depositions of amyloid- β peptide (A β) and (2) neurofibrillary tangles (NFT) containing hyperphosphorylated microtubule-associated protein tau. Quantitative evaluation has revealed that in early stages of AD there is a significant loss of neurons in brain regions specifically involved in memory. Genetic studies have identified causative genes, amyloid precursor protein (APP), presenilin-1 (PS1), and presenilin-2 (PS2), which established that aberrant proteolytic processing of the APP leading to the formation of the A β 1-40 and 1-42 is primarily responsible for the pathogenesis of familial AD. However,

the mechanisms by which APP processing leads to senile plaque deposition, NFT formation, and neuronal cell death remain elusive. The objective of this chapter is to review the current understanding of these mechanisms and the role played by neuroimmune interactions, primarily innate immunity in the CNS, in the disease process.

30.2 Clinical Features, Epidemiology, and Pathology

30.2.1 Symptoms (Memory Loss to Progressive Dementia)

Alzheimer's Disease is the leading cause of dementia, without effective therapy (Sisodia 1999). The symptoms of classic AD begin with a loss of short-term memory that slowly progresses to affect all cognitive functions, including long-term memory and executive functions (Corey-Bloom et al. 1994). Initially, impaired short-term memory often manifests itself as losing objects or forgetfulness in conversations. Subsequently, other early cognitive deficits occur; they include difficulty in word-finding, problem solving and spatio-temporal awareness. These symptoms are commonly accompanied by mental disorders, such as depression and apathy, and alternatively or subsequently agitation and irritability may occur. With further disease progression, memory failure becomes more profound and longer-term memory is affected. Patients with these deficits are frequently disoriented and can easily become lost, thus a close supervision of patients become necessary. About this stage, their language and complex motor skills also deteriorate. Psychosis and hallucinations can occur along with bradykinesia and rigidity. Patients ultimately become bed-ridden, unable to speak, and die from infection (such as pneumonia) or other medical conditions. Average survival time of Alzheimer's patients is about 8 years after onset of initial symptoms, although the rate of decline is quite variable.

30.2.2 Diagnosis

The elements for the diagnosis of AD include several components: (1) a history obtained from someone who knows the patient well, (2) a physical exam and an psychiatric exam to exclude other neurodegenerative diseases, (3) blood tests to exclude potential metabolic disorders involving the kidneys, liver, or thyroid, (4) a mental status test to determine dementia progression and (5) brain imaging (see Neuroimaging chapter for details). The first cognitive assessment widely used was the Mini-Mental State Examination (MMSE). MMSE assesses multiple cognitive tasks including spatio-temporal orientation, immediate/delayed word recall, naming, verbal repetition,

reading, writing, and spatial ability (Folstein et al. 1975). There are multiple reports of reduced cognitive performance in pre-clinical AD, notably impaired function in abstract reasoning, episodic memory, and new learning (see Fratiglioni for review) (Fratiglioni et al. 2001). Episodic memory deficits are dominant among early clinical and preclinical phases of AD. A diagnosis of dementia is usually determined using DSM-IV (Diagnostic and Statistical Manual of Mental Disorders) of the American Psychiatric Association (Association 1994). The final diagnosis is typically determined by autopsy using the criteria of NINDS-ADRDA (National Institute of Neurological Disorders and Stroke and Alzheimer's Disease and Related Disorders Association), which has been developed to document the neuropathology and underlying etiology (McKhann et al. 1984). Other diagnosis standard includes International Classification of Diseases (ICD)-10 guideline (Organization WH 1992). Since DSM-IV and ICD-10 criteria closely follow NINDS-ADRDA guidelines, diagnostic procedures for AD are notably consistent throughout the world. Given that AD is the primary cause of dementia, AD is often considered to be the likely cause of dementia while clinical tests are used to exclude other causes.

30.2.3 Epidemiology

Alzheimer's Disease affects estimated 5.2 million in the United States in 2014 and prevalence studies demonstrate an exponential rise of dementia with age (Katzman 2001). By 2050, the number of people age 65 and older with AD may nearly triple, from five million to as many as 16 million, barring the development of medical breakthroughs to prevent, slow or stop the disease. (Katzman and Fox 1999). AD is officially the sixth leading cause of death in the United States and the fifth leading cause of death for those aged 65 and older (Ewbank 1999).

In addition to age, other factors are associated with an increased risk of AD. In developed countries, AD appears to be more common in women than men (Mielke et al. 2014). Lack of education is a risk factor for senile dementia in China and Europe (Zhang et al. 1990; Schmand et al. 1997). Head trauma is also a risk factor for both sporadic (Mortimer et al. 1991) and familial AD (Guo et al. 2000). Silent myocardial infarcts and coronary stenosis triple the risk for AD (Aronson et al. 1990; Sparks et al. 1990), suggesting the importance of vascular risk factors. Other potential risk factors being studied include diabetes and hypertension (Ott et al. 1999; Peila et al. 2002; Qiu et al. 2005; Reitz and Mayeux 2014). As discussed below, a large number of genetic mutations are now associated with either early-onset AD or with increased risk of late-onset AD.

Identification of genetic mutations that cause early onset AD has helped to dramatically increase the understanding of

the origins of AD. Although cases of familial AD are relatively rare, they represent identified molecular mutations that cause AD. The genes identified to be responsible for early onset familial AD code for the amyloid precursor protein (APP), presenilin-1 and presenilin-2; these are found on chromosomes 21, 14, and 1, respectively. In addition to these dominantly-transmitted disease-causing mutations in early onset AD, still other studies have identified over 25 genetic risk factors that influence the appearance of the more common sporadic late onset AD. Current research is actively using genetically-modified mice to determine how specific protein modifications lead to the pathology of AD.

30.2.4 Genetic Studies of AD

Alzheimer's Disease is classified into early onset AD (EOAD, onset <65 years) and late-onset AD (LOAD, onset ≥65 years). EOAD and LOAD account for 1–5 % and >95 % of all cases, respectively. EOAD is generally associated with a more rapid rate of progression and are mostly familial AD. Three genes (*APP*, *PSEN1* and *PSEN2*) are identified in the EOAD pedigrees. All of them encode proteins involved in APP breakdown and Aβ generation. AD-linked mutations in these three genes exhibit high penetrance (>85 %), are mostly autosomal dominantly inherited. In contrast, the genes involved in LOAD increase disease risk in a non-Mendelian fashion. For two decades, only one genetic risk factor, the apolipoprotein E4 isoform (*APOEε4*) allele, located on chromosome 19q13, was an established risk gene in LOAD. APOE is a lipid-binding protein and is expressed in humans as three common isoforms coded for by three alleles, APOEε2, ε3, and ε4. A single *APOE-ε4* allele is associated with a two to threefold increased risk of LOAD; having two copies is associated with a five-fold or more increased risk (Kuusisto et al. 1994). A detailed discussion of ApoE biology can be found in Section 32.3.5.

Extensive genome-wide association studies (GWAS) have been conducted in a large cohort of LOAD subject in multiple institutions (Hardy and Singleton 2009; Sherva and Farrer 2011). The first set of studies identified *CLU*, *PICALM*, *CR1* and *BIN1* as susceptibility loci (Harold et al. 2009; Lambert et al. 2009; Seshadri et al. 2010). These loci mainly cluster in four pathways, namely immune response, APP processing, lipid metabolism and endocytosis. The second set of large GWAS studies identified additional susceptibility genes (*CD33*, *MS4A4A/MS4A4E/MS4A6E cluster*, *ABCA7*, *CD2AP* and *EPHA1*) (Hollingworth et al. 2011; Naj et al. 2011). All of these five loci are likely involved in the immune system while the *ABCA7* is in addition involved in lipid metabolism and APP processing. Finally, the largest GWAS to date, the International Genomics of Alzheimer's Project, performed a mega-meta analysis that included 74,046 sub-

jects (Lambert et al. 2013). In addition to *APOE*, *CR1*, *BIN1*, *CD2AP*, *EPHA1*, *CLU*, *MS4A6A*, *PICALM*, *ABCA7* and *CD33* this GWAS identified 12 additional susceptibility loci at genome-wide significance (*HLA-DRB5/HLA-DRB1*, *PTK2B*, *SORL1*, *SLC24A4/RIN3*, *DSG2*, *INPP5D*, *MEF2C*, *NME8*, *ZCWPW1*, *CELF1*, *FERMT2*, *CASS4*). Most of the 12 novel loci cluster in the specific pathways identified by the earlier GWAS, i.e. immune response (*HLA-DRB5/DRB1*, *INPP5D*, *MEF2C*), APP processing (*SORL1*, *CASS4*), Tau pathology (*CASS4*, *FERMT2*), cell migration (*PTK2B*) and lipid transport and endocytosis (*SORL1*). These results strongly reinforce the importance of these pathways in the etiology of LOAD.

TREM2: In the context of neuroimmune mechanism of LOAD, triggering receptor expressed by myeloid cells-2 (TREM2) is a transmembrane signaling molecule for phagocytosis and anti-inflammatory response and is genetically linked to LOAD, polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy (PLOS, also known as Nasu-Hakola disease), behavioral variant frontotemporal lobar degeneration (FTLD), Parkinson's disease (PD), and amyotrophic lateral sclerosis (ALS) (Guerreiro et al. 2013a, b; Jonsson et al. 2013; Paloneva et al. 2002; Giraldo et al. 2013; Rayaprolu et al. 2013; Cady et al. 2014). The detailed biology of TREM2 in microglia is discussed in Sect. 30.4.1.

30.2.5 Pathology

At autopsy, AD brains appear to have widespread neuronal and neuropil loss that thins cortical layers and expands ventricular and sulci spaces. However, there is not an obvious global loss of neurons in the cerebral cortex. Overall neuronal number appears relatively unchanged despite significant loss of brain tissue. Some of this apparent discrepancy is due to preferential loss of large pyramidal neurons in the cortex and relative sparing of smaller, densely packed neurons. Particularly vulnerable regions such as the entorhinal cortex and the CA1 of the hippocampus, show profound neuronal loss early in the disease. Wider involvement of temporal, frontal, and parietal cortices and a preferential loss of large neurons in these areas is seen as the disease progresses.

AD is characterized by an accumulation of senile plaques containing aggregated protein deposits of Aβ fibrils, numerous NFTs, reactive astrocytes, and activated microglia in the neocortex and hippocampus (Alzheimer 1907; Selkoe 1997). Senile plaques can contain either a diffuse amyloid deposition (presumably early senile plaques) or a dense core of insoluble Aβ with neuritic structures (mature senile plaques). Although Aβ deposition and NFT are commonly observed in non-demented elderly 80 years and older, increased levels of senile plaques are seen in AD brains (Berg et al. 1993; Schmitt et al. 2000). The degree of both Aβ deposition and

NFT formation are correlated with cognitive decline (Naslund et al. 2000; Berg et al. 1993; Wilcock and Esiri 1982; Braak and Braak 1995).

Although inflammation is a well-recognized phenomenon and is intensively investigated, the precise definition of brain inflammation has not yet been established (McGeer and McGeer 2001). Clinically, AD patients exhibit few of the classic signs of inflammation. Histopathologically, the classical acute inflammatory response (neutrophil recruitment), immunoglobulin precipitation, and T-cell accumulation are not seen suggesting that humoral or classical cellular immune-mediated responses are not involved in AD progression (Eikelenboom et al. 1994). However, AD brains show an increase in activated microglial clusters on senile plaques surrounded by astrocytes, indicating focal glial inflammation (Eikelenboom et al. 2002; Wyss-Coray and Mucke 2002). In particular, volume density of CD68⁺ mononuclear phagocytes (brain perivascular macrophages and microglia) is correlated with volume density of congophilic compact plaque deposits (Arends et al. 2000). CD68⁺ cells are present from very early preclinical phases to terminal phases of AD and are involved in disease progression, which will be further described later (Fonseca et al. 2004a; Akiyama et al. 2000). Moreover, deactivation of microglia has implications for therapy since long-term treatment of affected patients with non-steroidal anti-inflammatory drugs (NSAIDs) has been shown to inactivate microglia and retard the development and progression of AD (In't Veld et al. 2002), although NSAIDs may also directly affect the APP processing.

30.3 Molecular Pathogenesis, Animal Models, and Neuroinflammation

The molecular pathogenesis of AD is centered around A β production and its clearance. A β is generated by the processing of APP by β and γ -processing enzymes, and cleared from brain by its diffusion, export to vascular system, phagocytosis, or degradation. The following molecules are essential for understanding the molecular mechanism of A β processing.

30.3.1 Amyloid Precursor Protein (APP)

APP is the first gene to be identified as a causative gene of familial AD (FAD) and has been a key molecule in the study of the molecular mechanism of AD. As shown in Fig. 30.1, the APP molecule can be cleaved at different specific cleavage sites by various proteases to generate fragments of different sizes. APP is primarily expressed in neurons and cleaved at the α , β , and γ sites by APP processing enzymes (called α , β , and γ -secretases), producing A β (β - and γ -processing product), p3 (α - and γ -processing product), and

other APP fragments (Selkoe 1994). A β is composed of 39 to 43 amino acids, mainly 1-40 (A β 40) and 1-42 (A β 42). A β 42 is more amyloidogenic (faster to be aggregated) than A β 40, and early A β deposits are usually detectable with anti-A β 42 antibodies, but not with anti-A β 40 antibodies (Selkoe 1994). FAD mutations on APP gene are all linked to abnormal APP processing (increase in A β 42/A β 40 ratio), A β aggregation, and A β deposition (Scheuner et al. 1996).

30.3.2 PS1 and γ -Processing Enzyme Complex

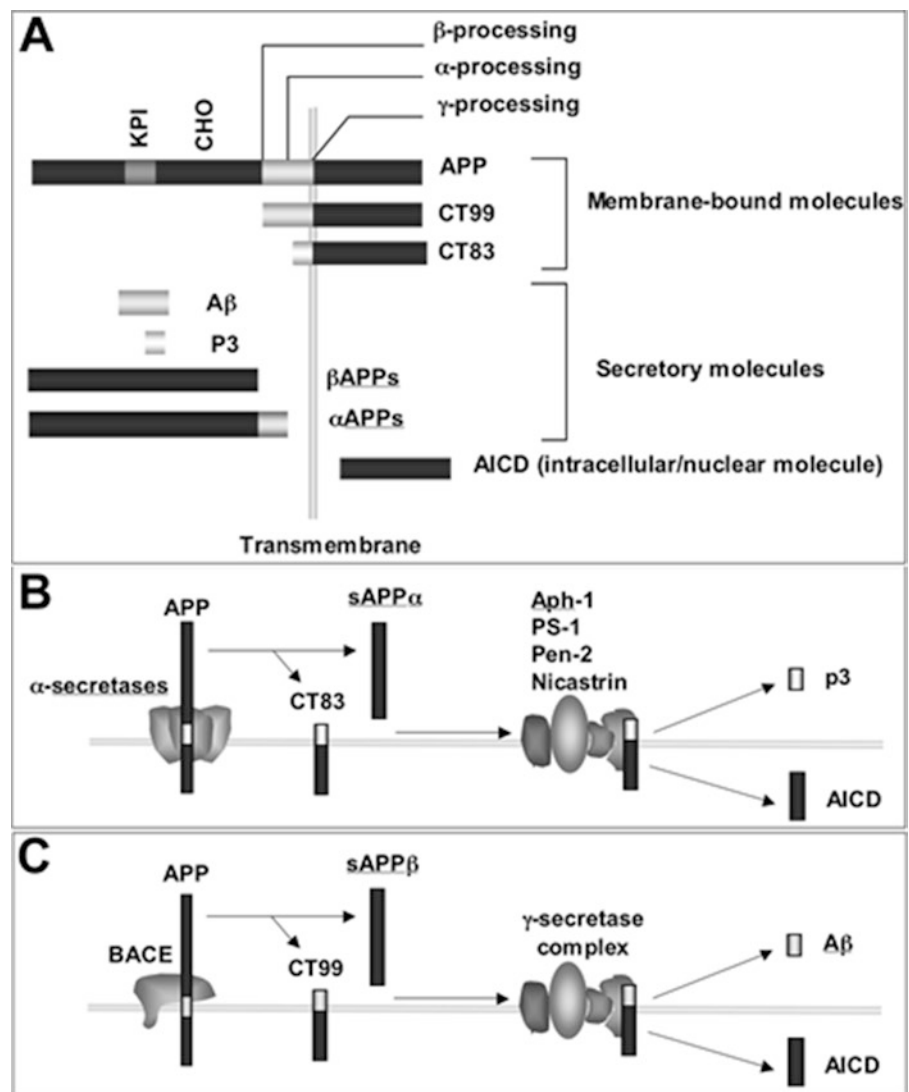

A combination of the presenilin genes (PS1 and 2), aph-1, pen-2, and nicastrin forms the γ -secretase complex (De Strooper 2003). The γ -secretase complex cleaves not only APP but also other transmembrane molecules, such as Notch, ErbB-4, and sterol regulatory element binding proteins (SREBPs). PS1 and PS2 have been established as causative genes of early onset FAD (Sherrington et al. 1995; Levy-Lahad et al. 1995). Transgene expression of PS1 FAD mutants enhances the A β 42/A β 40 ratio and accelerates A β aggregation and deposition in APP mice, which over-express Swedish FAD APP mutant in brains (Duff et al. 1996; Borchelt et al. 1997; Holcomb et al. 1998). PS2 FAD mutant over-expression converts A β 40 to A β 42, whereas PS2 wild type over-expression reduces both A β 40 and A β 42 (Mastrangelo et al. 2005). Taken together, these *in vivo* studies demonstrate the effect of PS1/2 FAD mutations on A β aggregation through transition of A β 40 to A β 42.

30.3.3 APP and PS1 Animal Models

30.3.3.1 Conventional APP and PS1 Mouse Models

Several established AD mouse models have made significant contributions to the understanding of AD pathogenesis (Price et al. 1998; Spire and Hyman 2005). Analyses of AD brain tissue obtained from autopsies provide only limited insight into the dynamic nature of the disease process. Currently, no AD mouse model has all of the characteristics of the human disease. However, several lines of transgenic mice expressing mutated APP and PS1 simulate prominent behavioral and pathological features of AD. These include, but not limited to, PDAPP expressing a platelet-derived growth factor gene promoter-driven human APP (isoforms 695, 751, and 770) with the V717F (Indiana) mutation (Games et al. 1995), Tg2576 expressing hamster prion gene promoter-driven human APP (isoform 695) gene with K670N/M671L (Swedish mutation) (Hsiao et al. 1996), APP23 expressing Thy1 gene promoter-driven human APP (isoform 751) with Swedish mutation (Sturchler-Pierrat et al. 1997), TgCRND8 expressing hamster prion gene promoter-driven human APP

Fig. 30.1 Scheme of APP processing. A, Cleavage sites and processing enzymes of APP. B, P3 and sAPP α production by α and γ -processing of APP. C, A β and sAPP β production by β and γ -processing of APP

695 gene with Swedish and Indiana mutations (Chishti et al. 2001), APP^{swe} x Hu PS1-A246E expressing mouse prion gene promoter-driven human APP 695 gene with Swedish mutation and human PS1 gene with A246E mutation (Borchelt et al. 1997), PS/APP expressing hamster prion gene promoter-driven APP 695 gene with Swedish mutation and human PS1 gene with M146L mutation (Holcomb et al. 1998), and 3xTg-AD mice expressing Thy1.2 gene promoter-driven human APP 695 gene with Swedish mutation, human tau gene with P301L mutation, and homozygotic P146L knock-in mutation of mouse PS1 gene (Oddo et al. 2003). Phenotypes displayed by these mice include age-related impairments in learning and memory, electrophysiological abnormalities, neuronal loss, microgliosis, astrogliosis, neuritic changes, amyloid deposition, oxidative stress, and abnormal tau phosphorylation (Price et al. 1998; Smith et al. 1998) (Fig. 30.2). Microglia in close proximity to fibrillar A β deposits are immunoreactive to interleukin (IL)-1 β and TNF- α , whereas activated astrocytes are immunoreactive to IL-1 β ,

transforming growth factor (TGF)-1 β , and IL-10 in Tg2576 mice (Frautschy et al. 1998; Benzing et al. 1999; Apelt and Schliebs 2001).

Tg2576 mice which express Swedish familial AD mutant (K670N/M671L) of APP695 under a hamster prion promoter show memory and learning impairments as determined by Morris water maze (Hsiao et al. 1996). The memory recall is impaired as early as 6 months of age, which persists without significant progression for up to 12 months of age, followed by impairment of both memory acquisition and recall after 12 months of age (Lesne et al. 2006). There is a strong correlation of such age-related memory decline to A β accumulation in the brain (Fig. 30.3) (Janus et al. 2000; Chen et al. 2000). A recent study in Tg2576 mice suggests that 9- or 12-mer A β oligomers are responsible for such memory loss, which can be isolated by Tg2576 and can induce transient memory loss in injected rodents (Lesne et al. 2006). Contextual fear conditioning tests, which represents hippocampal learning, show memory impairments in PDAPP mice

Fig. 30.2 3D reconstruction image of amyloid plaque deposition and glial accumulation in APP mouse brain. Cortical section of Tg2576 (14 months of age) was stained by thioflavin-S (compact amyloid plaque, purple), anti-IBA1 rabbit polyclonal (microglia, red), and anti-GFAP mouse monoclonal (astrocytes, green), and imaged using a laser scanning confocal microscopy (Zeiss 510 Meta). Z-stack images were deconvolved and 3D reconstructed using image processing software (AutoQuant)

Fig. 30.3 Schematic representation of the time course of A β deposition, A β oligomer accumulation, cognitive dysfunction, astrogliosis, and microgliosis in Tg2586 mice

as early as 4 months of age preceding the A β deposition (Jacobsen et al. 2006). These studies strongly suggest that onset of memory loss precedes the A β deposition, is more correlated with A β oligomer formation in the brain, may also be relevant to the clinical symptoms of AD patients.

30.3.3.2 APP Knocked-In Mouse Models

Transgene expression of recombinant molecules under the control of exogenous promoter derived from genetic fragment of other species are often associated with artificial phenotypes not predicted or commonly seen in human disease. Understanding the effects of elevated A β from those due to APP overexpression is a common challenge when interpreting the phenotypes of APP transgenic mice. To overcome this

issue, Saito *et al.* created a new APP knocked-in mouse models (APP^{NL-F} and APP^{NL-G-F}) (Saito et al. 2014). These mouse models avoid potential artifacts introduced by APP overexpression by using a knock-in approach to express APP at wild-type levels and with appropriate cell-type and temporal specificity. APP is not overexpressed, but levels of pathogenic A β are elevated due to the combined effects of two (in APP^{NL-F}) or three mutations (in APP^{NL-G-F}) linked to familial AD. Both APP^{NL-F} and APP^{NL-G-F} mice accumulate A β and recapitulate several AD-associated pathologies, including amyloid plaques, synaptic loss, and microgliosis and astrogliosis, especially in the vicinity of plaques. The presence of the Arctic mutation in APP^{NL-G-F} accelerates the pathology relative to APP^{NL-F} mice, and leads to particularly severe pheno-

types. A β deposition is observed starting at 2 months and is nearly saturated by 7 months. In contrast to APP^{NL-F} mice, the APP^{NL-G-F} mice develop subcortical amyloidosis in addition to cortical amyloidosis, consistent with the neuropathology observed in patients with the Arctic mutation. The mice also display age-associated cognitive impairment, specifically memory impairment as measured by the Y maze starting at 6 months. The cognitive impairment in APP^{NL-G-F} mice is more severe than the impairment in APP^{NL-F} mice. These mice will be suitable for future studies using APP mouse models.

30.3.4 β and α -Processing Enzymes

Beta-site APP-cleaving enzyme (BACE1, also called Asp2 or Memapsin2), a β -secretase, is an aspartic transmembrane proteinase (Vassar et al. 1999). BACE2 (also called Asp1 and DRAP) is a homolog of BACE1 and contains the same overall structural organization. BACE1 is essential for A β production as demonstrated by BACE1 gene-targeted mouse models (Cai et al. 2001). BACE over-expression enhances total A β production, deposition of both diffuse and compact A β plaques in brain parenchyma, and reduces cerebrovascular amyloid angiopathy in aged APP/BACE double transgenic mice (Willem et al. 2004; Mohajeri et al. 2004). However, this effect seems to be dose-dependent, since high BACE expression rather inhibits A β deposition (Lee et al. 2005). Thus, the effect of BACE upregulation in A β pathology in vivo is not conclusive. A Disintegrin And Metalloprotease (ADAM) 9, 10, and 17 have been identified as putative α -secretases (Asai et al. 2003). Overexpression of ADAM10 prevents A β deposition and hippocampal defect in APP mice (Postina et al. 2004), suggesting its therapeutic application for enhancing α -processing of APP.

30.3.5 ApoE

ApoE is the most well characterized genetic risk factor of AD. Evidence indicates that endogenous apoE in mouse brain enhances A β deposition in APP animal models (Bales et al. 1999; Sadowski et al. 2004). Tg2576 mice lacking mouse apoE exhibit diminished compact plaque deposition, while diffuse plaque load remained unchanged (Bales et al. 1999). Mouse apoE is rather amyloidogenic since apoE disruption significantly reduces the compact plaque formation in APP mice (Bales et al. 1999). In contrast, human apoE3 enhances A β clearance in mouse brain, while apoE4 weakly promotes A β clearance (Holtzman et al. 1999, 2000; Fagan et al. 2002). Although many studies concluded that astrocytes are the main apoE-producing cell in brain (Danik et al. 1999), recent reports suggest that microglial cells are also a source of apoE (Saura et al. 2003; Mori et al. 2004). A recent study of EGFP-ApoE knock-in mice demonstrated that apoE

is expressed in 75 % of astrocytes, and <10 % of microglia after stimulation. Thus, apoE is primarily an astrocyte protein (Xu et al. 2006).

30.3.6 A β Degrading Enzymes

The current knowledge of A β degradation biology is limited since only a few of the molecules involved have been characterized, namely insulin degrading enzyme (IDE) and neprilysin, which is also known as enkephalinase, and neutral endopeptidase metalloendopeptidase (NEP) (Selkoe et al. 2001; Iwata et al. 2000; Yamin et al. 1999). IDE was originally identified as a microglia-secreted A β degrading enzyme (Qiu et al. 1998), and is also found in neurons (Vekrellis et al. 2000). Neprilysin protein level is downregulated during aging, but is locally upregulated in activated astrocytes surrounding A β plaques in APP mice (Apelt et al. 2003). Thus the amount of IDE and neprilysin can be altered by chronic inflammatory reaction. Neprilysin, a neutral zinc metallopeptidase, plays a role in degrading insoluble and/or aggregated A β 42 (Selkoe et al. 2001; Iwata et al. 2000). Transgenic expression of both IDE and neprilysin show inhibition of A β accumulation in APP mice (Leissring et al. 2003). In addition, endothelin converting enzyme and matrix metalloprotease-2 and 3 are also new candidates of A β degrading enzymes (Choi et al. 2006; White et al. 2006).

30.3.7 Neurofibrillary Tangle Formation

Presence of NFT is one of the original neuropathological hallmarks of AD. NFT are fibrous tangles composed of insoluble, conformationally abnormal, hyperphosphorylated tau protein deposited in neuronal cell bodies. Hyperphosphorylated tau can form a specific insoluble structure known as a paired helical filament (PHF) (Lee et al. 2001; Buee et al. 2000). Six tau protein isoforms are generated by alternative mRNA splicing of the *tau* gene. Based on the repeat of the intermediate microtubule-binding domain, the majority of tau is classified as three repeat (3R) or four repeat (4R) tau. The primary function of tau is to bind to and stabilize microtubules, thereby promoting microtubule polymerization. Many tau phosphorylation sites flank microtubule binding domains and are believed to play a significant role in its microtubule binding (Lee et al. 2001; Planel et al. 2002). Hyperphosphorylation of tau appears to cause tau to dissociate from microtubules and form tau protein aggregates, which becomes PHF (Biernat et al. 1993; Bramblett et al. 1993; Alonso et al. 1996). Glycogen synthase kinase 3- β (GSK3 β), cyclin dependent protein kinase 5 / p25 complex, microtubule affinity regulating kinase, and recently tau-tubulin kinase 1 have been extensively characterized as

tau kinases that seem to be involved in the hyperphosphorylation of tau (Takashima et al. 1993; Ishiguro et al. 1992; Patrick et al. 1999; Drewes et al. 1997; Sato et al. 2006).

Tau-related neurodegenerative disorders, or “tauopathies”, include AD, argyrophilic grain dementia, corticobasal degeneration, diffuse neurofibrillary tangles with calcification, Down’s syndrome, frontotemporal dementia and Parkinsonism linked to chromosome 17 (FTDP-17), Gerstmann-Straussler-Scheinker disease, Niemann-Pick disease, non-Guamanian motor neuron disease with neurofibrillary tangles, Pick’s disease, progressive supranuclear palsy, subacute sclerosing panencephalitis, and tangle only dementia (Lee et al. 2001). Genetic studies show that mis-sense mutations in the *tau* gene (*Mtapt*) induce FTDP-17 supporting its importance in tauopathies (Hutton et al. 1998; Lee et al. 2001), although such mutations have not been found in AD.

These tau mutations develop similar pathology in transgenic animal models, such as P301L tau mouse (Gotz et al. 2001a; Lewis et al. 2000), R406W tau mouse (Sato et al. 2002), G272V tau mouse (Gotz et al. 2001b), and V337M tau mouse (Tanemura et al. 2002). However, P301L tau mice develop NFT-like tau aggregation not only in CNS but also in peripheral motor neurons, astrocytes and oligodendrocytes, that is correlated with gait disturbances (Lewis et al. 2000).

rTg4510 mice express FTDP-17-linked tau P301L mutant under the control of tetracycline response element (TRE), to which Ca^{2+} /calmodulin-dependent kinase II (CaMKII) promoter-driven tTA binds and suppresses the gene transcription in the presence of doxycycline (Dox) (Santacruz et al. 2005; Mayford et al. 1996). The CaMKII promoter is specifically activated in and largely restricted to the hippocampus, cortex, olfactory bulb, and striatum, and Tg4510 show age- and Dox-dependent tau aggregation and neurodegeneration in the brain subregions (Santacruz et al. 2005). This is, so far, one of most advanced tauopathy animal models with a clear neurodegeneration phenotype, which can be controlled by Dox treatment.

In the context of neuroinflammation, P301S tau mice, another FTDP-17 mouse model, show age-dependent neurodegeneration in entorhinal cortical and hippocampal regions, which is preceded by extensive microglial activation and can be suppressed by an immunosuppressive agent, FK506 (Yoshiyama et al. 2007), indicative of non-autonomous neuronal cell loss. Similarly, another P301S tau mouse model shows extensive neurodegeneration in brain stem and spinal cord, which is accompanied with neuroinflammation and M1-type mononuclear phagocyte accumulation (Allen et al. 2002; Bellucci et al. 2004). These studies reveal that specific type of neuroinflammation may be one of the mechanisms in the tauopathy-related neurodegeneration and a potential therapeutic target.

30.3.8 Neurotoxicity and Synaptic Dysfunction

30.3.8.1 A β -Mediated Neurotoxicity

It has been widely accepted that toxicity of A β requires aggregation of native A β monomers (Pike et al. 1993; Hardy and Higgins 1992). A β (A β 40 or A β 42) self-assembles to form low-n oligomers (dimers-hexamers), protofibrils, and fibrils (Roher et al. 1996; Lambert et al. 1998; Harper et al. 1997; Walsh et al. 1997). Since intermediates can further associate into higher-ordered aggregates, it is difficult to determine the oligomerization state of A β that causes pathogenicity. Nonetheless, several groups succeeded in isolating spherical non-fibrillar assemblies of synthetic A β (A β -derived diffusible ligands; ADDLs and amylospheroid; ASPD) (Lambert et al. 1998; Hoshi et al. 2003). These A β oligomers show more potent toxicity than fibrillar A β at lower concentrations (Lambert et al. 1998) and induce reversible synaptic loss through N-methyl-D-aspartate (NMDA) receptor interaction in organotypic hippocampal culture systems (Shankar et al. 2007). Thus, A β oligomers are a likely therapeutic target (De Felice et al. 2004).

A β can also potentially mediate neurotoxicity by activating microglia and glia and hereby promoting their secretion of a variety of neurotoxic factors. A β and secreted β -amyloid precursor protein (sAPP)-induce microglial activation and neurotoxicity (Giulian and Baker 1986; Meda et al. 1995; Barger and Harmon 1997; Ikezu et al. 2003). Neurotoxicity can be mediated through secretion of neurotoxic agents such as FasL, tumor necrosis factor (TNF)- α , reactive oxygen species (ROS), proteases, excitatory amino acids, and nitric oxides. Excitatory amino acids (glutamate, quinolinic acid, D-serine, among others) activate N-methyl-D-aspartate (NMDA) receptors, which are significantly involved in microglial-mediated neurotoxicity (Giulian et al. 1994; Piani et al. 1992). Indeed, both A β and sAPP activated microglia increase glutamate secretion (Barger and Basile 2001; Ikezu et al. 2003). Glutamate and ROS can exacerbate each other’s neurotoxic effects due to their relationships with the cystine/glutamate exchange system (Xc⁻) antiporter. A β /sAPP-induced microglial activation leads to ROS production and glutathione consumption, that in turn promotes cystine import to regenerate glutathione and, as a consequence, increased glutamate is exported in exchange through the Xc⁻ antiporter (Ikezu et al. 2003).

30.3.8.2 A β -Mediated Synaptic Dysfunction

There are a number of studies documenting the synaptic dysfunction of APP mice, which starts as early as 4 months of age, including enhanced paired-pulse facilitation, disturbed high frequency stimulation (HFS) burst, and rapid decay of LTP in the CA1 field of hippocampal slices (Larson et al. 1999; Hsia et al. 1999). In addition, impaired synaptic

transmission and LTP in both the CA1 and DG regions are also evident in Tg2576 mice (Chapman et al. 1999). A β oligomers block hippocampal long-term potentiation (LTP) *ex vivo* at nanomolar concentrations. *In vivo* applications of A β oligomers potently inhibit rat hippocampal LTP and cognitive function (Walsh et al. 2002; Cleary et al. 2005). These studies strongly suggest that A β oligomers induce memory impairment through inhibition of synaptic transmission and long-term potentiation in brain. One of the potential mechanisms of A β -induced LTP inhibition is through the activation of a number of inflammation-related molecules, such as c-jun N-terminal kinase, CDK5, p38 mitogen-activated kinase, inducible nitric oxide synthase, and superoxide, (Wang et al. 2004a, b). These data suggest significant involvement of microglial activation in the inhibitory mechanism.

30.3.8.3 Neurotoxicity By Tau Aggregation

Although NFT is a hallmark of AD, its direct involvement in neuronal cell death is still unclear. Presence of NFT does not appear to be highly toxic since clinical studies suggest long-term survival of NFT-bearing neurons (Morsch et al. 1999; Hof et al. 2003). These data are also supported by studies using FTDP-17 tau mutant mice showing NFT formation in the absence of neuronal cell loss (Santacruz et al. 2005) and a lack of cognitive impairment as assessed by a water maze test (Arendash et al. 2004). A new doxycycline-inducible tau transgenic mouse model suggests accumulation of intracellular tau protein rather than NFT formation is responsible for neurodegeneration and cognitive impairment (Santacruz et al. 2005; Ramsden et al. 2005). However, tau is known to be involved in A β aggregate-induced neurotoxicity in conjunction with protein kinase activation *in vitro* (Rapoport et al. 2002; Hoshi et al. 2003; Medina et al. 2005). Thus, it is possible that acute neuronal cytoskeletal destabilization by tau phosphorylation and its end-product (globular tau aggregates) are neurotoxic, but its subsequent subcellular compartmentalization as NFT/PHF is a preventive neuroprotective process used to contain neurotoxic aggregates. Further study will be necessary to characterize its effect on neurodegeneration or dementia.

30.4 Neuroimmunological Mechanism of AD

Neuronal loss, edema, and recruited mononuclear phagocytes (moving from blood to brain), are all classical hallmarks of brain inflammation in AD (Arvin et al. 1996). Gliosis, characterized by activation, proliferation, and hypertrophy of astrocytes and microglia, is one important feature of neuroinflammation. Amyloid plaques contain a number of proteins including complement proteins and pro-inflammatory cytokines and chemokines. Many of these proteins

are secreted by activated microglia and reactive astrocytes. Activated microglia integrate deeply into neuritic plaques and express major histocompatibility complex type II (MHC-II), a marker for microglial activation. MHC-II expression is significantly upregulated in AD brains (Rogers et al. 1988; Styren et al. 1990).

Neurotoxicity can be mediated through secretion of various factors, ROS, proteases, excitatory amino acids, and nitric oxides. Pro-inflammatory cytokines and chemokines can inhibit fibrillar A β phagocytosis by a murine microglial cell line (Koenigsknecht-Talboo and Landreth 2005). Such T-cell-mediated cytokines also inhibit post-phagocytosis intracellular A β degradation in human monocyte-derived macrophages. A β -microglia interaction results in two outputs: phagocytosis and signaling for priming and activation. A β binding to a complex of cell surface proteins (including CD36, integrin-associated protein (CD47), and $\alpha_6\beta_1$ -integrin) leads to src-like tyrosine kinase activation and ROS production (Bamberger et al. 2003). CD36 is necessary for full A β -induced mononuclear phagocyte activation and chemotaxis (El Khoury et al. 2003). These findings strongly suggest that A β aggregates activate microglia by its binding to specific cell surface molecules, which activates src-like tyrosine kinases and other signaling for A β clearance and neuroinflammation in AD brains.

30.4.1 Microglia-Mediated Phagocytosis

30.4.1.1 A β Scavenger Receptors

Our current knowledge of A β clearance is limited compared to the more detailed understanding of A β synthesis and aggregation mechanisms. It is well known that A β stimulation enhances microglial phagocytosis, *in vitro* (Kopec and Carroll 1998). The internalized A β in phagosomes initially migrate to acid hydrolase-containing late endosomes and lysosomal compartments, and then moves into perinuclear vesicles, that are morphologically similar to lysosomes, where it stays up to 20 days (Paresce et al. 1997). The long-term accumulation of A β has also been observed by using unlabeled A β aggregates in bone marrow-derived macrophages (Yamamoto et al. 2007b). In addition to microglia, astrocytes also contribute to the uptake and removal of A β in a manner enhanced by a CC-type chemokine, CCL2 (Wyss-Coray et al. 2003).

Microglia constantly take-up A β via potential A β receptors, including scavenger receptor type A (SR-A), CD36, and receptor for advanced glycation end product (RAGE) (El Khoury et al. 1996, 2003; Yan et al. 1996). Although SR-A was characterized as a major receptor for microglial phagocytosis of A β (Paresce et al. 1996), APP mice deficient in SR-A show no difference in amyloid plaque formation or synaptic degeneration (Huang et al. 1999). This suggests that

other scavenger receptors or A β -binding molecules, such as CD36, CD47, and $\alpha_6\beta_1$ -integrin, can compensate for the deficiency of SR-A. On the other hand, RAGE seems to enhance A β deposition. APP mice deficient in RAGE exhibit reduced A β deposition (unpublished observations), which is consistent with enhanced A β deposition in mice over-expressing RAGE (Arancio et al. 2004). P-glycoprotein (Pgp), an ATP binding cassette transporter/multidrug resistance-1 α and β , is another molecule involved in A β clearance from brain parenchyma. Disruption of Pgp exhibits enhanced A β deposition, suggesting its role in endothelial efflux of A β from the brain (Cirrito et al. 2005).

30.4.1.2 TREM2/TYROBP Pathway for Phagocytic Clearance and Disease

TREM2 is mostly expressed in myeloid cells (immature dendritic cells, microglia and osteoclasts). In the CNS, TREM2 is expressed at levels greater than 300-fold in microglia compared to astrocytes (Hickman and El Khoury 2014). Inflammation decreases TREM2 expression in microglia and their ability to phagocytize apoptotic neurons (Takahashi et al. 2007). TREM2 requires the interaction with the adaptor protein, TYRO protein tyrosine kinase binding protein (TYROBP; formerly DAP12) that facilitates the downstream signaling of phagocytosis (Paloneva et al. 2000). Thus, healthy coupling of TREM2 and TYROBP is essential for the phagocytic function of myeloid cells. No endogenous ligand has been confirmed for TREM2, but TREM2 is shown to bind to Gram⁺ and Gram⁻ bacteria and yeast in a charge-based method (Daws et al. 2003). Stimulation of TREM2 by a cross-linked TREM2 antibody is shown to activate TREM2. This activation causes actin polymerization and restructuring of the cytoskeleton (Takahashi et al. 2005).

TYROBP is a transmembrane adaptor protein that binds to TREM2 and signals through immunoreceptor tyrosine-based activation motifs (ITAMs). The ITAM signal is important for phagocytosis activation in microglia (Linnartz and Neumann 2013). Tyrosine phosphorylation of ITAM by Src family proteins activates TYROBP. The phosphorylated ITAM binds to protein spleen tyrosine kinase (Syk) (Fig. 30.1). Syk activates many downstream cascades linked to phagocytosis (Linnartz and Neumann 2013). The ITAM activation is negatively regulated by the immunoreceptor tyrosine-based inhibition motifs (ITIMs). When a regulatory ligand binds to receptor containing an ITIM, recruitment of SHP1/SHP2 occurs. SHP1/SHP2 can dephosphorylate and inhibit ITAM activation and other downstream cascades (Linnartz and Neumann 2013). TYROBP deficient mice show enhanced inflammatory phenotypes (Hamerman et al. 2005).

Mutations in TREM2 or TYROBP are thought to be the main cause of Nasu-Hakola (Paloneva et al. 2003). Nasu-Hakola diseases is polycystic lipomembranous osteodyspla-

sia with sclerosing leukoencephalopathy (PLOS), a rare autosomal recessive disease (Paloneva et al. 2003). Patients who are diagnosed with Nasu-Hakola disease suffer from bone cyst-like lesions and bone fractures often on their lower legs and also experience rapid pre-senile dementia (Paloneva et al. 2001, 2003). Around the age of 40, patients have severe neurodegeneration and suffer from severe dementia, gait disturbances, sensory agnosia, agraphia and in some cases develop tumors in the CNS (Hakola and Puranen 1993). The link between neurodegeneration and TREM2/TYROBP function provided by Nasu-Hakola disease indicates that the phagocytic and anti-inflammatory function of TREM2/TYROBP signaling is important for healthy brain function.

The missense R47H mutation in TREM2 is associated with LOAD, has an effect on both folding and ligand binding, and decreases the clearance of damaging debris (Abduljaleel et al. 2014). Similarly, FTDL-linked missense mutations in TREM2 (T66M and Y38C) also reduce phagocytic activity (Kleinberger et al. 2014). TYROBP is recently highlighted as one of the central genetic nodes and networks in LOAD (Paloneva et al. 2000, 2001; Zhang et al. 2013). Since both TREM2 and TYROBP are specifically expressed in myeloid cells and physically interact to transduce phagocytosis and anti-inflammatory signaling (Linnartz and Neumann 2013; N'Diaye et al. 2009; Paradowska-Gorycka and Jurkowska 2013), the TREM2/TYROBP pathway may play an important role for regulating peripheral or central inflammation.

30.4.2 Glial Inflammation and Innate Immunity

Innate immune responses in AD are mediated by a large number of inflammatory proteins, such as complement factors, acute-phase proteins, pro-inflammatory cytokines, and chemokines (McGeer and McGeer 2001; Akiyama et al. 2000). Upregulation of the complement system includes activation of both classical and alternative pathways and enhanced secretion of cytokines and chemokines including, but not limited to, IFN- γ , IL-1 α/β , IL-6, IL-8, IL-12, TGF- β 1/2, TNF- α , CD40L, CCL2 (MCP-1), CCL3 (MIP-1 α), CCL4 (MIP-1 β), S100- β (for review, see (Akiyama et al. 2000)). The interplay between A β aggregates, microglia and astrocytes results in secretion of pro-inflammatory cytokines that, in turn, may affect local APP expression in nearby neurons. This process results in local upregulation of A β and seeding of “new” A β deposits, which may therefore be a potential mechanism for the plaque accumulation typically seen in AD brains. A detailed review on this topic can be found in our recent publication (Varnum and Ikezu 2012).

30.4.2.1 Cytokines

IL-1

IL-1 upregulation seems to occur early in A β plaque formation since it is associated with diffuse plaques and also found in young children with Down's syndrome (Griffin et al. 1989, 1995). IL-1 induces S100 β , an astrocyte-derived neurite promoting cytokine (Kligman and Marshak 1985), and α 1-antichymotripsin (Das and Potter 1995). IL-1 upregulates APP synthesis in primary astrocytes (Rogers et al. 1999), and A β production when co-stimulated with IFN- γ in vitro (Blasko et al. 2000).

IFN- γ

IFN- γ is produced by Th1 type T cells and natural killer cells (Young and Hardy 1995), as well as macrophages (Fultz et al. 1993), astrocytes, and microglia (DeSimone et al. 1998). IFN- γ affects A β production, A β degradation (Yamamoto et al. 2007a), and neurotoxicity (Meda et al. 1999). IFN- γ , in conjunction with TNF- α , has been shown to enhance APP mRNA transcription and A β production (Blasko et al. 1999), and indirectly induce neuronal loss by stimulating release of NO from microglia (Chao et al. 1995). In the Tg2576 mouse model, astrocytes significantly upregulate IFN- γ mRNA in vivo (Abbas et al. 2002). We have recently found that transgenic APP mice (Tg2576) lacking IFN- γ receptor type I show marked reduction of A β deposition, microgliosis, astrogliosis, and astrocytic BACE expression (Yamamoto et al. 2007a). Thus, IFN- γ plays an important role for AD pathogenesis.

IL-4

IL-4 is a prototypical anti-inflammatory cytokine derived from Th2 cells. IL-4 is a particularly important cytokine for M2a skewing (Lyons et al. 2007b; Maher et al. 2005; Nolan et al. 2005). Microglia stimulated by IL-4 have a decrease in TNF- α production and an increase in secretion of insulin-like growth factor-1 (IGF-1), and they also induce neurogenesis in vitro (Butovsky et al. 2005, 2006). Stimulation of microglia by IL-4 enhanced neural differentiation (Kiyota et al. 2010). Gene delivery of IL-4 into APP+PS1 mice partially suppressed glial accumulation in the hippocampus, directly enhanced neurogenesis, restored impaired spatial learning, and also reduced A β deposition (Kiyota et al. 2010). Gene delivery of either IL-4 also reversed the LPS-induced deficit in LTP in the rat hippocampus (Lynch et al. 2004; Nolan et al. 2005). Thus, IL-4 is an important therapeutic target of AD.

IL-6

IL-6 is a pleiotropic pro-inflammatory cytokine, secreted from T cells, macrophages, astro/microglia, and is involved in a number of inflammatory signals, including the acute phase response. IL-6 and its receptor complex, IL-6R and

gp130/CD130, are all upregulated in AD brains in a region-specific manner (Hampel et al. 2005). IL-6 immunoreactivity is co-localized with diffuse plaques but not with compact plaques (Hull et al. 1996), suggesting its role in diffuse plaque reaction rather than compact plaque formation. Astrocyte-derived IL-6 induces expression of complement component C3, and may be involved in complement cascade activation in AD (Barnum et al. 1996).

IL-10

IL-10 is an anti-inflammatory cytokine induced by either pro or anti-inflammatory activation of immune cells, including T cells and mononuclear phagocytes. Instead of inducing alternative activation of immune cells (such as seen by IL-4 stimulation), IL-10 suppresses intracellular signaling to restore the resting status of activated cells. Our group recently identified that resting microglia express high levels of TGF- β 1, extracellular matrix-related genes, and IL-10 (Freilich et al. 2013). With gene delivery of IL-10 into APP+PS1 mice, there was suppression of astro/microgliosis and a restoration of impaired spatial learning and neurogenesis, and while there was no reduction in A β deposition, there was enhanced vascular transport of A β (Kiyota et al. 2011). Gene delivery of either IL-10 also reversed the LPS-induced deficit in LTP in the rat hippocampus (Lynch et al. 2004; Nolan et al. 2005). In accord, we recently identified that IL-10-stimulated microglia enhanced proliferation but not differentiation of neural stem cells in vitro (Kiyota et al. 2011). Thus, IL-10 has a significant potential as a therapeutic target of AD.

TGF- β 1/2/3

TGF- β 1/2/3 are expressed in the CNS and are involved in development, homeostasis, and repair (Finch et al. 1993). TGF- β 1 has been detected in plaques (van der Wal et al. 1993) and is elevated in cerebrospinal fluid and serum in AD (Chao et al. 1994a, b). TGF- β 2 has also been detected in reactive astrocytes, microglia, and in tangle-bearing neurons in AD brains (Wyss-Coray et al. 2000). TGF- β 1 transgenic mice show cerebrovascular amyloid deposition (Wyss-Coray et al. 1997). Over-expression of TGF- β 1 gene in APP mice accelerates vascular amyloid deposition although plaque burden was reduced in brain tissue (Wyss-Coray et al. 1997, 2001), suggesting its role in clearing A β from brain parenchyma. Since TGF- β 1 increases APP expression in astrocytes and microglia (Gray and Patel 1993; Monning et al. 1994; Harris-White et al. 1998), it may also be involved in TGF- β 1 glial A β production. Disruption of TGF- β 1 gene induces neurodegeneration and microgliosis (Brionne et al. 2003). APP mice over-expressing kinase-deficient TGF- β receptor type II, which inhibits endogenous TGF- β signaling, show enhanced A β deposition, neurodegeneration, and dendritic loss (Tesseur et al. 2006).

TNF- α

TNF- α , a pleiotropic pro-inflammatory cytokine, has been extensively investigated in AD. TNF- α is predominantly expressed by activated microglia, and to a lesser extent, astrocytes and neurons (Meda et al. 1995; Botchkina et al. 1997; Bezzi et al. 2001; Williams et al. 2005). In AD, TNF- α is upregulated in cerebrospinal fluid (Tarkowski et al. 1999), serum (Fillit et al. 1991), and cortex (Tarkowski et al. 1999). The effect of TNF- α on neurons is different dependent on the neuronal preparation and perhaps species; it is neurotrophic to rat cortical, hippocampal, and septal neurons (Cheng et al. 1994; Barger and Harmon 1997), while directly neurotoxic (or enhances glutamate neurotoxicity) to human cortical neurons (D'Souza et al. 1995; Williams et al. 2005; Chao and Hu 1994). This discrepancy could be due to the diverse signaling of two distinctly different TNF- α receptors, type I (p55 TNFR-1) and type II (p75 TNFR-2) (Botchkina et al. 1997; Dziewulska and Mossakowski 2003). TNFR-1, but not TNFR-2, contains an intracellular death domain, common to proteins in the TNF receptor family. TNFR-1 mediates both apoptosis and NF- κ B-mediated cell survival (Wallach et al. 1999; Gupta and Gollapudi 2005). Importantly, primary cultured hippocampal neurons derived from TNFR-1 null mice were resistant to A β -mediated neurotoxicity (Li et al. 2004). Thus, TNF- α -mediated neurotoxicity is bidirectional and the outcomes of TNF signaling depend distinctly on cell type and species.

CD40L

CD40L belongs to the TNF family and one of the most important T-cell mediated cytokines. CD40, the receptor of CD40L, is upregulated by A β -stimulation of primary cultured microglia in vitro (Tan et al. 1999) and is found to be expressed in reactive microglia in AD patient brain tissue (Togo et al. 2000). Transgenic APP (Tg2576) mice deficient in CD40L show reduced A β deposition, astro/microgliosis, and hyperphosphorylation of tau (Tan et al. 2002). In addition, chronic treatment of APP/PS1 bigenic mice with neutralizing anti-CD40L antibody reduces A β deposition and causes a modest improvement in cognitive performance (Tan et al. 2002; Todd Roach et al. 2004), suggesting its therapeutic application for AD.

CD200

CD200 is a type I transmembrane glycoprotein with an immunoglobulin superfamily (IgSF) domain (Clark et al. 1985). It is expressed on a number of cells involved in the immune response, including T cells, B cells, and particularly in neurons in the brain (Barclay 1981; McMaster and Williams 1979; Webb and Barclay 1984). The CD200R is expressed largely on cells of myeloid lineage, namely, microglia (Barclay 1981; Koning et al. 2010). It is a cell surface glycoprotein with IgSF domains and a single transmem-

brane region (Wright et al. 2000). Unlike CD200, however, it has a large cytoplasmic region allowing for intracellular signaling initiated by tyrosine phosphorylation (Wright et al. 2000). CD200 expression decreases with age where it is simultaneously associated with increased microglial activation (Lyons et al. 2007a). It is likewise decreased in the brains of AD patients and in the brains of A β -treated mice (Lyons et al. 2009; Walker et al. 2009). Interestingly, hippocampal slices from mice lacking CD200 also showed significant impairments in synaptic plasticity, specifically in LTP, tying the age-dependent decrease in CD200 with the decreased ability to form new memories in AD patients (Costello et al. 2011).

In animal models of AD, where the age-related increase in microglial activation was accompanied by an age-related or A β -induced decrease in CD200 expression, IL-4 treatment was able to restore that deficit (Kiyota et al. 2010; Lyons et al. 2007a, b). These tissues and glia from AD models lack IL-4 and have enhanced inflammatory responses to LPS (Lyons et al. 2009). In accord, our laboratory recently identified that over-expression of CD200 significantly reduced A β deposition and inflammatory changes in Tg2576 APP mice (unpublished observation). These studies indicate that CD200 is a novel therapeutic target of AD.

30.4.2.2 Chemokines

CCL2 (MCP-1)

CCL2 (MCP-1) is a member of the β chemokine subfamily and a candidate molecule for stimulating monocyte chemotaxis into the CNS (Charo et al. 1994). Activated astrocytes and cells of monocytic origin (such as microglia and macrophages) have been shown to express CCL2 in the brain (Calvo et al. 1996; Glabinski et al. 1996). CCL2 has been detected in senile plaques, reactive microglia and microvessels in AD brains (Ishizuka et al. 1997; Xia and Hyman 1999; Grammas and Ovase 2001), and is upregulated in cerebrospinal fluid and serum of AD cases and AD animal models (Sun et al. 2003; Galimberti et al. 2005; Janelins et al. 2005). Over-expression of CCL2 resulted in increased diffuse plaque deposition, microglial accumulation, and apoE expression in APP mice (Yamamoto et al. 2005), accompanied by cognitive impairment (Kiyota et al. 2009b). Intracerebral over-expression of dominant-negative CCL2 ameliorate the spatial learning of APP/PS1 mice (Kiyota et al. 2009a). On the otherhand, genetic disruption of CCR2 increases A β accumulation and neurodegeneration when crossed with APP mouse model, suggesting that physiological CCL2/CCR2 signaling is necessary for the A β clearance in brain (El Khoury et al. 2007). These results show that CCL2/CCR2 signaling is critical in mononuclear phagocyte accumulation and A β deposition in CNS.

CXCR Family

A number of other chemokines and their receptors have been identified in AD. CXCR2 is a member of the CXC chemokines receptor family and is a receptor for multiple ligands, including CXCL1/2/3 (GRO α / β / δ) (Zlotnik and Yoshie 2000). Both CXCR2 and CXCL1 have been detected in AD brains. In particular, CXCR2 expression has been identified in dystrophic neurites of senile plaques (Xia et al. 1997). CXCR3, another CXC receptor family, and its ligand CXCL10 (IP-10) have been found in both cortical and subcortical neurons in normal and AD brains. CXCL10 was significantly upregulated in AD brain (Xia et al. 2000). In addition, expression of CC chemokine receptors, such as CCR3 and CCR5, and their ligands, CCL4 (MIP-1 β) and CCL5 (RANTES), is also enhanced on reactive microglia in AD brain (Xia et al. 1998). Although the exact physiological functions of these molecules have yet to be characterized in the context of AD pathogenesis, modulation of such chemokine signaling might be beneficial to correct the detrimental imbalance of metabolic homeostasis and neuroinflammation in brain.

30.4.2.3 Toll-Like Receptors

One of the most important recent findings in the effort to understand innate immunity has been the identification of Toll-like receptors (TLRs). TLRs define a major class of pattern-recognition receptors critical to the initiation and tailoring of both innate and subsequent adaptive immune responses (Beutler 2004; Iwasaki and Medzhitov 2004). For example, bacterial cell wall components are recognized by TLR2, and lipopolysaccharide and viral envelope proteins are recognized by TLR4. Double strand RNA, single strand RNA, and unmethylated CpGs are recognized by TLR3, TLR7/8, and TLR9, respectively (for review, see (Akira et al. 2006)). Primary cultured human and mouse microglia express mRNA for TLR1-9, whereas human and mouse astrocytes express high levels of TLR3, and low-level TLR 1, 2, and 4-6 (Jack et al. 2005; Olson and Miller 2004) (McKimmie and Fazakerley 2005; Carpentier et al. 2005). A recent study on aged mouse brains demonstrated that TLR1, TLR2, TLR4, TLR5, TLR7 and CD14 expression were upregulated in correlation with age, whereas TLR9 was downregulated (Letiembre et al. 2007). Interestingly, a TLR4 polymorphism was also associated with successful aging (Candore et al. 2006), which further indicates a role of innate immune receptors in aging and potentially AD.

The role of TLRs in neuroinflammation during AD is poorly characterized. However, recent reports indicate that TLR9 ligand (CpG-containing oligonucleotide) induced enhancement of A β uptake by N9 microglia cell line (Iribarren et al. 2005), and A β stimulation modulates TLR-specific inflammation (NO and TNF- α release) in primary cultured mouse microglia (Lotz et al. 2005). These results

suggest that there is crosstalk between A β and TLR signaling that may regulate glial inflammation and A β clearance in CNS.

30.4.2.4 Matrix Metalloprotease

A β stimulation induces robust expression of matrix metalloprotease (MMP) 1, 3, 10, 12, 19, and disintegrin and metalloprotease (ADAM) 8 in primary cultured human microglia (Walker et al. 2005). Increased expression of MMP 1, 3 and 9 has been documented in AD brains (Leake et al. 2000; Yoshiyama et al. 2000; Backstrom et al. 1996) and may contribute to tissue damage (Cuzner and Opdenakker 1999). These molecules may be involved in A β degradation, cytokine/chemokine processing, and shedding of cell adhesion molecules for enhancing glial motility.

30.4.2.5 Other Inflammatory Molecules: Complement Complex and CD45

Complement C1q, the first complement of the classical complement pathway, is upregulated in AD brains and is found in senile plaques (Afagh et al. 1996). C1q binds to soluble A β and modulates its uptake by mononuclear phagocytes (Webster et al. 2000). C1q also directly induces neurotoxicity through its interaction with cell surface calreticulin, a C1q receptor (Luo et al. 2003). However, APP mice lacking C1q exhibited reduced glial and astroglial activation without changes in A β deposition (Fonseca et al. 2004b). Thus, C1q may be involved in AD pathogenesis by influencing neurotoxicity and glial inflammation, but its effect on A β metabolism is modest.

Complement C3 is upregulated in APP/TGF- β 1 bigenic mice and AD brains (Wyss-Coray et al. 2001). Overexpression of soluble complement receptor-related protein y (sCrry), a complement C3 inhibitor, resulted in enhanced A β accumulation and hippocampal degeneration (Wyss-Coray et al. 2002). Since C3 is known to promote phagocytosis by binding to specific C3 receptor on specialized cells, C3 is likely to be positively involved in A β clearance.

CD45, a transmembrane protein tyrosine phosphatase critically involved in negative regulation of T- and B-cell activation, and an antagonizing partner of the TNF superfamily (Tan et al. 2000b), is also upregulated in AD brains (Masliah et al. 1991). APP mice deficient in CD45 have increased brain levels of TNF- α and NO, suggesting CD45 negative regulation of neuroinflammation in AD (Tan et al. 2000a).

30.4.3 Oxygen Free Radicals

Production of ROS, factors involved in the aging process (Finkel and Holbrook 2000), is elevated in AD brain and may be an important cause of AD (Martins et al. 1986). Elevated

levels of oxidized lipids (lipid peroxidation, malondialdehyde, 4-hydroxynonenal) (Markesbery and Carney 1999), proteins (advanced glycation end product modifications, tyrosine nitration) (Takeda et al. 1998; Good et al. 1996), and nucleic acids (8-hydroxy-deoxyguanosine) have been documented in AD brains (Lyras et al. 1997). Mitochondria and nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex dysfunction can generate large amounts of ROS (Beal 1998), and down regulation of mitochondrial NADPH 15-kD gene have been found in AD cases (Manczak et al. 2004; Beal 1998). Markers of oxidative stress are elevated not only in the pathologic lesions in AD brain (Good et al. 1996), but also in cerebrospinal fluid of AD patients (Lovell et al. 1997). A β peptide can directly activate the NADPH oxidase complex of mononuclear phagocytes (Bianca et al. 1999) and microglia, which are mediated through the interaction of fibrillar A β to cell surface molecules (CD36, CD47, and α 6 β 1-integrin) and tyrosine kinase Vav signaling (Wilkinson et al. 2006). ROS is also known to mediate A β -induced neurotoxicity (Behl et al. 1994; Ikezu et al. 2003). In addition to NADPH oxidase, myeloperoxidase (MPO) is expressed by microglia in close proximity to A β plaques, and surprisingly, in neurons of AD brains (Reynolds et al. 1999; Green et al. 2004). MPO can catalyze both apoE and A β , generating oxidated and fragmented apoE (Jolivald et al. 1996) and stable A β 42 dimers through dityrosine bridge formation (Galeazzi et al. 1999; Jolivald et al. 1996).

30.4.3.1 Oxidative DNA Damage

DNA damage may also have a role in AD pathology. Recent studies indicate that aging-mediated DNA damage, including alterations in neuronal network and cognitive function-related gene expression profiles, is significantly increased after 40 years of age, (Lu et al. 2004). DNA damage induces cell cycle activation (Kruman et al. 2004), and cell cycle activation has been documented in AD brains (Nagy et al. 1998; Smith et al. 1999). DNA damage also potently induces p53, a tumor suppressor and transcriptional factor involved in neuronal apoptosis (Morrison et al. 2003; Kruman et al. 2004; Culmsee and Mattson 2005). Neuronal expression of p53 is increased in AD brains (de la Monte et al. 1997) and in APP mouse brains (LaFerla et al. 1996). These data suggest that DNA damage is involved in neurodegeneration in AD brain, or the result of neurodegeneration.

30.5 Immunotherapeutics Inventions

A detailed review on the immunotherapeutics of AD is referred to Sect. 3.2.1 (David Cribbs). Epidemiological studies using non-steroidal anti-inflammatory drugs (NSAIDs) has led to the proposal that NSAIDs reduce the risk of AD

(McGeer et al. 1996). These studies have been supported by data showing that treatment of APP mice with NSAIDs (such as ibuprofen and NO-flurbiprofen) in vivo results in reduced A β deposition and pro-inflammatory cytokine production (Lim et al. 2000; Jantzen et al. 2002; Yan et al. 2003). Microglial activation is suppressed by ibuprofen but rather enhanced by NO-flurbiprofen. Other studies have found that NSAID also affects γ -processing of APP through inhibition of the small GTP-binding protein Rho, which converts A β processing from A β 42 to A β 40 both in vitro and in vivo (Eriksen et al. 2003; Weggen et al. 2001; Zhou et al. 2003). Based on these observations, a new series of drugs derived from NSAIDs having a more specific effect on γ -processing has been developed (Kukar et al. 2005; Weggen et al. 2003; Czirr and Weggen 2006).

Proliferator-activated receptor γ (PPAR γ) agonists, such as the thiazolidinedione family, are also NSAIDs and can efficiently clear A β deposition in vitro and in vivo (Camacho et al. 2004; Heneka et al. 2005). PPAR is a nuclear transcription factor and its effect is different from ibuprofen and its derivatives. PPAR γ transcription factors play important physiological roles in the regulation of lipid metabolism (Mangelsdorf et al. 1995; Lemberger et al. 1996), suppression of inflammation (Heneka et al. 2000), and clinical treatment of diabetes type II (Dormandy et al. 2005). PPAR γ agonists enhance A β degradation (Camacho et al. 2004), as well as suppress BACE expression and microglial activation (Heneka et al. 2005).

Other anti-inflammatory/anti-oxidant dietary applications include curcumin, the yellow pigment in turmeric that targets multiple AD pathogenic cascades (Yang et al. 2005; Lim et al. 2001). The dietary omega-3 fatty acid, docosahexaenoic acid (DHA), also reduced amyloid, oxidative damage and synaptic and cognitive deficits in a transgenic mouse model (Lim et al. 2005; Calon et al. 2004). Both DHA and curcumin have favorable safety profiles, epidemiology and efficacy, and may exert general anti-aging benefits (Cole et al. 2005).

30.6 Review Questions

- Which is NOT the causative gene of familial Alzheimer's disease?
 - APP
 - Presenilin-1
 - Presenilin-2
 - Tau*
 - None of the above
- Presenilin-1 is a member of:
 - α -secretase
 - β -secretase
 - γ -secretase complex

- (d) A β degrading enzyme
- (e) None of the above
3. Amyloid-beta peptide is a processing product of amyloid precursor protein (APP) through a combination of
 - (a) α -secretase and Beta-site APP cleaving enzyme (BACE1)
 - (b) α -secretase and γ -secretase complex
 - (c) BACE1 and γ -secretase complex
 - (d) BACE1 and insulin-degrading enzyme
 - (e) none of the above
4. Microglia-mediated inflammatory reaction affects AD progression via
 - (a) cytokine production
 - (b) reactive nitrogen/oxygen production
 - (c) excitotoxin production
 - (d) *all of the above*
 - (e) none of the above
5. A β deposition in APP mouse brain can be reduced by vaccination with the following antigens except
 - (a) A β
 - (b) *apoE4*
 - (c) Copaxon-1
 - (d) transgenic potato expressing amyloid-beta peptide
 - (e) none of the above
6. Non-steroidal anti-inflammatory drugs (NSAIDs) can reduce A β deposition in APP mouse brain through
 - (a) suppression of brain inflammation
 - (b) suppression of A β 42 generation
 - (c) suppression of BACE expression
 - (d) *all of the above*
 - (e) none of the above
7. Describe the available animal models for studying AD. What is the limitation of the animal models?
8. Describe the potential immunotherapy of AD.

30.7 Answers

7. Common animal models of AD includes transgenic mice expressing familial-AD-linked mutation of APP (such as Tg2576, PDAPP, and APP23) and PS1 (such as PS1/APP and 3xTg-AD). These mouse models consistently develop amyloid plaques, neuroinflammation, cognitive dysfunction and neurophysiological impairment as determined by electrophysiology. The limitation of these animal models are the lack of two other neuropathology in AD: prominent neurofibrillary tangle formation and neuronal cell loss in cortical and subcortical regions. Many of the mouse model also takes many months to develop disease-like pathology, often over 1 year.
8. ANSWER: A conventional approach is either active or passive immunotherapy against A β . Active immunization of AD mouse models and human patients with synthetic

A β peptide was successful in reducing the clearance of amyloid deposition in the brain. However, this approach is largely obsolete due to the significant side effect associated with active immunization, such as meningoencephalitis. Passive immunization is also effective in lowering the amyloid load in the brain, although in a transient manner, without significant side effects. Passive immunization against A β is active in a large scale clinical trials, such as Anti-amyloid Treatment in Asymptomatic Alzheimer's disease (A4).

and Serge Przedborski

Abstract

Parkinson's disease (PD) is a common neurodegenerative disorder characterized by motor abnormalities and a loss of primarily, but not exclusively, dopaminergic neurons. Other neuropathological hallmarks of PD include the proteinaceous inclusions, Lewy bodies and various inflammatory changes. The inflammation is made up of resident innate and, to lesser extent, adaptive immune cells. These inflammatory changes are found in both sporadic and familial non-PD parkinsonian syndromes and in experimental models of PD. There are studies that suggest that inflammation initiates PD, but most investigations rather suggest that, in PD, inflammation is secondary to the demise of the neurons. Mounting evidence indicates that inflammation in PD and in related conditions can modulate the neurodegenerative process. However, there is still a lack of consensus about whether inflammation in PD plays a beneficial or a detrimental role.

31.1 Introduction

In this chapter, selected topics on inflammation in Parkinson's disease (PD) and in models of this human disease will be reviewed. To set the stage, the biological, clinical and pathological hallmarks of PD and related degenerative conditions

are reviewed. A more comprehensive view of PD can be found in the following references (Fahn and Przedborski 2005; Dauer and Przedborski 2003).

Parkinson's disease is the second most common neurodegenerative disorder of the aging brain after the dementing disorder, Alzheimer's disease (AD). The average age of onset is in the fifth to sixth decades of life with a reduced life expectancy for all onset ages but, as reported by Ishihara et al. (2007), this reduction is greatest in individuals with a young-onset PD (i.e. age at onset ≤ 40). It is estimated that more than one million individuals in the United States alone are affected with PD and, around 50,000 new cases are identified each year. The main clinical features of PD include resting tremor, slowness and paucity of voluntary move-

ments (i.e. bradykinesia), increased muscle tone (i.e. rigidity), and postural instability. Similar to many other prevalent neurodegenerative disorders discussed in this book, including AD and amyotrophic lateral sclerosis (ALS), PD presents itself essentially as a sporadic condition. However, as with AD and ALS, only a small fraction of PD patients (~10%) inherit the disease. In some of these familial cases, the genetic defect has been identified and linked to mutations in a variety of genes. Currently, over 15 disease-causing genes for PD have been identified (Trinh and Farrer 2013). The most salient motor features of PD cited above are similarly seen in both the sporadic and the familial forms of PD and have, especially for bradykinesia and rigidity, been attributed to a profound deficit in brain dopamine (Hornykiewicz and Kish 1987). Given this fact, it is not surprising that most of the attention has been geared toward the study of the dopaminergic pathways in PD.

Autopsy investigations have revealed that most of the ascending dopaminergic pathways in PD are affected, although to different degrees (Hornykiewicz and Kish 1987), the nigrostriatal pathway being consistently more affected than any other (Hornykiewicz and Kish 1987). The nigrostriatal pathway is made up of dopaminergic neurons whose cell bodies are located in the substantia nigra pars compacta and their projecting axons and terminals in the striatum (Fig. 31.1a). Among these dopaminergic neurons, it appears that those with the highest content of brown pigment called neuromelanin are the ones most prone to degeneration (Hirsch et al. 1988). In contrast to the damage to the ascending pathways, the descending dopaminergic pathways are generally spared (Hornykiewicz and Kish 1987). If the most salient clinical features of PD are indeed related to the damage in the dopaminergic system in the brain, it cannot be stressed enough that degenerative changes in PD are restricted neither to the nigrostriatal pathway nor to other

Fig. 31.1 Neuropathology of Parkinson's disease. **(a)** Schematic representation of the normal nigrostriatal pathway (in red). It is composed of dopaminergic neurons whose cell bodies are located in the substantia nigra pars compacta (SNpc; see arrows). These neurons project (thick solid red lines) to the basal ganglia and synapse in the striatum (i.e., putamen and caudate nucleus). The photograph demonstrates the normal pigmentation of the SNpc, produced by neuromelanin within the dopaminergic neurons. **(b)** Schematic representation of the diseased nigrostriatal pathway (in red). In Parkinson's disease, the nigrostriatal pathway degenerates. There is a marked loss of dopaminergic neurons that projects to the putamen (dashed line) and a much more modest loss of those neurons that project to the caudate (thin red solid line). The photograph demonstrates depigmentation (i.e., loss of the dark-brown pigment neuromelanin; arrows) of the SNpc due to the marked loss of dopaminergic neurons. **(c)** immunohistochemical labeling of intra-neuronal inclusions, termed Lewy bodies, in a SNpc dopaminergic neuron. Immunostaining with an antibody against α -synuclein reveals a Lewy body (black arrow) with an intensely immunoreactive central zone surrounded by a faintly immunoreactive peripheral zone (left photograph). Conversely, immunostaining with an antibody against ubiquitin yields more diffuse immunoreactivity within the Lewy body (right photograph). From Dauer and Przedborski, *Neuron* 39:889–909, 2003, with permission

dopaminergic systems (Hornykiewicz and Kish 1987; Agid et al. 1987). For instance, abnormal histological features can also be found in many non-dopaminergic cell groups including the locus coeruleus, raphe nuclei, and nucleus basalis of Meynert (Braak et al. 1995).

In PD, all affected areas of the brain also contain intra-neuronal proteinaceous inclusions called Lewy bodies (Shults 2006). These bodies contain alpha synuclein and neuromelanin and can readily be visualized by either classical histological methods, e.g. hematoxylin & eosin, or by immunohistochemistry using antibodies raised against alpha-synuclein or ubiquitin (Fig. 31.1b, c). Often, Lewy bodies are large and round, and occupy most of the cytoplasmic area of the few spared dopaminergic neurons. While identification of these proteinaceous inclusions is usually used for neuropathological diagnostic purposes, the actual pathogenic role of Lewy bodies remains controversial. Another, but often overlooked, salient neuropathological feature of PD is the presence of inflammatory changes within affected regions (Forno et al. 1992; McGeer et al. 1988). This inflammatory response is the topic of this chapter and will be described in further detail below.

31.2 Inflammatory Response in Parkinson's Disease

Before discussing the issue of inflammation in PD *per se*, it is worth reviewing briefly the question of innate resident immune cell topography in the normal brain. In a healthy adult brain, microglia constitute roughly 10% of all glial cells and are not evenly distributed in the brain (Lawson et al. 1990). In an unstimulated situation, microglia exhibit elongated, bipolar shaped cell bodies with spine-like processes that often branch out perpendicularly. Among the areas of the brain susceptible to the PD process, the density of microglia identified by the labeling of the specific plasma membrane glycoprotein F4/80 (a well-characterized macrophage marker that is part of the EFG-TM7 family and that shares a 68% amino acid homology with human EGF-like module-containing mucin-like hormone receptor-like 1) is higher in the substantia nigra compared to other regions of the brain, at least in adult mice (Lawson et al. 1990). In contrast to microglia, astrocytes in the normal adult brain are homogeneously distributed, except in the midbrain where the estimated density of glial fibrillary acidic protein (GFAP)-positive cells varies among the different catecholaminergic groups (Damier et al. 1993). The density of GFAP-positive cells is moderate in those midbrain areas most severely affected in PD, such as the SNpc, and high in those areas least affected, such as the central gray matter (Damier et al. 1993). Furthermore, it has been shown that the density of GFAP-positive cells within the SNpc is lowest in the

calbindin-D_{28K} SNpc where the loss of dopaminergic neurons is the highest (Damier et al. 1999).

Because of the notoriety of nigrostriatal dopaminergic damage in PD, information regarding inflammation in this common neurodegenerative disorder pertains essentially to the substantia nigra and the striatum. Consistently, it has been found that the loss of dopaminergic neurons in post-mortem PD brains is associated with microgliosis and astrogliosis (McGeer et al. 1988; Forno et al. 1992; Banati et al. 1998; Mirza et al. 2000). However, these changes have always been found to be more intense in the SNpc than in the striatum (McGeer et al. 1988). This situation contrasts with that of the loss of dopaminergic structures, which is more intense in the striatum than in the substantia nigra.

At the cellular level, the majority of the immunostained astrocytes in PD exhibit a resting-like morphology, with thinly shaped cell bodies and elongated processes, while only few exhibit a reactive morphology with hypertrophic cell bodies and short processes (Mirza et al. 2000; Forno et al. 1992; McGann et al. 2012). Furthermore, there seems to be only a minimal increase in astrocyte numbers when GFAP- or metallothionein I/II-positive cells are quantified (Mirza et al. 2000). Unlike the astrocyte alterations discussed above, the microglial changes in PD are striking (McGeer et al. 1988; Banati et al. 1998; Mirza et al. 2000; Imamura et al. 2003). Morphologically, microglial cells in both the substantia nigra and the striata of PD patients, unlike controls, typically exhibit thick, elongated processes (McGeer et al. 1988; Banati et al. 1998; Mirza et al. 2000). The number of these activated microglia, identified by HLA-DR or ferritin immunostaining, is much higher in PD than in controls (Mirza et al. 2000; Imamura et al. 2003). Activated microglia are found mainly near free neuromelanin in the neuropil and remaining neurons in the substantia nigra (McGeer et al. 1988). Similar microglial activation is also found in the striatum (Imamura et al. 2003). However, do these activated microglia contribute to the PD disease process via active processes .g. release of cytokines) or rather by passive ones, merely by failing to function properly (Kaushik and Basu 2013)?

31.3 Inflammatory Response in Parkinsonian Syndromes

While PD is the most common of the parkinsonian syndromes, more than 30 different neurological syndromes share the clinical features of PD (Dauer and Przedborski 2003). Many of these non-PD parkinsonian syndromes are sporadic (Table 31.1) and often exhibit both clinical (e.g., ocular movement) and neuropathological features typically not seen in PD (e.g., striatal or corticospinal track pathology). Of these syndromes, most, if not all, show evidence of nigrostriatal neurodegeneration (not always associated with

Table 31.1 Parkinsonian syndromes

<i>Primary parkinsonism</i>
Parkinson disease (sporadic, familial)
<i>Secondary parkinsonism</i>
Drug-induced: dopamine antagonists and depletors
Hemiatrophy-hemiparkinsonism
Hydrocephalus: normal pressure hydrocephalus
Hypoxia
Infectious: post-encephalitic
Metabolic: parathyroid dysfunction
Toxin: Mn, CO, MPTP, cyanide
Trauma
Tumor
Vascular: multiinfarct state
<i>Parkinson-plus syndromes</i>
Cortical-basal ganglionic degeneration
Dementia syndromes: Alzheimer disease, diffuse Lewy body disease, frontotemporal dementia
Lytico-Bodig (Guamanian Parkinsonism-dementia-ALS)
Multiple system atrophy syndromes: Striatonigral degeneration, Shy-Drager syndrome, sporadic olivopontocerebellar degeneration (OPCA), motor neuron disease-parkinsonism
Progressive pallidal atrophy
Progressive supranuclear palsy
<i>Familial neurodegenerative diseases</i>
Hallervorden-Spatz disease
Huntington disease
Lubag (X-linked dystonia-parkinsonism)
Mitochondrial cytopathies with striatal necrosis
Neuroacanthocytosis
Wilson disease

MPTP 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, *ALS* amyotrophic lateral sclerosis (From Dauer and Przedborski, *Neuron* 39:889–909, 2003, with permission)

Lewy bodies) and inflammation (Oppenheimer and Esiri 1997) at autopsy. Unfortunately, inflammation is casually mentioned in most published reports on non-PD parkinsonian syndromes, and when the authors of these reports do mention inflammation, it is often limited to vague, qualitative statements. For instance, in the initial reports on progressive supranuclear palsy (Steel et al. 1964) and on striatonigral degeneration (Adams and Salam-Adams 1986), *gliosis* was recognized as a prominent feature of the pathological changes seen in these syndromes, but this is the only reference to inflammation. However, whether or not gliosis, as mentioned in these studies, refers to alterations in astrocytes, microglia, or in both, remains unknown. Despite this limitation, it is remarkable that gliosis is not only described in these non-PD parkinsonian syndromes at the level of the nigrostriatal pathway, but also at the level of other regions in the brain, which are normally not involved in PD. This indicates a rather wide-spread neuropathology which is consistent

with the usual multisystemic nature of many of these parkinsonian syndromes (Table 31.1).

Aside from sporadic parkinsonian syndromes, several familial forms of PD also exist (Vila and Przedborski 2004). Like in sporadic PD, histological examinations revealed similar glial alterations in most of the familial forms of parkinsonian syndromes, whether the underlying genetic defect has (Vila and Przedborski 2004) or has not been identified (Dwork et al. 1993). Among these familial parkinsonian syndromes, the situation of the autosomal dominant form of PD linked to mutations in the gene coding for leucine-rich repeat kinase 2 (LRRK2) is interesting (Zimprich et al. 2004). In the six autopsies from patients carrying a LRRK2 mutation reported by Zimprich and collaborators (2004), all had nigrostriatal dopaminergic neuronal loss and gliosis in the substantia nigra. However, some of these patients had dopaminergic neuronal loss and gliosis without Lewy bodies, whereas others had dopaminergic neuronal loss and gliosis with Lewy bodies (Zimprich et al. 2004). In the latter cases, Lewy bodies were restricted to the brainstem, or widespread in the brainstem and cortex. In one case, there were also *tau*-immunoreactive lesions not only in neurons, but also in glial cells (Zimprich et al. 2004). In the autosomal recessive parkinsonian syndrome linked to *parkin* mutations there is also a loss of dopaminergic neurons associated with astrogliosis and microgliosis but, as in several LRRK2 mutation cases, not typically with Lewy bodies (Hayashi et al. 2000). These findings support the view that neuroinflammation is a generic feature that arises from neuronal death irrespective of the type of parkinsonian syndrome or neuropathological picture. This also suggests that the presence of Lewy bodies is not a prerequisite for the occurrence of inflammation in PD and related conditions.

31.4 Inflammatory Response in Experimental Models

As discussed above, autopsy studies from patients afflicted with parkinsonian syndromes have led to the conclusion that inflammation is part of the neuropathological picture of these neurodegenerative disorders. While the descriptive data provided by these studies are invaluable, the generated information remains correlative by nature and fails to provide mechanistic insights. This is why researchers rely heavily on experimental models of PD. These models help to define the temporal and topographical relationships between inflammation and dopaminergic neuronal death and, more importantly, to determine the potential pathogenic role of inflammation in the death of dopaminergic neurons.

There are a variety of animal models of PD (Lee et al. 2012) to study the basis of neurodegeneration in this disorder, ranging from invertebrates to non-human primates. These are either genetic or toxic in nature (Dauer and

Przedborski 2003). There are generally two types of animal models. The first type involves genetically mutated genes (α -synuclein or LRRK2) which are associated with an increased risk of PD. The second type involves the administration of toxic agents, such as MPTP, rotenone and paraquat, which have been associated with PD-like symptoms in humans. The neuropathological picture created in these animal models, particularly in the toxic models, is very close to that described for PD including, neurodegeneration and motor and behavioral effects. In almost all of the PD models, whether or not there is an overt loss of nigrostriatal dopaminergic neurons, a glial response is found in the substantia nigra. Some data on inflammation are available in rodent models produced by the herbicide paraquat (McCormack et al. 2002) and the mitochondrial poison rotenone (Sherer et al. 2003). Data can also be found from transgenic mice expressing mutant alpha-synuclein (Gomez-Isla et al. 2003). The limited amount of data on inflammation in these models however is in striking contrast to the wealth of information available for the 6-hydroxydopamine (6-OHDA) and the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) toxic models of PD. Perhaps this can be explained by the fact that both the 6-OHDA and MPTP models are not only more popular among PD researchers, but also they have been used for much longer than the other models cited above. Supporting the generic nature of the inflammatory response in neurodegeneration are the observations that both the type and magnitude of the glial alterations in rodents following the administration of 6-OHDA (Nomura et al. 2000; Przedborski et al. 1995; Sheng et al. 1993; Stromberg et al. 1986; Rodrigues et al. 2001; He et al. 1999; Akiyama and McGeer 1989) are comparable to those seen following the administration of MPTP (see below).

In the early eighties, several drug-addicts became intoxicated with MPTP after self-injecting contaminated street-batches of a meperidine analog (Langston et al. 1983). Among these individuals, some developed an acute, irreversible parkinsonian syndrome indistinguishable from PD (Ballard et al. 1985). Of the few MPTP-intoxicated individuals who died and underwent autopsy, post-mortem examination showed a profound loss of nigrostriatal dopaminergic neurons (Davis et al. 1979; Langston et al. 1999). This dramatic loss of large neuronal cells was in striking contrast with the obvious abundance of small cells immunoreactive for either the astrocyte marker GFAP or the microglia marker HLA-DR (Langston et al. 1999). Almost all of the GFAP- and the HLA-DR-positive cells exhibited morphological characteristics of, respectively, reactive astrocytes and activated microglia (Langston et al. 1999). Images of neuronophagia were also observed (Langston et al. 1999). Similar glial alterations were found in six monkeys, which survived 5–14 years after an acute MPTP intoxication (McGeer et al. 2003). In all of these monkeys, there was also evidence of extracellular neuromelanin and activated microglia in the

substantia nigra (McGeer et al. 2003). These monkeys also had an abundance of reactive astrocytes positive for the intracellular adhesion molecule-1 (Miklossy et al. 2005). The presence of intracellular adhesion molecule-1-positive reactive astrocytes, of activated microglia, and of neuronophagia in humans and monkeys subjected to an acute MPTP intoxication many years prior is remarkable as these neuropathological features suggest an active, ongoing inflammatory process. Microglial activation and neuronophagia would be expected to be seen in PD tissues in light of its progressive neurodegenerative nature. However, as stressed by McGeer and collaborators (2003), these neuropathological findings challenge the belief that MPTP, “produces an acute loss of cells, followed by healing and long-term stabilization of surviving neurons.” Alternatively, these neuropathological data raise the possibility that acute MPTP intoxication can set into motion a self-sustained cascade of detrimental effects on dopaminergic neurons. Corroborating this view is a positron emission tomography study in which 10 individuals exposed acutely to MPTP were scanned twice, seven years apart (Vingerhoets et al. 1994). This work revealed a decrease of [18 F]fluorodopa uptake in the striata of these patients between the first and second imaging studies (Vingerhoets et al. 1994). Also remarkable is the fact that three of the 10 MPTP-intoxicated participants were asymptomatic at the time of the first scan but became parkinsonian by the time of the second scan (Vingerhoets et al. 1994) supporting a progressive nature of the neurodegenerative process in this toxic parkinsonian syndrome, at least in primates.

In small animals such as mice, time course experiments have been performed to define not only the kinetics of dopaminergic neuronal death but also of the glial response. These studies demonstrated that the appearance of reactive astrocytes paralleled the destruction of dopaminergic structures in both the striatum and the substantia nigra in mice (Czlonkowska et al. 1996; Kohutnicka et al. 1998; Liberatore et al. 1999). Worth noting, GFAP expression remained high even after the main phase of neuronal degeneration (Czlonkowska et al. 1996; Kohutnicka et al. 1998; Liberatore et al. 1999). Also important to note is the fact that, on inhibition of the entry of the active metabolite of MPTP, 1-methyl-4-phenylpyridinium (MPP^+), into dopaminergic neurons, there is not only a protection of substantia nigra dopaminergic neurons, but also a lack of glial response (O’Callaghan et al. 1990). This critical observation indicates that inflammation in the MPTP model is a consequence of the demise of neurons and not the reverse. This interpretation may not be valid for all types of injury used to model PD as we will see for the endotoxin of gram-negative bacteria lipopolysaccharide (LPS). The activation of microglial cells is also quite robust after MPTP administration to mice (Fig. 31.2); this has been extensively documented in the MPTP mouse model (Czlonkowska et al. 1996; Kohutnicka et al. 1998; Liberatore et al. 1999; Dehmer et al. 2000). When the astrocyte and

Fig. 31.2 Effects of MPTP on dopaminergic neurons and glial cells in ventral midbrain of mice. For this illustration, mice received either 0.3 ml of MPTP (2 mg/ml) or vehicle (saline) in one day. (a, e) Two days after the last injection of MPTP, TH immunofluorescence (blue) reveals a marked reduction in dopaminergic neurons in the substantia nigra pars compacta compared to controls (saline). (b, c, f, g) The loss of TH labeling coincides with an increase in immunofluorescent labeling of microglial cells (Mac-1; green) and of astrocytes (GFAP; red).

(d, h) Overlay of the three cellular markers. When MPTP and saline tissue sections are compared, these images show that, upon reduction in the dopaminergic neuronal marker, there is an increase in the two glial markers. Ventral midbrain tissue sections (30 μ m) were immunostained with a rabbit polyclonal anti-TH (1:1000; Calbiochem, San Diego, CA), a rat anti-MAC-1 (1:1000; Serotec, Raleigh, NC), and a chicken anti-GFAP (1:500, Chemicon, Temecula, CA). Scale bar = 200 μ m

microglial responses are compared, however, it appears that microglial activation occurs earlier than that of astrocytes, and peaks just before or coincidentally with, the climax of dopaminergic neurodegeneration (Liberatore et al. 1999).

In addition to the response of the innate immune system in the MPTP mouse model, there has also been some descriptive data from Czelonkowska and collaborators (Kurkowska-Jastrzebska et al. 1999a, b) about the response of the adaptive immune system. Although this question will be developed in-depth in the chapter authored by Dr. Lee Mosley, herein it is included as a brief informative aspect. In the series of investigations performed by Czelonkowska and collaborators cited above, a marked increase of MHC-II antigen expression by microglia accompanied by a recruitment of T-cells in both the ventral midbrain and striatum of MPTP-injected mice were found. In contrast to the infiltration of the diseased areas of the brain with T-cells, there were no B-cells in the tissue samples. The investigators went further into their characterization of the adaptive immune system in this model by showing that the infiltrating T-cells were mainly of the CD8+ type, but some CD4+ were present too, and more than 50 % of the observed lymphocytes expressed the CD44 antigen.

One problem with any animal model of PD and, in particular, rodent models, is that the PD symptoms presented in these models appear acutely. In contrast, human PD is a late onset neurodegeneration that occurs over many decades.

31.5 Initiation of the Inflammatory Response in Parkinsonian Brains

If indices of inflammation are well recognized in tissues from virtually all neurodegenerative disorders including PD, how inflammation begins, remains. In reviewing the literature, two main hypotheses are emerging. One hypothesis posits that inflammation precedes and triggers the actual loss of dopaminergic neurons. Based on this model, the starting point of the neurodegenerative process would be an insult to the brain by pro-inflammatory factors such as LPS or other infectious-related molecules. Although there is no evidence that septic individuals with high levels of LPS develop PD (Lee et al. 2012), administration of this molecule to mice has been used to initiate dopaminergic neuronal death and the ensuing neuroinflammatory response (Lee et al. 2009). Relevant to this possibility is the demonstration that a

stereotaxic injection of LPS into a normal SNpc produces a local inflammatory response that is associated with the degeneration of dopaminergic neurons in adult rats (Liu et al. 2000). Similarly, LPS-induced inflammation led to the neurodegeneration of dopaminergic MES 23.5 cells or primary ventral midbrain neurons co-cultured with purified microglia (Le et al. 2001). Based on a series of investigations in rodents, it seems that even a prenatal exposure to LPS could produce a long-lasting inflammatory response in the brain (Ling et al. 2004). This striking observation led the authors to propose that “individuals exposed to LPS prenatally, as might occur if their mothers had bacterial vaginosis, would be at increased risk for PD.”

As much as the first hypothesis appears tantalizing, most of the available data are rather consistent with this second hypothesis which posits that inflammation in PD results from the detection of pathological alterations in neighboring neurons by the immune system. According to this model, inflammation in PD and related disorders is thus not the initiator of a primary event, but rather the consequence of neurodegeneration. However, how dysfunctional or dying neurons elicit the inflammatory response remains unknown. Many glial cells are located in close proximity to neurons. Therefore, it may very well be that inflammation could be initiated by some type of change in the nature or the quality of the neuronal contact with glial cells. In healthy cells including neurons, phosphatidylserine is located at the cytoplasmic side of the plasma membrane, while the outer monolayer is composed of phosphatidylcholine and sphingomyelin. A loss of this phospholipid asymmetry of the plasma membrane, with appearance of phosphatidylserine in the outer membrane leaflet, is a feature of cells undergoing apoptosis (van den Eijnde et al. 1998). It is thus possible that such an alteration of the neuronal membrane could be detected by the neighboring glial cells, leading to their activation.

Cell culture studies also show that inflammation can be triggered by soluble factors, either secreted or leaked by neurons. For instance, chromogranin-A is a glycoprotein widely distributed in the nervous system, and was shown to accumulate in areas of neurodegeneration (Nishimura et al. 1994). Noteworthy is the fact that once released or leaked by neurons, chromogranin-A could activate microglia (Ciesielski-Treska et al. 1998). Furthermore, dopaminergic neurons in both PD and experimental models of PD are the site of a robust induction of cyclooxygenase-2 (Teismann et al. 2003), which is a key prostaglandin-synthesizing enzyme. It is also plausible that once synthesized, prostaglandins exit neurons and activate their cognate receptors expressed by glial cells, thereby triggering inflammatory events. Similarly, neuromelanin, upon its release into the extracellular space from dying neurons, can strongly activate glial cells (Wilms et al. 2003). Furthermore, it has been demonstrated that human neuromelanin, extracted from PD brains, can cause a robust

inflammatory response when injected into the substantia nigra of normal rats (Zhang et al. 2011). Finally, it has been suggested that misfolded neuronal proteins and protein aggregates may contribute to glial activation in PD. This view has been prompted by the observations that mutations in the genes encoding for parkin and ubiquitin C-terminal hydrolase L1—two enzymes of the ubiquitin/proteasome pathway—and for alpha-synuclein—a main component of the intraneuronal proteinaceous inclusions Lewy bodies—are linked to familial PD (Vila and Przedborski 2004).

Although more work needs to be done to identify the factors that initiate inflammation in PD and related disorders, mounting evidence indicates that this immune response is probably not a standard event of dysfunctional and dying neurons. Currently, most researchers favor the idea that *specific* neuronal-derived molecules bind to *specific* transmembrane receptors, such as toll-like receptors (TLRs) present on glial cells (Bowman et al. 2003). Among the ten different TLRs, each is activated by a distinct ligand (Iwasaki and Medzhitov 2004), for instance, TLR9, according to Ros-Bernal et al. 2011, is up-regulated in PD brains and in the brains of animal models of PD. TLRs activation, studied in the past in the context of infection, is now being examined in relation to DA neuron death as it is now believed that inflammation in neurodegenerative disorders arises from the ligation of the particular TLR subtypes by molecules originating from dysfunctional and dying neurons. Relevant to this idea is the demonstration of wild-type alpha-synuclein, which upon overexpression can cause a familial form of PD (Eriksen et al. 2005), is secreted by neurons through unconventional exocytosis (Lee et al. 2005). Furthermore, it appears that the expression of markers of microglial activation parallels the extent of alpha-synuclein deposits in the substantia nigra of PD patients (Croisier et al. 2005). At this point, it would be quite interesting to know whether alpha-synuclein or any other mutant proteins linked to familial PD can bind to TLRs.

31.6 Role of Inflammation in Parkinson's Disease

Over the past decade, the idea that brain inflammation (also referred to as neuroinflammation) may modulate the neurodegenerative process in disorders like PD has attracted major interest among neuroscientists. How can this be explained given the fact that inflammation is likely a consequence of neurodegeneration? Neurons in all degenerative diseases die in an asynchronous manner (Pittman et al. 1999). Accordingly, in PD, dopaminergic neurons in the SNpc do not die simultaneously. Instead, only a small number of dopaminergic neurons are dying at any given time and, among these, many are in various stages along the cell death

process. Based on these premises, it may thus be envisioned that the very first neurons to succumb trigger inflammation. Thereafter, the cellular environment in which compromised but still living neurons are embedded becomes inflamed. Should this scenario be correct, it would be significant in opening the door to fostering the understanding of how inflammation could modulate the neurodegenerative process. While most experts do agree on the idea that glial cells play a role in the neurodegenerative process, the significance and, more importantly, the direction of the effect remains a matter of fierce debate (Streit 2002). This dispute is fueled, in part, by the fact that both *in vitro* and *in vivo* system models of human diseases have revealed both detrimental and beneficial effects of inflammation. For instance, the blockade of microglial activation by minocycline has been associated with either reduction or augmentation of dopaminergic neurodegeneration after MPTP administration (Du et al. 2001; Wu et al. 2002; Yang et al. 2003; Diguët et al. 2004). These divergent results may stem from the fact that inflammation is capable of exerting both neuroprotective and neurodestructive functions. Thus, depending on the local factors, the extent of the degenerative process, and even the etiology of the disease, inflammation can give rise to quite a distinct molecular and cellular phenotype.

31.7 Beneficial Role of Inflammation in Parkinsons' Disease

Several *in vivo* studies support the capability of inflammation to mediate neuroprotective and neurodegenerative actions in the nervous system (Drouin-Ouellet and Cicchetti 2012). One such example is the facial nerve axotomy paradigm in newborn rats and rabbits. In this system model, axotomized motor neurons recover coincidentally with the development of the glial response (Moran and Graeber 2004). Furthermore, one month after implantation of innate immune resident cells, such as microglia, into a small mechanically-produced cavity in the rat spinal cord, prominent neuritic growth was observed in the microglial grafts (Rabchevsky and Streit 1997). These results are agreed upon by some experts who believe that, in both normal and pathological situations, the function and survival of neurons rely on the presence of glial cells (Streit 2002).

The basis of the glial-derived beneficial role is likely multifactorial involving both cell contact and soluble mediators. For instance, glial cells play a critical role in maintaining ion and pH homeostasis, as well as extracellular volume. Glial cells can also protect neurons by scavenging and taking-up toxic molecules released by dysfunctional and dying neurons. A striking example of glial assistance in the process of neuronal well-being is glutathione, which is a tripeptide of great importance in the protection of neurons against reac-

tive oxygen species (ROS). Indeed, unlike glial cells, neurons do not possess an uptake system for cysteine (Pow 2001) which is necessary for the synthesis of glutathione. Instead, it has been proposed (Dringen 2000) that astrocytes assist neurons in their production of glutathione through a complex multistep process. First, the astrocytes would use extracellular substrates as precursors for glutathione. Second, glutathione would be released by astrocytes and then converted by the glial ectoenzyme gamma-glutamyl transpeptidase into the dipeptide CysGly. Third, CysGly would be taken-up by neurons and used as a precursor to neuronal glutathione. It has also been proposed (Dringen 2000) that glutamine produced by astrocytes would be used by neurons to produce glutamate, which is necessary for the synthesis of glutathione. Furthermore, astrocytes can avidly take up extracellular glutamate via the glutamate transporters GLT1 and GLAST. This fact may be quite relevant to PD pathogenesis as not only an excess amount of glutamate in the substantia nigra may emanate from dying neurons, but also from the subthalamic glutamatergic input (Benazzouz et al. 2000), which is increased in PD (DeLong 1990). Finally, through the production and maintenance of glutathione, astrocytes can protect against free radicals which can inhibit neurite outgrowth in the brain (Pizzurro et al. 2014). Thus, due to the ability of glial cells to maintain low concentrations of extracellular glutamate in the substantia nigra, the risk of excitotoxic injury to neurons here is prevented.

Aside from contributing to the protection of neurons against ROS and glutamate, glial and T-cells can produce trophic factors that are essential for the survival of dopaminergic neurons. Among these is the glial-derived neurotrophic factor (GDNF), which seems to be the most potent factor supporting nigrostriatal dopaminergic neurons during their period of natural, developmental death in post-natal ventral midbrain cultures (Burke et al. 1998). GDNF can be released by reactive astrocytes (Schaar et al. 1993) by the activation of microglia following a mechanical lesion of the striatum (Batchelor et al. 2000) and can be delivered locally through the implantation of astrocytes, a strategy that has been shown to be protective in 6-OHDA-injected rats (Drinkut et al. 2012). After MPTP administration to mice, however, it seems that reactive astrocytes in the substantia nigra do not engage in a significant production of GDNF (Benner et al. 2004) which may be due to the robustness of the MPTP dosing schedule. Brain-derived neurotrophic factor (BDNF) is another trophic factor that can also be released by reactive astrocytes (Rubio 1997; Stadelmann et al. 2002) and by activated microglia (Batchelor et al. 1999; Stadelmann et al. 2002), and can support the survival and development of dopaminergic structures in the striatum (Batchelor et al. 1999). Furthermore, stem cell-producing BDNF (Somoza et al. 2010) has been shown to be effective in PD animal models. Oligodendrocytes, whose main function is to provide

support to axons and to produce the myelin sheath which insulates axons, are also a type of glial cell capable of generating trophic factors (Du and Dreyfus 2002). For example, striatal oligodendrocytes have been shown to stimulate the survival and expression of phenotypic markers of mesencephalic dopaminergic neurons in culture (Sortwell et al. 2000). Taken together, these data support the contention that glial cells, especially astrocytes, could exert neuroprotective effects in PD. However, whether any of these slow the natural course of the disease in parkinsonian patients remains to be demonstrated.

31.8 Detrimental Role of Inflammation in Parkinsons' Disease

In addition to the body of literature on the beneficial role of inflammation, there is also a growing number of observations supporting the concept that activation of the innate immune system could worsen neurodegeneration (Drouin-Ouellet and Cicchetti 2012; Cappellano et al. 2013). Three theories have been proposed to explain the detrimental role of glial cells in diseases like PD. The first theory is called *glial cell senescence* (Streit 2004), which postulates that glial cells become progressively disabled during normal aging or disease progression. In this theory, it is assumed that glial cells lose their functional capacity to exert the type of beneficial effects described above. In this model, glial cells do not actively injure neurons; they simply stop supporting them, maybe due to aging (Streit and Xue 2009). Although still highly speculative, some investigations would suggest that glial cells may become dysfunctional in PD. For instance, Hishikawa et al. 2001 have found argyrophilic, alpha-synuclein-positive inclusions in glial cells from postmortem PD, but not from age-matched control brains. In addition, Gardai et al. 2013 found impaired cytokine release and phagocytosis in mice over-expressing alpha-synuclein, a finding that was extended to the human condition. The second theory about the detrimental role of inflammation in PD is called *facilitative neurotoxicity* (Streit 2002). During this theoretical process, glial cells would eliminate neurons that are compromised beyond viability and functionality by the primary pathological event. Based on this second model, glial cells would assume an active role in the demise of neurons that are destined to die and whose continued presence could hinder neuronal recovery. Finally, the third theory and probably the most popular in regards to the detrimental role of inflammation in PD is called *indiscriminate neurotoxicity*. Based on this third model, glial cells, upon activation, would engage in an array of cytotoxic events, which would stimulate neurodegeneration and promote both the progression and propagation of a disease such as PD. Over the past two decades, studies using experimental models of PD have

provided strong support for this last concept, which is based on the fact that activated glial cells, especially microglia, are known to produce a variety of noxious compounds including ROS, reactive nitrogen species (RNS), pro-inflammatory prostaglandins, and cytokines. Here, membrane proteins are repeatedly challenged which can detrimentally affect these proteins, thus leading to neuronal death (Kanfer et al. 1999).

Among the range of reactive species produced by glial cells, significant attention has been given to RNS due to the idea that the nitric oxide (NO)-mediated nitrating stress could play an important role in the pathogenesis of PD (Przedborski et al. 1996; Ara et al. 1998; Pennathur et al. 1999; Giasson et al. 2000; Przedborski et al. 2001). Along this line, it must be mentioned that inducible NO synthase (iNOS) is expressed in the SNpc of both PD patients (Hunot et al. 1996) and MPTP-intoxicated mice (Liberatore et al. 1999; Dehmer et al. 2000) in both astrocytes and microglial cells. Furthermore, the effects of NO are even noted at the molecular level as it has been shown that the s-nitrosylation of Parkin decreases its activity as a repressor of p53, which plays a role in apoptotic cell death (Sunico et al. 2013). Myeloperoxidase and NADPH-oxidase, two pro-inflammatory enzymes that produce strong oxidants, have also been identified in PD and MPTP brain tissues (Choi et al. 2005; Wu et al. 2003). Ablation of these three enzymes have been shown to attenuate MPTP-induced neurodegeneration in mice (Liberatore et al. 1999; Dehmer et al. 2000; Choi et al. 2005; Wu et al. 2003), supporting the involvement of inflammation-mediated oxidative/nitrative stress in the dopaminergic neurodegenerative process.

Prostaglandins and their synthesizing enzymes, such as Cox-2, constitute another group of potential offenders. Over the past few years, Cox-2 has emerged as a key cytotoxic factor associated with inflammation (O'Banion 1999). As mentioned above, compared to the normal basal ganglia where Cox-2 is minimally expressed, in the diseased basal ganglia in PD and in the MPTP mouse model, Cox-2 is robustly expressed (Teismann et al. 2003). Not surprisingly, the levels of Cox-2 products such as prostaglandin E₂ were also found to be increased in the substantia nigra of PD patients (Teismann et al. 2003; Mattammal et al. 1995). In the MPTP mouse model of PD, Cox-2 induction was shown to be mediated by a c-Jun N-terminal kinase (JNK)-dependent mechanism (Teismann et al. 2003; Hunot et al. 2004). Noteworthy, the inhibition of JNK activation, like inhibition of Cox-2, does attenuate MPTP-induced neurodegeneration (Hunot et al. 2004; Teismann et al. 2003). Conversely, while both inhibition and ablation of Cox-2 did attenuate MPTP-induced dopaminergic neurotoxicity, deletion of the constitutively expressed isoenzyme Cox-1 had no effect (Teismann et al. 2003).

Additional glial-derived molecules with cytotoxic potentials include the large group of pro-inflammatory cytokines. The expression level of many of these toxic

cytokines, assessed by gene profiling, appears increased in PD tissues (Mandel et al. 2005). In keeping with this result, tumor necrosis factor- α (TNF- α) and interleukin-1 β (IL-1 β) levels are increased in both SNpc tissues and cerebrospinal fluid of PD patients (Mogi et al. 2000; Mogi et al. 1996; Mogi et al. 1994). Of note, at this point, one cannot exclude that some of these alterations may be related to the chronic use of the anti-PD therapy levodopa (Bessler et al. 1999). Nevertheless, in autopsy tissue from PD patients, robust immunostaining for TNF- α , IL-1 β , and interferon- γ (IFN- γ) is observed in astrocytes at the level of the SNpc and in the MPTP-treated mouse at the level of the substantia nigra (Lofrumento et al. 2011). In terms of mechanism, these cytokines may operate in PD on at least two levels. First, once produced by reactive astrocytes, they can stimulate neighboring, quiescent astrocytes and microglia to elicit neurodegeneration (Mallajosyula et al. 2008). Consistent with this view is the upregulation of the microglial receptor Fc ϵ R11/CD23 in response to astrocyte-derived TNF- α , IL-1 β , and IFN- γ (Hunot et al. 1999). In this study, the authors show that, once upregulated, ligation of Fc ϵ R11/CD23 stimulates the expression of iNOS and the ensuing production of NO by microglial cells (Hunot et al. 1999). Second, astrocytic and microglial-derived cytokines may also operate directly on dopaminergic neurons by binding to specific cell surface cytokine receptors such as TNF- α receptor and FAS. However, the targeting of either TNF- α receptor (Rousselet et al. 2002; Ferger et al. 2004) or FAS (Hayley et al. 2004; Landau et al. 2005) has thus far generated conflicting results in the MPTP mouse model. Findings from several studies show that ablation of these receptors decreased MPTP-induced dopaminergic neurotoxicity (Ferger et al. 2004; Hayley et al. 2004), whereas other studies found that it increased MPTP-induced dopaminergic neurotoxicity (Rousselet et al. 2002; Landau et al. 2005). Upon activation, cytokine receptors trigger intracellular death-related signaling pathways, whose molecular correlates include translocation of the transcription nuclear factor- κ -B (NF- κ -B) from the cytoplasm to the nucleus. Relevant to this is the fact that PD patients show 70 times more dopaminergic neurons with nuclear NF- κ -B immunoreactivity compared to control subjects (Hunot et al. 1997). Despite the robust recruitment of NF- κ -B, it is not clear whether this transcriptional factor is instrumental in PD pathogenesis, as mice deficient in one of the main NF- κ -B polypeptides, P50, showed the same severity of MPTP-induced nigrostriatal pathway damage as that of their wild-type counterparts (Hunot et al. 2004). As exemplified above, at this point, experimental models of PD have not provided much insight into the role of cytokines in neurodegeneration for such conditions as PD and other related disorders.

31.9 Review Questions

1. What are the clinical and neuropathological hallmarks of PD?
2. What is the difference between parkinsonian syndrome and Parkinson's disease?
3. Provide examples of experimental models of PD.
4. What is the topography and composition of the inflammatory response in PD?
5. What are the similarities and differences in the inflammatory response among PD, the various parkinsonian syndromes, and the common experimental models of PD?
6. What are the arguments in favor of inflammation being a primary or a secondary event in PD?
7. How can dying dopaminergic neurons trigger inflammation in PD?
8. By which mechanisms could inflammation be beneficial in PD?
9. Name the three theories about the detrimental role of inflammation in PD and explain their respective basis.
10. Summarize the different cellular and molecular factors of inflammation that can actively mediate the demise of dopaminergic neurons in PD?
11. Which statement is incorrect about PD?
 - a. Parkinson's disease is the second most frequent neurodegenerative disorder.
 - b. *The neurodegenerative process in Parkinson's disease is restricted to the dopaminergic system.*
 - c. Parkinson's disease is mainly a sporadic condition.
 - d. More than 30 other neurodegenerative diseases can clinically look like Parkinson's disease.
 - e. Aside from the loss of neurons the neuropathology of Parkinson's disease includes Lewy bodies and gliosis.
12. What are the main inflammatory cells encountered in the substantia nigra of Parkinson's?
 - a. Astrocytes
 - b. Microglia
 - c. Oligodendrocytes
 - d. T-cells
 - e. *a and b*
13. Which statement is correct concerning inflammation in parkinsonian syndromes?
 - a. *It is often noted, but more wide-spread and less detailed than in Parkinson's disease.*

- b. The type of inflammatory response differs between the sporadic and familial parkinsonian syndromes.
 - c. The syndrome multisystem atrophy is unique in that inflammation is primarily made up of infiltrating T-cells.
 - d. The neuropathological pleomorphism in patients carrying a LRRK2 mutation refers to the fact that neither Lewy bodies nor gliosis is a consistent finding.
 - e. None of the above.
14. Which statement about experimental models of Parkinson's disease is true?
 - a. Both genetic and toxic models exist, but only the former are commonly used.
 - b. *Inflammation has been described in all popular models of Parkinson's disease.*
 - c. The MPTP monkey model suggests that an acute intoxication produces an acute neurodegenerative event that is completed in a few days.
 - d. The MPTP mouse model suggests that the toxin provokes inflammation, which, in turn, kills dopaminergic neurons.
 - e. Neuronophagia which suggests ongoing inflammation has been described in genetics, but not in toxic models of Parkinson's disease.
 15. Which of the following statements is true about inflammation in Parkinson's disease?
 - a. Free neuromelanin fails to activate microglia.
 - b. Astrocytosis is as robust as microgliosis.
 - c. The propensity of the different dopaminergic structures to degenerate in Parkinson's disease correlates with the basal density of glial cells.
 - d. *Both prostaglandin and alpha-synuclein count among the factors potentially responsible for triggering inflammation in Parkinson's disease.*
 - e. It is proven that prenatal infection and subsequent inflammation predispose one to Parkinson's disease.
 16. Which of the following statements is most correct?
 - a. *Inflammation can exert both beneficial and detrimental effects.*
 - b. Most experimental models favor the beneficial role of inflammation
 - c. The detrimental role of inflammation in Parkinson's disease is due to the disease-related impairment of glial functions vital to neurons.
 - d. Contrary to astrocytes, oligodendrocytes play no role in Parkinson's disease.
 - e. Three different theories have been proposed to explain how inflammation may support the survival of dopaminergic neurons.
 17. Which of the following glial functions may improve neuronal survival or regeneration?
 - a. Inhibit phagocytosis.
 - b. Secrete chemotactic molecules to recruit polynuclear cells.
 - c. *Produce trophic factors.*
 - d. Assist in the synthesis of neuronal superoxide dismutase.
 - e. Stimulate the formation of myelin to guide new axons.
 18. Glial cells can exacerbate neurodegeneration in Parkinson's disease by?
 - a. Losing their ability to assist neighboring neurons.
 - b. Accelerating the demise of compromised neurons.
 - c. A process of indiscriminate toxicity.
 - d. Decreasing extracellular glutamate levels.
 - e. *a, b and c*
 19. Regarding the cytotoxicity of inflammation, which statement is not correct?
 - a. Both oxygen and nitrogen reactive species can participate in the deleterious effects of inflammation.
 - b. *Inactivation of NADPH-oxidase, but not of nitric oxide synthase, mitigates MPTP-induced neurodegeneration in mice.*
 - c. The detrimental effects of inflammation on dopaminergic neurons can be mediated by soluble factors.
 - d. Astrocytes and microglial cells can mutually modulate their degree of activation.
 - e. Dopaminergic neurons express receptors for various deleterious cytokines.
 20. Among the following inflammatory factors which ones have been identified in the substantia nigra of patients with Parkinson's disease?
 - a. Tumor necrosis factor
 - b. Inducible nitric oxide synthase
 - c. Interferon-gamma
 - d. Myeloperoxidase
 - e. *All of the above*

31.10 Answers

1. Motor abnormalities and a loss of primarily, but not exclusively, dopaminergic neurons. Other neuropathological hallmarks of PD include the proteinaceous inclusions, Lewy bodies and various inflammatory changes.
2. Many of these non-PD parkinsonian syndromes are sporadic and often exhibit both clinical (e.g., ocular movement) and neuropathological features typically not seen in PD (e.g., striatal or corticospinal track pathology). Of these syndromes, most, if not all, show evidence of nigrostriatal neurodegeneration (not always associated with Lewy bodies) and inflammation.
3. Animal models and cell culture studies
4. the density of microglia identified by the labeling of the specific plasma membrane glycoprotein F4/80 (a well-characterized macrophage marker that is part of the EFG-TM7 family and that shares a 68% amino acid

homology with human EGF-like module-containing mucin-like hormone receptor-like 1) is higher in the substantia nigra compared to other regions of the brain, at least in adult mice. The density of GFAP-positive cells is moderate in those midbrain areas most severely affected in PD, such as the SNpc, and high in those areas least affected, such as the central gray matter.

5. Gliosis is not only described in these non-PD parkinsonian syndromes at the level of the nigrostriatal pathway, but also at the level of other regions in the brain, which are normally not involved in PD. The neuropathological picture created in these animal models, particularly in the toxic models, is very close to that described for PD including, neurodegeneration and motor and behavioral effects. In almost all of the PD models, whether or not there is an overt loss of nigrostriatal dopaminergic neurons, a glial response is found in the substantia nigra.
6. LPS-induced inflammation led to the neurodegeneration of dopaminergic MES 23.5 cells or primary ventral midbrain neurons co-cultured with purified microglia. Inflammation in PD and related disorders is thus not the initiator of a primary event, but rather the consequence of neurodegeneration. However, how dysfunctional or dying neurons elicit the inflammatory response remains unknown.
7. It may very well be that inflammation could be initiated by some type of change in the nature or the quality of the neuronal contact with glial cells.
8. The blockade of microglial activation by minocycline has been associated with either reduction or augmentation of dopaminergic neurodegeneration after MPTP administration
9. The first theory is called *glial cell senescence*, which postulates that glial cells become progressively disabled during normal aging or disease progression. In this theory, it is assumed that glial cells lose their functional capacity to exert the type of beneficial effects described above. In this model, glial cells do not actively injure neurons; they simply stop supporting them, maybe due to aging (Streit and Xue 2009). Although still highly speculative, some investigations would suggest that glial cells may become dysfunctional in PD. For instance, Hishikawa and collaborators have found argyrophilic, alpha-synuclein-positive inclusions in glial cells from postmortem PD, but not from age-matched control brains. In addition, Gardai et al. found impaired cytokine release and phagocytosis in mice over-expressing alpha-synuclein, a finding that was extended to the human condition. The second theory about the detrimental role of inflammation in PD is called *facilitative neurotoxicity*. During this theoretical process, glial cells would eliminate neurons that are compromised beyond viability and functionality by the primary pathological

event. Based on this second model, glial cells would assume an active role in the demise of neurons that are destined to die and whose continued presence could hinder neuronal recovery. Finally, the third theory and probably the most popular in regards to the detrimental role of inflammation in PD is called *indiscriminate neurotoxicity*. Based on this third model, glial cells, upon activation, would engage in an array of cytotoxic events, which would stimulate neurodegeneration and promote both the progression and propagation of a disease such as PD. Over the past two decades, studies using experimental models of PD have provided strong support for this last concept, which is based on the fact that activated glial cells, especially microglia, are known to produce a variety of noxious compounds including ROS, reactive nitrogen species (RNS), pro-inflammatory prostaglandins, and cytokines. Here, membrane proteins are repeatedly challenged which can detrimentally affect these proteins, thus leading to neuronal death.

10. Also important to note is the fact that, on inhibition of the entry of the active metabolite of MPTP, 1-methyl-4-phenylpyridinium (MPP⁺), into dopaminergic neurons, there is not only a protection of substantia nigra dopaminergic neurons, but also a lack of glial response. This critical observation indicates that inflammation in the MPTP model is a consequence of the demise of neurons and not the reverse.

Abstract

Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease characterized by the loss of upper and lower motoneurons, eventually culminating in respiratory failure and death. Great insight as to what causes ALS has resulted from discovery of more than 20 gene disease-causing mutations. Clinical heterogeneity cannot be explained by altered gene expression alone, and accumulating evidence implicates neuroinflammation in modifying clinical phenotypes. In ALS neurons do not die alone; neuronal injury is non-cell-autonomous and depends on a well-orchestrated dialogue involving glia, T cells and motor neurons, mediating neuronal viability and neuronal injury. This neuroinflammatory response differs in different ALS patients: patients progressing rapidly have decreased regulatory T lymphocytic responses, while patients progressing slowly had normal to increased levels of Treg and FoxP3 expression. Therapeutic efforts targeting neuroinflammation have the potential of changing an acute rapidly progressive disease into a more slowly progressing disease and a more sustainable quality of life.

32.1 Introduction: Clinical Features

Amyotrophic lateral sclerosis (ALS) is a devastating, relentlessly progressive, neurodegenerative disease that severely compromises the quality of life as well as the length of life. (Haverkamp et al. 1995). The incidence of ALS is 1–2/100,000 and the prevalence is 4–6/100,000. Ninety percent of ALS cases are sporadic (sALS), while 10% are familial (fALS). Despite intensive efforts the factors initiating disease in sALS patients are not understood, and no known pharmacotherapy can significantly influence either disease progression or survival. In sALS, the mean age of onset is 57 years and the median survival is approximately 4

years with younger patients surviving longer than older individuals. Males develop sporadic ALS more frequently than females with an overall ratio 1.7:1. However, in younger individuals, the ratio of males to females may exceed 3:1, while in older individuals the frequency of female involvement is increased and the ratio approaches 1:1 over the age of 65, similar to the ratio in fALS.

In the last two decades more than 20 mutant genes that cause fALS have been discovered. A defect in the gene encoding copper-zinc superoxide dismutase (SOD1) was first described in 1993 and is present in 20% of fALS cases (Rosen et al. 1993). More recently, the presence of a hexanucleotide repeat (GGGGCC) in C9orf72 was reported in 30–50% of fALS cases (Renton et al. 2011; DeJesus-Hernandez et al. 2011) and is now recognized as the most common cause of fALS.

The clinical presentations of both sALS and fALS, can be remarkably diverse, and phenotypic heterogeneity is the rule

rather than the exception. As a result, it may be extremely difficult to predict the clinical course in any single patient which is a major challenge when developing clinical trials for this population.

The clinical hallmark of ALS is the presence of upper motor neuron and lower motor neuron disease of brainstem and spinal regions (Fig. 32.1) ALS can present with first symptoms and signs in the teenage years or in the 80's; disease duration can be as short as 6 months or as long as 40 years; and the initial presentation can be with limb onset, bulbar onset, or less commonly with breathing difficulty or neck weakness.

Symptoms and signs may start with complaints of arm or hand weakness, wasting, or functional impairment, such as difficulty writing, buttoning, or holding onto objects, or leg weakness with stumbling, tripping, and falling. Onset is usually asymmetrical, progressing from one leg to the ipsilateral arm or the contralateral leg, and then proceeding rostrally. Clinically, ALS may be misdiagnosed as a painless cervical radiculopathy and myelopathy when initial signs and symptoms are restricted to a single limb or adjacent root accompanied by hyperreflexia in the legs and before electromyography (EMG) studies are performed. Ruling out significant cervical spinal cord compression with neuroimaging is mandatory. However, many patients may have the presence of both ALS and suggestive cervical cord compromise. By recognizing the common asymmetrical presentation of ALS as well as the slow but relentless progression of atrophy and weakness, in addition to EMG evidence of lower motor neuron involvement, these patients could

avoid surgery that could aggravate the clinical syndrome. An additional dilemma in the diagnosis of ALS is the patient that presents with progressive atrophy and weakness and EMG findings characteristic of lower motor neuron involvement, yet with reflexes that are slightly decreased. The absence of hyperreflexia suggests a lower motor neuron syndrome such as progressive muscular atrophy. However, in this clinical context corticospinal tract involvement cannot be simply ruled out with a reflex hammer, yet we are still awaiting the development of meaningful surrogate markers of upper motor neuron, including neuroimaging modalities, to resolve this diagnostic dilemma.

In patients with bulbar involvement, symptoms of hoarseness, slurred speech, and drooling often precede choking or swallowing problems. Bulbar symptoms and signs, in association with tongue atrophy and fibrillations, may be the presenting feature in 20–25 % of patients, with a large percentage in women over the age of 60 (Haverkamp et al. 1995). In general, onset of bulbar signs during the disease course carries a poorer prognosis.

Cognitive dysfunction due to fronto-temporal lobe involvement is a frequently associated feature in 50 % of ALS patients and ranges from mild, frontal executive dysfunction to outright frontotemporal dementia (FTD) in 15 % (Ringholz et al. 2005). Whereas, up to 40 % of FTD cases have measureable motor neuron dysfunction with 15 % of cases with outright ALS, supporting that ALS and FTD are on a spectrum of disease (Bennion Callister and Pickering-Brown 2014). ALS-FTD patients typically have onset of

symptoms in their 50's, like ALS alone, it is slightly more common in men than women. The ALS symptoms may precede, co-occur, or follow the symptoms of FTD, although the most common finding is to have cognitive change first followed by weakness.

The interval between the cognitive symptoms and motor weakness may be a few months to up to 7 years, with a mean of 2 years (Achi and Rudnicki 2012). In patients with FTD apathy is often the first symptom reported by caregivers. FTD patients exhibit a lack of empathy and are unaware of the emotions of others. They may be more withdrawn and self-centered, and lack concern for their personal appearance. They may become disinhibited, and develop impulsive or socially inappropriate behavior. Their reasoning, judgment and organizational skills become markedly diminished, and their personal hygiene and overall care represent significant problems for their caregivers.

The presence of frontal dysfunction also contributes significantly to disease heterogeneity with patients presenting with varying clinical signs on a continuum from pure ALS to pure FTD; patients with ALS can have normal executive function, extensive frontal executive dysfunction plus ALS, or severe FTD with only minimal signs and symptoms of ALS.

Pseudobulbar affect is also a common symptom in ALS patients and characterized as a sudden outbursts of uncontrolled laughter or tearfulness/crying that can occur spontaneously or in response to provocative stimuli, such as television commercial or posed question. The displays are dissociated from the patient's underlying emotional state or mood or are out of proportion to it. Expectedly, this syndrome can have profound social consequences for the patient and family, however, can be effectively treated with a relatively new FDA approved drug, Nuedexta®, which has been shown to significantly decrease the number and severity of these outbursts in patients (Pioro et al. 2010)

The history and physical examination provide the foundation for the diagnosis and should demonstrate the combination of lower motor neuron (LMN) compromise, manifested by weakness and muscle atrophy, and upper motor neuron (UMN) compromise, evidenced by increased tone and hyperreflexia, with involvement in at least three areas, including the limbs, tongue, and back muscles. Needle EMG and nerve conduction studies of an upper and lower limb, thoracic paraspinal muscles and tongue should be performed to confirm the diagnosis in all patients with suspected ALS.

32.1.1 Pathogenesis

Most early studies of the pathogenesis of ALS focused on changes within motor neurons that could reflect the mechanisms of cell injury and cell destruction. In the early 1990's the presence of glutamate excitotoxicity was implicated (Rothstein

et al. 1990). Other studies emphasized the importance of increased intracellular calcium (Engelhardt et al. 1997; Siklos et al. 1996) and free-radical mechanisms in mediating cell death in ALS (Bowling et al. 1993; Simpson et al. 2004). However, none of these explanations are mutually exclusive because altered calcium homeostasis, free radical stress, and glutamate excitotoxicity may all participate in a cell injury cascade leading to motor neuron death. In fact, alterations in one parameter can lead to alterations in other parameters, and each can enhance and propagate the injury cascade. Increased intracellular calcium can enhance free radical production (Dyken 1994) and glutamate release (Coyle and Putterfarcken 1993; Carriedo et al. 1998) which in turn can further increase intracellular calcium. Increased free radicals can impair the glial uptake of glutamate, increasing the extracellular glutamate available to interact with neuronal AMPA/kainate receptors, which in turn can increase intracellular calcium and/or free radicals. Free radicals in turn can enhance lipid peroxidation leading to increased intracellular calcium (Kakkar et al. 1992). These changes of increased intracellular calcium, increased production of free radicals, and enhanced glutamate excitotoxicity could critically impair motor neuron structures such as mitochondria or neurofilaments, and compromise energy production and axoplasmic flow. Once initiated, the changes could become self-propagating.

32.1.2 Role of Mutant Genes in ALS

In the last several decades discovery of more than 20 genetic mutations has dramatically changed approaches to the pathogenesis of disease in ALS. Collectively these mutations cause alterations in diverse cellular pathways that contribute to disease pathogenesis and include mitochondrial dysfunction, increased reactive oxygen species, altered axonal transport, altered RNA metabolism, splicing, and transport, altered proteasomal function, impaired autophagy, and endoplasmic reticulum stress. A common denominator in many of these pathologies is the presence of misfolded aggregated proteins.

The first mutation to be described was in the gene for superoxide dismutase, (SOD1) a ubiquitously expressed protein that catalyses the detoxification of superoxide (Rosen et al. 1993). More than 160 SOD1 mutations have been described, all of which result in SOD1 protein misfolding and a toxic gain-of-function and lead to impaired mitochondrial function, axonal degeneration in a distal to proximal pattern ("dying-back"), impaired proteasomal function, and endoplasmic reticulum stress. The cytotoxic effects of aggregated SOD1 are not confined to mutant SOD1, but also are noted with misfolded wild-type SOD1, which has been identified in motor neurons of sALS patients, and could contribute to disease pathogenesis in sporadic cases.

The next major milestone was the identification of TDP-43 inclusions in ALS brain and spinal cords in 2006, and the subsequent discovery of TDP-43 gene mutations in fALS patients (Sreedharan et al. 2008; Kabashi et al. 2008). TDP-43 is ubiquitously expressed as a DNA/RNA binding protein involved in transcription, and RNA splicing and transport. In fALS patients mutant TDP-43 is cleaved and aggregated, with localization shifted from the nucleus to the cytoplasm impairing nuclear function. In 2009 mutations in FUS/TLS were described, with cytoplasmic aggregates and impaired nuclear function and nuclear transport, similar to the functional changes noted with mutant TDP-43, (Kwiatkowski et al. 2009; Vance et al. 2009).

In 2011 the most common cause of fALS, accounting for 30–50 % of cases, was discovered as a hexanucleotide repeat (GGGGCC) in the gene C9orf72 (Renton et al. 2011; DeJesus-Hernandez et al. 2011). Expansions in C9orf72 have also been reported in 5–10 % of sALS patients. The specific pathogenic mechanisms whereby C9orf72 leads to ALS are still incompletely defined, but three different potential pathogenic mechanisms have been proposed: 1. Haploinsufficiency, due to impaired C9orf72 transcription, 2. RNA toxicity due to binding of critical transcription or splicing factors by the C9orf72 hexanucleotide repeat; and 3. Non-ATG translation yielding polypeptides that readily aggregate and promote cytotoxicity.

Other genetic mutations initiate changes in vital motor neuron pathways that lead to an ALS clinical phenotype. Mutations in SOD1 lead to impaired axonal transport and axonal degeneration; mutations in the profilin-1 gene that normally mediates actin polymerization lead to axonal dysfunction (Wu et al. 2012); and mutations in dynactin lead to defects in axoplasmic cargo transport (Münch et al. 2004). Mutations in genes for ubiquitin 2 and p62 have been reported to compromise proteasomal function and autophagy and result in the clinical picture of ALS. (Deng et al. 2011; Fecto et al. 2011).

Such genetic heterogeneity was anticipated to provide a major explanation for phenotypic heterogeneity, since each distinctive mutant gene might initially compromise a relatively specific motor neuron metabolic pathway and result in a specific clinical phenotype. However, clinical phenotypes are so heterogeneous in both sALS and fALS patients that it is even difficult to classify patients as belonging to the 10 % with fALS or the 90 % with sALS based solely on the presenting clinical syndrome without taking a careful family history and doing genetic testing. Thus the clinical picture alone cannot classify the patients as having fALS or sALS. Phenotypic heterogeneity is noted even within affected members of a family with the same mutation, and in different families the same genetic mutation can give rise to multiple clinical phenotypes. Conversely, different mutant genes can give rise to the same clinical phenotype.

Phenotypic heterogeneity at the level of the gene could also be explained by epistasis, the interactions of multiple genes, as well as by epigenetic modifications including DNA methylation, histone acetylation, chromatin remodeling, and non-coding RNA regulation. In accord, the inheritability of sALS is estimated between 12–21 % of cases suggesting genetic influence on such cases. A recent study, reported that up to 28 % of sALS patient and 80 % of fALS have novel variants in genes associated with an earlier disease onset of 10 years in those with >1 variants detected (Cady et al. 2014). Such studies support an oligogenic inheritance in ALS that is relevant to disease pathogenesis. With continuing advances in next-generation sequencing and application in genomic wide association studies, the interaction of these genes upon penetrance, progression and survival for the individual patient will become clearer.

Another reason that distinctive mutations might not solely explain phenotypic heterogeneity, and might, in fact, give rise to similar clinical syndromes is the interaction and interdependence of metabolic pathways within the motor neuron. For example, mutations in mSOD1 may initially compromise mitochondria and subsequently increase free radical species, alter calcium homeostasis, compromise axonal function, alter proteasomal function, autophagy, and RNA metabolic pathways, and lead to ER stress and the unfolded protein response. Similarly, mutations in mTDP-43 or FUS may initially compromise transcription, RNA splicing or transport, and subsequently impair multiple diverse pathways within the motor neuron.

The involvement of multiple metabolic pathways in the progression from motor neuron injury to cell death suggests cell autonomous toxicity with neurons dying alone without the contribution of non-neuronal cells. Yet such is not the case, at least in the transgenic mouse of mutant SOD1 where cellular contributions can be identified. Expressing the mSOD1 primarily in motor neurons in transgenic mice does not lead to motor neuron disease and cell death. In these models, neurons do not die alone; the process is non-cell autonomous. Injury to motor neurons may be necessary as an early event, but may not be sufficient to cause severe injury and cell death. Neuronal injury and cell death do not occur in isolation, but require the participation of non-neuronal cells such as innate immune microglia and adaptive immune T lymphocytes in the pathogenesis of motor neuron cell death in ALS.

32.1.3 Neuroinflammation in ALS Transgenic Mice

The presence of activated innate (microglia) and adaptive immune cells (T lymphocytes) within the brain and spinal cord is characteristic of neuroinflammation. Neuroinflammation was originally thought to be a secondary effect

or consequence of neuronal injury, but is now increasingly recognized to contribute significantly to motor neuron pathophysiology and disease propagation (Henkel et al. 2009; Zhao et al. 2013). The most cogent evidence derives from transgenic rodent models of ALS.

Transgenic mice (Gurney et al. 1994) overexpressing mutant $\text{Cu}^{2+}/\text{Zn}^{2+}$ superoxide dismutase (mSOD1) develop a progressive motor neuron disease that resembles the clinical and pathological features of human familial amyotrophic lateral sclerosis (ALS). The motor neuron degeneration in these transgenic mice appears to be non-cell autonomous, i.e., non-neuronal cells contribute to disease pathogenesis. Expression of mSOD1 either in astrocytes (Gong et al. 2000) or in neurons (Pramatarova et al. 2001; Lino et al. 2002) does not induce an ALS-like disease in mice; nor does expression of mSOD1 in microglia cause disease (Beers et al. 2006). Data from chimeric mice, using the original mSOD1 promoter, in the same genomic location, and with the same number of copies, suggest that mSOD1-overexpressing neurons surrounded by normal glia remain relatively intact, whereas normal neurons surrounded by mSOD1-overexpressing glia showed signs of injury (Clement et al. 2003).

Non-cell autonomy suggests that neuroinflammation characterized by activated innate immune microglia and adaptive immune lymphocytes might contribute to the pathogenesis of motor neuron cell death in ALS models. At presymptomatic stages, spinal cords from mSOD1 transgenic mice have increased ICAM-1 expression, deposition of immunoglobulin G (IgG) within motor neuron cell bodies, and increased Fc receptor (FcR) expression on microglia (Alexianu et al. 2001). Activated microglia are present as early as 80 days of age, prior to evidence of motor weakness.

After disease onset in the mSOD1 transgenic mouse, there are two clinical phases: an initial “slow” phase where the mouse does not appear to worsen clinically, followed by a “rapid” phase of accelerated weakness and death (Beers et al. 2011b). The spinal cords of mSOD1 transgenic mice in the early slow phase are characterized by increased protective regulatory T lymphocytes and anti-inflammatory M2 microglia/macrophages, with increased expression of IL-10, IL-4, BDNF, GDNF, IGF-1, and TGF β . During the later accelerated phase of disease activated microglia have a pro-inflammatory M1 phenotype with increased expression of NOX2, IL-1 β , TNF α , and IL-6. In vitro, activated M2 microglia are neuroprotective for motor neurons while activated M1 microglia are neurotoxic.

However, the most cogent evidence for the neuroprotective effects of M2 microglia and the cytotoxic effects of M1 microglia derives from in vivo studies in the mSOD1 transgenic mice: the adoptive transfer of wild-type M2 microglia slowed disease progression while transfer of mSOD1 M1 microglia accelerated disease progression (Beers et al. 2006).

T-cell involvement in disease pathogenesis was documented in experiments that depleted the entire T cell population by crossbreeding the mSOD1 transgenic mice with RAG2 $^{-/-}$ or TCR $^{-/-}$ knockout mice. Surprisingly, the disease course significantly worsened in these mSOD1 T cell deficient mice, indicating that T cells had been neuroprotective (Beers et al. 2008; Chiu et al. 2008). The most prominent neuroprotective T cells are regulatory T and Th2 lymphocytes with the former suppressing the proliferation of potentially neurotoxic T effector cells and both Treg and Th2 suppressing the pro-inflammatory functions of activated M1 microglia (Zhao et al. 2012). Th2 CD4 $^{+}$ T cells and Tregs can express high levels of the anti-inflammatory factor IL-4 polarizing microglia to the neuroprotective (M2) phenotype. The most compelling evidence for the neuroprotective effects of T cells derives from in vivo experiments in which adoptive transfer of CD4 $^{+}$ and specifically Tregs early in the course of disease rescued these mice and extended survival (Banerjee et al. 2008; Beers et al. 2011a). These T cells not only promote microglia-mediated neuroprotection but also astroglia-mediated neuroprotection by increasing production of neurotrophic factors such as glial-cell-derived neurotrophic factor (GDNF).

In the “rapid” phase of accelerated weakness and death, spinal cords of the mSOD1 transgenic possess decreased regulatory T lymphocytes and increased proinflammatory Th1 lymphocytes and M1 microglia/macrophages. This shift from neuroprotective cells to cytotoxic cells results in a marked decrease in expression of neuroprotective cytokines and trophic factors and a dramatic increase in pro-inflammatory cytokines, accelerating a self-propagating cascade of motor neuron injury and cell death. Tregs transferred at this late stage are not able to reverse the ongoing progressive clinical deterioration.

32.1.4 In Vitro studies

To help define the interactions of motor neurons with non-neuronal cells such as microglia, we used primary MN cultures to investigate the effects of microglia activated by lipopolysaccharide or IgG immune complexes from patients with amyotrophic lateral sclerosis (Zhao et al. 2004). Following activation, microglia induced MN injury, which was preventable by a microglial inducible nitric oxide synthetase (iNOS) inhibitor as well as by catalase or glutathione. Glutamate was also required to elicit MN injury; inhibition of the motoneuron AMPA/kainate receptor by CNQX prevented the cytotoxic effects of activated microglia. In fact, peroxynitrite, a toxic product of nitric oxide metabolism, and glutamate were synergistic in producing MN injury. We subsequently demonstrated that misfolded mSOD1 protein but not wild-type SOD1 protein could activate microglia to

release free radicals and proinflammatory cytokines and provoke motor neuron cell death. The misfolded mSOD1 protein did not injure motor neurons in the absence of microglia (Zhao et al. 2010). It has also been demonstrated that mSOD1 released from motor neurons derived from transgenic mice could activate microglia, and, in turn, lead to motor neuron injury and cell death (Urushitani et al. 2006). Such evidence suggests that misfolded proteins or their peptide fragments may well be the “danger signals” released from injured motor neurons activating a neuroinflammatory response of proinflammatory microglia and T lymphocytes, and triggering a self-propagating motor neuron injury and cell death.

32.2 Human ALS Studies

Although early studies of ALS tissue did not describe the presence of inflammatory cells in ALS, reports beginning in 1988 suggested that inflammatory cell infiltration might be relatively common (Troost et al. 1988; Troost et al. 1989). Further studies (Lampson et al. 1990) demonstrated activated microglia and small numbers of T cells in degenerating white matter of ALS cords. Activated microglia are also prominent in the ventral horn of spinal cords from ALS patients. In contrast to resting microglia, which have long, highly branched processes, activated microglia have hypertrophied soma and thickened, retracted processes. Reactive microglia express surface markers indicative of their activated state. These include the complement receptor, CD11b; leukocyte common antigen (LCA); and major histocompatibility complex (MHC) class II glycoproteins, such as human leukocyte antigen DR (HLA-DR). In addition to serving a phagocytic function, activated microglia may also communicate with and affect the function of cells in the local environment, by expressing a broad array of cytokines, chemokines, proteases, and neurotrophic factors (Gonzalez-Scarano and Baltuch 1999).

Our early studies documented the presence of lymphocytes in the spinal cord in 18 of 27 consecutive ALS autopsies (Engelhardt et al. 1993). Lymphocytes were predominantly CD4-positive in the vicinity of degenerating cortical spinal tracts, and CD4 and CD8 cells were found in ventral horns. Kawamata et al. (1992) demonstrated the presence of significant numbers of CD8 T cells and, to a lesser extent, CD4 T cells marginating capillaries in the parenchyma of spinal cord and brains of 13 ALS patients. Lymphocytes and activated microglia expressing MHC Class I and Class II, leukocyte common antigen, FcγRI and β-2 integrins were present in ALS tissue.

Our studies of T cells in ALS spinal cord documented a greater expression of Vβ2 transcripts in ALS specimens, independent of the HLA genotype of the individual (Panzara et al. 1999). As additional confirmation, cells were assayed from the cerebrospinal fluid (CSF) of 22 consecutive ALS patients for the presence of Vβ2 transcripts. This specific T-lymphocyte receptor was demonstrated in the CSF of 17 of

22 ALS patients, while only 4 of 19 control patients had similar expression. Vβ2 is a T-cell receptor known to respond to superantigens, and the presence of T lymphocyte restriction supports the involvement of adaptive immune mechanisms in the pathogenesis of ALS. Further evidence supporting the importance of immune mechanisms is the presence of dendritic cells in ALS tissues (Henkel et al. 2004). Dendritic cells are potent antigen-presenting cells that initiate and amplify immune responses (Reichmann et al. 2002). Immature (DEC205, CD1a) and activated/mature (CD83, CD40) dendritic cell transcripts were significantly elevated in ALS tissues. Monocyte/macrophage/microglia transcripts (CD14, CD18, SR-A, CD68) were increased in ALS spinal cord, and activated CD68 (+) cells were demonstrated in close proximity to motor neurons. Increased mRNA expressions of the chemokine monocyte chemoattractant protein-1, CCL2, which attracts monocytes and myeloid dendritic cells and the cytokine macrophage-colony stimulating factor (M-CSF), which stimulates the differentiation of dendritic cells and macrophages, were found in ALS tissues. CCL2 protein was expressed in glia in ALS but not in control tissues and was increased in the CSF of ALS patients. Patients who clinically progressed most rapidly expressed significantly more dendritic transcripts than patients who progressed more slowly.

These results provide circumstantial evidence for the involvement of an adaptive immune/inflammatory response in amplifying motor neuron degeneration in ALS. Also prevalent in ALS are reactive astrocytes, which stain intensively for the intermediate filament, glial fibrillary acidic protein (GFAP). These reactive astrocytes, with a hypertrophied appearance, are present throughout areas of degeneration. Reactive astrocytes can have multiple roles including a neuroprotective function (Liberto et al. 2004).

Numerous biochemical markers of neuroinflammation have been shown to be elevated in ALS tissue, cerebrospinal fluid and serum, including cytokines, chemokines, complement proteins, prostaglandins, interleukins, interferons, integrins, acute phase reactants, apolipoproteins, and proteases (Table 32.1).

Some of the inflammatory mediators enhance the entry of leukocytes from the periphery into the areas of degeneration. CCL2 is well known to enhance the entry of monocytes and dendritic cells into tissues based on interaction with the cognate receptor CCR2 on invading cells. Leukocytes that are observed in the postcapillary venules also express leukocyte function antigen 1 (LFA-1), a surface molecule, which gives activated leukocytes the ability to adhere to endothelial cells and migrate into central nervous system CNS tissue. This binding involves a specific interaction between LFA-1 and intercellular adhesion molecule-1 (ICAM-1), an adhesion molecule that is up regulated on endothelial cells in areas of inflammation (McGeer and McGeer 2003). Another molecule that is up regulated in ALS tissue is matrix metalloproteinase-9 (MMP-9) (Lim et al. 1996). MMP-9 is a proteolytic

Table 32.1 Proteins associated with the inflammatory state in ALS tissues

LCA (leukocyte common antigen, CD45)	Membrane-tyrosine phosphatase; expressed by all hematopoietic cells
LFA-1 (leukocyte function antigen 1, CD11a/CD18 integrin)	Appears on all leukocytes; promotes intercellular adhesion
ICAM-1 (intracellular adhesion molecule 1, CD54)	Cell surface or matrix molecule; promotes binding to LFA-1
GFAP (glial fibrillary acidic protein)	Intermediate filament protein highly expressed by activated astrocytes
Phospholipase A2	Breaks down membrane lipids to form arachidonic acid
COX-1 (cyclooxygenase-1)	Converts arachidonic acid into prostaglandin H ₂ ; rate-limiting step in prostaglandin synthesis
COX-2 (cyclooxygenase-2)	Converts arachidonic acid into prostaglandin H ₂ ; rate-limiting step in prostaglandin synthesis; inducible expression
PGE2 (prostaglandin E2)	Member of prostaglandin family; may have both pro- and anti-apoptotic actions
FcγR-1 (immunoglobulin Fc region receptor 1)	Receptor on phagocytes for IgG bound to an antigen
HLA-DR (human leukocyte antigen DR)	Antigen-presenting surface molecule on immunocompetent cells
IL-6 (interleukin 6)	Inflammatory cytokine released by activated astrocytes and microglia
IL-1β (interleukin 1β)	Inflammatory cytokine cleaved by caspase-1 and induces COX-2 in CNS
MCP-1 (monocyte chemoattractant protein-1) (now known as CCL-2)	Chemokine that attracts monocytes and myeloid dendritic cells
M-CSF (macrophage-colony stimulating factor)	Growth factor cytokine that acts on monocytes and macrophages to cause them to differentiate
MMP-9 (matrix metalloproteinase-9)	Proteolytic enzyme that can degrade components of the extracellular matrix
C3d (complement C3 fragment d)	Degradation product of activated C3
C4d (complement C4 fragment d)	Degradation product of activated C4
CD-11b (complement receptor 3)	Phagocyte surface receptor recognizing an activated complement fragment from C3
g-Interferon	Inflammatory cytokine released by activated T cells; potent activator of microglia and leukocytes

enzyme that is released by leukocytes and reactive astrocytes to degrade proteins of the extracellular matrix and enhance the entry of leukocytes into areas of inflammation.

Prostaglandins represent inflammatory molecules with both pro-apoptotic and antiapoptotic actions (Bezzi et al. 1998). In the first step of prostaglandin synthesis, membrane lipids are broken down by phospholipase A2 to arachidonic acid. Interestingly, phospholipase A2 has been identified in activated glial cells in areas of neurodegeneration (Stephenson et al. 1999). Next, cyclooxygenase (COX) catalyzes the rate-limiting step of prostaglandin synthesis: the conversion of arachidonic acid to prostaglandin G₂ (PGG₂). Two distinct COX isoenzymes, COX-1 and COX-2, can mediate this reaction, and they are 65 % homologous. COX-1 is constitutively expressed in most tissues, and COX-2 is constitutively expressed in the kidney, stomach, and CNS. However, COX-2 expression is strongly inducible and can be significantly up regulated by several cellular factors, including multiple growth factors, interleukin-1β, tumor necrosis factor-α, lipopolysaccharide (LPS), phorbol ester, and elevated intracellular calcium concentration. A marked increase in COX-2 levels has been seen in ALS spinal cords, consistent with previous reports of increased levels of prostaglandin E2 (PGE₂), a further product of prostaglandin synthesis (Almer et al. 2002). Both mRNA and protein levels of COX-2 were elevated in ALS spinal cords, and only in pathologically affected areas (Almer et al. 2001).

32.3 Regulatory T Lymphocytes Influence ALS Disease Progression

To determine whether regulatory T lymphocytes play a neuroprotective role in ALS patients as they do in mSOD1 transgenic mice, we examined T lymphocytes in the peripheral blood of ALS patients (Beers et al. 2011a; Henkel et al. 2013). Both numbers of Tregs and their FoxP3 RNA expression were reduced in rapidly progressing ALS patients and inversely correlated with progression rates. In slowly progressing ALS patients, Tregs and FoxP3 expression were the same as healthy controls. The mRNA levels of FoxP3, TGF-β, IL4 and Gata3, a Th2 transcription factor, were reduced in rapidly progressing patients and were also inversely correlated with progression rates. No differences in IL10, Tbx21, a Th1 transcription factor or IFN-γ expression were found between slow and rapidly progressing patients. A 3.5-year prospective study with a second larger cohort revealed that early reduced FoxP3 levels were indicative of progression rates at collection and predictive of future rapid progression and attenuated survival. Collectively, these data suggest that Tregs and Th2 lymphocytes influence disease progression rates in ALS patients as well as in ALS mice. Importantly, early reduced FoxP3 levels could be used to identify rapidly progressing patients and serve as a biomarker of accelerating disease.

32.4 The Failure of Immunosuppression in ALS

Immunosuppression with steroids, cyclophosphamide, plasmapheresis, total lymphoid irradiation, and cyclosporine has been ineffective in halting the progression of ALS (Brown et al. 1986; Appel et al. 1988; Drachman et al. 1994). This failure of immunosuppressant therapy has been cited as evidence against an immune-mediated mechanism of motor neuron injury, but other possible explanations could exist. Immune suppression may be too little and too late. By the time symptoms and signs appear, extensive CNS damage may already have occurred. Further, such therapies may not adequately access the CNS and suppress the selective inflammatory reactions of activated microglia, T cells, and/or dendritic cells. Immunosuppression has similarly failed to ameliorate type-1 diabetes or other immune mediated endocrinopathies without invalidating the potential importance of immune mechanisms in disease pathogenesis. Finally, conventional immunotherapies target all populations of T lymphocytes, including Treg/Th2 and Th1/Th17 lymphocytes, and would simultaneously suppress both protective and cytotoxic populations. What is needed is not merely to decrease all T cells, leaving intact the ratio of neurotoxicity to neuroprotection. Potentially beneficial therapeutic efforts should be focused on increasing Tregs/Th2 and decreasing Th1/Th17 lymphocytes, thereby changing the ratio of neurotoxic to neuroprotective T lymphocytes. Similar therapeutic strategies targeting microglia or monocyte/macrophage populations would require changing the ratio of neurotoxic (M1) to neuroprotective (M2) activity by enhancing M2 and suppressing M1 microglia.

32.5 Summary

In the last two decades there has been a quantum leap in our understanding of what causes motor neuron injury and cell death and what factors mediate the ALS clinical phenotype. Foremost in these advances is the discovery of more than 20 gene mutations that cause ALS. Each mutation can cause multiple clinical phenotypes (pleiotropy), and many gene mutations can cause the same clinical phenotype. Thus factors other than the specific mutation are needed to explain phenotypic diversity, and accumulating evidence implicates the importance of neuroinflammation in modifying clinical phenotypes. In fALS and transgenic mouse models, motor neuron injury is initiated by specific mutations resulting in misfolded proteins.

Neuronal viability is initially sustained both by intracellular repair mechanisms as well as by anti-inflammatory responses from surrounding glia and adaptive immune T cells. As intracellular injury increases and intra- and extracellular factors can no longer compensate, “danger” signals are released from motor neurons that trigger microglial activation to release pro-inflammatory cytokines and free radicals and

promote a self-propagating neurotoxicity. Thus activated glia and peripheral immune cells, the hallmarks of neuroinflammation, are not simply a late response to motor neuron injury and degeneration, but contribute actively to the balance between neuroprotection and neurotoxicity. However, the extent of this neuroinflammatory response differs in different ALS patients: patients progressing rapidly have dramatically decreased regulatory T lymphocytic responses, while patients progressing slowly had normal to increased levels of Treg and FoxP3 expression. Similar differences in populations of neurotoxic M1 and neuroprotective M2 monocyte/macrophage/microglia may also contribute to phenotypic diversity.

Clearly both the initiating intracellular injury and the extracellular neuroinflammatory processes contribute to the broad clinical diversity and phenotypic expression of ALS, and both represent potential therapeutic targets. Shutting down the production of the specific misfolded proteins has the potential of dramatically curtailing the initiation of motor neuron injury. Efforts targeting neuroinflammation to suppress neurotoxicity and enhance neuroprotection have the potential of changing an acute rapidly progressive disease into a more slowly progressing disease and a more sustainable quality of life. The combination of both therapeutic approaches could help arrest the progressive and devastating nature of ALS and provide hope for our patients.

Acknowledgements We are grateful to the Muscular Dystrophy Association, the NIH, the Kozmetsky Foundation, the Hamill Foundation, and Peggy and Gary Edwards for support of our ALS clinical and research programs.

32.6 Review Questions

- Clinical heterogeneity in ALS is readily explained by different gene disease-causing mutations.
 - True
 - False
- A single mutant gene can cause multiple clinical phenotypes, and many gene mutations can cause the same clinical phenotype. Answers
 - True
 - False
- The most common cause of familial ALS is
 - mutant SOD
 - mutant C9orf72
 - mutant FUS
 - mutant TDP-43
- Neuroinflammation in ALS is characterized by
 - Activated microglia
 - Activated T cells
 - Altered circulating T regulatory cells
 - All of above
 - None of above

Abstract

Multiple lines of evidence have implicated neuroinflammation as both a cause and an effect of neurodegeneration in Huntington's disease (HD). Studies of post mortem human HD brains and HD mouse models have demonstrated that the huntingtin protein (mHTT) has neurotoxic effects due to cell-autonomous defects in neurons and through cell-cell interactions with dysfunctional astrocytes and microglia in the brain. Neurodegeneration has been linked to excitotoxicity caused by ion and neurotransmitter concentrations in the brain, supported by evidence that extracellular levels of these molecules are modulated by astrocyte-specific mechanisms which are impaired in HD. mHTT causes monocytes and microglia to be hyper-reactive in HD patients and mouse models, contributing to neurodegeneration. Key pro-inflammatory players NFkB, IL-6, and TNF- α are implicated with disease progression, and several lines of evidence suggest that these molecules are associated with more severe neurodegeneration. Dysregulation of the NFkB activation pathway in particular is seen in HD neurons, astrocytes, microglia, and monocytes and thus may be a major component of the cellular response to mHTT with therapeutic potential. Collectively, the immune response and neuroinflammation are seen as key aspects of pathogenesis in HD, and multiple lines of evidence suggest that the neuroimmune response is both a cause and effect of neurodegeneration.

33.1 Introduction

33.1.1 Clinical Features

Huntington's disease (HD) is a dominantly transmitted neurodegenerative disorder, commonly of mid-life onset. The disease is characterized clinically by three cardinal features: (1) movement disorder, (2) cognitive changes, and (3) psychiatric features. While all individuals with HD experience movement disorder and some cognitive impairment, the severity of these can vary dramatically from one individual to the next. Consequently, the disease can present remarkably differently even among persons within the same family. Whereas some experience profound cognitive impairment or severe depression, others manifest very mild effects of these conditions. These varied presentations can make it difficult to anticipate the difficulties that an individual will encounter with HD, and make the recognition and diagnosis of onset difficult in the early stages of the disease.

Movement Disorder HD was originally defined by the dance-like nature of the movement disorder when George Huntington published his treatise "On Chorea" in 1872 (Huntington 1872). Chorea, Greek for dance, aptly describes the mid-stage characteristics of the adult presentation of the disease. However, because juvenile and adolescent onset cases often present with rigidity, and late stage adult disease may also include rigidity, chorea is not the only feature of the movement disorder worthy of mention. The nature of impaired movement early after onset is characterized by small subtle movements of extremities, face and tongue, which may not affect gait. In addition to the involuntary movement, there is also a slowing of voluntary movement.

Cognitive Changes The nature of cognitive impairment in HD has been the subject of studies and reviews (Paulsen 2011; van Duijn et al. 2007). Impairment of both short and long term memory is progressively involved, but varies significantly from one individual to the next. The relationship of cognitive impairment to cortical involvement on MRI has been found (Rosas et al. 2005) but the factors which are responsible for differential cortical versus subcortical neuropathological involvement are not known.

Psychiatric Features The most common behavioral feature of HD is depression, which may occur prior to onset of movement disorder and the severity of which may vary dramatically from one individual to the next. Other psychiatric diagnoses are also more common in HD, including psychosis, although this is not a common occurrence for this disease. However, a pattern of angry and aggressive out-

bursts, which may occur unexpectedly and out of proportion to the precipitating events is one of the most difficult for families with a loved one with HD to deal with, and can be challenging to manage medically. Because many HD patients are relatively young and robust, the threat of physically aggressive outbursts is unfortunately not uncommon and can alienate affected individuals from family and caretakers.

33.1.2 Genetics

Dominant Transmission The HD gene (*HTT*) is located on chromosome 4p16.3 (Gusella et al. 1983) and the mutation that causes the disease is an expansion in the number of repeats of the nucleotides cytosine, adenine and guanine (CAG) within the coding region of the first exon of the gene. A single copy of this alteration in the gene is sufficient to cause the disease and is responsible for the autosomal dominant mode of transmission (Group 1993). Descendants of HD gene carriers, regardless of the sex of the parent or the child, have a 50% chance of inheriting the gene. Because penetrance is high, with few exceptions, those who inherit the gene eventually develop the disease, unless they should die of another cause before onset.

CAG Repeat Size The nature of the genetic defect in the HD gene explains many of the genetic features of the disorder, including the variability in age at onset, tendency for juvenile disease to be inherited from fathers and sporadic appearance of new mutations to HD (Myers 2004). This CAG "triplet" is normally repeated about 20 times (normal range is 8–26 repeats), and an approximate doubling in the number of repeats to a threshold of 40 or more results in the expression of the disease (Group 1993; Duyao et al. 1993).

De Novo Mutation Repeats between 27 and 35, commonly known as intermediate repeats, can be meiotically unstable in paternal transmission whereby descendants of men with repeats in this range have been known to inherit disease associated repeats of 40 or more. In a sample of 1260 persons ascertained from HD families studied in the New England Huntington's Disease Research Center Without Walls, repeats between 27 and 35, represented about 3.2% of all repeats. The frequency in a non-HD sample of Parkinson disease cases allowed an estimation that the frequency of expansion of an intermediate repeat will expand to the clinical range as approximately 1/1000 (Hendricks et al. 2009). Thus while it is rare that intermediate allele carriers have progeny who inherit an allele in the clinical HD range, the frequency

Fig. 33.1 The distribution of age at motor onset for N=600 manifest HD subjects whose brains are maintained by from the McLean Hospital Brain Tissue Resource Center. Average age at onset is 43

Fig. 33.2 Scatter plot relating age at motor onset to CAG repeat size for N=600 HD subjects. Age at motor onset and CAG repeat size is correlated at $r = -0.74$

of intermediate allele carriers in the general population means that the *de novo* occurrence of HD is not rare in HD clinic populations.

Reduced Penetrance Repeats between 36 and 39 are also rare (2.7% in the New England series), and are associated with reduced penetrance, whereby some persons with repeats in this range develop HD and others do not. The estimate of penetrance is weak due to the small numbers of observations and that most of those observed are persons who develop HD whereas those who do not manifest symptoms are likely to go undetected. Nonetheless, penetrance increases as the repeat size approaches 40, and may vary from as low as 25% among persons with 36 repeats to as high as 90% for persons with 39 repeats (Myers 2004).

Age at Onset HD typically strikes in mid-life but can occur as young as age 2 or 3 and as old as age 80 or more (Fig. 33.1). Survival from onset to death averages 17–20 years with some evidence that older onset is associated with slower progression, although survival may not be increased as elderly cases may die of competing causes.

HD is a disorder with highly variable clinical expression, as evidenced by the wide variation in onset age. The strong inverse relationship between age at onset and number of CAG repeats is unequivocal (Duyao et al. 1993) (Fig. 33.2). For HD cases derived from a series of HD brains from the McLean Hospital Brain Tissue Resource Center, the correlation between repeat size and onset age is $r = -0.74$ and

accounts for about 55% of the variance in onset age. Much of the strength of this correlation derives from the small sample of persons (about 5% of the sample) who have very large repeat sizes, and very young onset ages. Thus although the correlation between repeat size and onset age is strong, it is widely acknowledged that the repeat size is a poor predictor of onset age. The predictive shortcomings can be appreciated by examining the range of onset age for persons with a particular number of repeats. For example, persons in Fig. 33.2 with 44 CAG repeats exhibit onset ages as young as 28 and as old as 59 years of age. The 31 year span in onset demonstrates not only the poor predictive power for onset of the repeat size, but also the substantial variation in onset age that is not explained by the *HTT* repeat.

Significant familial aggregation for the age at onset in HD has been reported (Djousse et al. 2003; Rosenblatt et al. 2001). Using onset ages adjusted for the size of the HD repeat mutation, pairs of affected siblings were found to have remarkably similar onset ages, independent of the size of the HD repeat. Estimates of heritability of onset age after adjustment for the repeat size range from 56% to 65% (Djousse et al. 2003; Rosenblatt et al. 2001). Thus 56–65% of the variation in onset age, that is not attributable to the repeat size, can be attributed to modifier genes.

Sex of Parent Effect Merritt et al. (1969) first observed that a disproportionate number of cases with onset before the age of 21 had inherited the HD gene from affected fathers. The observation of earlier ages at onset in successive generations,

termed anticipation, is seen in several of the trinucleotide repeat disorders. Meiotic instability of the HD repeat in paternal transmission explains the observation of anticipation in HD. While meiotic instability may occur in both maternal and paternal transmission, in paternal transmission there is a propensity toward expansion of the repeat, with occasionally large expansions that are not seen in maternal transmission. For maternal transmission, nearly equal numbers of expansions and contractions are seen, and the shifts are small, ranging from 1 to 3 repeats. The observation that paternally transmitted repeats are prone to large increases in size (Duyao et al. 1993; Zühlke et al. 1993; Ranen et al. 1995) explains why most juvenile onset HD is inherited through the male germline.

33.1.3 Neuropathology

The neuropathological characteristics of HD involve a specific pattern of neuronal degeneration with important differences and similarities to other neurodegenerative diseases. A hallmark of the disease is the presence of intranuclear inclusions seen in neurons throughout the HD brain. These inclusions consist largely of the fragments of the huntingtin protein (HTT) containing the polyglutamine repeat as well as numerous other proteins to which it appears to be pathologically bound. Similar protein aggregates are seen in virtually every major neurodegenerative disease, including Alzheimer's disease, Parkinson's disease, Amyotrophic Lateral Sclerosis and others. Nonetheless, the location and composition of these aggregates varies significantly from one disease to the next. The inability to process protein fragments and their abnormal protein accumulation appears to be a driving neurotoxic mechanism for HD and other neurodegenerative diseases. Whether the aggregates themselves are neurotoxic or a protective process to sequester and remove these fragments from cytoplasmic cellular regions is not known.

Based upon MRI studies, evidence of neuropathological involvement precedes the onset of signs of the disease by many years (Aylward 2014). Atrophy of cortical grey and white matter as well as subcortical regions is readily quantifiable and increases with proximity to disease onset. These studies emphasize the effects of the disease on the whole brain, although there are clearly regions of focal involvement, mainly in the striatum which target the medium spiny neurons.

Striatal Involvement In HD the initial evidence of neurodegeneration is seen microscopically in the tail of the caudate nucleus and progresses in a rostral to caudal direction. In the head of the caudate nucleus, early neuronal loss is most evident in the medial region near the ependymal surface adjacent to the lateral ventricle (Vonsattel et al. 1985). Parallel involvement in the putamen is seen in the medial regions

adjacent to the internal capsule. Striatal involvement is associated with the motor aspects of the disease. Several MRI studies have identified a strong relationship between clinical features and the extent of brain atrophy in HD, including the relationship between cognitive performance and cortical atrophy (Rosas et al. 2005). Striatal involvement is strongly related to the size of the CAG expansion where larger repeats are associated with more severe involvement (Hadzi et al. 2012).

The extent of striatal involvement has been well quantified and characterized (Vonsattel et al. 1985; Hadzi et al. 2012) and does not correlate well the cortical atrophy (Hadzi et al. 2012). Variability in the relative involvement of cortical and subcortical regions likely influences the wide range of motor versus cognitive and psychiatric symptoms recognized among HD patients.

Cortical Involvement While both cortical and subcortical regions are involved in HD, the cortex is considerably less involved than the striatum. Atrophy occurs across all cortical regions (Vonsattel et al. 1985; Sotrel et al. 1991; Cudkowicz and Kowall 1990). As expected for progressive neurodegenerative disease, cortical atrophy increases over the course of the disease, but the extent of cortical involvement may vary dramatically from one individual to the next and is only weakly related to the CAG size (Hadzi et al. 2012).

White Matter Studies of both post-mortem brains (de la Monte et al. 1988) and by MRI show significant white matter involvement in HD (Rosas et al. 2005). White matter atrophy contributes to the loss of brain weight and overall brain atrophy at a level comparable to that of grey matter.

33.1.4 Molecular Pathogenesis of HD

The HD gene encodes a large, 348 kDa cytosolic protein (HTT) that is widely distributed throughout the body, with its highest levels in the brain (Sharp et al. 1995; Trottier et al. 1995). The protein structure of HTT suggests it is a multifunctional scaffolding protein, with multiple Huntington, elongation factor 3, protein phosphatase 2A, yeast kinase TOR1 (HEAT) repeats and hydrophobic alpha-helices that assist in protein-protein interactions, and a nuclear export signal (Bessert et al. 1995) which aids in nuclear transport. HTT directly associates with the microtubule motor dynein (Caviston et al. 2011), and indirectly binds kinesin-1 through Huntingtin-associated protein 1 (Li et al. 1998), modulating the bidirectional transport of endocytic and exocytic vesicles along cytoskeletal tracks (Colin et al. 2008). Within RNA transport granules, HTT colocalizes with Argonaute 2, a component of the RNA-induced silencing complex, indicating it may play a role in localized translational control

through the silencing of RNA transcription (Savas et al. 2010; Ma et al. 2010). HTT is critical for nervous system development (Tong et al. 2011) and embryonic lethal in knockout huntingtin mice (Nasir et al. 1995). HTT may also play a role in cytokine production in monocytes and macrophages under normal and HD settings (Träger et al. 2014b).

The HD mutation produces a neurotoxic, mutant HTT protein (mHTT). The polyglutamine tract (polyQ) expansion caused by the HD mutation exists within the N-terminal region of the HTT protein (Group 1993), which leads to the formation of intranuclear and cytoplasmic inclusions in the brains of HD patients (DiFiglia et al. 1997) as well as in HD *in vitro* models (Scherzinger et al. 1997). The N-terminal region is cleaved by caspases and calpains to produce N-terminal fragments in both normal and HD cells, where only the expanded polyQ fragments of HD self-associate and seed aggregates (Kim et al. 2001; Scherzinger et al. 1999; Wellington et al. 2002). Cytosolic and intranuclear inclusions containing mHTT fragments in neurons of the striatum and cerebral cortex are a histopathological hallmark of HD (Gutkunst et al. 1999). In post-mortem HD brains, extensive aggregation is observed in the striatum and in layers V and VI of the cerebral cortex, though smaller numbers of aggregates are observed in other brain regions not primarily affected by neurodegeneration in HD, including the basal ganglia, hippocampus, and cerebellum (Gutkunst et al. 1999). In particular, striatal medium spiny neurons and cortical interneurons exhibit extensive aggregation, where aggregates initially localize to the soma and dendritic processes but later are found in the nucleus as the disease progresses (Gutkunst et al. 1999).

Aberrant nuclear localization of mHTT fragments precedes cell death in neurons (Li and Li 2004). However, the process by which preferential death of striatal, medium spiny neurons occurs is not fully understood. HD pathogenesis is likely caused by a gain-of-function of mHTT, where the polyQ repeat expansion contributes to the misfolding and aggregate form of HTT, resulting in a protein with new, toxic function (Di Prospero and Tagle 2000). In a mouse model expressing a truncated mHTT protein, nuclear aggregation of mHTT fragments was determined to be a cell-autonomous process in striatal medium spiny and cortical interneurons, but no locomotor deficits or significant neuropathology were observed in contrast to the pan-neuronal model which exhibits these effects (Gu et al. 2007). This suggests that cell-cell interactions are critical to cause neurodegeneration in these models. mHTT may cause neurodegeneration through a toxic gain of function in its misfolded monomeric form, in its self-assembled oligomeric or sticky, aggregated forms, or by the loss of wildtype HTT function (through a loss-of-function or dominant-negative effect). Gain-of-function is the most well accepted hypothesis for HD pathogenesis, where the polyQ repeat expansion contributes to the misfolding and

aggregate form of HTT, resulting in a protein with new, toxic function (Di Prospero and Tagle 2000). Transcription factors, such as CREB-binding protein (CBP) (Steffan et al. 2000), specificity protein 1 (SP1) (Li et al. 2002), TATA-binding protein (TBP) (van Roon-Mom et al. 2002) and p53 (Steffan et al. 2000), and transcriptional repressors such as REST/NSRF (Zuccato et al. 2003), spuriously bind to mHTT intranuclear inclusions impairing their normal activity, leading to transcriptional dysregulation (Cha 2000). The transcription factor nuclear factor kappa-light-chain-enhancer of activated B cells (*NfκB*), which is particularly related to immune function, has shown altered activity in HD due to direct, aberrant interactions with soluble mHTT (Marcora and Kennedy 2010; Godavarthi et al. 2009).

HD is associated with the disruption of an assortment of cellular processes, impairing cell adhesion (Consortium 2012), mitochondrial energetics (Koroshetz et al. 1997), cellular transport (Cattaneo et al. 2001), autophagic processing (Ravikumar et al. 2004), ubiquitin-proteasome system (Wang et al. 2008), synaptic plasticity (Usdin et al. 1999) and enhancement of glutamate-related excitotoxicity (Liang et al. 2005). HTT cleavage is mediated by caspases to produce an amino-terminal polyQ containing fragment (Wellington et al. 1998), and mHTT is more susceptible to cleavage than its normal counterpart. Activation of caspases induces apoptosis; thus, overactive caspases have deleterious effects on already stressed neurons.

Evidence of increased DNA-damage has been observed in post-mortem caudate nucleus (Browne et al. 1997) and in mitochondrial DNA from the parietal cortex (Polidori et al. 1999) of individuals with HD and in R6/2 mice (Bogdanov et al. 2001). HTT has been shown to be phosphorylated by the cyclin-dependent kinase 5 (*CDK5*) after induction of DNA damage in rat, mouse, and human *in vitro* settings and *in vivo* in mice, where a loss of phosphorylation causes neurotoxicity in striatal neurons while increased phosphorylation protected against polyQ-induced toxicity (Anne et al. 2007). In a study using human embryonic stem cell derived neurons, DNA-damage was shown to enhance cleavage of wild type HTT in an IκB kinase (*IKK*)-dependent manner, and, in a striatal neuronal line from HD knock-in mice, induction of DNA-damage was shown to enhance mHTT cleavage as well (Khoshnan et al. 2009). Other studies have also shown increased HTT-related *IKK* activity of neurons in humans and transgenic mice, linking increased neurotoxicity to specific phosphorylation events on the full length HTT and mHTT proteins by *IKKβ* (Khoshnan et al. 2004; Thompson et al. 2009). This is significant for neuroinflammation since aggregation of N-terminal mHTT fragments correlates with neurodegeneration and an increase in mHTT cleavage mediated by *IKK* implicates the *NFκB* pathway in neurons.

Figure 33.3 illustrates the manifold cellular and molecular mechanisms that characterize HD pathology. Given the

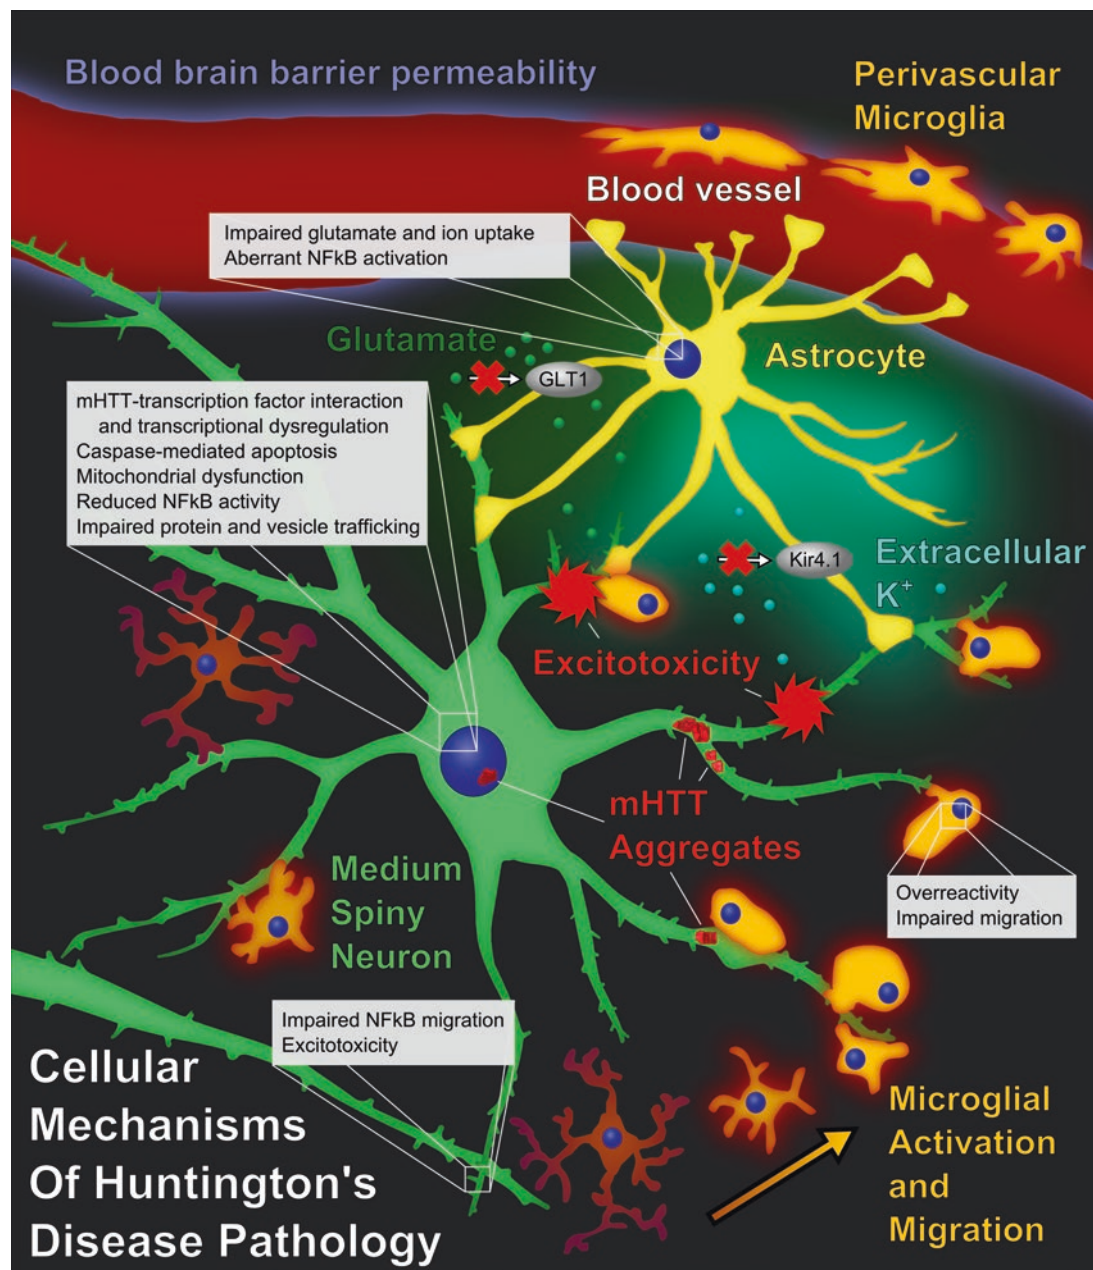

Fig. 33.3 Illustration of the primary cellular and molecular mechanisms that contribute to neurodegeneration in HD

complexity of HD pathogenesis and strain that HD neurons undergo, the role of the immune system the immune function in the brain may greatly impact the survival of stressed neurons. In the following sections, we will highlight the cellular and molecular roles of the immune system in HD.

33.2 Neuroinflammation in HD

In the central nervous system (CNS), both neurons and glia have been implicated in the neurodegenerative phenotype of HD. While neurons were initially thought to be the primary

affected brain cell type due to their selective degeneration, numerous studies have shown dysfunction in astrocytes and microglia due to mHTT expression. Studies focusing on peripheral tissues, especially in blood, also show signs of altered immune function in HD patients and mouse models.

33.2.1 The Neuroimmune Role of HTT in Neurons

Due to a number of factors including increased caspase-induced apoptosis, excitotoxicity, and transcriptional dysfunction, the

neurons affected by neurodegeneration in HD are stressed, suffer atrophy, and undergo apoptosis. As a result, damage associated molecular pattern molecules are released from severely challenged neurons, signaling for a large neuroimmune response. In a neuronal murine cell model of HD, increased expression of chemokines, such as murine chemokines KC (CXCL1), monocyte chemotactic protein 1 (*MCP-1*), as well as pro-inflammatory genes interleukin 6 (*IL-6*) and tissue inhibitor of metalloproteinases (*TIMP*) were observed in mHTT positive neurons as compared to controls, while the pro-inflammatory gene tumor necrosis factor alpha (*TNFalpha*) was significantly decreased (Godavarthi et al. 2009). Nuclear factor kappa B (*NFkB*) and proteasomal activity was observed to be significantly decreased in this study, suggesting these functions are cell-autonomous responses in the neurons of these mice.

Constitutive activation of *NFkB* in neurons has been shown to be neuroprotective and necessary for neuronal health (Bhakar et al. 2002; Fridmacher et al. 2003). *NFkB* normally resides in an inactive state outside the nucleus of neurons, localizing to the synapses, and is constitutively activated through glutamatergic transmission (Kaltschmidt et al. 1993, 1994; Wellmann et al. 2001; Meffert et al. 2003). Upon activation, *NFkB* is transported along dendritic spines in a HTT-dependent manner and imported into the nucleus. However, the transport of *NFkB* to the nucleus is impaired by mHTT (Marcora and Kennedy 2010), which may explain the observation that *NFkB* activity was decreased in an HD neuronal model derived from mice (Godavarthi et al. 2009).

33.2.2 The Neuroimmune Role of HTT in Glia

Considerable attention has been paid to the role of glia in mHTT mediated neurodegeneration. In particular, microglia and astrocytes have been directly linked to the severity of neurodegeneration in HD either through pro-inflammatory processes or increased excitotoxicity caused by dysregulated intercellular ionic and neurotransmitter concentration. No study to date has directly implicated oligodendrocytes with neurodegeneration in HD, though an increase in oligodendrocyte density was observed in the caudate nucleus of early-stage post-mortem human HD brains (Myers et al. 1991; Gomez-Tortosa et al. 2001).

33.2.2.1 HTT in Microglia

As the primary immune cells of the central nervous system, microglia are directly involved in many neurodegenerative diseases (Cunningham 2013) including HD and in response to brain injury in general (Hernandez-Ontiveros et al. 2013). Microglial activation is a hallmark of the symptomatic HD brain (Myers et al. 1991; Sapp et al. 2001; Pavese et al. 2006), and measures of the degree of activation have been used to predict onset of symptoms in presymptomatic HD

subjects (Tai et al. 2007; Politis et al. 2011). In symptomatic HD brains, the level of microglial activation is correlated with the amount of neurodegeneration, and the prefrontal cortex, a region not primarily affected by neurodegeneration, shows particularly strong evidence of activated microglia (Pavese et al. 2006).

mHTT is expressed in microglia (Kwan et al. 2012b). Studies in different HD mouse models indicate mHTT causes microglia to be more sensitive to acute inflammatory insult by lipopolysaccharide (LPS) injection than control mice (Franciosi et al. 2012; Hsiao et al. 2013; Crotti et al. 2014). Upon LPS injection, microglia in R6/2 mice show more nuclear localization of *NFkB* than LPS-treated wildtype (WT) mice, and the R6/2 mice show signs of chronic inflammation after acute inflammatory insult whereas WT mice do not (Hsiao et al. 2013). Microglia expressing the first exon of *HTT* containing the expanded polyQ tract (HDex1) transcribe more pro-inflammatory factors, in particular the cytokine *IL-6*, than microglia expressing WT *HTT*, and the genes associated with up-regulated mRNA species in these microglia compared with WT are enriched for innate immunity and inflammation overall (Crotti et al. 2014). The transcriptional mRNA profile of these HDex1 microglia appears to be controlled by the myeloid lineage-determining transcription factors PU.1, C/EBPalpha, and C/EBPbeta. Neurotoxic effects were observed when HDex1 microglia were cocultured with WT neurons, and this neurotoxicity increased when the cells were stimulated with LPS (Crotti et al. 2014). These studies suggest that microglia expressing HDex1 have a cell-autonomous, neurotoxic effect in the HD milieu.

The morphology and migration of microglia are also reported in HD. Microglia in the brain of full length mHTT mouse model YAC128 showed evidence of activation by enlarged cell bodies and decreased numbers as compared to WT mice (Franciosi et al. 2012). Expression of mHTT appears to impair microglial migration in humans and mice, possibly due to impaired actin remodeling as a result of aberrant mHTT-cofilin interaction (Kwan et al. 2012b), despite evidence of increased microglial localization to neurites in rat HDex1-cortico-striatal/microglial cell cultures (Kraft et al. 2012) and to the cerebrovasculature in the striatum in LPS-injected HD mice (Franciosi et al. 2012). The microglia that localize to neurites tend to cluster along thin processes and at points of intersection or overlap between neuronal processes, and particularly near process blebs and at the terminal ends of HDex1 striatal neurites with irregular morphology (Kraft et al. 2012). In this study, microglia were not observed to colocalize with neuronal mHTT fragment inclusions, suggesting cellular aggregates do not cause neurons to secrete microglia-activating signals at these locations. Localization of activated microglia to the cerebrovasculature seems to be due to evidence of blood brain barrier permeability upon induction of acute inflammation (Franciosi et al. 2012),

suggesting a part of the microglial response is due to defects in blood brain barrier integrity under pro-inflammatory conditions in HD. The correlation of microglial activation with severity of neurodegeneration, the apparent hyper-reactivity of microglia that express mHTT to pro-inflammatory insult, and altered migration capacity support a cell-autonomous mechanism in microglia that contributes to neurodegeneration in HD.

33.2.2.2 HTT in Astrocytes

Astrocytes are implicated in HD neuropathology in several ways. In a study of post-mortem HD human striatum, the number of glial fibrillary acidic protein (GFAP)-expressing astrocytes increased with grade of severity, and mHTT aggregates were co-localized with GFAP in grade 0 HD patients, suggesting astrocytic mHTT may be an early and progressive event that could be associated with the pathology of the disease (Faideau et al. 2010). Striatal astrocytes of R6/2 and human brain contain mHTT nuclear inclusions, though not all glia show evidence of aggregation (Shin et al. 2005; Tong et al. 2014). In astrocytes of R6/2 mice, nuclear inclusions were observed considerably later than those observed in neuronal cells, suggesting that astrocytes are more capable of clearing misfolded mHTT than neurons (Shin et al. 2005). The same study found no evidence that mHTT aggregation altered astrocyte morphology or directly killed cultured astrocytes *in vitro*, suggesting that mHTT fragments lead to glial dysfunction, rather than degeneration. In an HD mouse that selectively expressed either HTT or mHTT in astrocytes, HTT fragments were observed to be diffuse in the nucleus of cultured astrocytes, whereas mHTT showed nuclear aggregates (Bradford et al. 2009). The presence of mHTT aggregates in astrocytes, and the correlation of reactive astrocytes in human HD brain with disease severity, is strong evidence that these cells are affected by mutant HTT.

Astrocytes are responsible for maintaining neuronal health and function in part by controlling extracellular concentrations of ions and neurotransmitters, in particular potassium (K^+) and glutamate. One study reports astrocytes from symptomatic R6/2 mice were less able to maintain proper K^+ flux *in vivo* due to mHTT-driven inhibition of the Kir4.1 ion channel, resulting in altered excitability of nearby neurons (Tong et al. 2014). Exogenous introduction of Kir4.1 into these mHTT striatal astrocytes *in vivo* attenuated motor deficit and prolonged survival. Several studies report impaired glutamate uptake in astrocytes expressing mHTT (Bradford et al. 2009; Shin et al. 2005) and that the extent of this defect correlates with HD grade in human subjects (Faideau et al. 2010). Preliminary evidence showed that reduced expression of glutamate transporter 1 (*GLT-1*) was responsible for impaired glutamate uptake rather than altered protein function and that striatal neurons were more sensitive to glutamate toxicity than cortical neurons (Shin et al. 2005). The same study

showed that coculture of neurons expressing mHTT with WT astrocytes resulted in less neurodegeneration *in vitro*, and coculture of astrocytes expressing mHTT with WT neurons resulted in more neurodegeneration, which was linked to impaired glutamate uptake capacity in mHTT astrocytes. Oral administration of a kynurenine 3-monooxygenase inhibitor to R6/2 mice inhibits extracellular glutamate in the brain, prevents synaptic loss, reduces microglial activation, and extends survival (Zwilling et al. 2011). In astrocytes cultured from postnatal rat pup cortex, treatment with an autophagy inhibitor significantly increased mHTT aggregation, whereas treatment with an autophagy stimulator reduced aggregation, reversed changes in *GLT-1* expression, and glutamate uptake (Chen et al. 2012). The discovery methods to decrease neurotoxicity by rescuing ion channel dysfunction and glutamate uptake by astrocytes suggests a causal link from astrocytic dysfunction, glutamate concentration, and microglial activation to neurotoxicity.

33.2.2.3 HTT in Peripheral Cell Types

HTT is ubiquitously expressed throughout the body (Sharp et al. 1995) and several alterations in peripheral cell types have been observed in the presence of mHTT. mHTT fragments have been observed in monocytes, T-cells, and B-cells of presymptomatic and symptomatic HD patients and levels of mHTT transcripts correlated with disease progression in monocytes and T-cells (Weiss et al. 2012). Monocytes are of particular interest, since they are easily collected from HD patients and modifying migrating monocytes or precursors in the bone marrow may have therapeutic potential.

Blood monocytes originate in the bone marrow and derive from the same myeloid precursors that migrate to the brain to become microglia (Prinz and Priller 2014). mHTT has been detected in human monocytes (Weiss et al. 2012) and express increased levels of the cytokines IL-6, TNF α , and, upon differentiation into macrophages, IL-8 in presymptomatic HD subjects compared with controls, particularly after stimulation with LPS (Björkqvist et al. 2008; Godavarthi et al. 2009; Träger et al. 2014b). This hyper-reactivity of monocytes and macrophages in HD patients was attenuated when the levels of endogenous HTT was reduced using an anti-HTT short interfering RNAs (siRNA) (Träger et al. 2014a). In the same study, a reduction in cytokine production following anti-HTT treatment was also observed in control individuals, suggesting WT HTT plays a role in cytokine production in monocytes and macrophages under normal conditions. Hyper-reactivity was also observed in CD11b+ cells and myeloid cells derived from the spleen of R6/2 mice compared to WT mice after LPS treatment (Träger et al. 2014b). The increase in cytokine production seems to be due to increased interaction between HTT and IKK γ , leading to enhanced NF κ B activity (Träger et al. 2014a). These lines of evidence suggest that microglial hyperactivity

is influenced by mHTT via cell-autonomous changes that remain after differentiation from precursor myeloid cells.

Since microglia originate in the bone marrow and are affected by mHTT, bone marrow replacement may be a potential therapeutic for HD. Neither CD11b+ bone marrow myeloid cells nor macrophages derived from bone marrow cells exhibit increased pro-inflammatory cytokine production or phagocytosis as observed in more mature myeloid cells in R6/2 mice (Träger et al. 2014a). In a study where YAC128 and BACHD full-length mHTT mice were transplanted with WT bone marrow after lethal irradiation, the transplanted HD mice were more similar to WT mice in body weight and motor performance on hypokinetic assays (Kwan et al. 2012a). The untransplanted YAC128 mice demonstrated elevated levels of cytokines in the blood, consistent with previous studies (Björkqvist et al. 2008), and after transplantation with WT bone marrow these cytokine level differences between YAC128 and WT mice were abolished. The partial rescue of HD-like symptoms in two mouse models after bone marrow transplantation suggests that cell-autonomous effects caused by mHTT might be modified by manipulating the myeloid precursor cells in HD patients, but no studies testing this hypothesis have been performed to date.

Cannabinoid receptor 2 (*CB2*) has been linked to neuroprotection conferred through peripheral immune cells (Bouchard et al. 2012). In this study, genetic deletion of *CB2* accelerated onset of motor deficits and increased their severity in a slowly progressing HD mouse model. Treating normal BACHD mice with a *CB2* agonist ameliorated behavioral and neuropathological effects even at late stages, while coadministration with a *CB2* receptor antagonist that could not cross the blood brain barrier prevented the protective effects. This evidence is consistent with a model where neurodegeneration and *CB2* signaling are causally linked, and indeed *CB2* signaling dampens immune activation by decreasing activation of microglia after brain injury (Ashton and Glass 2007). Enhancing *CB2* activity in the periphery may therefore be a potential therapeutic for HD patients.

33.3 Molecular Players of Neuroinflammation in HD

Studies across HD human specimens, HD model organisms, and cell types reveal a consistent set of molecular players shown to be involved in HD. These include inflammation-related cytokines IL-6 and TNF α , the complement component system, genes within the NF κ B pathway, and extracellular glutamate in the brain. Multiple studies suggest that the activity of each of these groups of molecules is associated with neurodegeneration, and that modulating these systems can alter disease progression.

33.3.1 Cytokines and Chemokines

Pro-inflammatory cytokine levels are altered in human HD patients and mouse models. In humans, the cytokines *IL-6*, *IL-8*, *IL-4*, *IL-10*, and TNF α were increased in the blood and striatum of presymptomatic and manifest HD, where levels of the latter three were significantly associated with disease progression (Björkqvist et al. 2008; Godavarthi et al. 2009; Träger et al. 2014b). In addition to these, chemokine (C-C motif) ligand 2 (*CCL2*) and matrix metalloprotease 9 (*MMP9*) were increased in post-mortem HD striatum (Silvestroni 2009). A similar pattern is seen in mice (Kwan et al. 2012b; Kraft et al. 2012; Bouchard et al. 2012; Träger et al. 2014a; Crotti et al. 2014). In a neuronal murine cell model of HD, increased expression of chemokines murine chemokine (*KC*), monocyte chemoattractant protein 1 (*MCP-1*), and lipopolysaccharide-induced chemokine (*LIX*) were increased after acute induction of inflammation by LPS injection, whereas TNF α receptors were significantly decreased (Godavarthi et al. 2009).

33.3.2 Complement Cascade

Levels of the complement cascade proteins are elevated in HD patient blood. In particular, C3, C4, C7, and C9 were found in two studies of symptomatic human HD blood (Leblhuber et al. 1998; Dalrymple et al. 2007) and in neurons, myelin, and astrocytes of human HD striatum (Singhrao et al. 1999). The Singhrao et al. (1999) study found that complement mRNA levels were two to fivefold higher in human HD striatum compared to controls and showed C3 and C9 to be expressed in reactive microglia on the membranes of neurons, contributing to neuronal necrosis and proinflammatory activity. Genetic deletion of C3 from an HD mouse model did not show alteration of disease progression, however, suggesting this complement component is not critical for neurodegeneration (Larkin and Muchowski 2012).

33.3.3 NF κ B Pathway

Dysregulation of NF κ B by mutant HTT is a central theme in studies of human HD and HD mouse models, where mHTT affects the NF κ B pathway in two principle ways delineated by cell type. In neurons, WT HTT has been shown to directly interact with glutamate-activated NF κ B by transporting it from the synapse along dendritic spines to the nucleus (Kaltschmidt et al. 1993, 1994; Wellmann et al. 2001; Meffert et al. 2003). In HDex1 mice, mHTT seems to impair this transport, causing decreased nuclear concentration of NF κ B and likely NF κ B pathway dysfunction (Marcora and Kennedy 2010). Constitutive activation of NF κ B in neurons

has been shown to be neuroprotective and necessary for neuronal health (Bhakar et al. 2002; Fridmacher et al. 2003), suggesting this dysfunction may be a critical aspect of neurodegeneration. In contrast, R6/2 astroglia and human HD monocytes exhibit increased NF κ B activation due to aberrant interactions between mHTT and the IKK (Khoshnan et al. 2004; Hsiao et al. 2013; Träger et al. 2014a). Specifically, multiple lines of evidence suggest that mHTT exon 1 associates with IKK γ and activates the IKK complex, which in turn increases IKK β activity and subsequent NF κ B activation (Khoshnan and Patterson 2011). Blocking IKK β , inhibiting NF κ B, or inducing degradation of I κ B appears to reduce mHTT toxicity in these contexts. Each of these studies found an association between increased NF κ B activity and more severe degeneration. These studies suggest that NF κ B dysregulation in neurons and astrocytes is a major component of neurodegeneration in HD.

33.4 Outlook

Interventions in the immune response show potential as therapeutic avenues in attenuating the severity of neurodegeneration in HD. Dysregulated glutamate levels can be at least partially restored by rescuing astrocytic dysfunction in ion and neurotransmitter uptake pathways using mechanistically-linked compounds. Since the primary affected cell types are in the brain, identifying compounds that cross the blood brain barrier remains a major challenge in administering treatments in this context. However, administering treatments that affect immune cells in the periphery which can then migrate to the brain may have therapeutic potential. The hyper-reactive monocyte and microglia response can be dampened by modulating specific monocyte receptors in the periphery and by replacing bone marrow with myeloid precursors that lack mutant HTT. Studies have not suggested that manipulating peripheral monocytes in this way is curative, but delaying or ameliorating symptoms caused by immune-related neurodegeneration may be an important aspect of a combined therapeutic regimen. Anti-inflammatory therapeutics have shown promise in HD, so a first avenue of treatment might involve modifications of lifestyle to promote anti-inflammatory processes.

Clearly, challenges to our understanding of HD remain as well to how best to develop effective therapies. The widespread cell-specific changes in response to mHTT stand in stark contrast to the deceptively simple monogenic nature of the disease. For this reason, “silver bullet” treatments likely do not exist for this disease using currently available pharmacological tools. Successful therapies may therefore require multiple agents that specifically target the different sources of neurotoxicity. Neuroinflammation plays a central role in neurodegeneration in HD and thus may be fundamentally important to the development of future treatments.

33.5 Review Questions

- The age at onset of Huntington’s disease is highly variable. Studies suggest which of the following is the most likely sources of this variability?
 - Exposure to neurotoxins such as pesticides or organic solvents have been shown to be associated with earlier onset age.
 - Analyses of pairs of affected siblings show heritability of onset age suggesting other genes influence onset age.*
 - Maternal transmission of HD is strongly associated with early onset in HD.
 - The size of the CAG repeat expansion has been shown definitively to explain all of the variance in onset age of HD.
 - There are no known factors influencing onset age in HD.
- Which of the following cell types have been implicated in the neuroimmune response in HD?
 - Neuron
 - Microglia
 - Astrocytes
 - All of the above*
- Complement cascade proteins are one of the molecular mechanisms implicated in HD. What did studies of genetic deletion of C3 show in terms of clinical disease progression?
 - HD mouse models with C3 deletion showed protection against HTT protein accumulation and longer survival.
 - HD mouse models with C3 deletion showed more rapid disease progression and shorter survival.
 - HD mouse models with C3 deletion showed a reduced inflammatory response which was neuroprotective.
 - C3 deletion did not alter disease progression in HD mouse models.*
- DNA damage has been implicated in human HD post-mortem brain, and this has been associated with increased cleavage of HTT. This pattern is related to neuroinflammation in HD by which pathway?
 - Htt cleavage mediated by an I κ B kinase (IKK) implicates the NF κ B pathway in neurons.*
 - The aberrant cytoplasmic localization of mHTT fragments.
 - Dramatic increase in the pro-inflammatory gene tumor necrosis factor alpha (TNF α)
 - Facilitation and increase in NF κ B transport by mutant HTT.
- Which of the following is true regarding the role of microglia in HD?
 - Mutant HTT is not expressed in microglia.
 - Microglial activation is a hallmark of HD neuropathological involvement.*

- c. Microglial activation is only seen in the striatum in HD brain.
- d. Microglial activation occurs in HD brains but is not related to the extent of pathological involvement in the brain.

Qingzhong Kong and Richard A. Bessen

Abstract

The human prion diseases are a diverse group of neurodegenerative diseases that are classified by several criteria including disease etiology, *PRNP* polymorphisms at codon 129, PrP^{Sc} types and subtypes, prion incubation period and disease duration, clinical presentation and neuropathology. Creutzfeldt-Jakob disease (CJD) is unique in that it can have a sporadic, inherited, and infectious etiology, and all three forms can subsequently be transmitted following experimental inoculation of brain tissue. PrP^{Sc} is an unusual pathogen that fails to induce a prion-specific host immune response, but PrP^{Sc}-induced damage to the brain likely causes a proinflammatory response that contributes to neurodegeneration. The human prion diseases are primarily localized to the nervous system, but variant CJD (vCJD) also has a peripheral distribution in secondary lymphoid tissues that is consistent with oral exposure to bovine spongiform encephalopathy (BSE). The prion agent uses the immune system for targeting to lymphoid organs, agent replication, and neuroinvasion through fibers that innervate lymphoid tissues. In chronic inflammatory conditions in which lymphoid organogenesis can occur in non-lymphoid tissues, ectopic peripheral prion infection can be established and could play a role in prion transmission.

Keywords

Creutzfeldt-Jakob disease • Fatal insomnia • Gerstmann-Straussler-Scheinker disease • Kuru • Neuroinvasion • Prion • Protein misfolding • Protein-only hypothesis

34.1 Introduction

The modern history of the prion diseases is one of novel microbes, anthropological intrigue, and food safety mishaps. The prion diseases, also called the transmissible spongiform

We are very saddened that Dr. Richard Bessen passed away recently. Richard is a well-known scientist in the prion field. He has made significant contributions to many aspects of prions and prion diseases, including the etiology, strains, transmission, shedding and neuroinvasion of various prions. He will be missed.

encephalopathies, are fatal neurodegenerative diseases that can be sporadic, inherited, or infectious. These multiple origins are unique among human disease. The basis of all prion diseases is the misfolding of the host prion protein into the disease-specific prion protein conformation, called PrP^{Sc}. Transmission of PrP^{Sc} into naïve hosts can lead to additional prion protein misfolding and induction of neurodegenerative disease. Hence, prion diseases are transmissible but are caused by a novel pathogen that lacks a prion-specific nucleic acid genome.

In the 1950s Carleton Gajdusek, an American physician, was attracted to the highlands of New Guinea by reports of a mysterious condition called kuru that was ravaging the Fore stone-age tribes. Kuru primarily afflicts woman and young children and victims succumb to neurological illness that includes shivering and twitching but rapidly progresses to ataxia, paralysis, and eventually death. Gajdusek was perplexed

as to the cause of kuru and it was the observation of William Hadlow, a veterinary pathologist, which led to the recognition of the human prion diseases. Hadlow observed the striking similarity in neuropathology between scrapie, a transmissible disease in sheep, and kuru and reasoned that if kuru and scrapie are similar diseases, then kuru should be transmissible to non-human primates (Hadlow 1959). Gajdusek inoculated kuru into chimpanzees and transmitted neurological disease (Gajdusek et al. 1966). Once the infectious etiology of kuru was established, transmission of kuru was linked to ritualistic endocannibalism among the Fore people. Shortly afterwards, Gajdusek reported transmission of sporadic Creutzfeldt-Jakob disease (CJD), a neurological disease first described in the 1920s, to chimpanzees and they developed neuropathology characteristic of the prion diseases, which includes neuronal loss, spongiform changes, and astrogliosis. These pioneering studies established that kuru and CJD, which were thought to be unrelated diseases of unknown etiology, belong to the same group of human transmissible spongiform encephalopathies. Gajdusek received the Nobel Prize in Physiology or Medicine in 1976 for his work on human prion diseases.

Although the human and animal prion diseases were known to be transmitted by an infectious agent, the unusual resistance of these agents to chemical and physical inactivation was perplexing and led to theories that they were caused by an unconventional slow virus. In 1982, Stanley Prusiner reported that scrapie in sheep was caused by “prions”, which were defined as infectious proteinaceous particles that are devoid of a nucleic acid (Prusiner 1982). This hypothesis was met with immense skepticism from the scientific community since it challenged the central principle of molecular biology that genetic information flows from DNA to RNA to protein. However, Prusiner, and others, were able to build

upon this theory and his pioneering work was also recognized with a Nobel Prize in Physiology or Medicine in 1997.

Another bizarre chapter in prion diseases began in the mid-1980s with the identification of bovine spongiform encephalopathy (BSE) in cattle. This prion disease was transmitted by industrial cannibalism in which livestock feed was supplemented with meat and bone meal that was unknowingly derived from prion-infected sources, possibly from scrapie-infected sheep. BSE peaked at over 35,000 cases a year in the United Kingdom in the early 1990s but the prevalence has been greatly reduced by the removal of ruminant-derived protein sources in livestock feed. However, the BSE agent is a highly pathogenic strain of prion and is the causative agent for a new human prion disease called variant CJD (vCJD) (Will et al. 1996).

The human prion diseases, which include CJD, kuru, Gerstmann-Straussler-Scheinker disease (GSS), fatal insomnia, and the recently identified variably protease sensitive prionopathy (VPSPr), can be classified into three groups based on etiology (Table 34.1).

34.2 Prion Protein Gene and Gene Products

34.2.1 Prion Protein Gene and PrP^C

The prion protein is a normal cellular membrane protein that is expressed at high levels in the nervous system, testis, muscle, some hematopoietic cells, and follicular dendritic cells (Makrinou et al. 2002). In humans the prion protein is encoded by a single copy gene, which is called *PRNP* and is located on chromosome 20. As illustrated in Fig. 34.1a, *PRNP* has two exons and a single intron that span about 15 kilobases; exon 2

Table 34.1 Origin and prevalence of the human prion diseases

Human prion disease (percent)	Prevalence	Origin (distribution)
Sporadic (85–90 %)		
Creutzfeldt-Jakob disease	1 in 10 ⁶ /year	Spontaneous (worldwide)
Fatal insomnia	≥10 cases	Spontaneous
Variably protease sensitive prionopathy	≥21 cases	Spontaneous (US, UK, Europe)
Familial (10–15 %)		
Creutzfeldt-Jakob Disease		
E200K-129M	3–5 % ^a	Germline mutation in <i>PRNP</i>
All other families	>97 families	Germline mutations/insertions in <i>PRNP</i>
Fatal familial insomnia	≥44 families	Germline mutation in <i>PRNP</i>
Gerstmann-Straussler-Scheinker	>72 families	Germline mutations/insertions in <i>PRNP</i>
Acquired (~1 %)		
Variant CJD	229 cases	BSE infection (UK, Europe, others)
Iatrogenic CJD	≥470 cases	Medical practices (France, Japan, others)
Kuru	~2700 cases	Cannibalism (Papua New Guinea)

^aPercent of all human prion diseases based upon epidemiological data from Italy and Japan

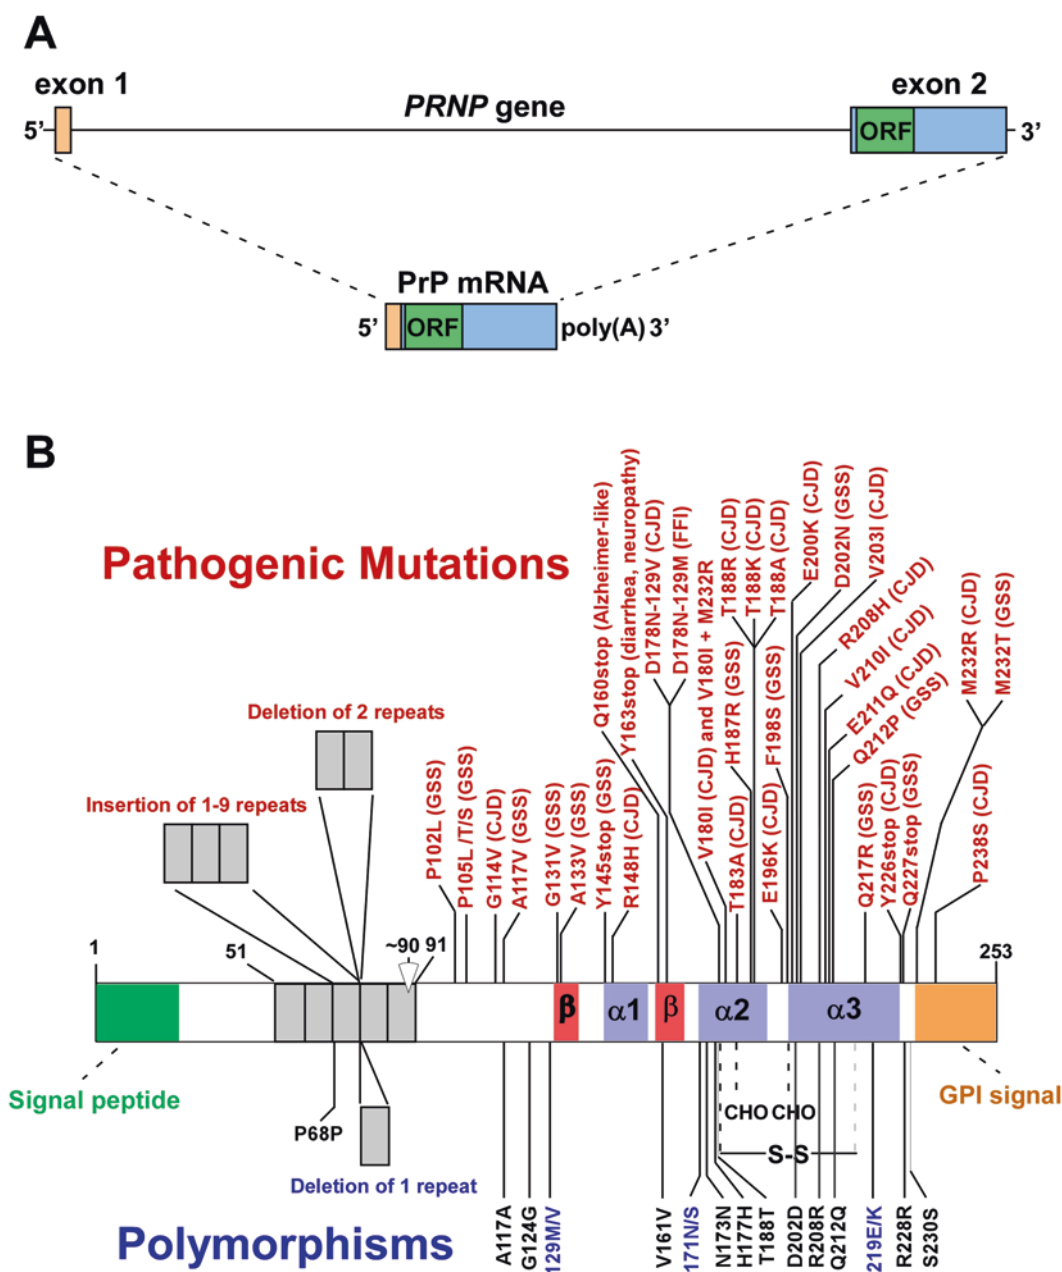

Fig. 34.1 Diagram of the *PRNP* gene and the PrP protein. (a) The prion protein gene and mRNA. The PrP ORF is located within exon 2 and is highlighted in green. (b) The PrP protein linear map with post-translational modifications, polymorphisms, and pathogenic mutations (modified from Fig. 2 in Kong et al. 2003). The numbers indicate the amino acid residue position in the prion protein and the single letter designation for amino acids is used to denote polymorphisms and mutations. The signal peptide at the amino terminus and the glycosylphosphatidylinositol (GPI) signal peptide at the carboxyl terminus

are indicated in green and orange, respectively. The octapeptide repeats are indicated by gray boxes, while the three α -helices and two short β -sheets are indicated by pale blue and red boxes, respectively. Mutations linked to the human prion diseases are illustrated in red type above the PrP map while normal polymorphisms are indicated below. The arrowhead at amino acid 90 indicates the major cleavage site for proteinase K, which degrades the N-terminal portion of PrP^{Sc}. The two N-linked carbohydrate groups (CHO) and disulfide linkage (-S-S-) are also illustrated.

contains the prion protein coding sequence (Makrinou et al. 2002). In the *PRNP* coding region there are a large number of pathogenic mutations that are linked to, or have been associated with, the familial prion diseases (Fig. 34.1b) (Kong et al. 2003). Polymorphisms are also present and the one at codon 129 (methionine or valine) plays an important role in deter-

mining susceptibility and/or the clinical phenotype/disease duration in the prion diseases.

The cellular form of the prion protein, called PrP^C, is synthesized as a 253 amino acid precursor protein in humans (Fig. 34.1b) (Prusiner 1991). The N-terminal 22 amino acid residues serve as the signal peptide that allows insertion of

Fig. 34.2 Schematic diagram of PrP^{Sc} types found in human prion diseases. The three major prion protein polypeptide glycoforms are illustrated on SDS-PAGE (*lane 1*). The relative amount of each PrP polypeptide in relation to the other glycoforms is indicated by the shading intensity of each band. The molecular weight of the major nonglycosylated PrP^{Sc} polypeptide band is indicated in kilodaltons (kD). PrP^{Sc}

types are defined after limited digestion with proteinase K (PK), which removes the N-terminal portion of the prion protein (*lanes 2–6*). PrP^{Sc} subtypes are defined by the molecular weight of the nonglycosylated PrP^{Sc} polypeptide, the ratio of the three PrP^{Sc} glycoforms, as well as the identity of codon 129. This is one criterion that is used for the molecular classification of the human prion diseases

the nascent PrP^C peptide into the secretory pathway during biosynthesis. The C-terminal 22 amino acid residues are involved in the covalent addition of the glycosylphosphatidylinositol (GPI) moiety to serine at residue 231 (i.e., Ser²³¹). The GPI anchor tethers PrP^C to the extracellular side of the plasma membrane. PrP^C has two N-linked glycosylation sites (Asn¹⁸¹ and Asn¹⁹⁷) that are the sites of attachment of complex carbohydrates. There are three major PrP^C glycoforms that are defined by the number of N-linked carbohydrate moieties; these are referred to as diglycosylated, monoglycosylated, and nonglycosylated forms (Fig. 34.2). The N-terminal region of PrP^C has five octapeptide repeats that bind metal ions (e.g., copper, zinc) but the structure of this domain is undefined, while the C-terminal portion consists of three α -helical and two short β -sheet domains (Fig. 34.1b). The cellular function(s) of PrP^C is diverse. It has been implicated in neurogenesis and differentiation (Steele et al. 2006), astrocyte maturation (Arantes et al. 2009; Hartmann et al. 2013), differentiation of pluripotent progenitors cells toward the neural lineage (Peralta et al. 2011), proliferation of oligodendrocyte precursor cells (Bribian et al. 2012), proliferation and self-renewal of neural progenitor cells (Santos et al. 2011; Prodromidou et al. 2014), hematopoietic stem cell self renewal (Zhang et al. 2006), cell-cell adhesion (Solis et al. 2013), microtubular cytoskeleton disassembly (Niezanski et al. 2006) and microtubule-dependent transport (Niezanska et al. 2012), metal ion transportation (Wong et al. 2001), antioxidant

activity, signal transduction, apoptosis, and sleep regulation (Tobler et al. 1996; Lasmezas 2003).

34.2.2 The Protein-Only Hypothesis for the Prion Diseases

Identification of the infectious agent causing prion diseases has been controversial due to its small size and resistance to procedures that inactivate most microorganisms as well as nucleic acids. Extensive efforts to detect a prion-specific small virus or nucleic acid genome have been unsuccessful (Safar et al. 2005). In contrast, procedures that destroy proteins also inactivate prion infectivity. Despite much debate, it is generally agreed that prion diseases are caused by prions, which are defined as proteinaceous infectious particles that lack a nucleic acid genome (Prusiner 1991). The protein-only hypothesis states that the infectious prion agent is a misfolded form of PrP^C devoid of specific nucleic acids (called PrP^{Sc} where “Sc” refers to scrapie). PrP^{Sc} has distinct biochemical properties from PrP^C that include partial resistance to degradation by proteolytic enzymes, insolubility in detergents, and aggregation into linear fibrils. The basis for these unusual features of PrP^{Sc} is a conformational conversion of α -helical to β -sheet conformation. This protein misfolding, or prion replication, has been postulated to occur by a protein self-assembly mechanism by which the abnormal PrP^{Sc} polymer or fibril can convert the monomeric PrP^C into a subunit of the growing PrP^{Sc} polymer (Jarrett and Lansbury 1993).

Although the scientific community was initially skeptical of the prion hypothesis, in the past 30 years several key experiments have demonstrated support for this novel concept. PrP null mice, in which the endogenous prion protein gene has been removed, do not make PrP^{Sc}, prion infectivity or develop prion disease when inoculated with the scrapie agent (Sailer et al. 1994). Additional studies used transgenic mouse models in which the prion protein transgene corresponds to a mutation common in Gerstmann-Straussler-Scheinker disease (GSS), a proline to leucine mutation at codon 102 (i.e. P102L). These transgenic P102L mice, when overexpressing the mutant PrP protein, spontaneously develop prion disease and the neuropathology is characterized by PrP^{Sc} amyloid plaques, which are similar to plaques found in GSS patients (Hsiao et al. 1990). This classic study demonstrated that mutations in *PRNP* are directly linked to the human prion diseases. More definitive proof of the prion hypothesis is the *in vitro* generation of infectious prions from recombinant prion protein (Legname et al. 2004; Deleault et al. 2007; Kim et al. 2010; Wang et al. 2010). Additional studies indicate that host cofactors also play a role in prion replication (reviewed by Ma and Wang 2014).

34.2.3 Molecular Classification of PrP^{Sc} in Human Prion Diseases

Biochemical characterization of PrP^{Sc} reveals heterogeneity in the polypeptide patterns among the human prion diseases and this has been useful for the molecular classification of PrP^{Sc} (Gambetti et al. 2003). Limited proteinase K digestion of PrP^{Sc} removes a ~7 kilodalton N-terminal fragment but leaves intact a protease-resistant PrP^{Sc} core. Typically, there are three protease-resistant polypeptide fragments, referred to as glycoforms, which differ in molecular weight by the addition of zero, one, or two N-linked carbohydrate groups (Fig. 34.2). Among the human prion diseases, PrP^{Sc} polypeptide fragments can vary in number (typically 1–3), molecular weight, and the ratio of the three glycoforms. Based on these criteria, PrP^{Sc} is classified into four operational groups called type 1, type 2 (a and b), GSS-type, and variably protease sensitive prionopathy (VPSPr)-type (Table 34.2, Fig. 34.2). Type 1 PrP^{Sc} is found in the majority of sporadic CJD (sCJD)

cases, some familial CJD (fCJD) cases, and at small amounts in all variant CJD (vCJD) cases (Yull et al. 2006). The type 2a PrP^{Sc} is associated with a minority of sCJD cases, sporadic fatal insomnia (sFI) and some fCJD cases. Many sCJD patients (20 % or more) possess both type 1 and type 2 PrP^{Sc}. In vCJD, PrP^{Sc} polypeptides have a similar molecular weight as found in type 2a PrP^{Sc} but the ratio of the three PrP^{Sc} glycoforms are different. Therefore, vCJD is referred to as type 2b PrP^{Sc} (Fig. 34.2). In GSS, a 7–8 kilodalton (kD) PrP^{Sc} polypeptide is referred to as GSS-type PrP^{Sc} and it is only found in GSS cases. In VPSPr, PrP^{Sc} consists of multiple PrP fragments [~7kD (GSS-like), ~17kD, ~20kD, ~23kD and ~26kD] (Table 34.2, Fig. 34.2) (Zou et al. 2010, 2013). The significance of the PK-resistant PrP-CTF12/13 fragments (Fig. 34.2) is not clear (Zou et al. 2003).

34.3 Epidemiology and Clinical Features of Human Prion Diseases

The human prion diseases are rare but fatal neurodegenerative diseases that have long incubation periods ranging from years to decades. The clinical course is progressive and exhibits a complex neurological pattern that also can last from months to years. Presenting symptoms vary depending on the type of human prion disease, but most will display cognitive, motor, and behavioral deficits during the clinical phase. Some of the prion diseases target to specific brain regions while others have a widespread distribution in the brain. The incubation time, age at onset of clinical symptoms, and disease duration is variable among the human prion diseases and there is often overlap in these features among the major types of human prion diseases (Table 34.1).

34.3.1 Sporadic Human Prion Diseases

Sporadic CJD is the most common human prion disease and accounts for 85–90 % of all human cases (Gambetti et al. 2003). Sporadic prion diseases are associated with type 1, type 2a (sCJD), or a mixture of type 1 and type 2 PrP^{Sc}. sCJD can be further classified into five subtypes based on a combination of molecular, clinical and pathological features

Table 34.2 Classification of PrP^{Sc} types in human prion diseases

PrP ^{Sc} type ^a	N-terminus, amino acid	C-terminus, amino acid	Nonglycosylated PrP ^{Sc} , kilodalton
Type 1	~82	231	~21
Type 2	~97	231	~19
GSS-type	74–90	147–153	7–8
VPSPr	~93	NA	~7, 17, 20

^aAfter limited proteolytic digestion with proteinase K

including 1) the genotype at codon 129 of *PRNP* (Methionine or Valine) and 2) the type of protease resistant PrP^{Sc} fragments (1 or 2). These subtypes are designated sCJMM1/sCJDMV1, sCJMM2, sCJDVV1, sCJDVV2, and sCJDMV2. These five subtypes of sCJD are associated with distinct clinical and/or pathological characteristics (Parchi et al. 1999; Gambetti et al. 2003). In addition to clinical symptoms, periodic sharp wave (PSW) complexes on electroencephalogram (EEG), MRI (hyperintense signal), and the presence of 14-3-3 protein in cerebral spinal fluid (CSF) are useful diagnostic markers for CJD.

The sCJMM1/sCJDMV1 subtype displays either MM or MV at PrP codon 129 and type 1 PrP^{Sc}. It is the most common subtype and accounts for 60–70 % of all sporadic human prion disease. This sCJD subtype has a mean age at clinical onset of 65 years of age and the mean duration of clinical symptoms prior to death is approximately 4 months. The symptoms at clinical presentation can include cognitive impairment, widened gait or ataxia, behavioral signs (including depression, anxiety, psychosis), and vision defects. Myoclonus and pyramidal signs develop at later stages of clinical disease. PSW complexes on EEG are present in the majority (~80 %) of subjects within 3 months of clinical onset. Protein 14-3-3 in CSF is found in 95 % of cases. Therefore, concurrent PSW and 14-3-3 positive CSF are often used as a diagnostic marker for sCJD.

The sCJDVV2 subtype has VV at PrP codon 129 and type 2 PrP^{Sc}. It is the second most common form of sCJD and accounts for ~16 % of all sporadic human prion disease. The mean age at onset is 60 years and the mean duration of the clinical phase is 6 months. Ataxia is the most common presenting symptom for this subtype. At later stages, dementia almost always develops and is accompanied by myoclonus and pyramidal signs. PSW on EEG is rare and CSF 14-3-3 is positive in ~80 % of cases.

The sCJDMV2 subtype has MV at PrP codon 129 and type 2 PrP^{Sc}, and it represents ~9 % of the sporadic cases. This subtype has a phenotype very similar to that of sCJDVV2 except for a longer clinical phase before death (mean of 17 months), greater involvement of cognitive and mental symptoms at earlier stages, and frequent aphasia and apraxia at later stages.

The sCJMM2 subtype has MM at PrP codon 129 and type 2 PrP^{Sc}, and it accounts for 2–8 % of the sporadic cases. The mean age at onset is 65 years and the mean clinical duration is 16 months. Cognitive impairment is the universal presenting symptom and is sometimes accompanied by aphasia. At later stages, myoclonus and pyramidal signs, and sometimes Parkinsonism, apraxia, and seizures, develop. There is no PSW on EEG while CSF 14-3-3 is positive in most cases.

The sCJDVV1 subtype has VV at PrP codon 129 and type 1 PrP^{Sc}, and it accounts for 1 % of the sporadic cases. The mean age at onset is 39 years and the mean clinical duration is

15 months. This younger age of clinical onset is unusual for a sporadic human prion disease and more closely resembles the age of onset that is characteristic in vCJD. This subtype shows dementia at the early clinical stages that is followed by myoclonus and pyramidal signs. There is no PSW on EEG and the CSF 14-3-3 is positive in all cases tested.

In sporadic fatal insomnia (sFI) there is MM at PrP codon 129 and type 2 PrP^{Sc}. sFI accounts for ~2 % of the sporadic cases and the phenotype is similar to that of inheritable FFI, which is characterized by insomnia, but visual signs, cognitive impairment, and motor signs are also common. The mean age at onset is 50 years, but has been observed as early as 13 years, with a mean clinical duration of 24 months.

In variably protease sensitive prionopathy (VPSPr) (Gambetti et al. 2008, Zou et al. 2010, 2013; Head et al. 2013) the PrP^{Sc} molecular properties and clinical symptoms are similar among patients with polymorphisms at codon 129 of *PRNP*, but there are some distinctions. In 129VV subjects, the mean age at onset was 72 years and mean clinical duration was 45 months; the symptoms included psychiatric signs, behavior and mood changes, and often language deficits and cognitive impairment. In 129MV subjects, the mean age at onset was 65 years and mean clinical duration was 23 months; the symptoms included psychiatric signs, Parkinsonism, and often ataxia and myoclonus. In the two 129MM subjects, the age of onset was 64 and 78 and clinical duration was 41 and 50 months; the symptoms included Parkinsonism, ataxia, progressive diffuse cognitive impairment and myoclonus.

34.3.2 Familial Human Prion Diseases

The familial prion diseases are inherited in an autosomal dominant manner and account for 10–15 % of all human prion disease. They include familial CJD (fCJD), GSS, and fatal familial insomnia (FFI) (Gambetti et al. 2003; Kong et al. 2003). The familial prion diseases are caused by pathogenic mutations in the *PRNP* coding sequence. To date, these include 24 mis-sense mutations that result in amino acid changes, 2 nonsense mutations that result in premature stop codons, and about 30 insertion or deletions that lead to changes in the octapeptide repeat number (Fig. 34.1b). There are 16 polymorphic sites in *PRNP* (Fig. 34.1b). The most important polymorphism is at codon 129, which affects the clinical symptoms in *cis* to the mutant allele and modifies the age of onset and disease duration in *trans* to the mutant allele (Kong et al. 2003).

There are 17 mutations in *PRNP* that have been linked to fCJD: G114V, R148H, D178N-129V, V180I, T183A, T188A/K/R, E196K, E200K, V203I, H208R, V210I, E211Q, Y226stop, M232R and P238S (Fig. 34.1b). In fCJD the disease phenotype is often similar to that found in sCJD, but there can be heterogeneity between individuals carrying dif-

ferent or even the same *PRNP* mutation. This is illustrated in the most common fCJD cases, which is caused by an E200K amino acid substitution in the prion protein. Some individuals with the E200K genotype have a methionine at codon 129 on the mutant allele (i.e. fCJD^{E200K-129M}) and a type 1 PrP^{Sc}, while others with the same E200K mutation have a valine at codon 129 (i.e., fCJD^{E200K-129V}) and a type 2 PrP^{Sc}. In fCJD^{E200K-129M}, the mean age at onset is 58 years and the average clinical duration is 6 months. Symptoms at clinical onset include cognitive and mental impairment that is often accompanied by cerebellar signs and sometimes by visual symptoms and myoclonus. Later in the disease course, seizures and motor and sensory peripheral neuropathy can also be present. These later signs are rare in sCJD. There is PSW on EEG and CSF 14-3-3 is also positive in the majority of affected subjects. In contrast, fCJD^{E200K-129V} individuals have a phenotype similar to that of sCJDVV2, which presents primarily as ataxia followed by myoclonus with PSW on EEG at late stages. This phenotypic difference between fCJD^{E200K-129V} and fCJD^{E200K-129M} illustrates the dramatic influence of the codon 129 polymorphisms on disease phenotype and PrP^{Sc} type. Other common fCJD mutations include D178N-129V and V210I-129M or insertions of one to four octapeptide repeats.

GSS is an inheritable prion disease characterized by PrP^{Sc} deposits in the form of amyloid plaques in the cerebral cortex, degeneration of pyramidal tracts, and a long clinical duration. In GSS there is a highly variable age at onset (between 20 and 73 years) and duration of the clinical phase (mean of 5 years, but range between 5 months and 21 years). The symptoms usually include a slowly progressive cerebellar syndrome, pyramidal signs, and cognitive decline that often develop into dementia. GSS could be mistaken for other common neurodegenerative diseases due to the similarity in clinical signs. These include olivopontocerebellar atrophy, spinocerebellar ataxia, Parkinson disease, amyotrophic lateral sclerosis, Huntington's disease, and Alzheimer disease (Kong et al. 2003). Mutations in *PRNP* that have been linked to GSS include P102L, P105L/T/S, A117V, G131V, A133V, Y145stop, H187R, F198S, D202N, Q212P, Q217R, Q227stop and M232T.

PrP^{P102L-129M} is the most common GSS genotype and is the first reported *PRNP* mutation linked to human prion disease. It has been reported in at least 28 families around the world and it may have occurred independently more than a single time since it is detected in families of different ethnicity. In GSS^{P102L-129M}, a protease-resistant PrP^{Sc} polypeptide of 7–8 kilodaltons is the major component of amyloid plaques in the brain. The age at onset is between 30 and 63 years with clinical duration of 1–10 years. However, some subjects have a CJD-like phenotype accompanied by a short clinical duration of 5–9 months. The initial symptoms include progressive cerebellar signs with ataxia, dysarthria, incoordination of saccadic movements, and occasional pyramidal and pseudobulbar signs. Dementia and akinetic mutism develop at

late stages of the disease. Polymorphic variants of the PrP^{P102L-129M} allele include PrP^{P102L-129V} and PrP^{P102L-129M-219K} and these have distinct disease phenotypes.

Fatal familial insomnia is the second most common inherited prion disease and is associated with a D178N-129M mutant allele (Kong et al. 2003; Montagna et al. 2003). The average age at onset is 49 years but can vary between 20 and 72 years. The duration of the clinical phase also is highly variable with an average of 11 months for 129MM subjects and 23 months for 129MV subjects. Severe insomnia is the most prominent symptom and is likely due to prion targeting to the thalamus, which is reflected in abnormal brain activities in this region on positron emission tomography (PET) and single-photon emission computed tomography (SPECT) scans. Other symptoms can include episodes of hallucinations and confusion, myoclonus, spasticity, and seizures. EEG is usually slowed and PSW complexes are often present in patients with long duration. There is a characteristic shortened sleep time and irregular transition between sleep stages on polysomnography. The same D178N mutation is found in fCJD but these individuals have a 129V genotype on the mutant allele and, as a result, the disease phenotype is different and does not include insomnia.

In addition, two recently detected *PRNP* mutations are not associated with conventional prion diseases. Patients with a PrP Q160stop mutation present with a Alzheimer's disease phenotype that is accompanied by widespread PrP deposition in the frontal cortex (Guerreiro et al. 2014). Patients with the PrP Y163stop mutation exhibit chronic diarrhea and an autonomic neuropathy associated with widespread PrP amyloid deposition in peripheral tissues, spinal cord and cortical regions of the brain, but prion transmission to mice was not observed (Mead et al. 2013).

34.3.3 Acquired Human Prion Diseases

The acquired prion diseases account for less than 1 % of all human prion disease cases and these include variant CJD, iatrogenic CJD (iCJD), and kuru (Will 2003). In these cases, prion infection is either orally acquired or associated with accidental transmission via medical practices. Many of these latter cases involve contamination with brain tissue, which contains the highest amount of prion infectivity, from the donor host.

Variant CJD was discovered in 1996 and is most likely due to ingestion of BSE-contaminated food products, but direct proof is lacking due to the long interval between exposure and onset of disease. Removal of meat and bone meal supplements from livestock feed in the late 1980's has greatly reduced the prevalence of BSE in the United Kingdom from over 34,000 cases in 1992 to less than 1000 cases in 2005. As a result, human exposure to BSE has also been

greatly reduced. To date, there are 229 cases of vCJD primarily in the United Kingdom and France (Maheshwari et al. 2014). The annual number of vCJD cases reached a peak at 28 in 1999, but this number of cases is relatively low considering that approximately 1,000,000 BSE-infected cattle have entered the human food chain in the United Kingdom (UK) during the 1980s and 1990s. Due to the long prion incubation period, it is difficult to predict the size of the vCJD epidemic. A retrospective survey of tonsils and appendix specimens (i.e. sites of prion agent replication) removed during routine surgery in the UK revealed only three PrP^{Sc} positive samples in >18,000 cases (Hilton et al. 2004), while another study of 63,007 archived tonsil samples using two PrP^{Sc} immunoassays was equivocal (Clewley et al. 2009). However, a recent screening of 32,441 fixed appendix samples in the UK detected 16 PrP^{Sc} positive samples, predicting an overall prevalence of 1 in 2000 people with subclinical vCJD infection in the UK population (Gill et al. 2013). How many of these subclinical carriers of vCJD will develop clinical disease is uncertain.

The clinical and pathological phenotype of vCJD is distinct from most of the other human prion diseases and these unusual features were important in the identification of vCJD (Ironsides et al. 2005). Unlike the common sporadic forms of human prion disease that mostly afflict individuals in their sixth decade, vCJD is found in younger individuals with mean age of onset at 28 years, ranging between 12 and 74 years of age (Will 2003). The length of the incubation period is uncertain but is estimated to be ~11 years (Cooper and Bird 2003). The mean clinical duration is ~14 months, which is longer than the 4 months for sCJDMM1 but comparable to that of 16 months for sCJDMM2. With the exception of one vCJD case that had PrP^{129MV}, all other vCJD subjects had PrP^{129MM}. The PrP^{129MM} genotype has a prevalence of 39% in the UK population so the higher distribution in vCJD cases indicates a stronger preference for younger people with a PrP^{129MM} genotype. There could be an age-related exposure or age-dependence for vCJD but none has been demonstrated. The type 2b PrP^{Sc} is characteristic of vCJD (Table 34.2, Fig. 34.2) and PrP^{Sc} deposits are present in florid amyloid plaques in the brain. In contrast to the diverse clinical symptoms among sCJD cases, the symptoms of vCJD subjects are more uniform. The presenting symptoms include psychiatric signs and occasionally neurological symptoms (persistent pain, memory impairment). After about 6 months, signs of ataxia, cognitive impairment, and involuntary movements become apparent. Bilateral pulvinar high signal in the thalamus on MRI is prominent in the majority of cases (~78%) (Zeidler et al. 2000). There is general slowing but no PSW complexes on EEG.

Iatrogenic CJD is the second most common acquired human prion disease and these cases are the result of accidental infection due to contact with prion contaminated tis-

ues or instruments during medical procedures (Table 34.1). The mode of prion infection include surgical equipment (e.g., surgical instruments, depth electrodes), transplantation of human tissues (corneal, dura mater), intramuscular injections with growth hormone or gonadotrophin extracted from human pituitary tissues, or blood transfusion (Will 2003). The most likely source of infection is from donors with subclinical sCJD, except for the two transfusion-related cases that have been linked to blood donors who developed vCJD several years later (Ironsides 2006). The incubation period in these transfusion related cases was 5–6 years, which is shorter than primary vCJD infection in humans.

The most common cases of iCJD are in recipients of dura mater graft or human growth hormone therapy that was used to treat children with growth deficits (reviewed by Will et al. 2013 and Brown 2013). There have been 226 iCJD cases reported in the USA, UK, France, and New Zealand and 5 other countries that have been linked to growth hormone extracted from cadaveric pituitaries. The clinical and pathological features of growth hormone therapy-related iCJD are distinct from sCJD. The mean incubation period is 17 years (range between 4.5 and 42 years) and the presenting symptoms include progressive cerebellar signs that are sometimes followed by dementia at later stages. A total of 228 iCJD cases have been found in recipients of dura mater homograft, mostly in Japan, Spain, France, Germany, Italy and UK. Afflicted individuals show typical sCJD symptoms with an incubation period of 12 years (range between 1.5 and 30 years).

Kuru is an acquired human prion disease of indigenous tribes in Papua New Guinea that is linked to ritualistic endocannibalism (Alpers 1979). More than 2700 cases have been recorded since the 1950s, but this disease has gradually disappeared since the cessation of cannibalism in the late 1950s. The mean incubation period for kuru is about 12 years, but the longest on record is over 50 years (Collinge et al. 2008). The clinical duration is 6–36 months in adults and the main presenting symptom is cerebellar signs, which are often followed by severe dysarthria at late stages in the absence of dementia.

34.4 Neuropathology of Human Prion Diseases

The three principal neuropathological features in human prion diseases are neuronal loss, gliosis, and spongiform changes primarily in grey matter (Mikol 1999). There is considerable diversity among the human prion diseases with respect to the location of pathology in the brain and type of neurons affected. Pathology is not confined to a single brain structure but is widely distributed in the CNS. For each of the human prion diseases, there are typical distinguishing features of neuropathology that are partially defined by the dis-

tribution of pathology in the cerebral cortex, subcortical grey matter, and brainstem. Spongiform changes can vary in density and size and range from microvacuolation to the fusion of vacuoles to produce status spongiosis. The degree of spongiform change does not appear to correlate with neuronal loss. Amyloid plaques are also present in the brain in some of the human prion diseases, most notably kuru, vCJD and GSS. These amyloid plaques exhibit birefringence when stained with Congo red and viewed under polarized light.

PrP^{Sc} deposition in the central nervous system is also a hallmark feature of prion disease (Prusiner 1991). The type of PrP^{Sc} deposit and its location varies among the human prion diseases. PrP^{Sc} is also a component of amyloid plaques. A characteristic of vCJD and kuru is florid amyloid plaques, which is a large cluster of PrP^{Sc} aggregates interspersed with vacuolar pathology. PrP^{Sc} deposition is also present in peripheral tissues of patients with vCJD, primarily in secondary lymphoid tissues. However, no histological changes are apparent in peripheral organs of prion-infected hosts.

In prion diseases there is a notable absence of encephalitis or inflammation in the brain. The lack of adaptive immune response to PrP^{Sc} is likely due to host tolerance to PrP^C. However, there is an increase in the numbers of microglia, activation of astrocytes, and an upregulation of inflammatory cytokines, chemokines and receptors. The complement pathways is also activated as evidenced by binding of C1q and C3b components to PrP^{Sc}, and complement membrane attack complexes associated with neurons in the brain (Burwinkel et al. 2004; Kovacs et al. 2004; Mabbott 2004). The precise role of these host responses in neuroprotection and/or neurodegeneration during prion infection is not clear.

The neuropathology among sCJD cases is not uniform and is variable in nature, severity and location in the brain. In most cases spongiform change is found in the cerebral cortex, cerebellar cortex, and/or the subcortical grey matter (Ironsides et al. 2005). This is accompanied by reactive gliosis and neuronal loss but there is not a consistent relationship between spongiform change and cell loss. In approximately 10 % of sCJD, PrP^{Sc} amyloid plaques are present in the cerebral cortex but most cases have a diffuse synaptic PrP^{Sc} distribution. In contrast to the clinical and pathological diversity present in sCJD, the pathology in vCJD is more uniform. The central pathological features in vCJD are the presence of florid PrP^{Sc} plaques in the cerebral and cerebellar cortex, severe spongiform change in the caudate and putamen, and neuronal loss in the thalamus and midbrain. PrP^{Sc} is also present in affected brain regions. The neuropathology of vCJD is distinct from the other human prion diseases.

In the familial human prion diseases there are also variable clinical and neuropathological features. GSS is characterized by unicentric and multicentric PrP^{Sc} amyloid plaques that are primarily found in the cerebellum, but can also be present in the cerebral cortex (Ghetti et al. 1995). Spongiform

change and neuronal loss can be focal but some GSS patients have no spongiform changes, while in other cases with a short duration, there is widespread spongiform change. In some GSS families, severe neurofibrillary tangle degeneration is prominent. A feature of FFI is a thalamic degeneration characterized by severe spongiform change, neuronal loss, and astrocytosis in thalamic nuclei (Gambetti et al. 1995).

In VPSPr patients there is brain atrophy and diffuse slowing of cerebral electrical activity (Zou et al. 2010). Spongiform change is modest in the cerebral cortex and focal spongiform vacuoles are occasionally found in the molecular layer of the cerebellum. The neuropathological lesions are usually more severe in the 129VV and 129MV than in the 129MM cases. The pattern of PrP^{Sc} immunostaining is slightly different among the three PrP genotypes.

34.5 Peripheral Prion Replication and Neuroinvasion

The sites of prion agent replication and spread are largely dictated by whether the etiology of prion disease is sporadic, familial, or acquired. For example, in sCJD and fCJD, disease initiates in, and is largely confined to, the nervous system. In vCJD, which is acquired via oral ingestion, infection likely begins in secondary lymphoid tissues prior to neuroinvasion and spread to the CNS.

34.5.1 vCJD and Oral Routes of Animal Prion Transmission

Variant CJD is BSE infection in humans and the most probable route of infection is by ingestion of BSE-contaminated food products. The spread of the vCJD agent following oral ingestion has not been directly investigated but evidence suggests it follows a similar pathway to that described for oral ingestion in the animal prion diseases. These pathways have been well described for scrapie in sheep and in rodent models and have three phases: agent entry and replication in secondary lymphoid tissues, spread from secondary lymphoid tissues to the CNS along peripheral nerves, and dissemination and degeneration in the CNS (Fig. 34.3). Following oral prion ingestion, the prion agent is initially found in the distal ileum (Heggebo et al. 2000). Entry is likely across the intestinal epithelium via the M cells in the Peyer's patches. Prions then spread to the draining gut-associated lymphoid tissue (GALT) where prion agent is found within months after ingestion (van Keulen et al. 1999). In the GALT, the prion agent is primarily associated with follicular dendritic cells and macrophages in the germinal center of lymphoid follicles. From the GALT the prion agent spreads to other secondary lymphoid tissues including lymph nodes and the spleen over the next several

Fig. 34.3 The stages of prion agent infection and neuroinvasion following oral ingestion of scrapie in sheep

months (van Keulen et al. 2000). The mechanism of prion agent dissemination in secondary lymphoid tissues has not been determined but is thought to be via prion-infected migratory cells that travel in the lymph. A blood borne route is also possible since low levels of prion infectivity have been found in the blood of sheep with scrapie and humans with vCJD (Ironsides 2006).

In scrapie-infected sheep, spread of the prion agent from the gut to the CNS occurs via peripheral nerve fibers. From the GALT, the prion agent enters the sympathetic nerves that innervate secondary lymphoid tissues and spreads to the spinal cord via the autonomic nervous system (McBride et al. 2001). The prion agent then ascends the spinal cord along spinal tracts into the brain (Fig. 34.3) (van Keulen et al. 2000). In a second pathway, after prion infection of the GALT, there is a delay before agent replication is found in the enteric nervous system. From these sites, the prion agent enters the vagal nerve and spreads to the brainstem where initial agent deposition is found in the dorsal motor nucleus of the vagus (van Keulen et al. 2000; Beekes et al. 1998). Early PrP^{Sc} deposition in this nucleus is indicative of neuroinvasion following oral ingestion. In vCJD, spread from secondary lymphoid tissues to the CNS is likely to take months to years.

After prions spread to the central nervous system they can spread away from the CNS along nerve fibers to additional peripheral sites. Recent advances in prion detection have led to the discovery that vCJD infection is found at low levels in some endocrine and reproductive tissues, muscle, kidney, and skin as well as in blood and urine (Peden et al. 2006; Notari et al. 2010; Moda et al. 2014). The ability to detect PrP^{Sc} in blood has resulted in more effective screening of patients with undiagnosed neurological diseases and patients at high risk for prion disease.

Evidence for oral ingestion in vCJD is provided by the peripheral PrP^{Sc} distribution. In humans with vCJD, PrP^{Sc} is present in the ileum and the sympathetic ganglia that provide autonomic innervation to the gut (Hilton 2006). Variant CJD infection is also present in FDCs in secondary lymphoid tissues including the Peyer's patches, tonsil, spleen, lymph nodes, and appendix. This distribution of the prion agent suggests that agent entry via oral ingestion results in the spread of vCJD infection to distal secondary lymphoid tissues (Hilton 2006). This peripheral distribution of the prion agent in lymphoid tissue and autonomic nervous system of the gut is not found in sCJD or the familial human prion diseases suggesting that vCJD is acquired by peripheral exposure.

34.6 CNS Pathogenesis of Sporadic, Familial, and Iatrogenic Prion Diseases

34.6.1 Sporadic CJD

In sCJD the process or events that lead to PrP^{Sc} formation and accumulation are thought to be limited to the CNS. Until recently PrP^{Sc} has not been found in the spleen, lymph nodes, tonsil or appendix in patients with sCJD (Head et al. 2004), and the apparent absence of prion infection in secondary lymphoid tissues has been cited as evidence against acquisition of prion infection from peripheral exposure. With improved detection methods PrP^{Sc} has now been found in secondary lymphoid tissue in sCJD (Rubenstein et al. 2013). However, there is an absence of infection in the sympathetic ganglia that provide autonomic innervation to the gut, indicating that it is unlikely that there is infection of the enteric nervous sys-

tem or acquisition of sCJD following ingestion of an unrecognized source of prion contamination. Prion infection also is detected in the peripheral nervous system of patients with sCJD. PrP^{Sc} deposition is found in retina, trigeminal ganglion, the olfactory nerves and epithelium, dorsal root ganglia and an occasional peripheral nerve (Head et al. 2004). This distribution is consistent with spread of the prion agent away from the CNS along cranial or spinal nerve fibers. PrP^{Sc} has also been found in skeletal muscle of patients with sCJD (Glatzel et al. 2003).

34.6.2 Familial Prion Disease

In familial prion diseases germline mutations in the prion protein gene leads to PrP^{Sc} deposition in the brain and nervous system. Prion agent has not been found in peripheral tissues in the limited number of familial prion disease cases that have been examined.

34.6.3 Iatrogenic CJD

Iatrogenic CJD can be acquired by either peripheral or CNS exposure to the prion agent from donor tissues or contaminated surgical equipment. The length of time to development of prion disease appears to be related to the site of prion inoculation. Shorter incubation periods are typically found following direct prion exposure to the brain (e.g., contact with stereotactic electrodes or instruments during neurosurgery) while longer incubation periods are seen following peripheral exposure (e.g., intramuscular injection of growth hormone) to the prion agent. In the latter cases, the incubation period can be up to several decades in duration (Will 2003). Due to the low number of iCJD cases, there are few studies examining the peripheral distribution of prion agent. One study reported the presence of PrP^{Sc} in the dorsal root ganglia and a few peripheral nerve fibers of two patients with dura mater related iCJD, while another study found PrP^{Sc} in small nerve fibers in muscle (Ishida et al. 2005). The pathway of neuroinvasion in iCJD associated with growth hormone therapy is less clear and prion infection was not found in secondary lymphoid tissues of a single patient, but the trigeminal ganglion and dorsal root ganglion were found to be sites of prion infection (Head et al. 2004). This limited amount of data would suggest that the prion agent is restricted to the CNS or PNS in iCJD.

34.7 Prion Agent Interaction with the Immune System

The immune system plays a central role in the pathogenesis of prion infection. In the acquired human prion diseases, it is the initial site of agent replication prior to entry into the ner-

vous system but the immune system does not appear to be essential in the pathogenesis of the familial and sporadic human prion diseases. Following peripheral exposure to the prion agent, the immune system can amplify prion infection but, interestingly, the adaptive immune response does not play a role in the clearance of the prion agent.

34.7.1 Prion Infection of Secondary Lymphoid Tissues

In the 1960s it was first described that the spleen is an early site of prion agent replication following peripheral scrapie infection of mice (Eklund and Hadlow 1969). Prion replication in the spleen is present shortly after peripheral exposure and reaches a plateau level prior to detection of prion agent in the brain. Mice that receive immunosuppressive therapy or splenectomy prior to peripheral inoculation experience a delay in prion replication in the periphery and spread to the CNS (Kimberlin and Walker 1989). Mice that are deficient in B cells also are resistant to peripheral prion infection, but B cells do not appear to be a target for prion infection (Mabbott and Turner 2005; Aguzzi and Heikenwalder 2005). One site of PrP^{Sc} deposition in the spleen and lymph nodes is in follicular dendritic cells (FDCs), and PrP^C expression on FDCs is required for prion infection of these cells (Mabbott and Turner 2005; Aguzzi and Heikenwalder 2005). FDCs are located in the germinal center of secondary lymphoid tissues and play a role in the presentation of antigen to B cells. B cells are important in FDC maturation and they secrete lymphotoxins (LT) that bind to LT receptors on FDCs. In the absence of B cells or LT, FDCs do not mature and are not susceptible to prion infection.

Several lines of evidence indicate that FDCs are important in prion agent replication in secondary lymphoid tissue (Mabbott and Turner 2005; Aguzzi and Heikenwalder 2005). Temporary de-differentiation of FDCs by injection of antibodies to LT receptors causes a loss of mature FDCs, a disorganization of the cytoarchitecture of the germinal center, and a delay or complete block in peripheral scrapie replication and neuroinvasion. A permanent loss of mature FDCs and disorganization of lymphoid structure is also found in null mice that lack LT or LT receptor genes. When these mice are peripherally challenged with the prion agent, they also demonstrate a greatly reduced capacity for agent replication and, in some cases, a complete block in peripheral prion pathogenesis. These studies indicate that FDCs are important sites of prion agent replication in lymphoid tissues and provide a critical step in the early pathogenesis of prion diseases.

34.7.2 Trafficking of the Prion Agent to Secondary Lymphoid Tissues

The complement system plays a role in the transport of the prion agent from peripheral sites of entry to FDCs in second-

ary lymphoid tissue (Mabbott 2004). Mice that lack the C3 complement receptor have a delay in prion replication in the spleen and in the onset of neurological disease. Complement component C3 plays a pivotal role in activation of both the classical and alternative complement pathways. Mice that lack the C1qa component or factor B and C2 complement components are deficient in the classical and alternative complement pathways, respectively, and these mice have a delay in prion agent replication in the spleen. As a result, they survive longer than wild type mice following intraperitoneal prion infection. If low doses of the prion agent are inoculated into the periphery of these complement-deficient mice, they do not develop prion disease while wild type mice remain susceptible to prion disease following peripheral infection. Mice that lack the C1qa component are the most resistant to peripheral prion challenge and binding of C1q to PrP^{Sc} can activate the classical complement pathway, and result in the targeting of PrP^{Sc}-complement complexes to CD21/35 complement receptors on FDCs (Mitchell et al. 2007; Zabel et al. 2007).

34.7.3 Trafficking of the Prion Agent to the Central Nervous System

The transfer of the prion agent from FDCs to peripheral nerves in the secondary lymphoid tissues is necessary for neuroinvasion. The FDCs are physically separated from the sympathetic nerve fibers but in chemokine receptor CXCR5 null mice there is a reorganization of the germinal center and the sympathetic nerves are now in close proximity to FDCs. Peripheral prion infection in these mice resulted in faster neuroinvasion into the spinal cord indicating that there is accelerated transfer of prion agent from the FDCs to the peripheral nervous system (Prinz et al. 2003). In transgenic mice that overexpress nerve growth factor, there is hyperinnervation of the sympathetic nervous system; these mice have a faster onset of prion agent replication in the spinal cord after peripheral challenge even though the onset of replication in the spleen is similar to wild type mice (Glatzel et al. 2001). Inhibition of sympathetic innervation in newborn mice with antibodies to nerve growth factor or chemical sympathectomy causes a delay in prion agent replication in the CNS (Glatzel et al. 2001). The transfer of the prion agent from FDCs to sympathetic nerves is crucial for prion neuroinvasion into the CNS.

34.7.4 Role of Inflammation in the Peripheral Distribution and Transmission of the Prion Agent

In a healthy host peripheral prion infection primarily involves infection of secondary lymphoid tissues such as the lymph

nodes and spleen. In mice with chronic inflammation in a peripheral organ that normally does not contain secondary lymphoid tissue, prion agent replication can also be found. In rodent models of nephritis, pancreatitis and hepatitis in which there is upregulation of lymphotoxins in the kidney, pancreas or liver, respectively, lymphoid tissue containing FDCs can develop in the inflamed organ. Following peripheral inoculation, prion infection can be established in these organs since transient secondary lymphoid tissues are present (Heikenwalder et al. 2005). In one model of prion infection in the kidney of mice with glomerulonephritis, prions could also be found in urine (Seeger et al. 2005). These findings indicate that chronic inflammation can lead to an altered organ tropism of the prion agent and induce excretion of the prion agent from a secretory organ.

In sheep with mastitis, a chronic inflammation of the mammary gland, and concurrent scrapie, prion infection is present in FDCs and macrophages in lymphoid follicles that develop adjacent to mammary ducts (Ligios et al. 2005). Secretion of the scrapie-infected macrophages in colostrum of sheep with mastitis could potentially enhance vertical transmission from ewe to lambs since milk is a natural source of scrapie infectivity (Konold et al. 2008; Lacroux et al. 2008).

34.8 A Broader Definition of Prions That Encompasses Neurodegenerative Diseases of Protein Misfolding

There is an emerging recognition that key events related to the misfolding of normal proteins in prion diseases are also common to many late-onset, human neurodegenerative diseases. As described above, a central feature of prion disease involves the misfolding of the monomeric cellular prion protein to form PrP^{Sc} polymers and, in some cases, PrP^{Sc} plaques. In related neurodegenerative diseases, normal host proteins that misfold and accumulate into altered pathogenic conformations include A β in Alzheimer's disease, α -synuclein in Parkinson's disease, tau in the tauopathies, superoxide dismutase-1 in amyotrophic lateral sclerosis, and likely nuclear RNA binding proteins in amyotrophic lateral sclerosis (reviewed in Prusiner 2013). In all these diseases the general mechanism of protein misfolding is mediated by the pathogenic protein polymer, which can serve as a template to further direct misfolding of the normal host protein. These prion-like human diseases are also similar to prion diseases in that they have genetic (10–20% of cases) and sporadic (80–90% of cases) etiologies, but epidemiological evidence suggests that they are not transmissible diseases. Interestingly, in transgenic mouse models of Alzheimer's disease and tauopathy, experimental inoculation of diseased human brain can accelerate protein misfolding of A β and tau, respectively,

and lead to earlier onset neurodegeneration (Meyer-Luehmann et al. 2006; Clavaguera et al. 2009). As these pathogenic proteins misfold within the CNS they follow defined neuroanatomical circuits and spread across neural synapses, which is also a common feature of PrP^{Sc} dissemination in the nervous system. In the future our understanding of prion diseases and neurodegenerative diseases with prion-like features may include common pathogenic events that initiate protein misfolding and induction of neurological damage.

34.9 Review Questions

1. What is a prion disease?
2. What is the “Protein-only hypothesis”?
3. What are the major types of human prion diseases based on clinical phenotypes?
4. What are the major PrP^{Sc} types in human prion diseases?
5. After peripheral infection, prion neuroinvasion is mediated through what cell type?
6. What is the role of B cells in prion neuroinvasion?
7. What are protein misfolding diseases?

34.10 Answers

1. Prion disease is a family of diverse transmissible neurodegenerative diseases that requires the prion protein for prion agent replication and pathogenesis.
2. The “Protein-only Hypothesis” proposes that the infectious prion agent is a misfolded form of PrP^C devoid of specific nucleic acids (called PrP^{Sc} where “Sc” refers to scrapie) that is capable of self-perpetrating replication using PrP^C as the substrate.
3. The major types of human prion diseases based on clinical phenotypes include CJD, GSS, Kuru, Fatal Insomnia, and VPSPr.
4. The major PrP^{Sc} types in human prion diseases include type 1, type 2 (a and b), the GSS type, and the VPSPr type.
5. Prion neuroinvasion is mediated by FDCs.
6. B cells are required for prion neuroinvasion because they generate lymphotoxins that are required for the maturation of FDCs.
7. Diseases characterized by a post-translational change in the conformation of a normal host protein which results in an altered protein structure and protein polymerization. The protein polymer accumulates in the CNS and acts as a template for protein mediated misfolding of additional host precursor protein.

Abstract

Glaucoma is defined as a disturbance of the structural or functional integrity of the optic nerve that causes characteristic changes in the optic nerve leading to permanent defects in the visual field. If left untreated, it can lead to blindness. Glaucoma is the leading cause of irreversible blindness throughout the world, and is second only to macular degeneration in the US. Amongst the risk factors, elevated intraocular pressure (IOP), thin corneal thickness (CCT), increasing age, and large cup to disc ratio are established. Concerning its pathogenesis, mechanical and vascular theories are fundamental. In addition, many other mechanisms contribute; such as immune factors, apoptosis, glutamate-induced excitotoxicity, free radicals, nitric acid synthase, and genetic mutations. To assess glaucoma; tonometry, gonioscopy, examination of optic disc, and visual field testing are essential. Animal models for glaucoma have been used to study the pathophysiological basis of glaucoma, aqueous humor dynamics, the trabecular meshwork, the ciliary muscle, and retinal ganglion cells. Animal experiments have provided a worthwhile means of evaluating diagnostic modalities and treatments, both medical and surgical.

Keywords

Glaucoma • Intraocular pressure • Optic nerve • Retinal ganglion cell

35.1 Introduction

The word glaucoma has its origin in ancient Greek (Hippocrates, approximately 400 BC), meaning clouded or blue-green hue, most likely describing a patient having a cloudy cornea or advanced cataract precipitated by chronic elevated pressure. Over the last 100 years, further understanding of the concept of glaucoma has accelerated.

Primary open-angle glaucoma (POAG) is a multifactorial chronic optic neuropathy with a characteristic acquired loss of optic nerve fibers. Cupping and atrophy of the optic disc occur in the absence of other known causes. Such damage develops in the presence of open anterior chamber angles and produces characteristic visual field abnormalities. Some

subsets of patients can exhibit the characteristic optic nerve damage and visual field defects while having an intraocular pressure (IOP) within the normal range (normal tension glaucoma). IOP is the only risk factor that can be currently modified in POAG. Elevated IOP in the absence of any clinically apparent optic nerve damage is referred to as ocular hypertension (OHT).

A neurodegenerative disease has loss of specific neuronal populations with axonal loss and a characteristic clinical syndrome which is progressive in nature. Glaucoma is a degenerative disorder of the retinal ganglion cells (RGC) leading to characteristic optic nerve morphology and visual field defects. This loss of axons continues in the lateral geniculate nucleus (Chen et al. 2013; Gupta et al. 2009) and in the visual cortex (Yu et al. 2013; Yucel and Gupta 2008). Untreated glaucoma progresses due to continued loss of RGC and visual field constriction.

Other forms of glaucoma include angle closure glaucoma, in which the outflow of aqueous humor is physically obstructed by the iris. Secondary glaucomas have obstruction of the aqueous humor pathways secondary to another disease process such as inflammation, trauma, bleeding, pigment, pseudoexfoliation and others. The only glaucoma that fits the definition for a neurodegenerative disorder is POAG and the rest of the chapter will primarily refer to POAG.

POAG is a major worldwide health concern because of its usually asymptomatic but progressive nature, and because it is the leading cause of irreversible blindness in the world. With appropriate screening and treatment, glaucoma usually can be identified and treated to prevent and slow significant visual loss.

35.2 Epidemiology

35.2.1 Prevalence

In the United States (US), multiple population studies [e.g., Framingham (Leibowitz et al. 1980), Baltimore (Tielsch et al. 1991), and Barbados (Leske et al. 1997)] have been performed to estimate the prevalence of eye diseases, including POAG and OHT.

Estimates of the prevalence of glaucoma [(Friedman et al. 2004a); Table 35.1] and blindness [(Congdon et al. 2004); Fig. 35.1] in the US demonstrate the following: glaucoma is a leading cause of irreversible blindness, second only to macular degeneration; only one half of the people who have glaucoma may be aware that they have the disease; and more than 2.25 million Americans aged 40 years and older have POAG.

More than 1.6 million people have significant visual impairment from glaucoma, with 150,000 bilaterally blind in the US alone (Tielsch et al. 1991). These statistics emphasize the need to identify and closely monitor those at risk for glaucomatous damage.

Approximately 6.7 million people are bilaterally blind from POAG worldwide, and more than 2 million people will develop POAG each year (Quigley 1996).

35.2.2 Prognosis

Several studies (Gordon et al. 2002) have shown the incidence of new onset of glaucomatous damage in previously unaffected patients to be approximately 2.6–3 % in patients with IOPs 21–25 mm Hg, 12–26 % with IOPs 26–30 mm Hg, and approximately 42 % with IOP higher than 30 mm Hg. The ocular hypertension treatment study (OHTS) found that

IOP intraocular pressure, CCT central corneal thickness

^aIn US, West Africa, Caribbean

approximately 10 % of patients with IOPs ranging from 24 to 31 mm Hg but with no clinical signs of glaucoma at baseline develop glaucoma over 5 years, with conversion to glaucoma reduced by 50 % if patients are preemptively started on IOP-lowering therapy (Kass et al. 2002). Significant subsets of higher and lower risk exist when central corneal thickness (CCT) is taken into account.

35.2.3 Risk Factors

35.2.3.1 Intraocular Pressure

In eyes suspected of being affected with glaucoma, loss of visual field develops at a rate of approximately 1–3 % per year of observation (Gordon et al. 2002). High IOP is the most important risk factor (Table 35.2). The relative impor-

tance of other risk factors also is indicated in Table 35.2. In population-based surveys, between 25 and 50 % of those with glaucomatous damage to the optic nerve have IOP in the normal range. However, the probability of injury increases exponentially with higher IOP (Heijl et al. 2002). Large diurnal fluctuation in IOP is another independent risk factor for glaucoma (Nouri-Mahdavi et al. 2004).

35.2.3.2 Race

Prevalence of POAG is 3–4 times higher in blacks than in whites in the US (Friedman et al. 2004b; Tielsch et al. 1991). Glaucoma is the most common cause of irreversible blindness in the US among people of African or Hispanic descent [(Congdon et al. 2004); Fig. 35.1]. Blacks in the US are more likely to develop glaucoma early in life, and they tend to have a more aggressive form of the disease.

The Barbados Eye Study (Leske et al. 1997) over 4 years showed a 5 times higher incidence of developing glaucoma in a group of black ocular hypertensives as compared with a predominantly white population. Some population studies have found the mean IOP in blacks to be higher than Caucasian controls. Other studies (Tielsch et al. 1991) found no difference. Consequently, further studies are required to clarify this issue.

The OHTS (Brandt et al. 2001) demonstrated that black patients in the US overall may have reduced CCT, thereby leading to underestimation of true IOP. The reduced CCT was associated with a higher risk of developing glaucoma. Therefore, CCT measurement is particularly important in African-American patients who are glaucoma suspects. The OHTS also demonstrated a larger cup to disc ratio in Blacks, which was an independent risk factor for the development of glaucoma [(Feuer et al. 2002; Gordon et al. 2002); Table 35.2]. These two confounding variables discovered in the multivariate analysis appeared to account for the apparent increased risk in blacks demonstrated in the univariate analysis (Gordon et al. 2002).

35.2.3.3 Age

Age older than 40 years is a risk factor for the development of POAG. Up to 15 % of African-American men are affected

by the ninth decade of life [(Friedman et al. 2004a); Table 35.1]. Consequently, glaucoma is found to be more prevalent in the aging population, even after compensating for the mean rise in IOP with increasing age in the US. However, the disease itself is not limited to only middle-aged and elderly individuals.

35.2.3.4 Central Corneal Thickness

CCT is an important risk factor for the development of glaucoma [(Gordon et al. 2002); Fig. 35.2]. CCT likely influences the measurement of IOP with many tonometers, including applanation techniques (Brandt et al. 2001). Increased CCT beyond the mean of 545 μm causes overestimation of IOP; lower CCT translates into underestimation of the IOP. A thin cornea (for example, 480 μm) may occur with glaucomatous visual field loss despite 'normal' applanation IOP because the measurements are fallaciously low. Conversely, a thick cornea (for example, 620 μm) might occur in an eye with high IOP, normal visual fields and a normal optic nerve because a thicker cornea results in false overestimation of true IOP. Ehlers et al (Ehlers et al. 1975) extrapolated that applanation tonometry is overestimated or underestimated by approximately 5 mm Hg for every 70 μm difference in measured CCT from mean thickness. It is also possible that CCT may itself constitute an intrinsic risk (or

IOP= Intraocular pressure

Fig. 35.2 Risk for developing primary open glaucoma varies with central corneal thickness. The numbers and percentage of participants in the observation group who developed primary open-angle glaucoma (median follow-up, 72 months) are indicated below each bar. Participants are grouped by baseline intraocular pressure of ≤ 23.75 mm Hg, > 23.75 mm Hg to ≤ 25.75 mm Hg, and > 25.75 mm Hg and by central corneal thickness measurements of ≤ 555 μm , > 555 μm to

≤ 588 μm , and > 588 μm . These percentages are not adjusted for length of follow-up. Reproduced with permission from: Gordon MO, Beiser JA, Brandt JD, Heuer DK, Higginbotham EJ, Johnson CA, Keltner JL, Miller JP, Parrish RK 2nd, Wilson MR, Kass MA (2002) The Ocular Hypertension Treatment Study: baseline factors that predict the onset of primary open-angle glaucoma. Arch Ophthalmol 120: 714–720

protective) factor for glaucomatous optic nerve damage or a marker of changes in aqueous humor dynamics (Gulati et al. 2011), independent of its ability to affect the IOP measurement.

35.2.3.5 Family History

Relatives of those with glaucoma are more likely to have the disease (Drance et al. 1981). However, there is no clear Mendelian pattern of inheritance for glaucoma. The Rotterdam Eye Study (Wolfs et al. 2000) concluded that the prevalence of glaucoma was 10.4% in siblings of patients with glaucoma and the relative risk of having POAG increased 9.2-fold for individuals with a first-degree relative with POAG. High IOP may be the inherited feature of glaucoma, or inherited risk factors independent of IOP may be involved. The genetics of glaucoma will be discussed further in section 3.

35.2.3.6 Systemic Risk factors

The association between diabetes mellitus (DM) and glaucoma has been unclear. Epidemiology studies in different populations have given conflicting results. The Blue Mountain Eye Study in Australia (Mitchell et al. 1997), The Rotterdam Study (Dielemans et al. 1996) and the Beaver Dam Study (Klein et al. 1994) in the USA have all shown DM to be associated with glaucoma. Other studies such as the Baltimore Eye Study (Tielsch et al. 1995) in the US or the Diabetes Audit and Research in Tayside Study in the United Kingdom (Ellis et al. 2000) have failed to show an association of POAG with DM. Since DM is a disease of small vessels of the body, it is plausible that it has an association with glaucoma.

Some reports have suggested an association between high blood pressure and glaucoma, but this relation is not fully understood and is not uniformly observed. There appears to be a subset of patients with low diastolic perfusion pressures who are at higher risk for POAG (Wilson et al. 1987). Some studies indicate that patients with DM have higher IOPs and a higher rate of glaucoma than people without DM. However, other studies fail to demonstrate this relationship. In a study in which the presence of DM was self-reported, diabetes protected against the development of glaucoma (Gordon et al. 2002). Other abnormalities in vascular function, including migraine headache (Cursiefen et al. 2000) and vasospasm in the extremities (Broadway and Drance 1998), appear to be associated with glaucoma as demonstrated in some studies.

Sleep apnea has been shown to be a risk factor for glaucoma in some studies (Mojon 1999). Myopia may be another risk factor for glaucoma (Daubs and Crick 1981). The relatively thin eye wall and large globe in severely nearsighted people may account for a possible susceptibility to optic nerve damage under the influence of IOP. The association between factors such as concurrent cardiovascular disease

(Tielsch et al. 1991) has not been demonstrated consistently.

In a retrospective study from the Mayo clinic, patients with POAG were found to have a lower intracranial pressure as compared to patients without POAG (Berdahl et al. 2008). This link between cerebrospinal fluid (CSF) pressure and glaucoma may be related to the mechanical effects of the intracranial pressure on the lamina cribrosa of the optic nerve.

35.3 Pathophysiology

As introduced at the beginning of this chapter, POAG is an optic neuropathy wherein IOP is the best characterized risk factor. Therefore, the pathophysiology can be viewed at two levels: factors leading to elevated IOP and neuronal injury and death consequent to elevated IOP.

35.3.1 Elevated Intraocular Pressure

The physiologic processes related to maintenance of physiologic IOP and the probable causes of its dysregulation are largely limited to the anterior segment of the eye. IOP is maintained by a balance between aqueous inflow and outflow. Aqueous humor in the eye is produced by the ciliary body in the posterior chamber, from where it passes through the pupil to the anterior chamber and exits the eye through structures in the anterior chamber angle, a point of confluence of outer corneoscleral layer and middle uveal layer of the eye (Fig. 35.3).

The outflow pathways for the aqueous can broadly be divided into 2 categories: conventional outflow and uveoscleral outflow. Conventional outflow is believed to be through the trabecular meshwork to the Schlemm's canal, to collector channels and aqueous veins, to the episcleral network of vascular channels called the episcleral veins. The trabecular meshwork and Schlemm's canal complex occupy the scleral sulcus. The site of most resistance in this complex primary determinant of IOP is believed to be the region along the inner wall of the Schlemm's canal and juxtacanalicular tissue (Johnson 2006; Rosenquist et al. 1989). The outflow through this pathway is believed to be pressure dependent and is driven by the pressure differential between the IOP and the pressure in the episcleral vessels. Outflow facility is a measure of the ease with which aqueous can flow through this system and is the inverse of the resistance in the pathways involved. Removal of the trabecular meshwork and the inner wall of the Schlemm's canal can eliminate approximately 75% of the resistance in the system with the remaining 25% believed to be contributed by more distal structures

Fig. 35.3 Optical coherence tomography of a normal anterior chamber angle. *Star*=cornea, *asterisk*=ciliary body, *arrowhead*=iris, *arrow*=Schlemm's canal with collector channel

(Grant 1963; Rosenquist et al. 1989). The second, unconventional, egress path of aqueous from the eye is less well defined and is believed to be routed through the root of the iris, to the interstitial spaces of the ciliary body and into the suprachoroidal space (Alm and Nilsson 2009). This uveoscleral outflow is pressure independent in the physiological range of IOP.

The relationship between these inflow and outflow parameters of the eye can be summarized by the modified Goldmann equation as follows:

$$\text{IOP} = (\text{Aqueous inflow} - \text{uveoscleral outflow}) / \text{Outflow facility} + \text{Episcleral venous pressure.}$$

The daytime aqueous inflow rate has not been found to be elevated in primary and secondary glaucomas (Brown and Brubaker 1989; Larsson et al. 1993; Larsson et al. 1995; Levene et al. 1976; Ziai et al. 1993). A slightly higher nighttime flow rate has been reported in patients with primary open angle glaucoma (Larsson et al. 1995). The primary pathology involved in elevated IOP has been an increased resistance in both the conventional pathway and reduced flow through the uveoscleral pathway (Grant 1951; Grant 1958; Johnson et al. 2008; Johnson et al. 2008; Toris et al. 2002; Toris et al. 2010). Elevated episcleral venous pressure has not been found in cases of POAG or OHT (Podos et al. 1968) but plays a role in some forms of secondary glaucoma such as that found in association with Sturge-Weber Syndrome (Cibis et al. 1984; Phelps 1978; Shiau et al. 2012).

Several anatomic correlates of increased resistance in the trabecular pathways have been described. Some of these are thickening and fusion of trabecular lamellae secondary to trabecular endothelial cell loss, collapse of trabecular beams,

increase in electron dense plaques and possible changes in the glycosaminoglycan composition of the basement membranes and stroma of trabecular meshwork (Tektaş and Lutjen-Drecoll 2009). The anatomic correlates of reduced uveoscleral outflow in OHT and POAG are not well defined at this time. Uveoscleral outflow has been shown to decrease with age (Toris et al. 1999) and administration of cholinergic agents (Crawford and Kaufman 1987) and increased with clinically used doses of prostaglandin analogs (Crawford et al. 1987; Gulati et al. 2012; Hayashi et al. 1987; Nilsson et al. 1989). An effect on matrix metalloproteinases and tissue inhibitors of metalloproteinases is believed to be the mechanism involved in the improvement of uveoscleral outflow with prostaglandins (Alexander et al. 1991; Brew et al. 2000; Murphy and Docherty 1992).

35.3.2 Optic Nerve Damage

Despite significantly elevated intraocular pressure, only a small percentage of subjects develop clinically manifest glaucomatous damage. At the same time glaucomatous optic nerve damage and consequent visual field loss has been shown to progress despite substantial IOP lowering. There is no clear explanation of this individual variability in the susceptibility of the optic nerve to varying levels of IOP. In general, the cause of glaucomatous optic neuropathy is unknown.

A unifying pathogenic mechanism, among differing hypothesis regarding the preceding mediator, appears to be stasis of axoplasmic flow at the level of the optic nerve head (ONH). The obstruction to the flow involves both the slow and the fast phases and both retrograde and anterograde

Fig. 35.4 Several mechanisms have been hypothesized to have a role in causing retinal ganglion cell death in glaucoma. IOP indicates intraocular pressure. Reproduced with permission from: Weinreb RN, Levin LA (1999) Is neuroprotection a viable therapy for glaucoma? *Arch Ophthalmol* 117:1540–1544

transport (Minckler et al. 1976; Minckler et al. 1977; Minckler et al. 1978; Quigley et al. 1979). In a non-human primate model of chronic IOP elevation, the flow obstruction preferentially affected the magnocellular layers of the lateral geniculate nucleus (Dandona et al. 1991).

The RGC death occurs as a consequence of triggering of apoptotic pathways, or programmed cell death. This could result from loss of essential trophic stimuli as a consequence of disruption of axoplasmic flow. Loss of axons involves early loss of axons by Wallerian degeneration and subsequent somal death after an abortive attempt at regeneration (Buckingham et al. 2008). Besides damage to the primary ganglion cells injured by the glaucomatous process, the apoptotic cells create a toxic environment leading to injury and death of surrounding cells by mechanisms that may involve glutamate excitotoxicity or free radical mediated injury (Hare et al. 2001). Glaucomatous damage appearing as loss of discrete groups of nerve fiber bundles may be reflective of this proximity of cells being injured or a primary pathological process at the lamina cribrosa where these axons come together.

Many pathophysiological mediators common to all neurodegenerative diseases, including glaucoma, have been identified, such as increase in glutamate, conformationally altered self-proteins, increase in inflammation-associated factors [cyclooxygenase-2 (COX-2), tumor necrosis factor (TNF- α), nitric oxide (NO)], increase in extracellular matrix proteins and growth-associated inhibitors (myelin-related proteins), oxidative stress, and malfunctioning of local immune cells (microglia). These mediators evoke a response for which the tolerance of the neural tissue is minimal.

Multiple theories exist concerning how IOP can be one of the factors that initiates glaucomatous damage in a patient (Fig. 35.4). Two of the fundamental theories include the mechanical and vascular theory.

The mechanical theory proposes that elevated IOP causes a backward bowing of the lamina cribrosa, resulting in kinking of the axons as they exit through the lamina pores (Müller 1858). Damaged RGC axons are affected by neurotrophin deprivation leading to subsequent apoptosis and cell death. The vascular theory proposes that cell death is triggered by ischemia, whether induced by elevated IOP or as a primary insult (Jaeger 1858). It is possible that in any given patient one or both factors may play out to varying degrees. Intuitively, the mechanical damage hypothesis may play a larger role when the IOP is significantly elevated above normal levels and the vascular predispositions may play a prominent role in cases where glaucoma continues to progress despite adequate IOP lowering.

35.3.3 Role of Intracranial Pressure

Recently, there has been an interest in the role that CSF pressure may have in the pathophysiology of glaucoma (Jonas et al. 2015). This is based on the theory that higher CSF pressure may provide some sort of tectonic support to lamina cribrosa faced with elevated IOP, and glaucomatous damage at the ONH may be consequent to an imbalance between IOP and CSF pressure (Ren et al. 2011). Experimental reduction of CSF pressure in monkeys has been shown to produce nerve fiber and optic nerve damage similar to glaucoma (Yang et al.

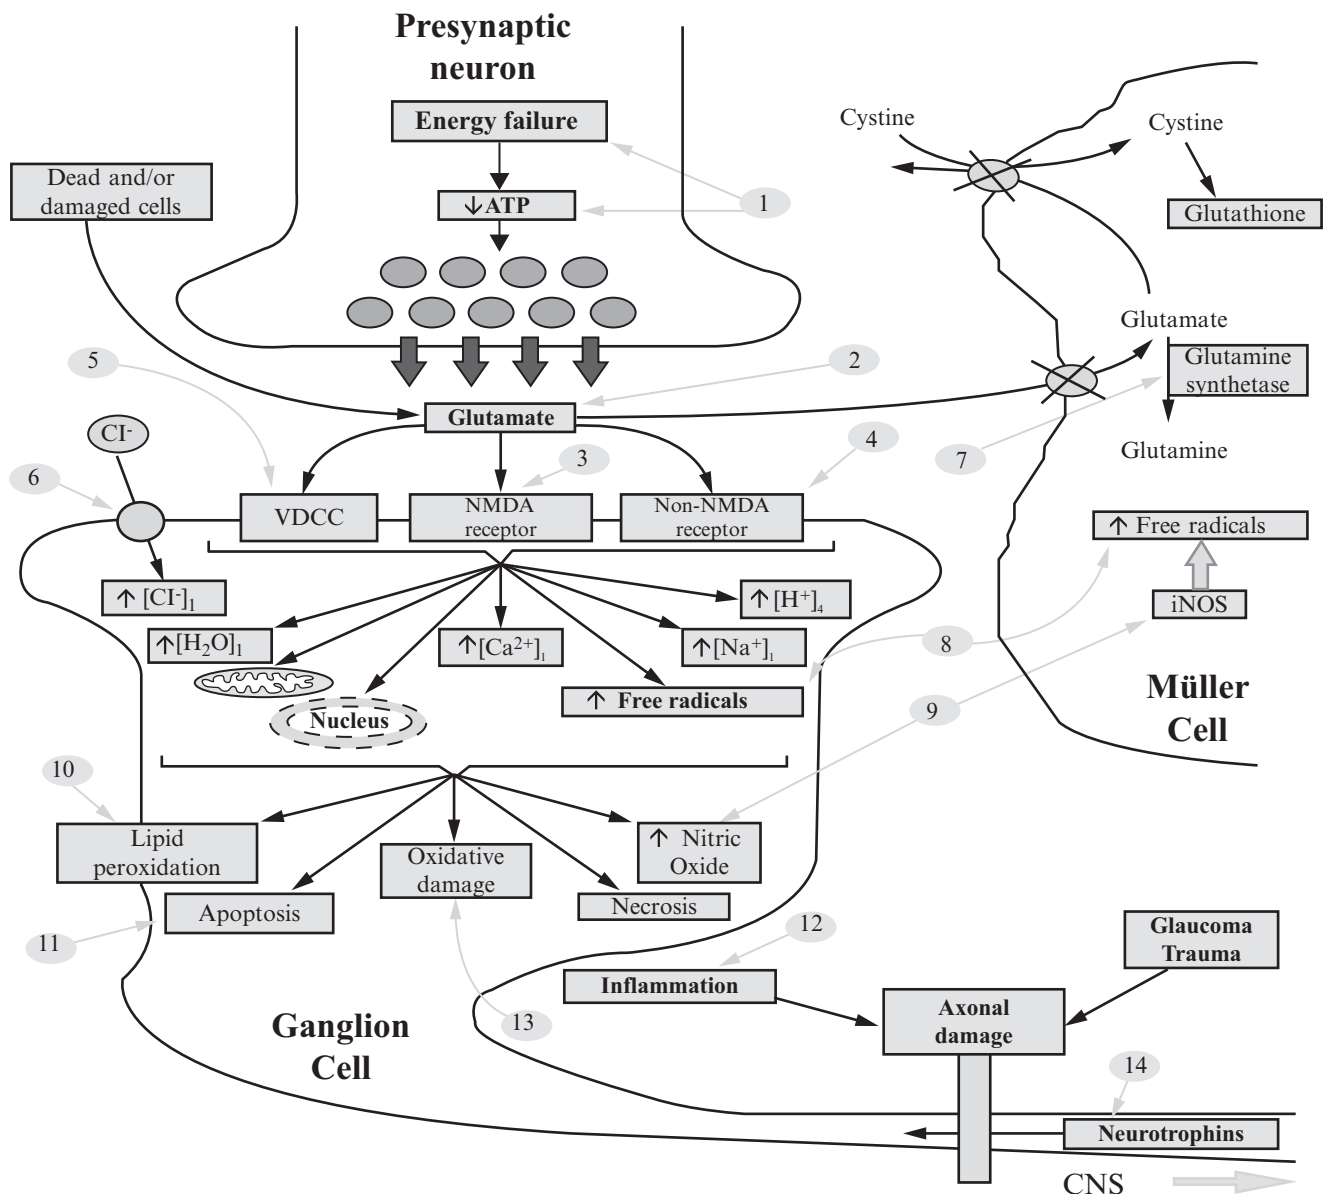

Fig. 35.5 Diagrammatic summary of potential targets for intervention in ganglion cell death. (1) Prevent energy loss, (2) reduce extracellular glutamate, (3) block ionotropic NMDA receptors, (4) block non-NMDA ionotropic glutamate receptors, (5) block excessive influx of Ca^{2+} through voltage-gated channels, (6) prevent influx of chloride and water, (7) enhance intracellular glutamate catabolism, (8) prevent excessive production of free radicals, (9) prevent detrimental effects of

nitric oxide, (10) prevent lipid peroxidation, (11) prevent induction of apoptosis, (12) reduce any inflammation, (13) stop oxidative damage, and (14) maintain neurotrophin support. Reproduced with permission from: Osborne NN, Ugarte M, Chao M, Chidlow G, Bae JH, Wood JP, Nash MS (1999) Neuroprotection in relation to retinal ischemia and relevance to glaucoma. *Surv Ophthalmol* 43 Suppl 1:S102–S128

2014). Intracranial pressure has been found to be significantly lower in POAG and normal tension glaucoma as compared to control subjects with no glaucoma (Berdahl et al. 2008).

35.3.4 Glaucoma Therapy

Based on the above pathophysiology there are broadly speaking two therapeutic targets in glaucoma management. One is

to lower the IOP. The other is to facilitate ganglion cell survival independent of IOP lowering, also referred to as neuroprotection (Fig. 35.5). Almost all of clinical glaucoma management at this time targets IOP lowering. Numerous well designed clinical trials have proven the benefit of IOP lowering in the preservation of visual function in glaucoma patients (AGIS Investigators 2000; Collaborative Normal-Tension Glaucoma Study Group 1998; Gordon et al. 2002; Leske et al. 2003; Lichter et al. 2001). Despite tremendous interest in

neuroprotection there are currently no well proven neuroprotective strategies available for glaucoma management. Various agents have shown promise in preclinical studies. Some of these are *N*-methyl-D-aspartate (NMDA) antagonists (memantine), alpha-2 agonists, calcium channel blockers, antioxidants and nitric oxide synthetase inhibitors. Memantine has been the subject of 2 phase III clinical trials, the results from these have not been published. Even though a clinical trial comparing the efficacy of timolol and brimonidine did report better visual field preservation with brimonidine, the study is limited by several potential biases involved, as detailed in a recent Cochrane review (Krupin et al. 2011). The review concluded that the current evidence in support of neuroprotective strategies in the management of open angle glaucoma to be inconclusive (Sena and Lindsley 2013). The review also comments on the current lack of availability of adequately sensitive outcome measures to be able to detect a neuroprotective effect of agents, if there was one.

35.3.5 Potential Therapeutic Targets for Neuroprotection

Figure 35.5 is a diagrammatic representation of some of the potential neuroprotective targets characterized at this time.

35.3.5.1 Immune Mechanisms

Neural injury has long been considered self destructive and progressive primarily due to the autoimmunity to self antigen. The anti-self antigen response has been shown in these experiments to have a coincidental beneficial and modulating effect (Schwartz 2005). The autoimmune T cells limit the activity of the microglial framework and blood-borne macrophages, affecting their ability to deal with a local excitatory situation. Such a controlling effect has a beneficial impact on both survival and regrowth. Boosting the beneficial effect by the use of a safe antigen that can cross-react with self-antigens at the site under stress might provide an effective therapeutic approach that influences both rescue and regeneration (Schwartz 2005). Copolymer 1 (Cop-1), an approved drug for the treatment of multiple sclerosis, can be used as a treatment for autoimmune diseases and as a therapeutic vaccine for neurodegenerative diseases (Kipnis and Schwartz 2002). These results have special implications for glaucoma therapy since glaucoma is the most common cause of optic neuropathy.

35.3.5.2 Apoptosis

Apoptosis is classically defined by an orderly pattern of internucleosomal DNA fragmentation, chromosome clumping, cell shrinkage, and membrane blebbing (Wyllie et al. 1980). This is followed by disassembly of the cell into multiple membrane-enclosed vesicles that are engulfed by neighboring cells with-

out inciting inflammation. Apoptosis has often been labeled as '*programmed or physiological cell death*'.

Several gene families have been identified that play either positive or negative roles in determining whether a cell (in glaucoma, the RGC) will undergo apoptosis. Caspases are cysteine proteases that play a central role in both propagating apoptotic signals and carrying out disassembly of the cell (Hutchins and Barger 1998). Many triggers activate caspases, including increased intracellular calcium, changes in cellular energy balance, and adenosine 3'5' cyclic phosphate.

The main inhibitors of apoptosis are Bcl-2 and related proteins. They have multiple complex functions, such as inhibiting intermediate proteins that activate caspases, gauging intracellular damage and maintaining organelle integrity in ways that are not fully understood. For example, over expression of Bcl-2 inhibits both apoptotic and necrotic cell death by suppressing lipid peroxidation (Adams and Cory 1998).

35.3.5.3 Glutamate-Induced Excitotoxicity

The excitatory amino acid glutamate is known to cause neurotoxicity via binding of glutamate to the NMDA receptor and the kainate receptors. This can be secondary to many types of cellular damage, including other final common pathways of damage such as oxidative stress or free radical damage (Osborne et al. 1999). Activation of these receptors allows entry of excessive amounts of calcium. Abnormally high concentrations of calcium lead to inappropriate activation of complex cascades of proteases, nucleases, and lipases. These directly damage cellular constituents and lead to ganglion cell death.

One neuroprotective strategy, therefore, is to interrupt the resultant excitotoxic cascade by blocking the NMDA receptor with drugs such as memantine (Lipton 2003).

35.3.5.4 Free Radicals

Free radicals are generated not only through activation of glutamate receptors but also as the inevitable by-product of normal oxidative metabolism. This is especially true in the retina and the RGCs, which have an extremely high metabolic rate. This triggers further changes including calcium release that causes cell damage (as summarized in section 3.5.3. above). Endogenous antioxidants such as vitamins E and C, superoxide dismutase (Greenlund et al. 1995), and glutathione normally inactivate free radicals.

35.3.5.5 Nitric Oxide Synthase

Nitric Oxide Synthase (NOS) is postulated to have a role in RGC axonal toxicity. Inducible NOS is known to be up regulated in the optic nerve in glaucoma (Liu and Neufeld 2001). Inhibitors of NOS, such as 3-aminoguanidine, decreased the RGC loss by 70 % in rat eyes with raised IOP (Neufeld et al. 1999).

35.3.5.6 Dopamine Deficiency

Dopamine has been recognized to have neuroprotective actions in glaucoma. Retinal dopaminergic cells can be detected by the immunohistochemical staining of tyrosine hydroxylase, the rate-limiting enzyme in dopamine synthesis. It has been observed that NMDA induced RGC toxicity dramatically decreased tyrosine hydroxylase immunostaining at the junction between the inner nuclear layer and inner plexiform layer in glaucoma (Kitaoka and Kumai 2004).

35.3.5.7 Heat-Shock Proteins

Heat-shock proteins (Hsp) are known to be an intrinsic protection mechanism associated with an early response against physiologic and environmental stress (Wax and Tezel 2002). Certain Hsp have special effects upon neurons, including Hsp 72, 27 and 60. Hsp 27 and 60 have been demonstrated to be upregulated in RGCs of glaucoma (Tezel et al. 2000). Recent work has shown that geranylgeranylacetone can induce Hsp 72 in RGCs and protect them from glaucomatous damage in a rat glaucoma model (Ishii et al. 2003).

35.3.5.8 Calcium Channel Blockers

Calcium channel blockers may reduce the ischemic apoptotic stimulus by improving perfusion through their vasodilatory effects (Osborne et al. 2004a; b). In addition calcium channel blockers may also interfere with the calcium influx mentioned in the glutamate induced cytotoxicity above (Choi 1988; Schurr and Rigor 1992; Siesjo and Bengtsson 1989). The vascular dilation effects associate with beta 1 agonists may also be mediated through inhibition of calcium influx of the cell membrane through the voltage gated calcium channels (Bessho et al. 1991; Hester et al. 1994; Setoguchi et al. 1995). At this time there is some limited evidence to support the effect of calcium channel blockers in preservation of visual fields in glaucoma patients (Koseki et al. 1999; Sawada et al. 1996).

35.3.5.9 Genetic Mutations

Myocilin (MYOC) is one gene that has been associated with early- and late-onset POAG. The MYOC gene was mapped to the open-angle glaucoma locus (GLC1A) region of chromosome 1q25, and mutations were discovered in patients with adult and juvenile open-angle glaucoma. Mutations in this gene are found in 3–5 % of adult-onset POAG patients and in 8–20 % of juvenile-onset POAG patients (Wiggs et al. 1998). Different mutations are associated with juvenile and adult glaucoma. In particular, the most common mutation associated with adult glaucoma is a nonsense mutation, whereas all the mutations associated with juvenile glaucoma are missense mutations.

Mutation studies and genetic linkage analyses have shown a causative effect of the CYP1B1 gene in the development of primary congenital glaucoma. The CYP1B1 locus has also

been implicated as a modifier gene in the development of POAG, and in some cases as the causative gene in POAG and other anterior segment dysgeneses (Vasiliou and Gonzalez 2008).

Using single large pedigrees affected by POAG, seven genetic loci have been described (GLC1A-G), and glaucoma-predisposing genes have been identified in three of these loci: GLC1A, myocilin (Wiggs et al. 1998); GLC1E, optineurin (Rezaie et al. 2002); and GLC1G, WDR36 (Monemi et al. 2005). Each of these genes is only responsible for a small fraction of cases of POAG, reflecting the small percentage of POAG that is inherited as a Mendelian trait rather than as a complex trait.

The optineurin protein may function to protect the optic nerve from TNF-alpha-mediated apoptosis, and the loss of function of this protein may decrease the threshold for RGC apoptosis in patients with glaucoma. Surprisingly, mutations in this gene do not appear to contribute significantly to the optic nerve degeneration that is a component of typical high-pressure POAG (Wiggs et al. 2003). Optineurin has been associated with subjects that experience progressive glaucomatous optic nerve changes at low or normal pressures, so called “normal pressure glaucoma.” Optineurin has also been implicated in sporadic amyotrophic lateral sclerosis with or without superoxide dismutase-1 mutations, confirming optineurin’s role in a separate progressive degenerative neuropathy (Maruyama and Kawakami 2013; Deng et al. 2011).

More recent genome wide association studies have demonstrated a strong POAG association at the SIX1/SIX6 locus (Wiggs et al. 2012). Deletions of SIX1 and SIX4 have been associated with bilateral anophthalmia and pituitary abnormalities (Bennett et al. 1991). In animal models, mutations at the SIX1/SIX6 locus result in early exit from the cell cycle among RGC progenitors. A common risk variant at the SIX6 locus, His141, is present in approximately 40 % of subjects of European descent, and 99 % of subjects of African descent. In POAG and non-glaucomatous eyes that are homozygous for the risk allele there is a significantly thinner retinal nerve fiber layer at the superior and inferior poles of the optic nerve, the site of the earliest nerve fiber loss in glaucoma (Carnes et al. 2014; Cheng et al. 2014; Kuo et al. 2015).

The exact role that IOP plays in combination with these other factors and the latter’s significance in the initiation and progression of subsequent glaucomatous neuronal damage and cell death requires further studies to elucidate.

35.4 Clinical Features

35.4.1 History

The initial patient interview is important in the evaluation for glaucoma. Because of the “silent” or asymptomatic nature of

POAG, patients usually will not present with any visual complaints until late in the course of the disease. A history should include the following:

1. Past ocular and medical history including:
 - Eye pain
 - Redness
 - Multicolored halos (indicative of intermittent IOP elevation and related corneal edema)
 - Headache
 - Previous ocular disease such as cataracts, uveitis, diabetic retinopathy or vascular occlusions
 - Previous ocular laser or surgery
 - Ocular or head trauma
 - Pertinent vasculopathic systemic illnesses, including Raynaud's phenomenon or migraine
2. Current medications, including any anti-hypertensive medications or corticosteroids used topically or systemically. Systemic and topical medications can effect IOP and ONH perfusion. Sulfa-derivative medications can result in a rare idiosyncratic reaction that causes ciliary body effusion and secondary angle closure related IOP elevation.
3. Family history of glaucoma in first-degree relatives.

35.4.2 Physical Exam

Screening the general population for POAG is most effective if targeted at those at higher risk, such as African Americans, those with a family history of glaucoma, and elderly individuals, especially if the screening includes IOP measurements, assessment of the optic nerve and screening visual fields.

For individuals of age 65 years or above, recommended frequency for a comprehensive adult medical eye evaluation is 6–12 months when risk factors for glaucoma are present and 1–2 years in the absence of risk factors. For glaucoma suspect individuals under 40 years, the frequency of the eye evaluation should be 2–4 years and 5–10 years in the presence and absence of risk factors for glaucoma, respectively (American Academy of Ophthalmology Glaucoma Panel 2010a).

A standard comprehensive eye examination, including gonioscopy, is performed at the initial visit. If any visual field or optic nerve changes consistent with glaucoma are present, additional testing should be done to establish the diagnosis, help in defining target (or safe) levels of IOP, and developing a treatment and follow-up plan.

In patients with glaucoma, factors that determine frequency of evaluations include the severity of damage, the stage of the disease, rate of progression, extent to which the IOP exceeds the target pressure, and the number and significance of other risk factors for damage to the optic nerve. If the target IOP has been achieved and there is no progression

of damage, it is recommended to follow up with ONH exam and visual field testing at 6 to 18-month intervals in those with mild to moderate glaucoma, and as frequently as every 4 months in patient with severe stage glaucoma (American Academy of Ophthalmology Glaucoma Panel 2010b). On the contrary, if there is evidence of progression of damage and the target IOP has not been achieved, more frequent testing is required until stability is confirmed.

35.4.2.1 Tonometry

When checking IOP, record measurements for both eyes, the method used (Goldmann applanation is most commonly used), and the time of the measurement. IOP varies from hour-to-hour in any individual. Many studies indicate that the circadian rhythm of IOP peaks in the early hours of the morning just after waking. Intraocular pressure measurements should be made at different times of the day to check for diurnal variation. A diurnal variation of more than 5–6 mm Hg indicates an increased risk for glaucoma.

IOP can also change with body position, rising transiently when changing from an upright to a supine position. The positional change in IOP is greater in people with OHT and glaucoma (Prata et al. 2010). Aqueous humor outflow facility does not change with the body position, implying other ocular parameters are causing the IOP change observed (Selvadurai et al. 2010).

A difference between contralateral eyes of 3 mm Hg or more indicates greater suspicion of glaucoma. An average of a 10% difference between individual measurements is expected. In most circumstances, the measurements should be repeated on at least 2–3 occasions before deciding on a treatment plan.

35.4.2.2 Gonioscopy

The angle of the eye is examined by gonioscopy, which requires the use of special lenses. Gonioscopy is performed to rule out angle-closure or secondary causes of IOP elevation, such as angle recession, pigmentary glaucoma, exfoliation syndrome, and trabeculitis. The peripheral contour of the iris is examined for plateau iris, and the trabecular meshwork for peripheral anterior synechiae, as well as for neovascular or inflammatory membranes and cell aggregates. Schlemm's canal may be seen if blood refluxes into the canal. This might indicate elevated episcleral venous pressure caused by conditions such as a carotid-cavernous fistula, Graves orbitopathy, idiopathic elevated episcleral venous pressure, or Sturge-Weber syndrome.

Ultrasound biomicroscopy (Fig. 35.6) and anterior segment optical coherence tomography (Fig. 35.3) are also helpful in assessing the angle, iris, and processes of the ciliary body to rule out anatomical pathology and secondary causes of elevated IOP.

Fig. 35.6 Ultrasound biomicroscopy in an eye with narrow angle and bombé configuration of the iris. *Star*=cornea, *asterisk*=ciliary body, *arrowhead*=iris

Fig. 35.7 Stereo photographs representing normal optic nerve head with small central cup (*left*) and typical glaucomatous changes with advanced cup and visualization of temporal lamina cribrosa pores and peripapillary atrophy (*right*)

35.4.2.3 Optic Disc and Nerve Fiber Layer

The optic disc is examined to estimate the cup-to-disc ratio and to identify excavation and enlargement typical of glaucoma. The optic disc is a complex, three-dimensional anatomic structure. Stereoscopic viewing during slit-lamp examination improves the accuracy of disc evaluation. Single cutoff values for the cup to disc ratio designed to distinguish between normal subjects and those with glaucoma are imperfect for screening, since the normal ratio varies considerably with optic disc size. When the cup to disc ratio equals or exceeds 0.6, the probability of glaucoma increases dramatically. In screening for glaucoma, however, even combined criteria that includes the level of IOP and cup to disc ratio identifies only two thirds of patients with glaucoma.

The disc should be viewed stereoscopically to assess for evidence of glaucomatous damage. The following characteristics should be noted: cup-to-disc ratio in the horizontal and vertical meridians; color and slope of the cup; appearance of the disc; progressive enlargement of the cup (comparison to prior photos); evidence of nerve fiber layer damage using a red-free filter; notching or thinning of disc rim, particularly at the superior and inferior poles; pallor; presence of nerve fiber layer hemorrhage; asymmetry between cups; peripapillary atrophy (association with the development of glaucoma when Beta-zone atrophy is present); or congenital nerve abnormalities. Stereo fundus photographs are acquired as a baseline for future comparisons (Fig. 35.7).

Other imaging techniques that utilize different physical properties of light for optical analysis can document the status of the optic nerve and the nerve fiber layer. Furthermore, they can be used to detect changes over time (Medeiros et al. 2004). The value of these technologies for diagnosing glaucoma and for determining progression over time has been demonstrated in early to moderate glaucoma but their utility in advanced glaucoma is diminished with severe loss of the retinal nerve fiber layer making serial measurements difficult and less predictable of glaucoma progression.

Confocal scanning laser ophthalmoscopy can evaluate the optic disc and peripapillary retina in 3 dimensions and provide quantitative information about the cup, neuroretinal rim, and contour of the nerve fiber layer. Scanning laser polarimetry measures the change in the polarization state of an incident laser light passing through the naturally birefringent nerve fiber layer to provide indirect estimates of peripapillary nerve fiber layer thickness. Optical coherence tomography uses reflected light in a manner analogous to the use of sound waves in ultrasonography to create computerized cross-sectional images of the retina and optic disc, and also gives quantitative information about the peripapillary retinal nerve fiber layer thickness that can be compared to age matched controls (Fig. 35.8).

Fluorescein angiography, ocular blood flow analysis via laser Doppler flowmetry, color vision measurements, contrast sensitivity testing, and electrophysiological tests (e.g., pattern electroretinography, visual evoked potentials) are used as research tools in the evaluation of POAG patients. Routine clinical use is not advocated at this time.

35.4.2.4 Visual Field Testing

Automated threshold testing (e.g., Humphrey 24-2) is performed to evaluate for glaucomatous visual field defects. If the patient is unable to perform automated testing, Goldmann perimetry may be substituted. New onset glaucomatous defects are found most commonly as an early nasal step, temporal wedge, or paracentral scotoma (more frequent superiorly). Generalized depression also may occur, but is less specific for glaucomatous damage.

Swedish Interactive Threshold Algorithm (SITA)-based software (Fig. 35.9) decreases testing time and boosts reliability, especially in older patients (Schimiti et al. 2002). Short wavelength automated perimetry (SWAP) or blue-yellow perimetry may provide a more sensitive method of detecting visual field deficits, especially in patients with OHT without defects demonstrated by standard testing. If the Humphrey standard automated perimetry results are normal, SWAP can be utilized in detecting visual field loss earlier. Prior studies suggest SWAP may detect visual loss or progression up to 3–5 years earlier than conventional perimetry, as well as in 12–42 % of patients previously diagnosed

with only OHT (Racette and Sample 2003). Because the testing time may be lengthened, SWAP testing may be strenuous for some patients. However, more recent SITA-SWAP algorithm software may speed up the testing time and improve reliability (Bengtsson 2003).

The pupil size should be documented at each testing session since pupillary constriction can reduce retinal sensitivity and mimic progressive visual field loss. This is especially important in patients that are using miotic therapy with pilocarpine.

To establish a reliable baseline, visual fields may have to be repeated several times on successive visits, especially if initial testing shows low reliability indices. Newer glaucoma progression analysis software can help identify reliable perimetric baselines, and probability-based analyses of subsequent fields can assist in distinguishing true progression over time from fluctuation or artifact. In follow-up, if the patient is at low risk for onset of glaucomatous damage, then repeat testing may be performed once a year. If a high risk of impending glaucomatous damage is present, then testing frequency is adjusted accordingly (as frequent as every few months).

Frequency doubling perimetry (also termed frequency doubling technology or FDT) is a relatively new technology that may detect functional visual loss at an earlier stage in the glaucomatous disease process, thereby detecting more patients who currently are misdiagnosed as having OHT instead of early POAG. Current sensitivities and specificities are continuing to improve, but more baseline data are needed to determine under what circumstances these new techniques will prove to be most useful.

35.5 Differential Diagnosis

Several disorders may mimic glaucomatous ONH and/or visual field changes. Those that resemble structural glaucomatous optic neuropathy or interfere with assessment of glaucomatous cupping include optic disc anomalies, tilted disc syndrome, optic nerve drusen, optic nerve pits, optic nerve colobomas, myelinated nerve fibers, ischemic optic neuropathy and optic atrophy.

Factors that mimic glaucomatous visual field loss include: branch retinal artery and vein occlusions; chorioretinal scars; retinal areas treated by photocoagulation or cryotherapy; demyelinating disorders; cerebrovascular accidents, tumors, or other lesions affecting the optic nerve, chiasm, optic tract, optic radiation, and/or the remaining course of nerve fibers to the occipital cortex. Other abnormalities that could account for “pseudo-glaucomatous” visual field defects or vision loss include vitreous hemorrhage, proliferative retinopathy or other retinal disorders.

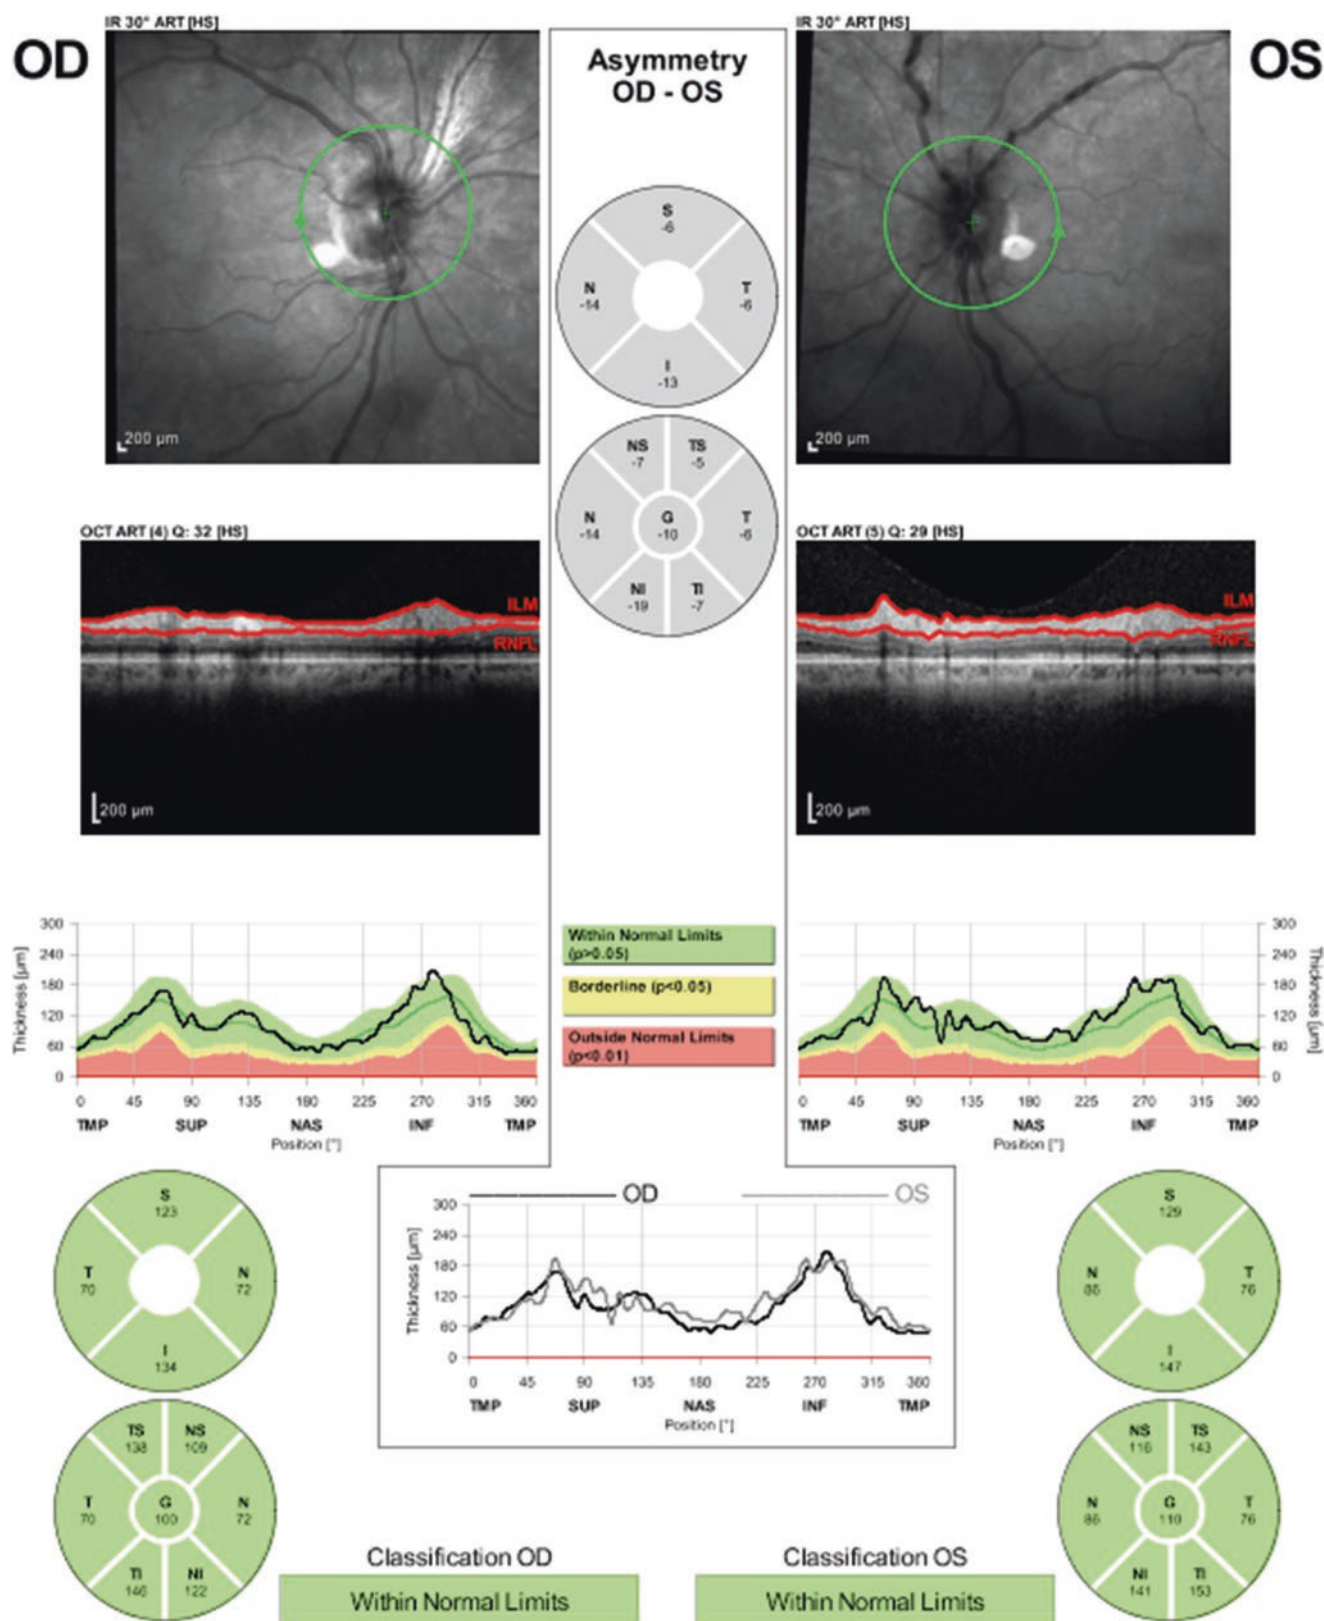

Fig. 35.8 Optic nerve optical coherence tomography in a patient with a normal optic nerve. *Top row*—red free optic nerve photo. *Second row*—cross sectional identification of the retinal nerve fiber layer (outlined in red). *Bottom section*—comparison with age-matched control population

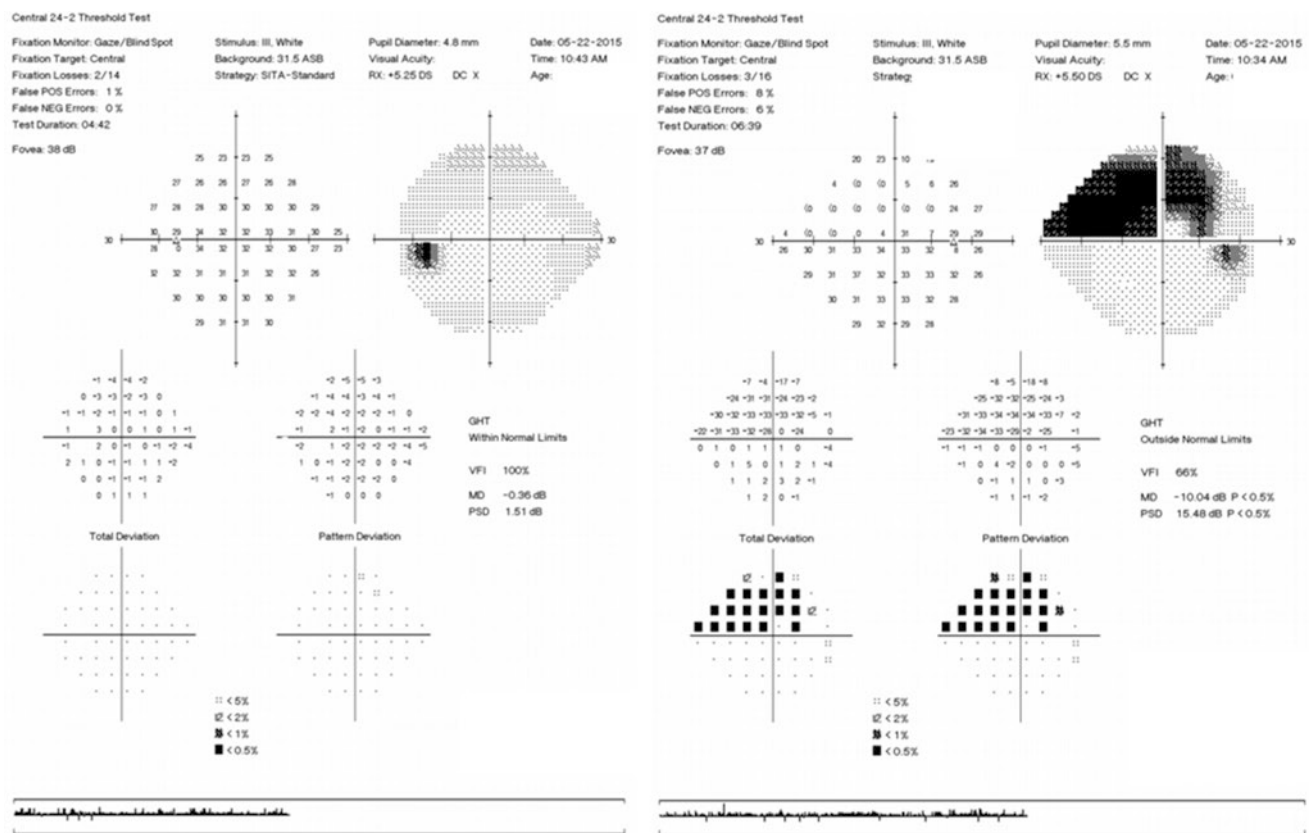

Fig. 35.9 Humphrey 24-2 SITA standard Visual Field Test. Normal right eye visual field. Left eye demonstrating a superior arcuate scotoma of severe stage glaucoma related visual field loss in a patient with exfoliative glaucoma

35.6 Animal Models

Animal models for glaucoma have been used to study the pathophysiological basis of glaucoma. Animal based experiments are more representative than cell culture models particularly in the study of aqueous humor dynamics, the trabecular meshwork-ciliary muscle complex, RGC, ONH axons, ONH framework, and vascular flow dynamics in glaucoma subtypes (Weinreb and Lindsey 2005).

Conducting studies in animal models often are challenging and occasionally require anesthesia, which might affect the parameter being assessed. Conditioned reflex training may help elicit cooperation. Use of remote controlled implants and newer drug delivery options represent advances made on this front.

Animal experiments have provided excellent means to study medical and surgical treatments for glaucoma prior to human trials. Animal models are required to study *de novo* drugs and their structural and functional influence on ocular tissues.

Genetic modulation of animal models is another area of research. Mice are genetically engineered to suit experimen-

tal needs. New models are required and will be developed to advance our understanding of the glaucomatous disease process. Mouse mutants with glaucoma provide models for human glaucoma. From the clinical standpoint, some mouse model share occasional similarities with various aspects of glaucoma occurring in humans. The life span and replication time (one mouse year is equal to 30 human years) allow developmental and invasive studies and make it possible to follow glaucoma progression in a reasonable span of time (Chang et al. 2005). Some of the new mouse glaucoma models used are: Gpmb [glycoprotein (transmembrane)] with mutation on chromosome 6 to study iris pigment dispersion (Anderson et al. 2002); Trypl with chromosome 4 mutation to study iris stromal atrophy (Anderson et al. 2002); Nm2702 with chromosome 11 mutation to study inner retina loss and optic nerve cupping (Chang et al. 2005); CALB/Rk and si/si model to study early enlargement of optic cup or coloboma (Chang et al. 2005); AKXD-28 for ganglion cell loss and optic nerve cupping (Anderson et al. 2001); E50K optineurin transgenic mouse for normal tension glaucoma (Tseng et al. 2015); and nm1839-model for Axenfeld's syndrome, anterior segment dysgenesis or buphthalmos (Chang et al. 2005). Due to complex regulatory gene interactions and a still

^aThe human and monkey genomes are sufficiently similar that data from the human genome project often can be applied to experiments using non-human primates

incomplete understanding of the effects of SIX6, no mouse model yet exists. The effect of glaucoma on the electroretinogram response has been evaluated in mice and is currently being evaluated for its role in diagnosis and monitoring glaucoma in humans.

The pig as a model for glaucoma shares many phylogenetic similarities with that of the human and is more readily available compared to the non-human primate model (Ruiz-Ederra et al. 2005). The porcine retina is more similar to human than other large mammals such as dog, goat or cow. Techniques used for glaucoma diagnosis in humans such as optical coherence tomography or multi-focal electroretinography can be reliably studied in pig eyes. Studies of the pig aqueous outflow system demonstrate it to be an acceptable model for specific glaucomas (McMenamin and Steptoe 1991).

The non-human primate model of OHT with its resultant optic neuropathy closely reflects the optic neurodegeneration associated with human glaucoma. Utilization of the glaucoma model in monkeys has helped to further the understanding of aqueous humor dynamics, glaucomatous damage in the RGCs and other structures along the visual pathway, and the effects of pharmacological agents on ocular tissues (Rasmussen and Kaufman 2005). Fundus photographs of glaucomatous monkeys show the morphologic changes consistent with human OHT with the advantage of observing progressive changes over a shorter period of time by withholding treatment despite very high IOPs (Gaasterland and Kupfer 1974). The ability to correlate histologic changes in glaucomatous monkey eyes with functional and imaging data is a major advantage of the monkey model. Humphrey visual field defects can be performed by trained glaucomatous monkeys (Harwerth et al. 2002). The types of visual field defects are similar to those in glaucomatous humans.

Utilization of an experimental glaucoma model in non-human primates has led to advances in the understanding of glaucomatous changes in the visual pathways from photoreceptors to the visual cortex (Rasmussen and Kaufman 2005).

Newer investigative modalities such as contemporary perimetry techniques have been studied in primate models. Electroretinography can be performed in monkeys to evaluate changes produced by glaucomatous optic neuropathy.

The choice of animal is governed by the objectives and requirements of the study (Table 35.3). Size of the animal eye, similarity with human eyes, cost and availability are factors that influence the selection of the animal type.

35.7 Review Questions

1. The estimated world population that is bilaterally blind from primary open angle glaucoma is:
 - a. 2–3 million
 - b. 3–4 million
 - c. 4–5 million
 - d. 5–6 million
 - e. 6–7 million
2. The primary pathology in open angle glaucoma is believed to be
 - a. Increased aqueous production
 - b. *Increased resistance in conventional outflow*
 - c. Increased episcleral venous pressure
 - d. Decreased intra cranial pressure
3. The pathway followed by aqueous in eye sequentially involves
 - a. Episcleral veins, anterior chamber, trabecular meshwork, Schlemm's canal, ciliary body
 - b. Anterior chamber, trabecular meshwork, Schlemm's canal, ciliary body, episcleral veins
 - c. *Ciliary body, anterior chamber, trabecular meshwork, Schlemm's canal, episcleral veins*

- d. Ciliary body, anterior chamber, Schlemm's canal, trabecular meshwork, episcleral veins
4. Mechanisms that might contribute to optic nerve damage in glaucoma include:
 - a. Apoptosis
 - b. Glutamate-induced excitotoxicity
 - c. Nitric oxide synthase
 - d. Free radicals
 - e. *All of the above*
5. Mutations in which of the following genes have been shown to be associated with the pathogenesis of glaucoma?
 - a. GLC1A
 - b. Myocilin
 - c. Optineurin
 - d. GLC1G
 - e. *All of the above*
6. Which gene product is implicated is associated with normal pressure glaucoma and amyotrophic lateral sclerosis?
 - a. GLC1A
 - b. Myocilin
 - c. *Optineurin*
 - d. GLC1G
 - e. SIX6
7. Which of the following are characteristic changes that might be observed in the optic nerve head in primary open angle glaucoma except:
 - a. Increased cup to disc ratio
 - b. Notching of the neural rim
 - c. Disc hemorrhage
 - d. New vessels within the disc
 - e. *All of the above are changes associated with glaucoma*
8. Which racial background portends the greatest risk for glaucoma and glaucoma related blindness
 - a. Caucasian
 - b. *African*
 - c. Latino
 - d. Asian
9. All of the following are examples of tests to evaluate the anterior chamber angle, EXCEPT:
 - a. Gonioscopy
 - b. Anterior segment OCT
 - c. Ultrasound Biomicroscopy (UBM)
 - d. *A-scan Ultrasound*
10. All of the following are methods to assess for visual field loss when glaucoma is suspected, EXCEPT:
 - a. Humphrey Automated Perimeter
 - b. Goldmann Perimeter
 - c. *Full field Electroretinogram (ERG)*
 - d. Frequency doubling technology (FDT)

and Quan Dong Nguyen

Abstract

Ocular manifestations may be the initial, presenting features of various neuro-immune and neuro-degenerative diseases. Ophthalmic involvement may present as orbital, intraocular or adnexal inflammation or as discrete lesions involving different components of the eye and may serve as the barometer for the severity of the underlying systemic diseases. Often, the lesions may present as an ophthalmic emergency, requiring aggressive therapy before the diagnosis can be confirmed. The clinician scientist must be vigilant and maintain a high level of suspicion in order to diagnose the condition early and institute prompt therapy. The ocular signs and symptoms may be associated with a constellation of neurological complaints. Therefore, an integrated approach with close collaboration among ophthalmologists, neurologists, internists and pathologists is required to ensure optimal patient care, preserving not only the vision but also the lives of the patients.

Adamantiades-Behçet's disease • Cornea • Optic nerve • Retina • Uveitis • Vogt-Koyanagi-Harada disease

36.1 Introduction

The eye has been recognized as an immune-privileged organ due to the presence of non-permeable blood-ocular barriers. However, over the years, a number of systemic disorders have been associated with characteristic ophthalmologic manifestations, which may often lead to severe visual morbidity. Recognition of such pathological changes in the eye may provide valuable clues leading to the diagnosis of the associated systemic immunologic dysfunction. Typically,

systemic immunologic conditions affect musculoskeletal, gastrointestinal, renal and neurological systems. Identification of the constellation of ocular and systemic signs may allow the clinician to consider a definitive diagnosis and plan appropriate management.

Intraocular inflammation of the uvea (uveitis) is the hallmark of ophthalmic involvement associated with systemic autoimmune diseases. In addition, there may be concomitant involvement of extraocular structures and the periorbital. Pathological changes such as inflammation of the retinal and/or choroidal vasculature, optic nerve swelling, macular edema, exudative retinal detachment, corneal ulceration and granulomatous inflammation of the uveal tissue are common causes of visual loss in these patients (Vodopivec et al. 2014).

Autoimmune diseases may also present initially only with ophthalmologic manifestations. The diagnosis of the underlying systemic disease, which may be life-threatening, may be delayed, unless the clinician scientist maintains a high level of suspicion. With appropriate screening, comprehensive examination and laboratory evaluation, the underlying

systemic immunologic dysfunction can be identified and treated to prevent further ophthalmic, neurologic and systemic morbidity. Similarly, detailed evaluation of ocular symptoms and periodic, routine eye examination of patients with autoimmune diseases may allow early detection, treatment and prevention of significant visual loss.

36.2 Pathophysiological Basis of Ocular Disease

The immune privilege of the eye is maintained due to interplay of several complex mechanisms that include both innate and adaptive arms of immunity and by contribution of both, local and systemic factors that decrease inflammatory responses (Stein-Streilein and Caspi 2014). Anatomical barriers in the eye, such as the blood-ocular-barrier, avascularity of structures such as the cornea and sclera, lack of lymphatic channels, blood-retinal-barrier and highly-regulated production and maintenance of aqueous and vitreous humor contribute towards immune-tolerance of eye-derived antigens (Caspi 2014).

The ocular tissues have characteristic differences compared to other tissues with regards to their immunologic make-up. The ocular milieu has lower expression of major histocompatibility factors, soluble cell-surface receptors, growth factors and pro-inflammatory cytokines. This results in a decreased T- and B-cell response in the eye and production of non-complement fixing antibodies (*anterior chamber-associated immune deviation - ACAID*). The biochemical microenvironment of the eye actively decreases the response of the immune system. Thus, ordinarily, systemic immune response to non-ocular antigens does not illicit damage to the eye (Taylor and Kaplan 2010).

However, various systemic autoimmune diseases are characterized by ocular manifestations that may precede systemic symptoms. These conditions are associated with breakdown of immune-privilege mechanisms of the eye, and frequently of the brain, as well. Various antigens that incite an inflammatory response are found both in the eye and the nervous system. Immune response against such antigens (e.g. Vogt-Koyanagi-Harada syndrome) results in disease manifestations that affect both organ systems.

36.3 Clinical Features of Select Autoimmune Diseases

36.3.1 Vogt-Koyanagi-Harada Disease

Vogt-Koyanagi-Harada (VKH) disease is characterized by diffuse, non-necrotizing granulomatous inflammation of the uveal tissue along with involvement of the central nervous system, auditory system and the integumentary system. VKH

consists of two entities: Harada's disease and Vogt-Koyanagi syndrome. Harada's disease (first reported by Einosuke Harada in 1926) is characterized by bilateral exudative retinal detachment along with cerebrospinal fluid (CSF) pleocytosis. Vogt-Koyanagi syndrome is associated with anterior segment inflammation (chronic anterior uveitis) along with alopecia, vitiligo and poliosis (described in 1906 by a Swiss resident in Ophthalmology—Alfred Vogt). These findings were brought together below one umbrella term, VKH, by Babel in 1932 (Herbert and Mochizuki 2007). Presently, the International Workshop on Vogt-Koyanagi-Harada Syndrome and Sympathetic Ophthalmia provides the guidelines for diagnosis, investigations, imaging interpretation and management of VKH.

36.3.1.1 Epidemiology

There is a wide geographic and ethnic variation in the incidence of VKH, with higher proportion of Japanese, Asian, Hispanic and Native Americans diagnosed with the disease. In the US, VKH disease accounts for less than 5% of all the uveitis clinic referrals. The incidence is higher in Japan, where VKH disease accounts for approximately 7% of all the uveitis referrals. Higher incidence of the disease among individuals with dark pigmented skin may be linked to the pathogenesis of the disease. Women may be more commonly affected. The most common age group for the occurrence of the disease is between the second to the fifth decade of life (Ohno et al. 1977).

36.3.1.2 Etiology and Pathogenesis

The etiology of VKH appears to be granulomatous inflammatory response to antigens located in the ocular, auditory and central nervous systems. Electron microscopic analysis of uveal tissues has revealed predominance of T-cell population in close association with melanocytes (Yamaki et al. 2000). In addition, histopathological and immunohistochemical findings suggest that VKH occurs as a result of altered T-cell response against yet undiscovered ligands of the melanocytic proteins (Sugita et al. 1996). Tyrosine-related proteins (Hayakawa et al. 2004), molecular mimicry (Sugita et al. 2007) and immunologic cross-reactivity with various external antigenic stimuli such as those caused by cytomegalovirus infection have also been shown to play a role in the etiology of VKH.

Derangement in cytokines and inflammatory mediators, such as increased levels of IL-17, IL-1 β (Li et al. 2010), IL-6 and tumor necrosis factor (TNF)- α and decreased levels IL-25 (Xu et al. 2014) has also been linked to the pathogenesis of VKH. Interleukin (IL) -21 may promote secretion of IL-17 resulting in pleiotropic effects on the immune system (Li et al. 2010). In addition, role of decreased IL-25 and increased release of IL-1 β , IL-6 and tumor necrosis factor (TNF)- α by peripheral blood mononuclear cells may play a role in the pathogenesis of the disease (Xu et al. 2014).

VKH disease has a strong immunologic basis with higher prevalence of the disease among individuals with HLA-DR1 and DR4 as compared to controls (Weisz et al. 1995). The predominant alleles associated with VKH include HLA-DRB1*0405 and HLA-DRB1*0410 (Shindo et al. 1994). The relative risk of developing VKH is higher with HLA-DR1 as compared to HLA-DR4 (4.11 versus 1.96) (Arellanes-Garcia et al. 1998; Tiercy et al. 2010). Thus, various population-based studies indicate that specific Human Leukocyte Antigen (HLA) genes may confer increased susceptibility for the development of VKH disease.

The demographic, immunologic and laboratory features of VKH disease closely resemble those of sympathetic ophthalmia (Rao 1997). This may explain the similarities in the morphological manifestations of both the diseases.

36.3.1.3 Clinical Features

Ocular features of VKH disease are divided into various stages including prodromal, acute, chronic and convalescent/recurrent stage. The disease may present initially with a viral-like illness. The patient may complain of malaise, headache, fever, orbital pain, meningisms and nausea. CSF analysis at this stage may indicate presence of pleocytosis in 80% patients. This stage is followed by the acute uveitic

stage characterized by *bilateral exudative panuveitis* that is usually symmetric (Fig. 36.1). There is anterior segment inflammation, vitritis, bilateral exudative retinal detachment (which may be multifocal and bullous), hyperemia and edema of the optic nerve head and retinochoroidal thickening detectable by ultrasound B-scan. Mutton-fat keratic precipitates and iris nodules may be visualized. Fundus fluorescein angiography reveals an impressive picture with multiple hypofluorescent dots initially followed by multiple, focal areas of hyperfluorescence (Fig. 36.1). Choroidal vessel leakage and hyperfluorescence can be detected using Indocyanine green angiography (ICGA) (Sakata et al. 2014; Cunningham et al. 2014).

This stage is followed by the stage of chronic uveitis heralded by integumentary signs such as vitiligo, poliosis and choroidal depigmentation. *Sugira's sign*, which is perilimbal vitiligo, may be observed at this stage. Depigmentation of the choroid gives an appearance of *sunset-glow fundus*. Retinal pigment epithelium (RPE) may show a moth-eaten appearance. Along with disc pallor, focal areas of yellow, well-circumscribed chorioretinal atrophy, especially in the inferior mid-periphery (earlier referred to as Dalen-Fuch's nodules), may be seen. Approximately two-third of the patients may have recurrent disease resulting in complications

Fig. 36.1 Fundus photographs (right eye) of a 19-year-old girl diagnosed with Vogt-Koyanagi-Harada Syndrome. (a) shows the fundus photograph at presentation, with vitreous cells, optic nerve head edema and exudative retinal detachment. (b) shows improvement in the media clarity, decreased vitreous haze and exudation after 5 days of intravenous methylprednisolone (1 g/day). At 2 months (c), the media clarity has

much improved with resolution of the exudative retinal detachment. The patient received a course of oral prednisone and azathioprine. (d)–(f) show the fluorescein angiography at baseline (left eye) of the same patient. In the early phase (d), there are focal areas of hypofluorescence (temporal to fovea), which become progressively hyperfluorescent (e and f) along with pooling of the dye due to exudative retinal detachment

Table 36.1 Revised diagnostic criteria of Vogt-Koyanagi-Harada disease proposed by the first international workshop (Read et al. 2001)

I. Complete disease (criteria 1 to 5 must be present)	
	1. No history of penetrating ocular trauma or surgery preceding the initial diagnosis of uveitis
	2. No clinical or laboratory evidence suggestive of other ocular disease
	3. Bilateral ocular involvement (a or b criteria must be met, depending upon the stage of the disease at which the patient is examined)
	(a) Early manifestations of the disease
	– Diffuse choroiditis (focal areas of subretinal fluid; bullous serous retinal detachments), OR
	– Characteristic fluorescein angiography AND echography evidence of diffuse choroidal thickening
	(b) Late manifestations of the disease
	– History suggestive of prior uveitis with the above described characteristics AND ocular depigmentation (sunset glow fundus, Sugiura's sign)
	– AND other ocular signs (nummular chorioretinal depigmented scars, retinal pigment epithelium clumping and/or migration, or recurrent/chronic anterior uveitis)
	4. Neurological/auditory findings
	– Meningismus OR tinnitus, OR cerebrospinal fluid pleocytosis
	5. Integumentary findings (NOT preceding the onset of central nervous system or ocular disease)
	– Alopecia, OR poliosis, OR vitiligo
II. Incomplete disease (criteria 1 to 3 and either 4 or 5 must be present)	
III. Probable disease (isolated ocular disease; criteria 1 to 3 must be present)	

Table 36.2 Clinical findings predictive of Vogt-Koyanagi-Harada disease (Rao et al. 2010)

Acute stage	Chronic stage
Bullous retinal detachment ^a	Sunset glow fundus ^a
Choroidal thickening ^a	Sugiura's sign ^a
Subretinal fluid ^a	Vitiligo ^a
Alopecia ^a	Choroidal thickening
Hearing loss	Nummular choroidal scars
Vitiligo	Retinal pigment epithelium clumps/migration
	Hearing loss

The clinical findings with $\geq 50\%$ positive predictive value (PPV) and negative predictive value (NPV) have been listed in the table

^aIndicates clinical findings associated with $\geq 75\%$ PPV and NPV

such as subretinal fibrosis, neovascular glaucoma, cataract and painful blind eye (Rao et al. 2010).

The diagnosis of VKH may be challenging since patients may presented with a limited ocular disease without systemic manifestations. The international workshop on VKH has divided the disease into complete, incomplete and probable disease (Table 36.1).

Involvement of other melanin-containing organs presents with dermatological features (vitiligo over the head, trunk, eyelids; poliosis of the eyebrows; alopecia), neurological features (headache, meningo-encephalitis and/or focal neurological deficits) and auditory involvement (sensorineural hearing loss, tinnitus and vertigo). The frequency of distinguishing features and findings most predictive of VKH disease obtained from a cohort of 1147 patients has been summarized in Table 36.2 (Rao et al. 2010).

36.3.2 Adamantiades-Behçet's Disease

Adamantiades-Behçet's disease (ABD) is a multi-system inflammatory vasculitis characterized by autoimmune ulceration of mucous membranes, involvement of ocular, central nervous system, and articular and renal systems. Majority of the patients may present with isolated mucous membrane or ocular involvement, making the diagnosis challenging.

ABD is named after two eminent clinicians, a Greek ophthalmologist, Benedictos Adamantiades and a Turkish dermatologist, Hulusi Behçet. The disease is more prevalent in the Middle East and the Mediterranean region, or the silk route of Europe. The description of association of ocular signs and other systemic involvement dates back to the writings of Hippocrates (Zouboulis and Keitel 2003). However, due to the growing recognition of the potential visual-

blinding complications of this condition despite aggressive therapy, an International Workshop on Granulomatous Uveitis and Ocular Behçet's Disease has proposed criteria for the diagnosis and classification of ABD.

ABD is characterized by non-necrotizing uveitis along with necrotizing obliterative retinal vasculitis. It affects many organs and tends to recur every 1–2 months without therapy. Data from large population based studies from countries such as Japan, Turkey, Germany and USA suggest that the aggressive disease course may lead to legal blindness within 4 years in the absence of immunosuppression (Evereklioglu 2005).

36.3.2.1 Epidemiology

The highest prevalence of ABD has been reported from Turkey, with as many as 420 cases per 100,000 in Istanbul. The prevalence in US and Europe ranges from 0.12 to 7.5 cases per 100,000 population. The incidence of ABD is $\leq 20\%$ among all uveitis in Japan, Taiwan, Israel, Saudi Arabia, Australia and China. Thus, the disease may be associated with HLA alleles more common in certain ethnic groups. Dissemination of genetic information across gene pools may be responsible for spread of the disease to the Asian and Western population (Zouboulis and Keitel 2003).

The disease usually affects younger individuals between the second and third decades of life. Recently, ABD has been recognized as an important cause of pediatric uveitis with cases reported in patients as young as 2 months of age (Hatemi et al. 2014).

Population-based studies from the Middle East have shown that the male:female ratio of the disease is approximately 2.3:1 and it is believed to have worse prognosis in males as compared to females, who may present with less organ involvement. The rates of ocular involvement vary from 28 to 50% cases depending upon the sampled cohort.

Tables 36.3 and 36.4 provide the diagnostic criteria for ABD as per the International Team for the Revision of the International Criteria for Behçet's disease (ITR-ICBD) (2014) and the International Uveitis Study Group on Behçet's disease (1990).

36.3.2.2 Etiology and Pathogenesis

The exact etiology of ABD is unknown. The disease is multifactorial and it is accepted that ABD occurs in immunologically and genetically susceptible population, triggered by environmental agents or infections. Bacterial cross-reactivity with human antigens, cytokines and circulating immune-complexes are also implicated in the pathogenesis of this condition (Park et al. 2014).

Although classical Mendelian inheritance pattern has not been described for ABD, strong association with specific HLA genotypes has been shown. Subjects with HLA-B51/B5 have an increased risk of developing ABD. The prevalence of HLA-B51 allele among Japanese, Greek, Iranian, Italian and Saudi Arabian patients varies between 60 and 77%. The most common allele associated with ABD is HLA B*5101. Apart from HLA B51, there are several other genes located in close proximity that may be implicated in the pathogenesis of ABD (Wallace 2014).

A large number of infectious agents have been linked to the pathogenesis of ABD. Among these, the most common associations have been found with herpes simplex virus (HSV-1), *streptococcus* spp and *mycoplasma fermentas* based on oral, salivary and respiratory tract cultures. Streptococcal antigens may increase the T-lymphocyte cell-mediated IL-6 and interferon (IFN) γ release. Various antigens such as heat shock proteins, cytotoxins of *Helicobacter pylori* may play a role in the vascular damage typical of ABD (Hatemi and Yazici 2011).

Pathological immune dysfunction involving both the innate and adaptive immunity may occur in ABD. Low levels of mannose binding lectins, altered expression of toll-like receptors in monocytes and activation of adenosine deaminase may contribute towards increased T-cell expression in patients with ABD. Increased levels of TNF- α , IL-6, IL-8, IL-10 and IL-12 may increase leucocyte migration, activation of neutrophils, fibroblast proliferation and synthesis of prostaglandins. In ABD, both Th1 and Th2 cells seem to be involved in the pathogenesis. In addition to the T-cells, B cell population also plays an important role by presenting the antigens to the T-cell population (Park et al. 2014).

Table 36.3 International criteria for Behçet's disease (ICBD) by the international team for the revision of the international criteria for Behçet's disease (ITR-ICBD) (2014) (Davatchi et al. 2014)

Sign/symptom	Points
Ocular lesions	2
Genital aphthosis	2
Oral aphthosis	2
Skin lesions	1
Neurological manifestations	1
Vascular manifestations	1
Positive pathergy test ^a	1

Score of ≥ 4 indicates Behçet's disease

^aPathergy test is optional and primary scoring system does not include the test

Table 36.4 International study group for Behçet’s disease diagnostic criteria (1990) (IUSG 1990)

Mandatory: Recurrent oral ulceration (<i>minor aphthous, major aphthous, or herpetiform ulceration observed by a physician or patient, which recurred at least three times in 1–12 month period</i>)
Plus two of the following criteria:
Recurrent genital ulceration (<i>aphthous ulceration or scarring, observed by physician or patient</i>)
Eye lesions (<i>anterior uveitis, posterior uveitis, or cells in the vitreous, or retinal vasculitis observed by ophthalmologist</i>)
Skin lesions (<i>erythema nodosum observed by physician or patient, pseudofolliculitis, or papulopustular lesions, or acneiform nodules observed by physician in post-adolescent patients not on corticosteroid treatment</i>)
Positive pathergy test (<i>read by physician at 24–48 hours</i>)

Fig.36.2 Various skin and mucous membrane lesions in Adamantiades- Behçet’s disease (ABD). (a) shows a large, pustulo-nodular lesion with central ulceration in the thigh of a young male patient. (b) shows multiple erythematous, acneiform lesions at the elbow in another Caucasian

patient with ABD. (c) shows a dark, plaque-like lesion during the active stage of the disease. (d) shows a large, oral aphthous ulcer on the buccal mucosa of a patient with ABD

Vascular thrombosis in ABD is associated with increased levels of nitric oxide, plasma metabolites, low concentration of Protein C, increased platelet activation and lower plasma levels of tissue plasminogen activator. These may occur as a result of endothelial dysfunction leading to a generalized state of hypercoagulability, especially in cases with neuro-Behçet’s disease. Plasma and cerebrospinal fluid concentrations of vascular endothelial growth factor have been shown to increase in patients with neurological complaints in ABD (Evereklioglu 2005; Hatemi et al. 2014).

36.3.2.3 Clinical Features

The most frequent, disease-defining clinical feature of ABD is painful oral *aphthae* and mucocutaneous ulcers. These are more common in males and appear round-bottomed, yellowish-white surrounded by an erythematous halo. Major ulcers (more than 1 cm in diameter) may leave behind residual scarring. Genital ulcers are less common and not mandatory for the diagnosis of ABD. They usually involve the scrotum or vulva. Epididymitis and salpingitis are rarer complications of the disease. Acneiform skin lesions, erythema

nodosum and pyoderma gangrenosum-like lesions are other dermatological manifestations of ABD (Fig. 36.2).

Vascular involvement may lead to aneurysms, cardiovascular events, hemoptysis, dyspnea and gastrointestinal manifestations due to Budd-Chiari syndrome. Aches and pains due to asymmetric, non-erosive, non-deforming arthritis are common in ABD (Mat et al. 2014).

Central nervous system involvement may occur due to thrombosis of dural venous sinuses. Neurological involvement usually occurs after 5 years of the diagnosis and affects 5% patients with ABD. There may be small vessel vasculitis (*vascular-Behçet*), focal neurological deficits, headache, pyramidal, cerebellar or cognitive defects, memory loss, aseptic meningitis, extrapyramidal symptoms, euphoria and disinhibition, or magnetic resonance imaging (MRI) abnormalities but absence of symptoms (*silent-Behçet*). Neuromuscular involvement may present with multiple mononeuritis or myositis (Siva and Saip 2009; Saip et al. 2014).

Ocular manifestations may occur in as many as 83–95% males and 67–73% females with ABD. Ocular symptoms usually follow mucocutaneous lesions and recurrence is common. All the structures of the eye may be involved in ABD, leading to severe debilitating visual loss. The classical finding in the anterior segment is presence of iridocyclitis with *mobile hypopyon*, which may be seen in less than one-third cases. Anterior chamber may show cells, flare, fibrin and endothelial dusting suggestive of non-granulomatous inflammation. There may be evidence of episcleritis or conjunctival ulcers. Posterior segment may show vitritis and retinal vasculitis involving both arteries and veins. Perivascular sheathing and hemorrhages may be observed. Vascular thrombosis may lead to branch or central retinal vein/artery occlusion. Papillitis and papilledema may occur that may progress to optic atrophy. Retinitis may be seen in as many as 52% patients with ocular involvement. Larger lesions of retinitis may lead to scarring resembling viral retinitis. Exudative retinal detachment may also occur (Khairallah et al. 2009; Bonfioli and Orefice 2005) (Fig. 36.3).

Fluorescein angiography may reveal vascular tortuosity, occlusion, staining of vessel walls and capillary leakage (Fig. 36.4). Shunt vessels and neovascularization may develop due to widespread ischemia. ICGA may reveal irregular filling of choriocapillaris and other choroidal perfusion defects (Durrani et al. 2007).

36.3.3 Sarcoidosis

Sarcoidosis is a multi-system chronic inflammatory disease characterized by presence of non-caseating granulomas most commonly affecting the respiratory system, lymph nodes, central nervous system, skin and the eyes. This condition was first recognized by Hutchinson in 1869 and the term '*sarkoid*' was coined by a Norwegian dermatologist, Caeser

Boeck in 1899 to describe the skin lesions. Association of sarcoidosis with uveitis was first described in early twentieth century as a combination of facial nerve palsy and uveoparotid fever (Heerfordt's syndrome). Acute systemic inflammation may present as Löfgren's syndrome (fever, polyarthritis and erythema nodosum). In the last few decades, there has been a great increase in knowledge regarding the pathogenesis and manifestations of the disease.

Ocular disease may occur in up to one-third patients with the disease at any time during the natural history of the condition. Uveitis is the most common ocular manifestation and is usually bilateral. Granulomas may involve the periorbital, lacrimal gland, extraocular muscles and adnexa (conjunctiva and lid). The spectrum of disease manifestations is very wide; neuro-ophthalmologic signs such as optic neuropathy or Horner's syndrome may also occur in sarcoidosis.

The diagnosis of sarcoidosis is often challenging due to variable manifestations, which may often appear to overlap with other clinical entities. Since most of the patients have a chronic progressive disease, early recognition and treatment can prevent ocular complications and systemic sequelae of sarcoidosis. The diagnostic criteria for ocular sarcoidosis by the first International Workshop on Sarcoidosis (IWOS) is provided in Table 36.5.

36.3.3.1 Epidemiology

Sarcoidosis accounts for nearly 5% of all the adult uveitis cases and 1% of the pediatric cases (Hoover et al. 1986). Ocular involvement in sarcoidosis may be in up to 40% cases. The incidence of sarcoidosis is higher among African Americans as compared to Caucasians, with an incidence of 35.5 per 100,000 individuals versus 10.9 per 100,000 individuals respectively. The African American population is more likely to have a chronic, progressive course with higher number of patients developing ocular manifestations. Thus, blinding complications are also more common in this ethnic group. The incidence of sarcoidosis peaks between the age groups of 20–39 years. The incidence of the disease is higher among women across all racial and ethnic groups. Overall, the highest annual incidence is seen in northern European countries (Iannuzzi et al. 2007).

36.3.3.2 Etiology and Pathogenesis

The etiology of Sarcoidosis remains unknown. Due to multi-system involvement, environmental causes and occupational influences such as irritants, inorganic particulate matter and metals in furnaces, have been evaluated as possible causative agents. Investigators have also reported mycobacterial DNA in the sarcoidal tissue. A number of ubiquitous environmental influences may play a role in the alteration of immune response in sarcoidosis.

The most common HLA associated with sarcoidosis is HLA B8. Genetic factors located in the HLA class II region,

Fig. 36.3 Fundus photographs of an 18-year-old male diagnosed with Adamantiades-Behçet's disease. Slit-lamp photography of the anterior segment (a) shows ciliary congestion, cells in the anterior chamber and

a hypopyon. Posterior segment examination revealed dense vitritis (b), multiple exudates in the vitreous cavity (c), forming posterior hypopyon (d)

Fig. 36.4 Fluorescein angiography of the same patient as in Fig. 36.3 shows media haze in the early frame (a), diffuse hyperfluorescence in the mid-phase (b), optic disc leakage and vascular staining in the late

phase (c), suggestive of active vasculitis and optic neuritis in a case of Adamantiades Behçet's disease

Table 36.5 Diagnostic criteria^a for ocular sarcoidosis by the first international workshop on ocular sarcoidosis (IWOS) (2009) (Herbert et al. 2009)

Definite ocular ^b sarcoidosis	Biopsy-supported diagnosis with a compatible uveitis
Presumed ocular ^b sarcoidosis	Biopsy not done; presence of BHL with a compatible uveitis
Probable ocular ^b sarcoidosis	Biopsy not done; negative BHL; presence of three suggestive intraocular signs and two positive investigational tests
Possible ocular ^b sarcoidosis	Biopsy negative; four suggestive intraocular signs positive; two positive investigational tests

BHL bilateral hilar lymphadenopathy

^aAll other causes of uveitis, especially tuberculosis must be ruled out in all cases

^bThe term 'ocular' is used for both intraocular inflammatory lesions in patients with systemic disease and in patients with disease seemingly limited to the eye without any clinically detectable involvement of any systemic organ

i.e. DRB1 and DQB1 have been also implicated in the pathogenesis. HLA DQB1*0201 and DRB1*0301 have been associated with a better prognosis. In addition, familial pattern of disease occurrence has also been described. Sarcoidosis is also noted to occur after organ transplantation (Iannuzzi et al. 2007; Umur et al. 2012).

CD4 T helper cell population that interacts with antigen presenting B cells may play a central role in the pathology of sarcoidosis. Th1 cells produce IL-2, IFN- γ and TNF- α resulting in information of multisystem granulomas. Hyperglobinemia and hypercalcemia are other laboratory abnormalities in sarcoidosis (Boyd et al. 2001).

36.3.3.3 Clinical Features

Sarcoidosis most commonly presents with anterior uveitis. Posterior uveitis, retinal vasculitis, vitritis, choroidal granulomas and papillitis are other manifestations of the disease. The disease may involve the lacrimal gland resulting in enlargement, orbital inflammatory disease (*pseudotumor*), myositis, scleritis, keratitis and cranial nerve palsies. Uveitis can precede systemic involvement in 30% cases of sarcoidosis (*limited ocular sarcoid*).

Anterior uveitis may be non-granulomatous or chronic granulomatous (more common) with large mutton-fat keratic precipitates, iridocyclitis and attacks of glaucoma. Interstitial keratitis and conjunctival nodules may be noted.

Posterior segment disease may present with vitreous snowballs and debris. The classical perivascular sheathing in sarcoidosis is termed as '*candle wax drippings*' (*taches de bougie*). There may be multiple, round, punched-out choroidal lesions associated with macular edema (Fig. 36.5). Choroidal granulomas are observed as whitish elevated mass. Optic nerve leakage may be seen on fluorescein angiography. There may be papillitis, optociliary shunt vessels and macro-aneurysms. Clinical signs suggestive of ocular sarcoidosis are provided in Table 36.6.

Neurological manifestations associated with sarcoidosis (*neurosarcoid*) include encephalopathy, hypothalamic dysfunction, cranial nerve palsies, and pituitary disorders. Chiasmal syndromes and motility disorders may occur.

Direct infiltration of the sarcoid mass can affect the optic nerve, leading to optic atrophy (Fig. 36.5). Facial nerve palsy may be associated with significant corneal sequelae due to exposure keratopathy (Umur et al. 2012; Jamilloux et al. 2014).

36.3.4 Multiple Sclerosis

Multiple sclerosis (MS) is a chronic, relapsing demyelinating disease involving the central nervous system and the eye. Ocular and neuro-ophthalmic manifestations of the condition are diverse and the disease may affect virtually any anatomical structure including the components of the visual pathway. MS is one of the most common diseases of the central nervous system and its discovery dates back to the anatomical drawings from autopsies in the early nineteenth century. MS was recognized as a clinical entity in 1873 by Dr. Walter Moxon in England and Dr. Edward Seguin in 1878 in the US. Since then, efforts were made by scientists worldwide to establish the etiopathogenesis of the disease (Murray 2009).

Optic neuritis and uveitis are the two main clinical manifestations of MS in the eye. The association between MS and uveitis was first described in 1910. However, despite decades of intensive research and multicenter clinical trials, much needs to be learnt about the pathology of ocular disease in MS.

36.3.4.1 Epidemiology

MS affects individuals of all ages and race. The disease prevalence varies greatly and the incidence is higher in North America as compared to Asia. The typical onset of MS is between the second and the fifth decade of life. However, MS can occur in childhood as well as old age. Women are more commonly affected. Data from two large uveitis centers in the US and Germany showed that more than 90% patients presenting with uveitis associated with MS were females. The mean age of presentation in this cohort was 40.6 years (Toosy et al. 2014).

Fig. 36.5 Dense vitritis in a patient diagnosed with ocular sarcoidosis (a). (b) demonstrates tent-like posterior synechiae, observed in retroillumination anterior segment slit-lamp photograph of a patient diagnosed with sarcoidosis. (c) shows diffuse vasculitis (termed as frosted

branch angiitis) in another patient with sarcoidosis. (d) and (e) show fundus photographs of a patient diagnosed with neuro-sarcoidosis. The optic nerve heads in both eyes show direct infiltration with the sarcoid mass

Table 36.6 Ocular signs predictive of sarcoidosis as per the international workshop on ocular sarcoidosis (IWOS) (Herbort et al. 2009)

1.	Mutton-fat keratic precipitates (large/small) and/or iris nodules at pupillary margin (Koeppe) or in stroma (Bussacca).
2.	Trabecular meshwork nodules and/or tent-shaped peripheral anterior synechiae
3.	Snow-balls/string of pearls vitreous opacities
4.	Multiple chorioretinal peripheral lesions (active and atrophic)
5.	Nodular and/or segmental periphlebitis (\pm candle wax drippings), and/or macro-aneurysm in the inflamed eye
6.	Optic disc nodule(s)/granulomas(s) and/or solitary choroidal nodule
7.	Bilaterality (assessed by clinical examination or investigational tests showing subclinical inflammation)

36.3.4.2 Optic Neuritis and Multiple Sclerosis

Optic neuritis may be the presenting symptom of MS in 25 % of the cases (*MS-associated optic neuritis*). About 70 % patients with MS may develop optic neuritis during the disease course, usually in the relapsing-remitting stage. MRI studies have revealed disseminated white matter lesions suggestive of demyelinating disease in more than 50 % patients

with optic neuritis. As many as 72 % patients with MRI abnormalities convert to MS within 15 years (*clinically silent MRI lesions*). Bilateral simultaneous optic neuritis is rare, but sequential involvement of the fellow eye is common (Toosy et al. 2014).

Optic neuritis is usually preceded by periorbital or ocular pain in a majority of the patients. The pain may be

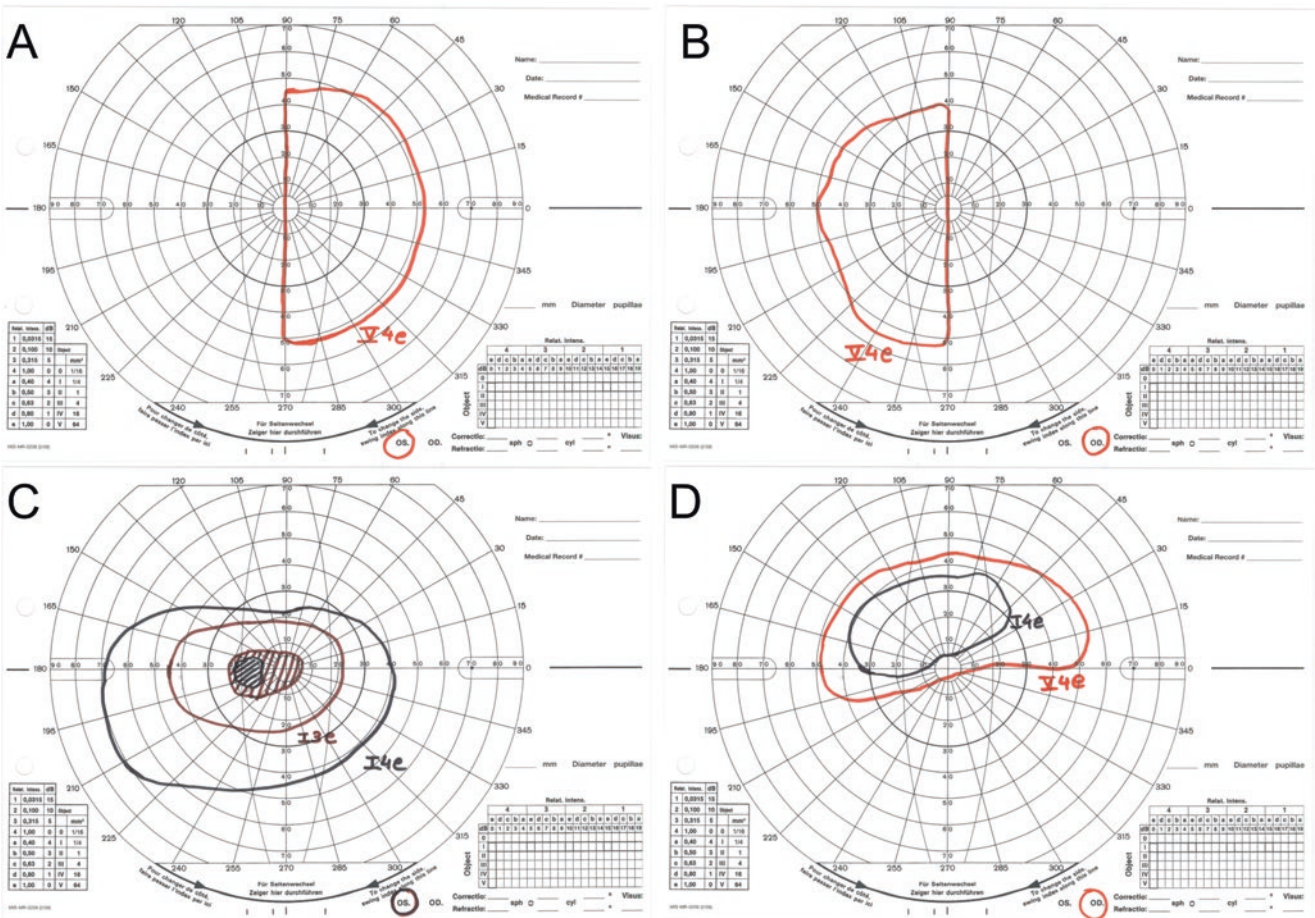

Fig. 36.6 Various visual field defects that can be observed in patients with optic neuritis secondary to multiple sclerosis using Goldman Visual Fields (GVF). (a) and (b) demonstrate bitemporal hemianopia. (c) shows a patient with cecentral scotoma. Panel (d) demonstrates altitudinal defect in a patient with optic neuritis

Table 36.7 Visual phenomena in optic neuritis associated with multiple sclerosis (Toosy et al. 2014)

Phosphenes	Bright fleeting, flashes of light that tend to be connected to eye movement
Uhthoff's phenomenon	Worsening of vision provoked by small increases in body temperature attributed to exercise, hot baths or showers, or hot weather conditions
Pulfrich's phenomenon	Anomalous stereoscopic perception of objects in motion due to asymmetrical conduction between the optic nerves

increased with extraocular movements and usually lasts several days. Optic neuritis usually presents with acute monocular vision loss, the severity of which may vary from mild visual field defects to no light perception. The peak usually reaches in about 2 weeks. Visual field defects include diffuse loss, central scotoma, arcuate and nasal-step scotomas, and altitudinal defects (Fig. 36.6). Visual field mapping with short wavelength automated perimetry may be more sensitive than conventional perimetry in detecting these losses. Color vision and contrast sensitivity may be impaired in more than 75 % patients. The disease course is characterized by foggy vision, dyschromatopsia (blue-yellow or red-green), phosphenes, *Uhthoff's phe-*

nomenon and *Pulfrich's effect* (Brodsky et al. 2008) (Table 36.7).

Clinical examination reveals relative afferent pupillary defect (Marcus Gunn pupil) in the affected eye. The appearance of the optic disc may be normal initially. However, later stages of the disease are characterized by swelling of the optic nerve head, peripapillary flame-shaped hemorrhages, and loss of spontaneous pulsations (Fig. 36.7). About two-third of patients may show normal appearance of the optic disc (*retrobulbar optic neuritis*). Retinal peripapillitis may occur but retinal exudates forming macular star, or vitreous cells should arouse a suspicion of an alternate diagnosis (Jacobs and Galetta 2004; Kaur and Bennett 2007).

Fig. 36.7 Fundus photographs of two patients diagnosed with optic neuritis. (a) shows a patient diagnosed with papillitis with blurring of the disc margins, hyperemia of the optic nerve head and retinal nerve

fiber layer edema. (b) shows a normal appearing optic nerve head of a patient diagnosed with retrobulbar optic neuritis

Visual improvement in optic neuritis associated with MS correlates poorly with initial loss. Visual recovery is generally good with $\geq 90\%$ patients achieving visual acuity of 20/40 or better. However, the incidence of persistent defects such as color vision, contrast sensitivity, pupillary reactions and motion perception (indicating damage to the magnocellular pathway) are high (Beck et al. 1994).

36.3.4.3 Uveitis Associated with Multiple Sclerosis

The incidence of uveitis ranges from 0.4 to 26.9% among patients diagnosed with MS; however, it is infrequently recognized as an important association with the disease. Uveitis is 10 times more common in patients with MS as compared to the general population. Most cases are bilateral and present with intermediate uveitis that affects the vitreous, peripheral retina and the pars plana. Macular involvement with cystoid macular edema is the most important prognostic factor for visual outcome. The incidence of MS among patients with intermediate uveitis is 16% and is higher among individuals with HLA DR15 allele.

Intermediate uveitis is characterized by inflammation of the pars plana and the peripheral retina. There are vitreous cells, usually in the anterior vitreous. Pars plana exudates can result in formation of a snow-bank. The complications of this condition may lead to formation of cataract, glaucoma and epiretinal membrane.

Uveitis in MS may present as an isolated granulomatous anterior uveitis with mutton-fat keratic precipitates, similar to VKH or sarcoidosis. Since the clinical findings of anterior

uveitis are not pathognomic for any condition, a high level of suspicion is necessary to rule out MS (Kaya et al. 2014; Messenger et al. 2015).

36.3.4.4 Neuro-Ophthalmic Manifestations of Multiple Sclerosis

MS may be associated with a diverse range of ocular motor defects and nerve palsies. Isolated cranial nerve palsies most commonly affect the abducens nerve. Oculomotor and trochlear nerves are less commonly involved. This may lead to development of gaze palsies and deficits in pursuit, saccades and vestibular eye movement. Saccades, ocular flutter, opsoclonus and saccadic oscillations may also occur.

Lesions in the dorsal mid-brain may result in convergence retraction nystagmus, pupillary light-near dissociations. Nystagmus can be vertical, vestibular, pendular or periodic alternating. *Internuclear ophthalmoplegia* (INO) is the commonest form of nystagmus in patients with MS and occurs in up to 40% patients with the disease. INO is characterized by limitation of adduction of the ipsilateral eye and rapid nystagmus during abduction of the contralateral eye due to lesions in the medial longitudinal fasciculus. MS is associated with an increased risk of bilateral INO.

The other neuro-ophthalmic manifestations of MS include diplopia, skew deviation, oscillopsia and blurring of vision. These manifestations may greatly reduce the quality of vision among patients with MS (Kaur and Bennett 2007). The rarer manifestations of MS include Charles Bonnet Syndrome, characterized by complex visual hallucinations in a person with partial or complete blindness (Pula and Reder 2009).

36.3.5 Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease with protean ocular and neuro-ophthalmic manifestations. The presentations are diverse and the disease may have a life-threatening course. Formation of autoantibodies and presence of circulating immune complexes resulting in tissue damage are the hallmark of this condition. The altered immune response in SLE is associated with inflammatory and thrombotic effects. Anti-phospholipid syndrome is a component of SLE characterized by formation of autoantibodies against plasma proteins resulting in venous and arterial thrombosis (Tsokos 2011).

36.3.5.1 Epidemiology

Approximately 90% patients with SLE are females. The peak of the disease occurs between late teens to the fourth decade of life. The prevalence of the disease varies from 40/100,000 individuals in North Europe to more than 200/100,000 among African Americans (Tsokos 2011).

36.3.5.2 Etiology and Pathogenesis

Since the prevalence of the disease is higher among women, a role of female sex hormones has been described in the pathogenesis of SLE. Lupus can be drug-induced or may follow an antecedent viral-like illness. Other environmental factors linked with SLE include exposure to ultraviolet radiation (Mak and Tay 2014).

Genetic factors have also been implicated in the pathogenesis of SLE. The concordance rate is 25% among monozygotic twins and 2% among dizygotic twins. The pathogenesis of the disease has also been linked to HLA haplotypes such as HLA A1, B8 and DR3. The HLA subtype may be associated with enhanced response of the T cells to antigenic stimuli. In addition, genetic influences leading to deficiency of early complement factors such as C1q or C2 have also been linked to SLE.

Autoantibodies play a key role in the pathogenesis of SLE. Activation of T- and B lymphocytes occurs via various cellular pathways along with tissue injury due to formation of circulating immune complexes. Antibodies associated with SLE include anti-RO, anti-LA, anti-C1q, anti-Sm, anti-nucleosome and anti- α actinin, among several others (Tsokos 2011).

36.3.5.3 Clinical Features

Ocular manifestations may occur in more than one-third of patients diagnosed with SLE. SLE can occur at almost any anatomical location in the eye and the visual pathway. The most common finding of SLE is dry eye or keratoconjunctivitis sicca. SLE may be associated with secondary Sjögren's syndrome. Slit-lamp examination may reveal diffuse or localized corneal epitheliopathy and reduced tear production.

Severe corneal involvement may present with peripheral ulcerative keratitis, interstitial keratitis and corneal melt/ulceration. SLE may be associated with conjunctivitis, episcleritis and scleritis (Read 2004).

Anterior segment involvement can present with anterior uveitis. Lupus associated retinopathy may occur in 3–29% patients with the disease. SLE-associated retinopathy is secondary to microangiopathy caused by immune-complex mediated damage to retinal vascular endothelium. It is characterized by cotton wool spots, intraretinal hemorrhages, arteriolar narrowing, retinal edema and exudation. Severe vaso-occlusive disease is rare but can present with sight-threatening complications. Large vessel (central or branch retinal arteriolar/venular) occlusions may be observed. Patients with diffuse retinal vascular damage are at high risk for visual loss. Frosted branch angiitis and extensive macular exudation has also been reported in association with SLE (Palejwala et al. 2012). Although less known than retinopathy, lupus choroidopathy may be more common than what is generally appreciated. It usually serves as a sensitive indicator of lupus activity. The presence of SLE choroidopathy is generally indicative of coexistent (although sometimes occult) nephropathy, central nervous system (CNS) vasculitis, and other SLE visceral lesions (Nguyen et al. 2000).

Approximately 30–40% patients may present with involvement of the central nervous system (*neuropsychiatric lupus*). This condition is characterized by psychosis, neurological deficits resulting from thrombosis, limbic encephalitis, mononeuritis complex and polyneuropathy (Hanly 2014). Optic neuritis in association with SLE is rare (Lin et al. 2009).

36.3.6 Systemic Vasculitides Associated with Ophthalmic Manifestations

Systemic vasculitis is caused by an autoimmune process and is characterized by leucocytic infiltration of the vascular wall and necrosis. Rarely, systemic vasculitis may be associated with concomitant ophthalmic manifestations, including inflammation of the ocular vasculature. This is distinguished from retinal vasculitis, which is a term used to describe inflammatory involvement of retinal arterioles or venules. Retinal vasculitis usually occurs as an isolated, idiopathic disease.

Systemic vasculitis can have protean ophthalmic manifestations and these may precede systemic involvement, making the diagnosis challenging. Central nervous system involvement may result in neuro-ophthalmologic symptoms in addition to ocular inflammation. Among systemic vasculitis, granulomatosis with polyangiitis (GPA; previously known as Wegener's granulomatosis), polyarteritis nodosa (PAN) and giant cell arteritis (GCA) are common entities with ophthalmic manifestations (Abu El-Asrar et al. 2005).

36.3.6.1 Granulomatosis with Polyangiitis

GPA is a rare, systemic autoimmune disease associated with anti-neutrophil cytoplasmic antibody (ANCA)-mediated vasculitis and predilection to involve the respiratory tract and kidneys. Ocular involvement is known to occur in 28–59 % patients with GPA. On the other hand, neurological manifestations may occur in 10–45 % patients. The disease is most common in the Caucasian population and the peak incidence is observed in the fifth decade of life (Tarabishy et al. 2010).

The most common ocular manifestation seen in GPA is necrotizing scleritis, which may occur in more than 50 % patients with ocular GPA. Thinning of the sclera may result in perforation. GPA may also be associated with episcleritis and tarso-conjunctival disease resulting in formation of fibrosis, granulomas and eyelid abnormalities such as trichiasis and entropion. Orbital inflammatory disease (pseudotumor) may present with pain, epiphora, proptosis, lacrimation and movement disorders (Isse et al. 2013). Paranasal granulomas in GPA may result in *bony erosion* and secondarily involve the orbit and adnexa (Jiang et al. 2013). Optic nerve dysfunction may occur, either due to compression or direct invasion with granuloma formation. Ensuing fibrosis may result in orbital socket compression and enophthalmos (Tan et al. 2014).

Corneal involvement may present with peripheral ulcerative keratitis, interstitial keratitis or it may be associated with scleritis (*sclerokeratitis*) (Florine et al. 1993). Retinal disease results in severe visual morbidity. Retinal involvement may present with chorioretinitis, macular edema, exudative retinal detachment or retinal necrosis. Associated retinal vasculitis may result in central or branch retinal artery or vein occlusion.

36.3.6.2 Polyarteritis Nodosa

PAN is a multisystem necrotizing vasculitis affecting small and medium-sized arteries in the heart, kidneys, central nervous system and gastrointestinal system. Ocular involvement in PAN is seen in 10–20 % of the cases. The incidence of PAN is higher among males between the age-groups 40 and 60. The most common ophthalmic association is *choroidal ischemia*, which is usually recognized at autopsy (Vodopivec et al. 2014).

The ocular manifestations of PAN include retinal vascular diseases such as retinal vasculitis, hemorrhage, edema and central or branch retinal artery occlusion. Vascular supply of the optic nerve may be affected resulting in anterior or posterior ischemic optic neuropathy (Emad et al. 2007). Similar to GPA, PAN may be associated with scleritis, episcleritis, keratitis, non-granulomatous iritis and exudative retinal detachment.

Neurological disease may manifest with papillitis, Extraocular muscle palsies, amaurosis fugax, homonymous hemianopia and rarely, nystagmus. Mononeuropathy

multiplex is among the most common findings in patients with PAN (Paula De Carvalho Panzeri Carlotti et al. 2004).

36.3.6.3 Giant Cell Arteritis

GCA is the most common form of granulomatous medium-to-large vessel vasculitis. The most common vessels affected include aorta, extradural cranial vessels, ophthalmic artery, posterior ciliary arteries, superficial temporal artery and occasionally, the central retinal artery. The disease is most common above 50 years of age and the incidence increases with age. Individuals of Scandinavian or North European origin have the highest incidence of the disease. Familial clustering of the disease is noted along with HLA DRB1*04, DRB1*01 and DW6 associations (McAlinden et al. 2014).

Visual loss in GCA was first described by Jennings in 1938. Ophthalmic involvement in GCA presents as sudden-onset visual loss and is considered to be an *ophthalmic emergency*. The diagnosis of the condition is confirmed by biopsy of the temporal artery, which presents as nodular granulomatous infiltration of the vessel wall. However, the treatment with high-dose glucocorticosteroids is initiated prior to the biopsy results due to the high risk of blinding complications and fellow eye involvement. The involvement of the fellow eye can occur within 14 days in one-third of the untreated cases (Kale and Eggenberger 2010).

The most common ocular manifestation of GCA is arteritic anterior ischemic optic neuropathy (AAION), which can result in acute visual loss in 60 % patients. Up to 21 % patients may have no light perception. AAION manifests with a chalky white optic disc edema. Posterior ischemic optic neuropathy usually presents with a normal appearing optic nerve head. Central retinal artery occlusion can occur in up to 10 % patients with GCA (Kale and Eggenberger 2010).

Neuro-ophthalmic manifestations of GCA include extraocular muscle ischemia resulting in paresis/palsies, Horner's syndrome, anterior segment ischemia, hypotony and diplopia. Uveitis is an uncommon manifestation of GCA. Temporal or occipital headache, scalp tenderness, *jaw claudication* and constitutional symptoms such as fever, malaise, anorexia and myalgia are important clues to the diagnosis of this condition (Chew et al. 2009).

36.3.7 Systemic Arthritides Associated with Ophthalmic Manifestations

36.3.7.1 Rheumatoid Arthritis

Rheumatoid arthritis (RA) is the most common systemic autoimmune condition affecting 1 % of the population. The principle target of the inflammatory damage in RA is the

Fig. 36.8 Systemic deformities seen in patients with rheumatoid arthritis (RA) and relapsing polychondritis (RP). (a) shows characteristic ulnar drift, swelling of metacarpal joints and rheumatoid nodules in an elderly patient. (b) shows appearance of an inflamed vessel in a patient

with RA. (c) shows inflammation and destruction of the auricular cartilage in a patient with RP. (d) shows the characteristic saddle nose deformity due to cartilage destruction in a patient with RP. Figures A-D are courtesy of Professor C. Stephen Foster (Walham, MA, USA)

synovial tissue and cartilage (Fig. 36.8). However, RA may be associated with a number of extra-articular systemic manifestations including ophthalmic involvement. Autoimmune damage affecting other visceral organs in RA can be life-threatening.

The most frequent ophthalmic involvement in patients with RA is the damage to the ocular surface, resulting in dry eyes. The involvement of ocular surface in patients with RA has immunologic similarities to the joint disease, with evidence to suggest a heightened state of both, adaptive and innate immune system responsiveness. *Keratoconjunctivitis sicca* is characterized by increased number of antigen-presenting cells, and decreased anti-inflammatory cytokines such as IL-13 and decreased suppressor T cells (T_{reg}) (Tong et al. 2014). Dry eye may be complicated with chronic kera-

titis, ulceration and corneal melt due to poor tear-film. Frequency of dry eye syndrome may be as high as 45–71% in patients with RA.

Patients with RA may develop *peripheral ulcerative keratitis (PUK)*, an inflammatory thinning of the peripheral cornea that may lead to perforation. PUK occurs in approximately 3% patients with RA and is bilateral in 40% patients. Usually, PUK appears as a crescent-shaped peripheral corneal infiltration associated with scleritis. RA is the most common cause of scleritis and is associated with 20% of the cases. In 10% cases, the diagnosis of scleritis may precede the diagnosis of RA. Necrotizing scleritis is an extra-articular condition associated with an increased risk of death in patients with RA. Scleritis may be complicated by scleral perforation (*scleromalacia perforans*). Other ocular mani-

festations in patients with RA include conjunctivitis and episcleritis (Artifoni et al. 2014; Galor and Thorne 2007).

36.3.7.2 Sero-Negative Spondyloarthropathies

Sero-negative spondyloarthropathies (SSpAs) are a group of chronic inflammatory conditions affecting the axial skeleton, characterized by a negative serum rheumatoid factor. SSpAs are strongly associated with HLA B27 positivity. SSpAs include ankylosing spondylitis, reactive arthritis, psoriatic arthritis and arthritis associated with inflammatory bowel disease (Crohn's disease and ulcerative colitis), among other entities. Inflammatory eye disease is the most common extra-ocular manifestation of SSpAs with incidence of 25 % in patients with ankylosing spondylitis and 10 % with psoriatic arthritis (Zagora and McCluskey 2014; Zochling and Smith 2010).

The hallmark manifestation of SSpA is anterior uveitis, occurring in up to 40 % cases. Anterior uveitis is typically acute, unilateral or alternating between the two eyes. Epidemiological data suggests that there may be a mean of 5 attacks of uveitis during the course of the disease (Monnet et al. 2004). Ankylosing spondylitis may be associated with *hypopyon uveitis*. Episcleritis, scleritis and conjunctivitis may occur with SSpAs. Involvement of the posterior segment is less common. Infrequently, posterior or panuveitis may develop in patients with inflammatory bowel disease (Zagora and McCluskey 2014).

36.3.7.3 Relapsing Polychondritis

Relapsing polychondritis (RP), first coined by Pearson et al., is a multisystem chronic inflammatory disease primarily affecting the musculoskeletal system. The disease spectrum may vary from mild intermittent episodes of auricular and nasal cartilage pain to life-threatening airway disease. The peak age of onset of the disease is in the fifth decade of life and it is thought to be more common among women. The etiology of RP remains unknown thus far. Circulating antibodies against collagen II, IX and XI, as well as immune-complex deposition have been implicated in the pathogenesis of the condition (Sharma et al. 2013).

Most patients with RP present with auricular chondritis sparing the ear lobule. Progressive destruction and deformities may also involve the nasal cartilage in more than 80 % patients, resulting in *saddle nose deformity* (Fig. 36.8). Approximately 33 % patients may present with joint pain. The most common cause of death in these patients is due to laryngotracheal involvement leading to destruction, dislocation and stricture formation (Puechal et al. 2014; Sharma et al. 2013).

Ocular disease is seen in approximately 50 % patients with RP. Common ocular manifestations include scleritis, episcleritis and conjunctivitis (Rucker and Ferguson 1965). There may be associated corneal thinning. Uveitis is seen in

25 % patients and usually presents as sclerouveitis or iridocyclitis. Retinal involvement may present with exudates, hemorrhages and retinal vascular occlusion (Isaak et al. 1986). Orbital involvement manifests as proptosis, periorbital edema or extraocular muscle palsy (Yoo et al. 2011).

36.3.8 Myasthenia Gravis

Myasthenia gravis (MG) is a systemic autoimmune disease affecting the neuro-muscular junction and presenting with a wide variety of ophthalmic manifestations. Ocular MG is a localized form of the disease characterized by involvement of extraocular muscles, levator palpebrae superioris and orbicularis muscles with sparing of the pupillary muscles. This condition can easily masquerade cranial nerve palsies and INO due to nystagmus and limitation of movements. A history of weakness with diurnal variation and fatigue should raise a suspicion of ocular MG (Weinberg et al. 1994).

36.3.8.1 Epidemiology

Ocular MG may affect any age group and there is no racial or geographic predilection. The onset of the disease is rare in the first decade and after the seventh decade of life. Overall, women are affected more than men. However, the incidence of the disease is higher in men above the age of 50 years. Among individuals with pure ocular MG, the incidence is higher among men (Vaphiades et al. 2012).

36.3.8.2 Clinical Features

Among patients presenting with ocular disease, about 50–80 % progress to a generalized disease. Extraocular muscles are frequently affected in ocular MG as they are composed of fast-twitch muscle fibers and have a higher rate of synaptic firing. The tonic fibers, which are responsible for gaze, may be affected resulting in gaze paresis. Ptosis and diplopia are initial signs of the disease in over 50 % patients with MG. The ptosis worsens under stress such as prolonged upward gaze. Lifting of eyelid may result in enhancement of ptosis of the contralateral side. Ice-pack applied to the eyelid may result in improvement in the degree of ptosis. Ptosis can be unilateral or bilateral and is usually asymmetric (Elrod and Weinberg 2004).

Small amplitude upward movement of the eyelid (*hopping*) during lateral gaze is referred to as the *Cogan lid twitch sign*. Reverse Cogan lid twitch sign is the downward movement of the eyelid elicited by saccade to primary position from upgaze. Lid retraction and orbicularis weakness are other eyelid signs of MG. *Peek sign* is the increased visibility of the sclera due to drifting apart of the eyelid without forceful opening (Barton and Fouladvand 2000).

Extraocular muscle weakness in MG may mimic cranial nerve palsies or INO (*pseudo-INO*). However, gaze-evoked

vertical nystagmus, classical feature of INO, is absent in ocular MG. Medial rectus is the most commonly affected muscle. Ocular MG may thus, mimic incomitant strabismus. Saccadic movements and nystagmus is also common in MG (Vaphiades et al. 2012; Nair et al. 2014).

Various clinical tests such as the ice pack test, edrophonium (Tensilon) test or sleep test, and laboratory evaluations such as repetitive nerve stimulation or single-fiber electromyography may help in the diagnosis of this condition (Nair et al. 2014).

36.3.9 Graves' Disease

Graves' ophthalmopathy (GO), also known as thyroid eye disease, is an autoimmune thyroid disease with orbital manifestations. While more than 25 % patients with Graves' disease manifest with GO, subclinical disease can be found in over 70 % patients using imaging techniques such as orbital MRI. Unless treated appropriately, patients with severe GO may develop sight-threatening sequelae with a high risk of permanent blindness (Wiersinga and Bartalena 2002).

36.3.9.1 Epidemiology

The incidence of GO is approximately 16 per 100,000 in females and 2.9 per 100,000 in males in the United States. The estimated prevalence of the disease is 0.25 %, ranging from 0.1 to 0.3 % world over. The disease is more common in women with female to male ratio ranging from 9.3 to 1.4 depending upon the severity of the disease. Men are more commonly affected with severe forms of the disease with a female to male ratio of 1:4. The disease has bimodal age distribution with peaks in the 40s and late 60s. GO is rare in children with an incidence of <0.1 per 100,000 (before puberty). A number of racial, anatomical and environmental factors play a role in the epidemiology of GO. Cigarette smoking plays an important role in the development and occurrence of GO and adversely affects the severity of the disease. More than 80 % patients with GO have hyperthyroidism at the onset of the disease. Approximately 50 % patients with euthyroid Graves' disease develop hyperthyroidism within 2 years of the disease onset (Carter and Utiger 1992; McAlinden 2014).

36.3.9.2 Clinical Features

The most common presenting feature of GO are eye lid signs such as lid retraction and lid swelling. There may be widened palpebral fissure with decreased blink rate (*frightened face*). The patients may develop lid lag in downgaze (*von Graefe's sign*), and loss of eyebrows in the extreme third of the lid (*Hertoge's sign*). Hyperpigmentation of the superior eye lid folds is known as *Jellinek's sign*. Upper eye lid retraction resulting in excessive scleral show is known as *Stellwag's*

sign. Due to an increase in the orbital fat volume and infiltration by inflammatory cells, there is proptosis and enlargement of extraocular muscles (sparing the tendons) resulting in diplopia. If left untreated, the muscles may lose the ability to contract and become rigid, resulting in increased intraocular pressure in the up-gaze (*Sattler's sign*). Eventually, patients may develop paralytic strabismus and permanent lid lag. Lack of convergence of the eye balls is known as *Moebius's sign*. Patients may develop limitation of abduction and rotation of eyeball (*Jendrassik's sign*). Horizontal nystagmus or complete ophthalmoplegia may develop.

Complications such as exposure keratopathy may occur resulting in staining of the corneal surface. Neglected cases may develop corneal ulceration that may progress to perforation. Due to excessive mechanical stretch, the optic nerve may develop edema and atrophy (*dysthyroid optic neuropathy*), which may develop in approximately 3–7 % patients with GO. Corneal and optic nerve complications may lead to permanent visual loss among patients with GO (Saraci and Treta 2011; Yeatts 1995).

36.4 Miscellaneous Neuroimmune Diseases with Ophthalmic Involvement

36.4.1 Susac's Syndrome

Susac's syndrome (SS) is a rare, autoimmune microangiopathy characterized by infarcts in the brain, retina and cochlea. The classical triad of SS includes neurological dysfunction (*encephalopathy*), multiple branched retinal arteriolar occlusions (*BRAOs*) and sensorineural hearing loss. The disease typically occurs in young women and is often misdiagnosed as MS. Fluorescein angiography may detect presence of multiple BRAOs that may result in variable visual field loss. In addition to BRAOs, SS may be associated with retinal vasculitis (Greco et al. 2014). Unusual neurological manifestations, such as cauda equine syndrome, may occur in patients with SS (Allmendinger et al. 2014).

36.4.2 Cogan's Syndrome

Cogan's syndrome is characterized by non-syphilitic interstitial keratitis and bilateral audio-vestibular defects secondary to an autoimmune process. The autoantibodies may be directed against antigenic peptides expressed in epithelial cells in the inner ear. Corneal involvement presents with granular, irregular corneal infiltrate affecting the posterior stroma and endothelium. Ocular inflammation may manifest as scleritis, episcleritis, conjunctivitis, retinal vasculitis or papillitis. More than 90 % patients have associated systemic

symptoms. Neurological disease includes aseptic meningitis, hemiparesis or hemiplegia, pyramidal syndrome, vigilance disorders or trigeminal neuralgia. One-fourth patients may also present with cardiovascular, gastrointestinal or musculoskeletal disease (Kessel et al. 2014; Azami et al. 2014).

36.4.3 Reactive Arthritis

Reactive arthritis is a multi-system autoimmune seronegative disease that develops 1 to 3 weeks after gastrointestinal or genitourinary infection. Antigens from gram negative intracellular bacteria may trigger an inflammatory cascade with CD4 T Helper cell and CD8 response following mucosal invasion (Stavropoulos et al. 2015). While there are no diagnostic criteria established for reactive arthritis, the condition primarily affects the joints resulting in arthritis similar to psoriasis and is associated with urethritis and conjunctivitis/uveitis. Some forms of reactive arthritis developing the triad were previously referred to as 'Reiter's syndrome'. However, the term reactive arthritis encompasses a broader category of the disease (Selmi and Gershwin 2014). Ocular manifestations are often frequent in this condition, with more than 50% men experiencing conjunctivitis or acute anterior uveitis. Patients may also develop genital lesions and other visceral involvement, including cardiac valvular abnormalities and conduction defects.

36.4.4 Primary Sjögren's Syndrome

Sjögren's syndrome is a multisystem autoimmune condition with lymphocytic infiltration of the exocrine glands, such as the salivary and lacrimal glands. In addition, the disease can affect the nervous system in about 20% cases resulting in *sensory ganglionopathy* or transverse myelitis. Other visceral manifestations include interstitial lung or kidney disease, autoimmune hepatitis or pancreatitis. Ocular manifestations include dry eye, corneal haze/scarring, *sterile corneal melt* and papillary or cicatrizing conjunctivitis. Sjögren's may be associated with scleritis, episcleritis or uveitis (Akpek et al. 2015). Cases with optic neuritis and retinal vasculitis have been reported in literature (Tang and Wei 2013).

36.4.5 Dermatomyositis

Dermatomyositis is an inflammatory myopathy characterized by cutaneous manifestations that occur in the presence of minimal muscle involvement. Other features of the disease may include multiple systemic involvement and/or underlying malignancies. The typical rash of dermatomyositis is described as heliotrope rash (face), Gottron's papules (hands and elbows), and trunk (shawl and 'V' sign). The dis-

ease has two distinct forms—adult and juvenile (Luo and Mastaglia 2015). In a large series of 108 patients with juvenile dermatomyositis, eye lid manifestations (supraciliary heliotrope line with or without telangiectatic vessels, lid scarring, or pox-like lesions) were the most common manifestations. Other ocular manifestations include cataract (posterior subcapsular variety), retinal hemorrhages, and retinal vasculitis that may manifest as frosted branch angiitis (Lee et al. 2011).

36.5 Review Questions

- The following clinical features are seen during the acute stages of Vogt-Koyanagi-Harada disease except:
 - Exudative retinal detachment
 - Subretinal fluid
 - Choroidal thickening
 - Sun-set glow fundus*
- The pathogenesis and clinical features of Vogt-Koyanagi-Harada disease is most closely related to which of the following condition:
 - Serpiginous choroiditis
 - Sarcoidosis
 - Sympathetic Ophthalmia*
 - Graves' disease
- Choroidal manifestations in Vogt-Koyanagi-Harada disease include all of the following except:
 - Choroidal excavation*
 - Choroidal thickening
 - Choroiditis
 - Nummular choroidal scars
- Most common Human Leucocyte Antigen (HLA) associated with Adamantiades-Behçet's disease includes:
 - HLA B-27
 - HLA B51/5*
 - HLA A29
 - HLA DRB1
- Which of the following is the most common systemic manifestation of Adamantiades-Behçet's disease?
 - Central nervous system vasculitis
 - Genital ulcers
 - Oral ulcers*
 - Uveitis
- According to recent estimates, which of the following individuals are at an increased risk of developing sarcoidosis?
 - Caucasian males
 - Hispanic females
 - Caucasian females
 - African-American females*
- Which of the following cells play a central role in the pathogenesis of sarcoidosis:
 - CD4 -T Helper cells*
 - Cytotoxic CD8 cells

- c. Eosinophils
- d. Natural Killer cells
8. Worsening of vision provoked by small increases in body temperature attributed to exercise, hot baths or showers, or hot weather conditions among patients with Multiple Sclerosis is described as:
 - a. Sugiura's sign
 - b. Uhthoff's phenomenon
 - c. Pulfrich's phenomenon
 - d. Von Graefe's sign
9. Among patients with rheumatoid arthritis, the most common ocular involvement includes:
 - a. Dry eye syndrome
 - b. Optic neuritis
 - c. Choroiditis
 - d. Subretinal fluid
10. Susac's syndrome is characterized by presence of:
 - a. Central retinal artery occlusion
 - b. Branch retinal vein occlusion
 - c. Cilio-retinal artery occlusion
 - d. Branch retinal artery occlusion
11. Cogan Lid Twitch sign is described as:
 - a. Small amplitude upward movement of the eyelid during lateral gaze
 - b. Nystagmoid movements of the eyes
 - c. Presence of internuclear ophthalmoplegia
 - d. Ptosis

Tomomi Kiyota

Abstract

Neurogenesis is the complex process of generating new neurons in the central nervous system (CNS). Classically, neurogenesis was believed to only occur during embryonic development, never after the postnatal stage. However, the evolution of technologies in cellular and molecular biology, radiology, and so forth has resulted in the discovery of neurogenesis and neural stem cells (NSCs)/neural progenitor cells (NPCs) in the adult brain. While the discovery has led to the potential for the repair of the injured or diseased brain, there are a number of issues yet to be resolved. The complex-three dimensional structure and organization of the adult brain limits the differentiation and integration of implanted NSCs/NPCs and thereby for the repair. In this chapter, recent advances in the study of embryonic and adult neurogenesis will be described including the defining of mechanisms, molecular markers and regulatory factors operative during neurogenesis, as well as recent findings into the role of adult neurogenesis in brain disorders and brain repair.

37.1 Introduction

Neurogenesis is a complex process for generating new neurons in the brain and spinal cord. The process includes cell proliferation, production of migratory progeny, differentiation and functional integration into the neural circuitry in the central nervous system (CNS). The classical dogma of neurogenesis asserts that the process only occurs during embryonic development and prenatal stage, and new neurons are never generated after postnatal stage. Santiago Ramón y Cajal described that “in the adult centers the nerve paths are something fixed,

ended and immutable. Everything may die, nothing may be regenerated” (Ramón y Cajal 1913). This long-held theory was based on a concept that the brain is a complex-three dimensional structure with a very complex and hierarchically organized neural circuitry for the integration of new neurons as compared to other organs. However, the dogma was invalidated by Joseph Altman, who discovered new neuron generation in the brains of adult mammals, thus called adult neurogenesis, in the 1960s (Altman and Das 1965a, b; Altman 1969). Although the sensational discovery of the seminal phenomenon of adult neurogenesis was out of the neuroscience mainstream, it was re-recognized a few decades later in songbirds (Goldman and Nottebohm 1983) and then mammals including rodents, rabbits, monkeys and even in humans (Emsley et al. 2005; Ming and Song 2005; Martino et al. 2011). Moreover, the idea of adult neurogenesis was further affirmed by the discovery of neural stem cells (NSCs)/neural progenitor cells (NPCs) that can proliferate by growth

factors: epidermal growth factor (EGF) and fibroblast growth factors (FGFs), and differentiate directly into neurons and glia throughout life in the mammalian brain (Reynolds and Weiss 1992; Lois and Alvarez-Buylla 1993). These observations have incited enormous and attractive interest among neurobiologists and clinicians to study adult neurogenesis in hopes of harnessing capability of brain repair.

Gliogenesis, the generation of new glial cells, occurs from late embryogenesis stage and throughout postnatal stages, as well as in the adult brain where both astrocytes and oligodendrocytes are produced (Rowitch and Kriegstein 2010; Gallo and Deneen 2014). In contrast, neurogenesis is initiated at an early developmental stage and continued throughout early postnatal stages. However, neurogenesis is inactive in the adult brain except in two main neurogenic niches: the subventricular zone (SVZ) of the lateral ventricle (LV) and the subgranular zone (SGZ) of the hippocampal dentate gyrus (DG) (Gage 2000; Alvarez-Buylla and Lim 2004; Zhao et al. 2008; Ming and Song 2011). Over the last two decades researchers have studied adult neurogenesis in the two neurogenic niches as a model for understanding of which genetic factors and stimuli propel NSCs/NPCs toward a neuronal fate, differentiate them into neurons, guide their final destination and facilitate their integration into the neural circuitry. A thorough understanding of adult neurogenesis will ultimately contribute to exploiting these processes for brain repair to treat neurological disease. This chapter delineates recent advances in embryonic neurogenesis and in defining mechanisms, molecular markers and regulatory factors operative during adult neurogenesis. The descriptions also serve to introduce experimental outcomes for brain repair in animal models of neurological disease.

37.2 Neural Development

37.2.1 Early Embryonic Neurogenesis

In embryonic development, node cells intercalate and migrate toward rostral side of the embryo to generate the prechordal plate and notochord during gastrulation. Both prechordal plate and notochord are the “organizers” and signaling centers that induce formation of the monolayer neural plate including neuroepithelial cells (NECs) that serve as the primary neural precursors of the CNS. While the notochord defines the primitive axis that is ultimately replaced with the spinal cord, the prechordal plate plays a critical role in defining brain vesicles. The neural plate is shaped and then bended with V-shaped cross-section of the neural groove. In parallel, the neural plate is folded at its edges that are fused at midline of the embryo for neural plate closure, which is initiated at the hindbrain/cervical boundary and

extends simultaneously to what will become the brain and spinal cord. The closure results in formation of the early neural tube, constituted of pseudostratified epithelium with a central canal underneath ectoderm that completes at the anterior and posterior neuropores. This series of events, called primary neurulation, creates the primordial portions of the brain and most of the spinal cord (Colas and Schoenwolf 2001; Copp et al. 2003).

After neural tube formation, neurogenesis occurs in temporally and spatially defined configurations along the anterior-posterior (AP), ventral-dorsal (DV), and lateral-medial body axes (Taverna et al. 2014). Along these axes NECs are patterned by morphogen gradients that govern the pattern of guiding tissue and development and where and how various specialized neural cell types develop. Well-studied morphogens involved in this process include sonic hedgehog (SHH), bone morphogenetic proteins (BMPs), wntless/int (Wnt) proteins, and FGFs. For the DV axis, SHH is ventrally expressed in the floor plate and released toward the dorsal side. In contrast, BMPs and Wnts are dorsally expressed in the roof plate and contribute to the patterning of the dorsal-ventral axis of the neural tube. Importantly, SHH signaling antagonizes BMP signaling to generate a counteracting gradient that defines the spatially different expression patterns of transcription factors (Pax6, Pax7, Irx3, Dbx2, Olig2, Nkx2.2, Nkx6.1, among others) (Fig. 37.1a). Therefore, neural progenitor fates in each pattern are determined by the morphogens along the DV axis of the neural tube, which mostly becomes the spinal cord at the later stage (Ulloa and Briscoe 2007; Dessaud et al. 2008; Cohen et al. 2013). Regarding DV patterning in anterior parts (future brain region) of the neural tube, SHH plays as a ventral key center as seen in posterior parts (spinal cord). However, detailed mechanisms that establish the DV axis differ from those in posterior parts of the neuraxis. In particular, activity of Gli3 that acts as a repressor of its target genes is antagonized by SHH signaling to determine DV patterning in the development of the telencephalon (Rallu et al. 2002a). Deficiency of *Shh* or *Gli3* gene activity causes persistent expression of ventral telencephalic markers (Dlx2 and Gsh2), indicating that the balance of activities between SHH and Gli3 is critical for establishing DV patterning in the telencephalon (Rallu et al. 2002b).

The initial AP axis including specification of the forebrain is determined before and during gastrulation. At the gastrulation stage, non-neuronal tissues, anterior visceral endoderm (AVE) and the prechordal plate below the developing nervous system, are required for head induction and maintenance (Wilson and Houart 2004; Stern 2001). AVE and the prechordal plate play critical roles as signaling centers in specifying neural fate in the early forebrain development. The centers seem to produce morphogen antagonists to inhibit diffusible posteriorizing factors including Wnts,

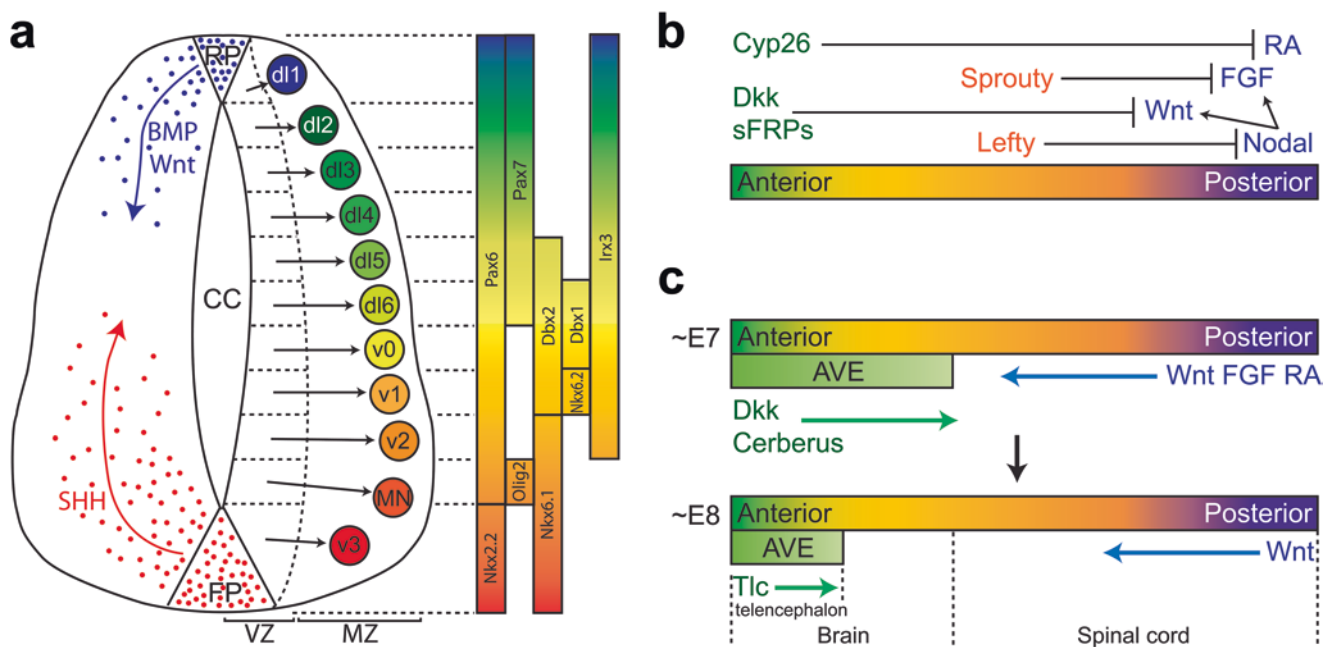

Fig. 37.1 (a) (Left) Diagram of a section of the spinal cord. The left half shows morphogen gradients of BMPs/Wnts from the roof plate (RP) and SHH from the floor plate (FP). The right half indicates the 11 neuronal progenitor domains located in the ventricular zone (VZ), medially adjacent to the central canal (CC). The morphogen gradients spatially control position identity of the progenitor domains where distinct neuronal subtypes are generated. Postmitotic differentiated neurons are divided into six types of dorsal domains (dl1–dl6), four types of ventral interneuron domains (v0–v3) and motor neurons (MN) in the mantle zone (MZ). (Right) The spatial pattern of morphogen gradients regulates transcription factor expression. Different combinations of transcription factors define individual progenitor domains. (b) Anterior-

posterior (AP) patterning during CNS development in fish and frogs. In neurulation, retinoic acid (RA) and Nodal, inducing Wnt and FGF, serve as diffusible posteriorizing factors. They are antagonized by Cyp26, Lefty, Frizzled-related proteins (Frzb: secreted FRPs) and dickkopf (Dkk), respectively, at the posterior part of embryos to specify the AP axis. (c) During mammalian development, Wnt, FGF and RA characterize the AP axis in the neural plate as in fish and frog embryos. Dkk and Cerberus are expressed in the anterior visceral endoderm (AVE) and antagonize Wnt signaling, shaping the anterior neural plate domain. Subsequently, Tlc, a member of FRPs, further antagonizes Wnt signaling to subdivide the domain, designating future telencephalon region. E, embryonic day

FGFs, Nodal and retinoic acid (RA) (Altmann and Brivanlou 2001; Schier 2001). Studies in fish and frogs have implicated that secreted Frizzled-related proteins (Frzb) and dickkopf (Dkk1–3 in mice) are expressed in the anterior endoderm (equivalent to the AVE) of frog embryos and antagonize Wnts. Nodal and FGF signaling are inhibited by Lefty and Sprouty, respectively, and Cyp26 proteins degrade RA into its polar metabolites to inhibit discrete levels of RA signaling at the posterior part of the embryo (Fig. 37.1b) (Tuazon and Mullins 2015). Although it is unclear how morphogen antagonists function in mammalian development, studies regarding removal or transplantation of the AVE, or mutations in genes such as *Otx2*, *Lim1* and *Hesx1* that are expressed in the AVE, support the concept that the AVE serves as a determinant to specify forebrain fate in unpatterned NECs (Rallu et al. 2002a). After anterior neural induction, Tlc, a member of Frzb, also serves as an antagonist of Wnt signaling, plays an important role in mediating establishment of telencephalon at the anterior neural ridge, and partitions the forebrain into its subdivisions of telencephalon, diencephalon and optic territories (Fig. 37.1c) (Houart et al. 2002).

37.2.2 Cerebral Cortex Development and the VZ/SVZ

The telencephalon gives rise to the cerebral cortex comprised of the neocortex and allocortex (also known as heterogenetic cortex). Fundamental telencephalon territory is determined at around mouse embryonic day (E) 9.5. NECs initially form symmetric cell divisions that provide lateral and radial expansion of their cell population for cerebral cortex development (Rakic 1995). The process is active at the anterior edge in particular, as well as in the area surrounding the lumen of the neuraxis. Meanwhile, NECs are polarized along the apical-basal axis with mitosis occurring at the apical-most germinal layer that is closest to the lumen and one of the germinal niches called the VZ. In the VZ, NECs form a belt of linkage called adherens junctions (AJ), connecting neighboring NECs to one another (Marthiens and French-Constant C 2009). NECs, now transformed into neural progenitor cells (NPCs), undergo interkinetic nuclear migration (INM), nuclear migration in the cytoplasm along the apical-basal axis of the neuroepithelium during S-phase in mitosis,

and form a pseudostratified epithelium (Sauer and Walker 1959; Taverna and Huttner 2010).

The earliest cortical neurons are generated from NPCs at around E10.5, and settle within the preplate (PP) (De Carlos and O'Leary 1992), which is split into the superficial marginal zone (MZ, Layer (L)1 of the postnatal cortex), the cortical plate (CP, the postnatal L2-L6) and the subplate (SP) underneath the CP. Starting at around E11-12, NPCs transform into radial glial cells (RGCs) with their somata locating at the VZ and integrating into AJ belts, their short processes reaching the ventricle (apical side), and their long processes reaching basal lamina. RGCs express astroglial markers such as glial fibrillary acidic protein (GFAP), glutamate/aspartate transporter (GLAST) and brain lipid binding protein (BLBP) (Campbell and Gotz 2002). Like NPCs, RGCs undergo INM in the VZ, and begin cell divisions both symmetrically and asymmetrically to produce daughter RGCs and intermediate progenitor cells (IPCs) or neurons (Gotz and Huttner 2005). Newly formed neurons migrate radially from the VZ toward the pial surface through the intermediate zone using RGC basal processes as guiding scaffolds and then reach their final destination (Rakic 1972, 1988). Cajal-Retzius (CR) cells have a major role in neuronal cell migration. The CR cells are generated as the earliest cortical neurons, and lie in the superficial MZ, and serve as “a director” to regulate the identity of radial glia and migration of neurons during cerebral cortex development. They are transient as most of the cells disappear by cell death at postnatal stages (Derer and Derer 1990; del Rio et al. 1995; Soriano et al. 1997). IPCs migrate from AJ belts, accumulate and line up above the VZ, and form a second germinal zone, called the SVZ. IPCs lose their processes and AB polarity, down-regulate astroglial markers, and undergo one round of symmetric neurogenic division to generate a pair of neurons that also radially migrate from the SVZ to their final destination using RGC basal processes (Gal et al. 2006). Newly generated neurons from both RGCs and IPCs migrate into the cerebral cortex and reach the most superficial side of the CP to form the mantle layer, overlaying leading neurons so that the CP is formed in order of L6–L2. At around E17, the end of embryonic neurogenesis, RGCs retract their basal processes and become gliogenic to generate astrocytes and ependymal cells (ECs) that line the ventricles (Fig. 37.2) (Kwan et al. 2012; Florio and Huttner 2014; Bjornsson et al. 2015).

37.2.3 Hippocampal Formation During Development

The allocortex is comprised of three subtypes: the periallocortex, paleocortex and archicortex. The hippocampal primordium is located within the archicortex. The hippocampus

originates from the caudomedial edge of neuroepithelium, a transient structure after the invagination of the roof in the dorsal telencephalon (Lee et al. 2000). Although the hippocampal DG originates from the VZ, the hippocampus formation including the DG is very unique. At around E 14.5, dentate NPCs migrate from the dentate neuroepithelium (also called the primary matrix), a part of the VZ in the archicortex and adjacent to the cortical hem (CH), toward the pial-midline side of the archicortex to form the secondary matrix. This migration is directed by orchestration of the CH-derived CR cells (Del Rio et al. 1997). Continuously, dentate NPCs migrate away from the secondary matrix towards the hippocampal fissure to form the tertiary matrix, which is a component of the future DG, using glial scaffolds that connect the CH (the future hippocampal fimbria) to the pial surface and the hippocampal fissure and generate granule cells (GCs) that form GC layer (GCL). In the VZ, RGCs undergo asymmetric cell divisions to give rise to daughter RGCs and hippocampal neurons, which migrate via RGC basal processes to the hippocampal cornu ammonis (CA) 1-3 to become pyramidal neurons. Dentate NPCs persist postnatally, but only in the tertiary matrix for a few weeks after birth; proliferation of NPCs is eventually restricted to the subgranular zone (SGZ) of the DG (Urban and Guillemot 2014; Yu et al. 2014).

37.3 Neurogenesis in the Adult Brain

While neurogenesis occurs in the entire brain during embryonic development, it becomes restricted to specific neurogenic niches that include the SVZ of the LV and the SGZ of the hippocampal DG in the adult brain. In both specialized niches, radial glia “-like” cells undergo asymmetrical cell division to produce progenitors, followed by generation of neuroblasts that migrate to their final destination, differentiation into neurons and integration into the neural network. Many of the features and the functions of progenitors and neuroblasts are similar in both niches, although the names of discrete progenitor cell types, markers that are expressed by each progenitor, and their final cell types at final destination differ in the SVZ and SGZ. While neuroblasts from the SVZ migrate rostrally to the olfactory bulb (OB) and differentiate mainly into GABAergic granule interneurons without axons and form dendro-dendritic synapses, dentate neuroblasts give rise to glutamatergic dentate granule cells and mature in the GCL of the DG. Indeed, their microenvironmental cues, including extracellular matrix molecules, growth factors and local neurotransmitters are essential for regulating their niche-specific proliferation and differentiation of progenitors (Basak and Taylor 2009; Conover and Notti 2008; Ming and Song 2011; Lepousez et al. 2015).

Fig. 37.2 Schematic of neuronal generation and migration in mouse neocortical development. The earliest cortical neurons (CNs) are generated from neural progenitor cells (NPCs) at around E10.5, and settle within the preplate (PP), which is split into the superficial marginal zone (MZ or Layer (L)1 of the postnatal cortex), the cortical plate (CP, the postnatal L2-L6) and the subplate (SP) at the later stages of development. At around E11-12, NPCs transform into radial glial cells (RGCs) with their somata positioned at the ventricular zone (VZ) and their long processes reaching basal lamina. RGCs divide both symmetrically and asymmetrically to produce daughter RGCs and intermediate progenitor cells (IPCs) or neurons. Newly formed neurons radially migrate from the VZ toward the pial surface through the intermediate zone using RGC basal processes as guiding scaffolds, and reach their

final destination. The Cajal-Retzius (CR) cells lie in the superficial MZ, and serve as “directors,” regulating the identity of radial glia and the migration of neurons. IPCs migrate above the VZ, form a second germinal zone called the subventricular zone (SVZ), and undergo one round of symmetric neurogenic division to generate pairs of neurons that also radially migrate from the SVZ to their final destination using RGC basal processes. Newly generated neurons from both RGCs and IPCs migrate into the cerebral cortex and reach the most superficial side of the CP to form the mantle layer, overlaying leading neurons to form the CP in order of L6 to L2. At around E17, RGCs retract their basal processes and become gliogenic, generating astrocytes and giving rise to ependymal cells (ECs) that line the ventricles

37.3.1 Adult Neurogenesis in the SVZ of the LV

Adult NSCs/NPCs are present in the SVZ, a shallow niche between the ependymal cell layer (ECL) lining the CSF-filled ventricles and the striatal walls (Fig. 37.3a) (Doetsch et al. 1999; Shen et al. 2008). The putative NSCs are quiescent but slowly proliferating radial glia-like cells called type B cells, which exhibit hybrid characteristics of astrocytes and immature progenitors and express nestin, vimentin and GFAP. Cell bodies of the type B cells line the ECL, and project their processes into the ventricles through the ECL to contact the CSF, and onto a planar SVZ vascular plexus where they contact blood vessels (Mirzadeh et al. 2008; Tavazoie et al. 2008). The type B cells receive their microenvironmental cues from both the vascular plexus and CSF

compartments, as well as from ECs, to regulate their proliferation and differentiation. The type B cell in the adult SVZ niche seem to have similar functional aspects to, but differ from RGCs in the embryonic VZ/SVZ, due to the state of maturation and location surrounding the cells, which results in distinct cue signatures. *First*, ECs are immature during embryonic development but postnatally mature. *Second*, ECs produce cue molecules to regulate neurogenesis in the adult SVZ. *Third*, cue molecules produced from other sources such as microglia, pericytes, blood vessels and the CSF including choroid plexus in the adult SVZ are distinct from cue molecules in the embryonic SVZ (Bjornsson et al. 2015).

Upon activation, type B cells divide and develop into transient-amplifying progenitor cells called type C cells, which express *Ascl1* (achaete-scute complex homolog 1)

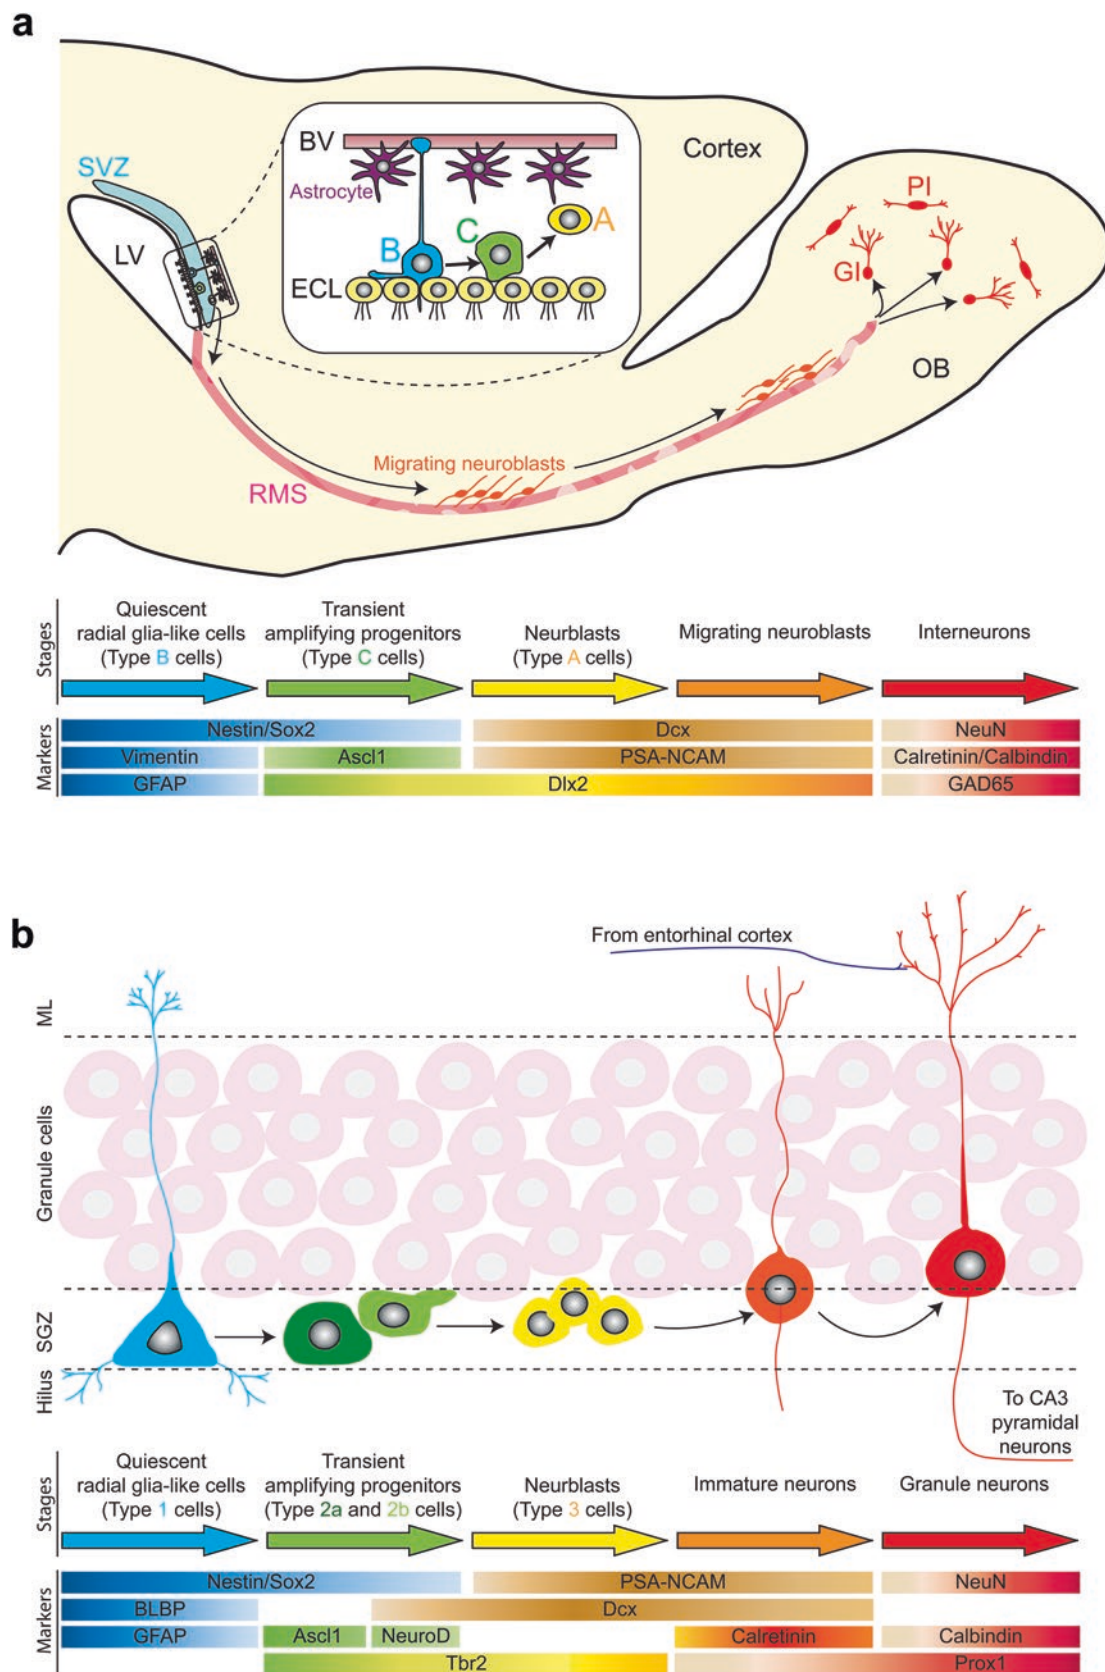

Fig. 37.3 Adult neurogenesis in the mouse brain. **(a)** Adult neural stem cells (NSCs)/neural progenitor cells (NPCs) are present in the subventricular zone (SVZ), a shallow niche between the ependymal cell

layer (ECL) lining the CSF-filled lateral ventricle (LV) and the striatal walls. The putative NSCs are quiescent but slowly proliferating radial glia-like cells called type B cells. Cell bodies of the type B cells line the

and *Dlx2*, and amplify their daughter cells to expand the population of the cells. The proliferating type C cells rapidly divide and give rise to type A cells, immature neuronal marker doublecortin (*Dcx*)-expressing neuroblasts or glial cells (oligodendrocytes or astrocytes). The type A neuroblasts exit the SVZ to enter chains along the rostral migratory stream (RMS), a dense channel of olfactory ensheathing glia, and migrate towards the OB, where SVZ-derived neuroblasts differentiate mostly into GABAergic granule interneurons in the GCL of the OB, but also into a variety of phenotypes including GABAergic or dopaminergic periglomerular interneurons and glutamatergic juxtglomerular neurons in the glomerular layer, and then integrate into the existing neuronal circuitry. The neuroblasts also differentiate into oligodendrocytes (Carleton et al. 2003; Brill et al. 2009; Kriegstein and Alvarez-Buylla 2009; Kosaka et al. 1995; Tatti et al. 2014).

37.3.2 Adult Neurogenesis in the SGZ of the DG

NSCs are believed to be quiescent radial glia-like cells called type 1 cells residing in the SGZ of the hippocampal DG. The cells are self-renewing and multipotent. They generate granule neurons through several steps (Fig. 37.3b), where a finely tuned balance regulated by both intrinsic and extrinsic stimuli, including signaling of BMP, IGF (insulin-like growth factor), Notch, Wnt, transcriptional factors, lipid metabolic processes and excitatory GABAergic inputs determines whether the cells keep their quiescent status or undergo proliferation and differentiation (Lledo et al. 2006; Braun and Jessberger 2014; Urban and Guillemot 2014). The type 1 cells express stem cell markers *Sox2* and *nestin*, but also have astrocytic features as shown their molecular markers such as GFAP and BLBP. The type 1 cells extend their radial processes through the entire GCL and ramify in the inner molecular layer (ML) of the DG. Upon activation, they undergo asymmetric divisions to generate intermediate

NPCs called type 2 cells. They are transient amplifying cells that continue to express *Sox2* and *nestin*, but lose GFAP/BLBP expression and their radial processes. The type 2 cells are categorized into two subtypes (type 2a and type 2b) based on differences in molecular markers between the subtypes. While the type 2a is *Ascl1*-positive during early stage of type 2 cells, the type 2b is *NeuroD* and *Dcx*-positive during late stage. Subsequently the type 2b cells give rise to *Dcx*-positive neuroblasts called type 3 cells, and expand the neuroblasts pool. The type 1, 2 and 3 cells are in mitotic cycles and have the ability of self-renewal. Once exiting the cell cycle, the type 3 neuroblasts enter the post-mitotic phase, start to branch out their processes, and undergo neuronal differentiation through a tightly regulated process. The neuroblasts differentiate into *Dcx* and calretinin-positive immature neurons around 2 weeks after the first division of the type 1 cells. Subsequently, the immature neurons migrate up into the GCL, undergo neuronal maturation regulated by *Cdk5* and *Disc1*, and then eventually become neuronal nuclei (*NeuN*)/calbindin/*Prox1*-positive glutamatergic dentate granule cells. Over a period of 3–6 weeks, newly developed neurons in the GCL extend their large dendritic arbor into the ML, and project axons into the hilus and CA3 regions for integration into existing hippocampal circuitry, and become fully functional. The integration is dependent on glutamate-mediated NMDA receptor responses (Kempermann et al. 2004; Mu et al. 2010; Bonaguidi et al. 2011; Imayoshi and Kageyama 2011; Ming and Song 2011; Urban and Guillemot 2014).

37.4 Methods to Detect Newly Generated Cells

37.4.1 Cell Proliferation Markers

Altman and colleagues first used a radiolabelled nucleoside, ^3H -thymidine ($[^3\text{H}]\text{dT}$), to show existence of newly generated neurons in the OB and DG of the hippocampus in adult

Fig. 37.3 (continued) ECL, and project their processes into the ventricles through the ECL to contact the CSF, and onto a planar SVZ vascular plexus where they contact to blood vessels (BV). Upon activation, the type B cells divide and amplify their daughter cells to expand the population of the cells as well as give rise to transient-amplifying progenitor cells called type C cells. The proliferating type C cells rapidly divide and produce type A neuroblasts, which exit the SVZ to enter chains along the rostral migratory stream (RMS), a dense channel of olfactory ensheathing glia, and migrate towards the olfactory bulb (OB). Here, SVZ-derived neuroblasts differentiate into GABAergic granule interneurons (GI), among a variety of other phenotypes including GABAergic or dopaminergic periglomerular interneurons (PI), and integrate into the existing neuronal circuitry. At each of these stages, cells express stage-specific markers. (b) The type of NSCs/NPCs in the SGZ of the hippocampal dentate gyrus (DG). NSCs are quiescent but self-renewing and multipotent radial glia-like cells (type 1 cells). The type 1 cells have radial processes that extend through the entire granule cell layer (GCL) and ramify in the inner molecular layer (ML) of the DG. Upon activation, they undergo asymmetric divisions to generate type 2 cells, which are intermediate, transient amplifying cells, and lose their radial processes. The type 2 cells are further categorized into two subtypes (type 2a and type 2b) based on differences in a set of molecular markers between the subtypes. The type 2b cells give rise to type 3 neuroblasts, and expand the neuroblast pool. The type 1, 2 and 3 cells are in mitotic cycles and are able to self-renew. Once exiting the cell cycle, the type 3 neuroblasts enter the post-mitotic phase, in which they start to branch out their processes, and undergo neuronal differentiation through a tightly regulated process. The neuroblasts differentiate into immature neurons. Subsequently, the immature neurons migrate up into the GCL, undergo neuronal maturation and become mature glutamatergic dentate granule cells. Newly developed neurons extend their large dendritic arbor into the ML, and axons into the hilus and area CA3 for integration into existing hippocampal circuitry, and become fully functional.

rats (Altman and Das 1965a; Altman 1969). Exogenous [^3H] dT is incorporated into newly synthesized DNA in cells at the S-phase during cell cycles, inherited into cell progeny, and can be visualized with autoradiography. This was based on a new stoichiometric technique to label dividing cells with [^3H]dT by intraperitoneal injection developed in late 1950s, and to allow quantitative analysis of proliferation, differentiation, and survival of new-born cells (Sidman et al. 1959; Kempermann et al. 1997; Miller and Nowakowski 1988). However, this methodology had disadvantages including limited detection depth from surface of sections due to the small half-distance of the beta-particle emitted by tritium atom decay ($\sim 1\text{ }\mu\text{m}$), long-term processes of developing autoradiographs (3–12 weeks), the logistics of handling radioactive materials and cost (Bisconte 1979; Duque and Rakic 2011).

The introduction of bromodeoxyuridine (BrdU), another synthetic thymidine analog, has brought a marked, rapid progress in the field of the adult neurogenesis. BrdU is also intraperitoneally administrated into animals and incorporated into newly synthesized DNA as an S-phase marker during cell cycles like [^3H]dT (Gratzner 1982). BrdU can be detected with immunohistochemistry and immunofluorescence with significant penetration of antibodies to BrdU that labels all proliferating cells throughout the section. This methodology can be used to perform stereological quantification and phenotypic analysis of proliferation, differentiation, and survival of newly generated cells that can be confirmed with various phenotypic markers (Kempermann et al. 1997; Miller and Nowakowski 1988). Thus, this is currently the most common technique to detect newly generated cells, especially for studies of the neurogenic niches of the adult brain. BrdU was also used to show the first evidence of adult neurogenesis in humans. BrdU staining in human postmortem brain tissues from cancer patients, who received BrdU administration for diagnostic purposes, revealed existence of dividing cells in both the SGZ and the SVZ of the human brain (Eriksson et al. 1998). Recently, a small molecule 5-ethynyl-2'-deoxyuridine (EdU) has been developed as another alternative thymidine analog to label newly synthesized DNA in embryos and adult rodents (Salic and Mitchison 2008). EdU can be detected using a sensitive fluorescent reagent containing an azide, that effectively permeates alive and fixed tissues and accesses EdU in genomic DNA, by “click” chemistry reaction, a copper-catalyzed covalent reaction between an azide and an alkyne in the EdU nucleoside without DNA denaturation.

These thymidine analogs are incorporated not only into synthesized DNA but also into nicked and damaged DNA undergoing active DNA repair even with a low frequency (Selden et al. 1993). It is also possible to mark cell cycle re-entry in postmitotic neurons before apoptosis using thymidine analogs (Katchanov et al. 2001; Kuan et al. 2004).

Therefore, care must be taken upon data conclusion for incorporation of both ^3H -thymidine and BrdU. To properly examine neurogenesis, careful analyses with confocal microscopy using multiple cell-type-specific markers along with the thymidine analogs, mainly with BrdU, are necessary (Rakic 2002). Moreover, detectable levels of BrdU incorporation with a single administration are limited and reduced after several rounds of cell division (Hayes and Nowakowski 2002). Results of BrdU uptake for proliferative, repairing or dying cells are dependent on each experimental paradigm, thus dose and duration of BrdU administration must be appropriately planned to avoid misunderstanding the data.

As an alternative to thymidine analogs, Ki-67 can be utilized to detect proliferating cells with immunohistochemistry. Ki-67 is a nuclear protein, expressed in dividing cells during the entire mitotic process in mammals including rodents and humans, and detectable with Ki-67-specific antibodies (Endl and Gerdes 2000; Scholzen and Gerdes 2000). Since Ki-67 is an endogenous protein, it has no adverse effect on living cells unlike [^3H]dT or BrdU, which are known to be toxic by intraperitoneal administration, causing stress affecting neurogenesis (Ehmann et al. 1975; Kolb et al. 1999; Breunig et al. 2007; Taupin 2007). Despite the lack of adverse effects, the short half-life of Ki-67 renders it less suitable in the analysis of differentiation and survival of newly formed cells.

37.4.2 NSC/NPC Markers

Nestin is an intermediate filament protein that is expressed by NECs and NSCs/NPCs during CNS development (Alvarez-Buylla et al. 2001). In the adult brain, it is observed in the neurogenic niches of both the SVZ and the SGZ where nestin expression is found in radial glia-like cells (type B and type 1), continues through transient progenitor stages in both niches (type C and type 2a/2b), and disappears in neuroblasts (type A and type 3) (Fig. 37.3) (Kempermann et al. 2004; Ming and Song 2011). Using a transgenic mouse expressing green fluorescent protein (GFP) under the control of the regulatory regions of the nestin gene (Yamaguchi et al. 2000), NSCs/NPCs can be labeled and visualized with GFP that allows for analyses of morphology and identification of newly formed cell types using other molecular markers in the adult brain (Fig. 37.4a) (Kempermann et al. 2004).

Retroviruses have a single-stranded RNA viral genome that integrates into the host genome for viral replication with the reverse transcription process and transgene expression in the host cell. Retroviruses without nuclear import mechanisms carry out viral integration only during mitosis when the nuclear membrane disappears (Lewis and Emerman 1994), they can be used to label and track only proliferating NSCs/NPCs by a live reporter such as GFP, allowing for

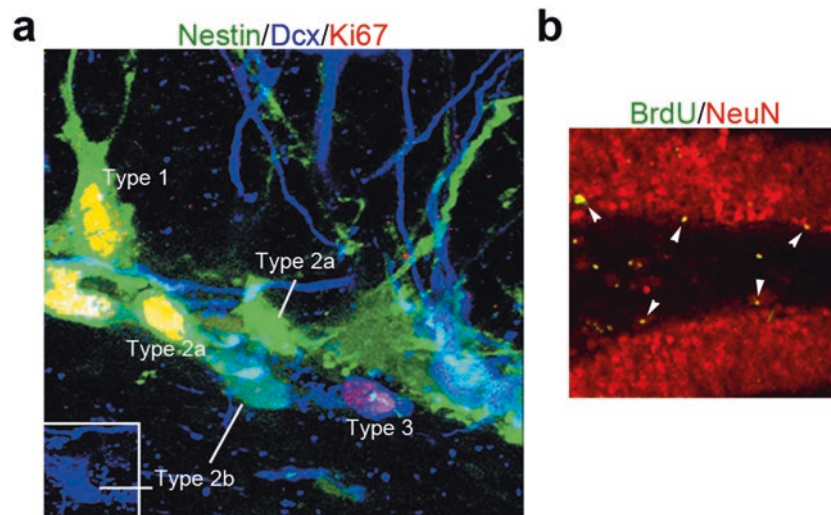

Fig. 37.4 (a) Identification of cell types in hippocampal adult neurogenesis using a transgenic mouse expressing green fluorescent protein under the control of the regulatory regions of the nestin gene. Confocal image shows multi-stained cells of Nestin (green)/Ki67 (red)-positive type 1 cell, Nestin/Ki67-positive proliferating type 2a cell, Nestin/Ki67-negative type 2a cell, Nestin/Dcx-positive type 2b cell, and

Nestin-negative and Dcx/Ki67-positive proliferating type 3 neuroblast. Cited from (Kempermann et al. 2004) (b) BrdU (green)/NeuN (red) staining in the subgranular zone of the hippocampal dentate gyrus 3 weeks after BrdU administration shows BrdU incorporation into matured newly formed neurons and neuronal survival (yellow, arrowheads)

visualization and analysis of living newly developed cells (van Praag et al. 2002). Since GFP is distributed throughout infected neurons, the entire morphology of the newly formed neurons including their dendritic trees and axonal arborization can be observed, enabling electrophysiological analysis of the labeled cells. This methodology, however, has several disadvantages. *First*, invasive stereotaxic injection is required to introduce the virus to areas of interest. *Second*, since retroviral infection is sporadic and unpredictable, labeling efficiency is not constant between individuals, thus hindering accurate quantification. *Third*, spurious GFP expression caused by fusion with retrovirus-infected microglia is found in mature neurons (Ackman et al. 2006), resulting in immune-mediated side effects and data misinterpretation. With these limitations, this methodology may not be ideal for studies of neurogenesis in the neurogenic niches (Gould 2007).

37.4.3 Neuronal Markers

The *Dcx* gene was originally identified as a causative gene of human cortical disorders. Mutant alleles of the gene affect NPC migration during cortical development, which leads to X-linked lissencephaly, a neuronal migration disorder associated with epilepsy and mental retardation in humans (des Portes V et al. 1998; Couillard-Despres et al. 2001). *Dcx* is a microtubule-associated protein expressed at high levels during neuronal migration in mouse CNS development, and retained within the two neurogenic niches in the adult brain (Francis et al. 1999; Nacher et al. 2001). It is expressed

throughout neurons including in the cytoplasm, nuclei, leading processes and growth cones of neurites (Brown et al. 2003; Schaar et al. 2004). In the adult brain neurogenic niches, *Dcx* expression is transient, seen mainly in type A migrating neuroblasts in the SVZ, and type 2b, 3 and postmitotic immature neurons in the SGZ (Brown et al. 2003; Ming and Song 2011).

Polysialylated neural cell adhesion molecule (PSA-NCAM) is a cell surface glycoprotein in the CNS. It is a polysialylated form of NCAM, which is post-translationally modified and is considered to facilitate NPC migration, neural plasticity, axon pathfinding and synaptogenesis. The level and distribution of PSA-NCAM are correlated to learning and memory (Becker et al. 1996; Fox et al. 2000). It is expressed widely in the brain during embryonic development, postnatally in immature neurons in the SGZ and the SVZ-RMS-OB system of the adult brain, and overlaps with *Dcx* in migrating neuroblasts (Bonfanti and Theodosis 1994; Ming and Song 2005). PSA-NCAM is also found in mature neurons in paleocortex layer II, the septum and the amygdala (Kiss and Rougon 1997; Rutishauser 2008; Nacher et al. 2013).

NeuN is a neuron-specific nuclear protein in the vertebrate CNS. It was originally identified by immunoreactivity with a monoclonal antibody (clone A60) that was generated by immunization of BALB/c mice using cell nuclei isolated from the brains of a strain, *Mus caroli*. It is expressed in postmitotic neurons with some exceptions including cerebellar Purkinje cells and Golgi cells, mitral cells in the OB, and photoreceptor cells in retina (Mullen et al. 1992). In the neurogenic niches in the adult brain, it is hard to distinguish newly

developed neurons from existing neurons by NeuN expression, since Dcx expression is down-regulated before NeuN expression is initiated in postmitotic neurons. A number of studies employ BrdU incorporation and fluorescent doublestaining with antibodies to BrdU and NeuN to evaluate newly formed and matured neurons and their survival (Fig. 37.4b) (Butovsky et al. 2006; Becker et al. 2007; Choi et al. 2008; Kiyota et al. 2011; Kiyota et al. 2015).

37.5 Factors Regulating Adult Neurogenesis

37.5.1 Aging

Aging is a major negative factor in adult neurogenesis. While embryonic neurogenesis occurs in the entire brain during development, postnatal adult neurogenesis is tightly restricted only in the two neurogenic niches aforementioned. Adult neurogenesis is a dynamic process that produces many thousands of neuroblasts, followed by neuronal differentiation, everyday throughout life in both neurogenic niches in rodents, primates and humans (Cameron and McKay 2001; Kempermann and Gage 2002; Knott et al. 2010; Curtis et al. 2007; Sanai et al. 2007; Spalding et al. 2013). Although a significant number of new cells are produced, only a small fraction of neuroblasts and immature neurons survive and are able to become functionally integrated into pre-existing neural circuitry, and most of them are eliminated by apoptosis and cell death (Carleton et al. 2003; Dayer et al. 2003). Therefore, aging causes rapid decline in adult neurogenesis (Kuhn et al. 1997; Heine et al. 2004b; Manganas et al. 2007). Recent studies report a significant decline in SVZ neurogenesis after infancy in the human SVZ/OB system (Sanai et al. 2011; Bergmann et al. 2012). In the DG, granule cells generated during embryonic development are replaced by postnatally generated granule cells with aging-dependent reduction in the hippocampal neurogenesis (Spalding et al. 2013). Aging-associated decline of neurogenesis can be attributed to changes in sizes of quiescent and active NSC pools (Lugert et al. 2012; Mira et al. 2012), or to termination of differentiating ability of NSCs into neurons in the hippocampus (Encinas et al. 2011).

37.5.2 Life Habit

Various environmental stimuli dynamically regulate the process of adult neurogenesis. Factors include exercise, enriched environment, dietary modulation, and so forth (Zhao et al. 2008; Lucassen et al. 2010). Generally, exercise is beneficial to our quality of life. In laboratory rodents, certain voluntary running exercises enhance the number of cell proliferation

and newly developed cell survival, and accelerates the formation of mushroom spines in the SGZ (van Praag et al. 1999; Zhao et al. 2006). This has also been observed in aged animals, and associated with improvement in learning and memory functions in the Morris water maze (MWM) (van Praag et al. 2005). Voluntary running-dependent neurogenesis is likely mediated by trophic growth factors: brain-derived neurotrophic factor (BDNF) and vascular endothelial growth factor (VEGF), and is associated with long-term potentiation (LTP) induction in the DG (Olson et al. 2006). Although exercise can be beneficial, an excess amount of running negatively affects the hippocampal progenitor proliferation. Long-term running for 24 days results in a significant reduction of progenitor proliferation rate, because of a gradual activation of the hypothalamic–pituitary–adrenocortical (HPA) axis. During the activation, corticotrophin-releasing factor (CRF) is released from neurons of the paraventricular nucleus in the hypothalamus, and promotes adrenocorticotrophic hormone release from the pituitary gland. The adrenocorticotrophic hormone stimulates the adrenal cortex to synthesize and release glucocorticoid hormones (GCs; corticosterone in rodents; cortisol in humans). Elevated GCs affect the hippocampal neurons to reduce dendritic branching causing atrophy (Sapolsky 2000). While it is suggested that the GCs regulate the hippocampal neurogenesis through the serotonin system, the mechanism behind this process is not exactly determined yet (Bruehl et al. 2007; Alenina and Klempin 2015). The HPA axis can be attenuated by adjusting the daily running distance to an appropriate level (Ulrich-Lai and Herman 2009; Lucassen et al. 2010).

Classically, an enriched environment—equipped with nesting materials, a rearrangeable set of plastic tubes, tunnels and running wheels in a cage—has been known to induce experience-dependent neuroanatomical plasticity, which includes morphological changes in the size of hippocampus, augmented dendritic arborization and an increased number of glial cells. Survival of newly formed cells is increased in the hippocampal DG of animals exposed to an enriched environment (Kempermann et al. 1997). Although many newly developed cells die within 4 weeks after birth, environmental enrichment promotes cell survival of immature neurons, especially within the 1–3 weeks after birth, associated with VEGF expression and subsequent improvement of learning and memory function in the MWM task (Kee et al. 2007; Tashiro et al. 2007; Zhao et al. 2008).

Dietary modulation influences adult neurogenesis and hippocampal function. Simple sugars and saturated fats are major components causing excessive energy intake that facilitates insulin resistance, obesity, diabetes and cardiovascular disease (Gross et al. 2004; Everitt et al. 2006). In the rodent brain, high-calorie diets affect learning and memory associated with deficits in hippocampal neurogenesis and synaptic plasticity, as well as reduced BDNF expression in

the hippocampus (Molteni et al. 2002; Lindqvist et al. 2006; Farr et al. 2008; Stranahan et al. 2008). In contrast, dietary restriction (DR) not only extends life span but also has a beneficial role in enhancing hippocampal neurogenesis (Park and Lee 2011). DR mimetics such as 2-deoxy-D-glucose, metformin and resveratrol protect hippocampal neurons in models of neurodegenerative diseases, and facilitate survival of newly generated neurons (Lee et al. 1999; El-Mir et al. 2008; Rocha-Gonzalez et al. 2008). Similarly, several antioxidants have been shown to boost and protect adult neurogenesis. For instance, curcumin, an yellow substance from the root of the plant *Curcuma longa*, has its neuroprotective effect associated with prevention from cognitive impairment (Frautschy et al. 2001). Its neuroprotective effect is attributed to an increase in the number of hippocampal proliferating cells rather than enhancing cell survival (Xu et al. 2007). These findings are associated with elevated levels in hippocampal BDNF expression and other neurotrophic factors such as neurotrophin-3 (NT-3) and IGF-1 (Park and Lee 2011).

37.5.3 Stress

Stress is one of the most potent environmental factors to negatively impact adult neurogenesis (Mirescu and Gould 2006). An ever-present part of life, the stress response can be induced by a number of physical and psychological stimuli from social pressures, job demands, illness, sleep disruption, inappropriate diet, excess exercise, exposure to an unfamiliar environment, and so on. They are mostly correlated to perturbations of a biological nature associated with metabolic changes, blood loss, and/or inflammation, and eventually bring physical and emotional symptoms of depression (Lucassen et al. 2010). Both acute and chronic stress exposures negatively affect cell proliferation, neuronal renewal and survival (Mirescu and Gould 2006; Oomen et al. 2007). Acute stress reduces cell proliferation and increases the number of apoptotic cells. Chronic stress seems to reduce apoptosis but it also decreases cell proliferation through activation of cell cycle inhibitor p27Kip1 (Heine et al. 2004a; Heine et al. 2004c). A variety of stress paradigms causes elevated levels of adrenal GCs through the activated HPA axis, thus reducing cell proliferation in the SGZ. Stress-mediated suppression of the proliferation can be prevented by adrenalectomy (Mirescu and Gould 2006).

Stress impacts levels of neurotransmitters including serotonin, norepinephrine or noradrenalin, GABA, and dopamine, resulting in reduced SGZ neurogenesis. Administration of antidepressants can lessen these effects (Warner-Schmidt and Duman 2006). Stress has been also linked to changes in levels of growth and neurotrophic factors (BDNF, IGF-1, nerve growth

factor (NGF), EGF, and VEGF), altering the regulation of adult neurogenesis. An enriched environment can mimics antidepressant effects by reducing expression of these factors, stimulating SGZ cell proliferation, thereby increasing neurogenesis (Zhao et al. 2008; Lucassen et al. 2010).

37.6 Adult Neurogenesis in Brain Disorders and Brain Repair

Finding that neurogenesis continues to occur in the neurogenic niches throughout life led to further investigation into the role of neurogenesis in various neurodegenerative diseases using animal models of human diseases. In fact, adult neurogenesis is strikingly altered in the diseased/damaged brains in two main ways. *First*, overall reduction of NSC/NPC activity and/or cell survival causes a decline in neurogenesis. *Second*, aberrant maturation of newly developed neurons results in an increased number of cells and abnormal integration into neural circuitry. Neurogenesis is particularly up-regulated in the neurogenic niches in certain diseases such as stroke, seizures, and traumatic brain injury (TBI) (Quadrato et al. 2014). Although up-regulated neurogenesis in disease conditions indicates a compensatory mechanism for self-repair in the damaged brain, it cannot completely repair the brain insults where survival and integration of newly formed neurons into the neural circuitry is abnormal. Therefore, understanding the exact mechanisms that modulate endogenous stem cells in the brain under various diseased conditions, and developing strategies to increase the number of functional NPCs and their survival may allow us to develop therapeutics.

Furthermore, the transplantation of somatic or pluripotent stem cells isolated from exogenous sources into the damaged brain also has therapeutic potential as another cellular-based strategy to repair neurological insults. During the last few decades, drastic advancements in the field of regenerative medicine have been made toward repairing injured organs including the brain. Well-known stem cells include embryonic stem cells (ESCs), mesenchymal stem cells (MSCs), immortalized human NSCs/NPCs, primary isolated NPCs, and induced pluripotent stem cells (iPSCs) (Liu et al. 2009; Martino et al. 2011). The goal of stem cell transplantation is to replace damaged and dysfunctional cells with new functional ones, and it has been effective in disease and injury models (Pluchino et al. 2003; Rafii and Lyden 2003; Cummings et al. 2005; Le Blanc et al. 2008). Although there are many challenging issues to be resolved regarding therapeutic use of grafted stem cells, some of the cells have the features of resident stem cells allowing for appropriate integration into the neural circuitry. In the following the relevance and therapeutic potential of adult neurogenesis in several brain disorders will be discussed.

37.6.1 Ischemia

Cerebral ischemic injury triggered by vascular occlusion in the brain is the most common form of stroke causing adult-acquired behavioral and cognitive disabilities. Focal (stroke) or global (e.g. cardiac arrest) cerebral ischemia arises from temporary or permanent blockage of blood supply, causing oxygen and glucose deprivation to the brain. Several events such as edema, deafferentation, and inflammation occur acutely around the infarct after ischemic injury, consequently triggering a secondary complex chain of events: oxidative stress, excitotoxic neurotransmitter release, disruption of the blood-brain barrier, and eventually cell necrosis affecting neurons, glia and blood vessels (Broughton et al. 2009). Early functional recovery can resolve the injurious events to a limited extent through incompletely understood mechanisms. Accumulating evidences suggest that a number of endogenous regenerative responses, including immunomodulation, altered gene expression, enhanced angiogenesis, neuroplasticity and neurogenesis, may be involved in the longer-term recovery of function following cerebral ischemia (Ergul et al. 2012; Hermann and Chopp 2012). Notably a number of studies demonstrate that cerebral ischemia potently stimulates neurogenesis in both the SVZ and the hippocampal DG (Liu et al. 2009). For example, it enhances neuroblast production in the rat SVZ, as well as in the cortex, outside of the neurogenic niches, in both rat stroke models and biopsy specimens of human brains (Shimada et al. 2010; Jin et al. 2006). Such reactive responses are considered to be attempts of self-repair in the damaged brain after injury. However, they are insufficient in generating adequate amounts of new neurons that can appropriately survive, integrate into the neural circuits, and recover functionality. Hence it is important to understand the cellular and molecular mechanisms of the post-ischemic responses in order to establish therapeutic strategies for treating stroke patients.

Recent therapeutics targeting stem cells promise a means of augmenting brain repair. Therapeutic targets include promotion of endogenous neurogenesis reinforced by stimulators and transplantation of various kinds of exogenous stem cells. Stroke is non-progressive and involves a focal loss of all cell types around the infarct, not targeting specific cells as in other neurodegenerative disorders. As described in the former section, adult neurogenesis is also increased in response to ischemia in both within and outside of the neurogenic niches. Thus stem cell therapy is not restricted to a paradigm of replacing only specific cell types, instead it may be able to dynamically act on multiple mechanisms in a temporally and spatially regulated microenvironment as stromal cells. Enhancing therapeutic effects, the use of extrinsic molecules such as hepatocyte growth factor, statins and fluoxetine have also been shown to boost neuroblast production, associated with angiogenesis, synaptogenesis and increased VEGF expression (Shang et al. 2011; Chen et al. 2003; Sun et al. 2015).

The therapeutic effects of a variety of stem cells have been explored in animal models of stroke. While the use of ESCs yet face ethical, religious and moral objections, *in vitro* fertilization programs currently utilize ESCs for medical purposes (Kalladka and Muir 2014). Studies using ESCs in animal models of middle cerebral arterial occlusion (MCAO) inducing stroke show that transplanted ESC-derived NSCs within the infarct core can survive and differentiate into mature glial cells and electrophysiologically functional neurons with high yield. Transplantation exhibits no chromosome abnormalities, no tumor formation and improved sensory recovery (Buhnenmann et al. 2006; Daadi et al. 2008; Drury-Stewart et al. 2013). Intracerebral implantation of human NSCs shows cell migration to ischemic regions, behavioral improvements, more than 50% cell survival beyond 2 months, and some differentiated neurons with forming synapses in rats after MCAO (Darsalia et al. 2011; Zhang et al. 2009; Song et al. 2011; Daadi et al. 2009). Invention of iPSCs enables resolution of the religious, legal, moral and ethical issues of ESCs. iPSCs produce patient-specific autologous cells, although there are still several clinical hurdles for this approach such as limited yields, long-term processes, and potential risks of tumorigenesis from viral transfection and oncogenic transcription factors (Malik and Rao 2013). Intracerebral implantation of undifferentiated iPSCs results in the production of neuroblasts and differentiated mature neurons, but also teratoma formation in MCAO rat models (Kawai et al. 2010). However, transplanted human iPSC-derived long-term self-renewing neuroepithelial-like SCs can survive without forming tumors, differentiate into mature neurons that exhibit proper electrophysiological properties, and receive synaptic input from host neurons, suggesting that predifferentiation of SCs may be essential to minimizing the risk of tumorigenesis (Oki et al. 2012). Alternatively, bone marrow-derived MSCs and many other cell types with similar properties to the MSCs have been used almost exclusively as therapeutics over the last decade. Numerous studies with animal stroke models have demonstrated beneficial roles of implanted MSCs, which produce trophic/growth factors (BDNF, glial-derived neurotrophic factor (GDNF), NT-3, VEGF, FGFs and thrombospondins) at the ischemic boundary in response to the local microenvironment, associated with stimulation of neurogenesis, angiogenesis and immunomodulation. Several Phase I and II clinical trials using MSCs are ongoing (for more detail see a review: (Liu et al. 2009; Kalladka and Muir 2014)).

37.6.2 Epilepsy

Epilepsy is a debilitating and multifarious disease, frequently associated with other mood disorders such as anxiety and depression. It is clinically defined by at least two or more

unprovoked seizures, which originate from different regions of the brain. While epileptic seizures induce the proliferation of NPCs including neuroblasts in both neurogenic niches of the adult brains, many studies exclusively focus on investigating adult neurogenesis in the hippocampal DG, since chronic epilepsy is strongly associated with cognitive problems and memory disturbances (Hermann and Seidenberg 2007). To generate animal models of seizures, chemoconvulsant drugs such as pilocarpine or kainic acid are used to induce status epilepticus. The drugs cause precipitating injuries and acute cell loss, followed by spontaneous seizures during phases lasting between days to weeks, becoming more frequent later (Williams et al. 2009). In parallel, dentate neurogenesis is dramatically increased in rodent models of temporal lobe epilepsy. However, a majority of newly formed cells after the epileptogenic injury integrate aberrantly (Murphy et al. 2011). During normal adult neurogenesis in the dentate SGZ, matured granule cells correctly migrate into the GCL and project their apical dendrites into the dentate molecular layer. In the neurogenesis in the epileptic brain, the seizure has several unique effects. *First*, it leads to mossy fiber sprouting of pre-existing neurons, which forms recurrent excitatory synaptic connections with neighboring granule cells and is hypothesized to promote hyperexcitability in the hippocampus. *Second*, it induces ectopic migration of new granule cells into the dentate hilus. *Third*, it promotes the granule cells to project their basal dendrites into the dentate hilus and receive excess recurrent input. Seizure induces abnormal functional integration of new neurons into the neural circuitry. Therefore, enhanced neurogenesis seems to be not a compensatory mechanism in response to neuronal death, and eventually declines to basal or even lower levels. However, declined neurogenesis can be recovered by antidepressant fluoxetine administration at the later stage. Conversely, valproic acid, an antiepileptic drug, blocks seizure-induced neurogenesis in rats with status epilepticus, associated with improved learning and memory (Barkas et al. 2012; Jessberger et al. 2007). The level of the neurogenesis has no correlation with epileptic susceptibility, thus the role of seizure-induced aberrant neurogenesis is yet under investigation (Zhao et al. 2008; Danzer 2012).

37.6.3 TBI

TBI is mostly caused by physical impact shocks including direct collision (e.g.: in traffic accidents and sport related injuries) and blast shock waves from explosion in battlefields. Patients suffering from TBI have deficits in sensory motor function, cognition, and become comatose in the worst cases. Within a few seconds such shocks lead mechanical tissue damage as the primary insult. The secondary insult consists of many events including ischemia, metabolic dysfunction, release of purinergic signaling molecules and excitatory

neurotransmitters, which affect resident astro/microglial function causing production of pro-inflammatory mediators, and eventually induce hippocampal neuronal cell death (Davalos et al. 2005; Laird et al. 2014; Sun 2014). TBI increases cell proliferation in both the SVZ and the hippocampal DG in mouse and rat models of TBI including fluid percussive injury, controlled cortical impact and diffuse weight drop injury (Dash et al. 2001; Chirumamilla et al. 2002; Gao et al. 2009), newly formed neurons that integrate into the neural circuitry in the hippocampus (Emery et al. 2005; Sun et al. 2007), suggesting innate attempts of regenerative response to repair brain tissues after TBI. Administration of growth factors and drugs including EGF, FGF-2, VEGF, erythropoietin, progesterone, statins, and imipramine has shown to enhance neurogenesis in both the SVZ and the DG (Sun 2014). Recent stem cell therapies using NSCs, NPCs, MSCs, iPSCs and human ESCs in animal models of TBI, or autologous bone marrow MSCs in patients with TBI have shown improved behavior and neuropathology (Harting et al. 2009; Bakhtiyari et al. 2011; Galindo et al. 2011; Heile and Brinker 2011; Dunkerson et al. 2014; Chang et al. 2015).

37.6.4 Alzheimer's Disease

Alzheimer's disease (AD) is the most common form of cognitive impairment affecting the elderly. Massive neuronal loss and brain atrophy are major diagnostic signs and neuropathogenic features. AD is characterized by the presence of extracellular senile plaques and intraneuronal neurofibrillary tangles (NFTs) in affected brain tissues. While NFTs consist of abnormally hyperphosphorylated microtubule associated protein tau, senile plaques are the aggregation of amyloid- β peptides (A β), which induce neuroinflammation, consequent synaptic and neuritic injuries, tau hyperphosphorylation and ultimately neuronal death (Hardy and Selkoe 2002). How adult neurogenesis is altered in human AD pathology is incompletely understood, since there seems to be conflicting observations about whether hippocampal neurogenesis is a positive or negative effect. Although one report shows that hippocampal TUC-4 (TOAD/Ulip/CRMP family protein 4) and Dcx-positive cells are increased in human AD brains (Jin et al. 2004b), others show decreases in Sox2 and Dcx-positive cells, associated with increased BMP6 levels as a negative regulator of neurogenesis, and failure in maturation of newly developed neurons (Li et al. 2008; Crews et al. 2010). While the vast majority of AD cases are late-onset sporadic form, transgenic AD animal models with familial AD (FAD) mutations in transgenes including A β precursor protein (APP) and presenilin, causing an early-onset form of AD, show altered adult neurogenesis. In such animal models, however, the positive or negative effects on neurogenesis regulation depend on types of transgenes, their expression,

promoters, age of animals and onset of the disease. Most AD animal models with FAD mutants lead to impaired neurogenesis in the hippocampal DG (see reviews for the detail: (Lazarov and Marr 2010; Mu and Gage 2011)). Conversely, some strains such as J20 transgenic mice expressing human APP (hAPP) with Swedish and Indiana mutations driven by a PDGF promoter, and APP23 mice expressing hAPP with Swedish mutation driven by a Thy-1 promoter show increased NPC proliferation and differentiation. Facilitation of neurogenesis may be a compensatory response representing self-repair mechanisms within the diseased brain, providing a potential therapeutic strategy to treat AD (Jin et al. 2004a; Lopez-Toledano and Shelanski 2007; Ermini et al. 2008). Based on those findings, a number of compounds, drugs and molecules have been tested to investigate whether they could modulate endogenous stem cells resident in the brain of AD animal models. These treatments include antidepressants, anti-inflammatory drugs, antioxidants, cholinesterase inhibitors, dietary modifications, immunomodulators and lithium, and all able to improve impaired neurogenesis (Butovsky et al. 2006; Kotani et al. 2008; Kim et al. 2013; Crupi et al. 2013; Maruszak et al. 2014; Fiorentini et al. 2010). Infusion of neurotrophic/growth factors such as NGF, BDNF, GDNF and FGF2 has a beneficial effect by enhancing neurogenesis or neuroprotection, associated with improved synaptic plasticity and performance in learning and memory (Nagahara et al. 2009; Revilla et al. 2014; Schaeffer et al. 2009; Kiyota et al. 2011). Some studies report that AD symptoms are ameliorated by cell transplantation-based therapies in AD animal models. For example, engrafted NSCs, isolated from postnatal day 1 GFP transgenic mice, differentiate into neurons, astrocytes, and oligodendrocytes in the recipient hippocampus. Transplantation of the NSCs results in improved synaptic plasticity, learning and memory, and increased BDNF levels in AD mouse models (Blurton-Jones et al. 2009; Zhang et al. 2014). An shRNA-mediated down-regulation of BDNF levels abolishes the improvements, suggesting that BDNF is critical for NSC therapy to treat AD (Blurton-Jones et al. 2009). Transplantation of NSCs stably overexpressing NGF transduced by adeno-associated virus promotes survival and differentiation of these cells, and improves cognitive function in AD rats (Wu et al. 2008). It is unclear whether such improvements are due to maturation, differentiation or integration of transplanted cells into the preexisting neural circuitry. However, embryonic MGE-derived progenitor cells of interneurons transplanted into the hippocampal hilus of aged AD mice differentiate into mature interneurons and integrate into the hippocampal circuitry, showing improvements in learning and memory. These findings indicate a significant therapeutic potential of utilization of human MGE-like cells, which might survive well and function in the human diseased brains (Tong et al. 2014). Additional

studies using human ESCs and iPSCs show that GABAergic interneurons are immature with limited integration or without fast spiking interneurons (Nicholas et al. 2013; Maroof et al. 2013), suggesting incomplete therapeutic potential for methodologies employing these cell types.

37.6.5 Neuroinflammation and Microglia

Neuroinflammation is not strictly a CNS disorder as is beneficial, neurophysiological responses to maintain brain homeostasis and plasticity. However, it is mostly associated with neurodegenerative disorders and brain injuries, influencing adult neurogenesis within both detrimental and beneficial consequences, depending on how resident microglia, infiltrated macrophages, and astrocytes are activated and how long the inflammation continues in affected areas of the brain (Russo et al. 2011; Hu et al. 2015). Notably microglia is the first immunological barrier against pathogens and environmental insults as they generally clear apoptotic cellular debris by phagocytosis (Hanisch and Kettenmann 2007; Sierra et al. 2010). Activated microglia produce proinflammatory cytokines (e.g. interleukin (IL)-6, IL-1 β , tumor necrosis factor- α : classic activation), and affect neurogenesis with detrimental consequences for neuronal viability as well as proliferation, differentiation and survival. These factors are also secreted by reactive astrocytes, meaning reactive astrogliosis has a negative impact on adult neurogenesis and contributes to the neuropathogenesis in the diseased brain. NPCs also regulate microglial function with NPC-derived secreted factors and expression of several neuroimmunoregulatory factors, thereby maintaining the balance between adult neurogenesis and microglial activation in the neurogenic niches (Biber et al. 2007; Mosher et al. 2012). Conversely, alternative activation of microglia under certain pathological conditions may positively regulate neurogenesis, and orchestrate neuronal restorative processes in the adult brain (Butovsky et al. 2006; Kiyota et al. 2012; Mathieu et al. 2010). Gene delivery of anti-inflammatory cytokines, IL-4 and IL-10 into the hippocampus protects hippocampal neurogenesis and restores impaired spatial learning in animal AD models (Kiyota et al. 2010; Kiyota et al. 2012). In particular, IL-4 directly induces CD200 expression in cultured neurons (Varnum et al. 2015). CD200 is a type I transmembrane glycoprotein with an immunoglobulin superfamily domain, and has anti-inflammatory effects through interaction of CD200-CD200 receptor expressed by microglia (Clark et al. 1985; Lue et al. 2010). Thereby overexpression of CD200 restores impairment in both proliferation and differentiation of hippocampal neurons in an AD mouse model (Varnum et al. 2015). Thus, adult neurogenesis can be both down-regulated by neurotoxin-induced inflammation and restored by anti-inflammatory treatments (Fuster-Matanzo

et al. 2013; Hu et al. 2015). Additionally, recent studies demonstrate that immunological processes such as the complement system and Toll-like receptor-mediated innate immunity may play a role in adult neurogenesis regulation with different molecular mechanisms from general immune responses (Zhao et al. 2008).

37.7 Closing Remarks

Since the first discovery of adult neurogenesis about half a century ago, a vast amount of information has been gathered. It includes the establishment of *in vitro* cultures of SVZ and SGZ-derived NSCs as neurospheres that are able to self-renew and differentiate into neurons and glia (Reynolds and Weiss 1992; Kilpatrick and Bartlett 1993; Gage et al. 1995), as well as methods to detect proliferating/differentiating NSCs/NPCs in the adult brain, along with comprehensive cellular and molecular biological and stem cell technologies. These breakthroughs have provided crucial platforms to further investigate the developmental potentialities of NSCs/NPCs, the mechanisms of proliferation and differentiation, and the applications to brain repair. Despite such progresses, however, the clinical applications of utilizing drugs that promote endogenous neurogenesis or implanting NSCs/NPCs have not yet materialized. This is due to challenging hurdles yet to overcome. Notably the brain is a very complex three-dimensional structure consisting of the extensive heterogeneity of neuronal subtypes alongside other cells such as glia and endothelial cells. During the development of the brain, different types of neurons are produced and organized temporally and spatially in tightly regulated manner driven by molecular signaling. Thus, complication of structure and organization of the adult brain limits the differentiation of implanted cells into neuronal subtypes and their integration into specific areas for repair. Even though endogenous or exogenous cells can successfully migrate and functionally integrate into the preexisting neural circuitry, the number of the cells is very small and the vast majority of them fail. One possible strategy is to develop methods to directly differentiate cells into the specific subtypes and then transplant. Further investigation into these methodologies will open a door to overcome the limitations of repairing the diseased brain.

37.8 Review Questions

1. What are the distinctions between neural stem cells and neural progenitor cells?
2. As currently identified, which growth factors contribute to maintaining neural progenitor cells?
3. Briefly summarize the production, migration, and maturation of new neurons into the dentate granule cell layer.

4. What primary region is supplied with new neurons from the SVZ in the adult brain? What type of neurons? Placement of neurons? Pathway for migration?
5. Explain the flow that new neurons are derived from GFAP-positive radial glia-like cells.
6. What stimuli are required to maintain a neurogenic environment?
7. What is important to develop therapeutics targeting successful adult neurogenesis following injury?
8. What types of stimuli have been shown to enhance basal levels of adult neurogenesis?
9. How can the microglia and astrocyte responses occurring with brain injury influence neurogenesis?

37.9 Answers

1. Stem cells can replicate indefinitely, whereas progenitor cells can divide only a limited number of times.
2. EGF and FGF.
3. Quiescent but self-renewing and multipotent radial glia-like cells called type 1 cells in the subgranular zone are activated and undergo asymmetric divisions to generate daughter radial glia-like cells and intermediate, transient amplifying type 2 cells, which give rise to type 3 neuroblasts, and expand the neuroblast pool. The neuroblasts differentiate into immature neurons. Subsequently, the immature neurons migrate up into the granule cell layer, undergo neuronal maturation and become mature glutamatergic dentate granule cells.
4. SVZ-derived neuroblasts migrate through chains along the rostral migratory stream, and differentiate mostly into GABAergic granule interneurons in the olfactory bulb.
5. GFAP-positive radial glia-like cells co-express stem cell markers nestin and Sox2. They undergo asymmetric divisions to generate daughter radial glia-like cells but also intermediate progenitor cells (IPCs), which lose GFAP expression. The IPCs become Dcx-positive and eventually NeuN-positive matured neurons.
6. Factors include exercise, enriched environment, dietary modulation, and so forth.
7. Although up-regulated neurogenesis in disease conditions indicates a compensatory mechanism for self-repair in the damaged brain, it cannot completely repair the brain insults where survival and integration of newly formed neurons into the neural circuitry is abnormal. Therefore, understanding the exact mechanisms that modulate endogenous stem cells in the brain under various diseased conditions, and developing strategies to increase the number of functional NPCs and their survival may allow us to develop therapeutics.
8. Administration of growth factors and drugs including EGF, FGF-2, VEGF, erythropoietin, progesterone, statins,

and imipramine has shown to enhance neurogenesis in both the SVZ and the DG.

9. Notably microglia is the first immunological barrier against pathogens and environmental insults as they generally clear apoptotic cellular debris by phagocytosis. Activated microglia produce proinflammatory cytokines (e.g. interleukin (IL)-6, IL-1 β , tumor necrosis factor- α : classic activation), and affect neurogenesis with detrimental consequences for neuronal viability as well as proliferation, differentiation and survival. These factors are also secreted by reactive astrocytes, meaning reactive astrogliosis has a negative impact on adult neurogenesis and contributes to the neuropathogenesis in the diseased brain.

Abstract

Chronic traumatic encephalopathy (CTE) is a progressive neurodegenerative disorder that can only be diagnosed post-mortem and has been retrospectively linked to a history of neurotrauma involving repeated concussive and subconcussive head injuries. Such a pattern of neurotrauma is commonly found among military veterans and athletes participating in contact sports. A post-mortem diagnosis depends on the detection of abnormal hyperphosphorylated-tau (p-tau) neuropathology that is characterized by an irregular, focal, perivascular distribution largely localized to cortical sulci. Although p-tau is not unique to CTE, this distribution pattern helps distinguish it from other degenerative tauopathies. High molecular weight p-tau proteins tend to accumulate in neurons and glia as pretangles, neurofibrillary tangles, extracellular tangles and neuropil threads. Supportive non-p-tau pathologies include TDP-43 and β -amyloid in neuronal cytoplasmic inclusions and dot-like structures in the tangles. Progressive tauopathies can share a broad range of neuropsychiatric sequelae, which for CTE are identified through next-of-kin interviews or verbal autopsies. A better understanding of how CTE relates to other neuropsychiatric and neurodegenerative disorders will require carefully controlled prospective studies involving both in vitro and in vivo model systems as well as parallel efforts to develop and validate fluid biomarkers and tau-specific neuroimaging technologies. Such an approach will improve the odds of advancing multiple, targeted therapies from preclinical studies to clinical trials. This chapter covers etiology, pathophysiology, experimental model systems, biomarkers and potential therapeutic strategies pertaining to CTE.

Keywords

Alzheimer's disease • Biomarkers • Chronic traumatic encephalopathy • Neurofibrillary tangles • Traumatic brain injury

38.1 Introduction

Chronic traumatic encephalopathy (CTE) refers to an incurable brain pathology induced by direct physical head injury that can trigger a slowly progressive pathophysiological cascade producing abnormal neuronal protein aggregates (hyperphosphorylated tau pathology) that lead to brain inflammation and irreversible neurodegeneration (Iqbal et al. 2016). The primary risk factor for CTE is a long-term history of repetitive traumatic brain injuries (TBI, e.g., concussive

and subconcussive impacts). Not only is this neurodegenerative disorder incurable, it's further complicated by the facts that symptoms often aren't manifested for years or decades after the last traumatic event and a definitive diagnosis can only be made post-mortem. Because CTE can assume a progressive neurodegenerative process, its symptoms run the gamut of cognitive, affective/mood, and motor dysfunction, many of which are shared with other neurodegenerative diseases, such as Alzheimer's and Parkinson's. Although the tau pathology generally characteristic of CTE might not develop until long after a series of typically sports-related, repetitive concussive and subconcussive impacts, it can also arise from single severe traumatic events (Johnson et al. 2012, 2013) that are more isolated yet involve tremendous forces, such as vehicle collisions, falls or bomb blasts. During head trauma, the brain may be subjected to the compressive and shearing forces of rapid acceleration and deceleration. Goldstein et al. (2012) hypothesized that the rapid acceleration-deceleration forces of concussive impact trauma (e.g., the "bobblehead effect") were key to CTE pathogenesis in both sports- and blast-induced TBI. These authors confirmed their hypothesis in a mouse model wherein mice were exposed to a blast wind inside a shock tube. Only mice whose heads were not restrained developed CTE neuropathologies. In the case of blast-induced head trauma, even without direct cranial impact, tissue damage can also result from a blood surge throughout the cerebrovasculature and implosive cavitation of dissolved gases induced by the massive overpressure shock wave. Thus, depending on the type of head trauma, their frequency and cumulative impact, the resulting physical brain injuries can range from mild to severe and be either localized contusions in specific brain regions (e.g., coup-contrecoup injuries) or extensive and diffuse, which may influence the suite of symptoms that are manifested based on the brain regions affected. Although head trauma is the proximate cause of CTE, whether or not an individual will develop CTE may depend on other risk factors, including genetics (Jordan et al. 1997; Gandy and DeKosky 2012) that may predispose them to the underlying pathophysiological processes.

Martland (1928), publishing his opinion in the medical literature regarding the punch drunk syndrome, was the first physician to posit a link between multiple concussions, the development of progressive degenerative lesions, and symptoms characteristic of the Parkinsonian syndrome. As accounts of the neurological effects of boxing grew, a new term was coined, dementia pugilistica (Millspaugh 1937). With the attention still on boxing, Critchley (1957) appears to be the first to apply the term "chronic traumatic encephalopathy". However, aside from the neurological studies aimed at boxing throughout much of the twentieth century, other high-impact or contact sports garnered much less attention toward the potential lingering or chronic effects of repeated concussive or subconcussive blows to the head. Beginning in the late 1980s, research was being published on

the potential for brain injury in soccer players, with particular focus on the practice of heading the ball. For example, Tysvaer and Løchen (1991) reported that, out of 37 retired soccer players tested, 81 % exhibited cognitive deficits. But it was not until after the early 2000s that CTE became a hot topic with both news and social media outlets. This is when medical professionals began publishing case studies of retired National Football League (NFL) players with a history of both multiple concussions and the psychological and neurological correlates of traumatic brain injury (Guskiewicz et al. 2005; Omalu et al. 2005, 2006; Cantu 2007). In the U.S. alone, the number of contact sports- and recreation-related concussions occurring each year has been estimated to range between 1.6 and 3.8 million (Langlois et al. 2006). More recently, an examination of the brains of former NFL football players revealed that 87 of 91 tested CTE-positive (Concussion Legacy 2015). Furthermore, just as the scope of sports-related CTE was encompassing the NFL, the U.S. was engaging in two wars in Afghanistan and Iraq. Due to significant improvements in armored transport, body armor, and battlefield medicine, the ratio of wounded to deceased soldiers is at an all-time high (IOM 2014) and the 'signature' wounds now are post-traumatic stress (PTSD) and traumatic brain injury (TBI). In the war on terror, roughly 20 % of veterans are estimated to have experienced TBIs (McKee and Robinson 2014). Post-mortem studies of the neuropathology of war veterans published by Omalu et al. (2011a, b) and Goldstein et al. (2012) indicated that blast-induced TBI could likely contribute to the development of progressive tau protein-linked neurodegeneration, which is the hallmark of CTE seen years after sports-related concussions.

Thus, whether acquired while engaging in contact sports, or during active military service, or even in an injury accident, a history of TBIs is now recognized as a risk factor for CTE. Functional deficits due to both primary and secondary brain injuries contribute to TBI outcomes (Table 38.1). Primary injury caused by an immediate mechanical insult occurs followed by secondary injury that results from the pathophysiological changes, including a persistent heightened neuroimmune response (Blaylock and Maroon 2011; Bramlett and Dietrich 2014), occurring over a period of days to months to years leading to chronic progressive neurodegeneration. Single moderate-to-severe TBI has been associated with accelerated neurodegeneration and increased risk of AD, PD and ALS, whereas repetitive mild-to-severe TBI is associated with persistent, long-term debilitating effects, progressive neurodegeneration and CTE (McKee et al. 2009, 2010, 2013; Goldstein et al. 2012; Hall 2016). Not surprisingly, the socioeconomic costs of TBI/CTE are staggering. The Centers for Disease Control and Prevention (2015) estimates the direct and indirect medical costs in 2010 at \$76.5 billion. Other aspects of the costs associated with neurotrauma were reviewed by Humphreys et al. (2013). The development of effective therapies for CTE will

Table 38.1 Primary injuries and secondary damage in TBI

Mild TBI	Moderate TBI	Severe TBI
Primary Injury: Mild to Severe CNS Trauma		
Predominantly non-penetrating blast	Frequently mixed, non-penetrating blast	Complex, penetrating blast
Loss of consciousness: <30 min	Loss of consciousness: >30 min <24 h	Loss of consciousness: >24 h
Amnesia: <24 h	Amnesia: >24 h	Amnesia: >7 days
GCS: 13–15	GCS: 9–12	GCS: <9
Imaging: negative	Imaging: transient changes	Imaging: positive, lasting abnormalities
Secondary damage: Mild to severe diffuse injury, impaired axonal transport, neuronal circuit damage and cell death		
<u>Neuropathological deficits</u>		
Contusion, mild edema, uncertain short-term neuropathology, abnormal protein aggregates, neuro-fibrillary tangles (tau pathology)	Significant neuropathological deficits, abnormal protein aggregates, neurofibrillary tangles (tau pathology), β -amyloid pathology	Severe, chronic neurological deficits, chronically impaired neuronal homeostasis, abnormal protein aggregates, amyloid- β pathology
<u>Neuropsychiatric deficits</u>

require concerted efforts at unraveling the cellular-molecular mechanisms underlying its pathogenesis. The pre-clinical research towards this end relies on animal models that recapitulate the chronic cognitive and neuropathological symptoms documented in human patients. It is imperative that we move beyond the current understanding of CTE, which rests on retrospective clinical-pathological correlations, to establishing causal links between TBIs and the clinical and neuropathological manifestations labeled as CTE. This will require both animal and human studies of CTE based on randomized before-after control-impact designs employing protein-based assays, biofluid-based biomarkers and neuroimaging.

38.2 Clinical Signs and Symptoms of CTE

CTE represents a chronic disease process (Masel and DeWitt 2010) initiated by mechanical force-induced head trauma that can progressively worsen in response to repeated head trauma. Individual head injury events can range from mild to severe, and as the severity increases so does the robustness of associated acute clinical symptoms (McCrory et al. 2013) within the first hours and days after exposing the head to a biomechanically forceful impact. However, these acute symptoms typically dissipate within days or weeks. Although mild, moderate and severe TBIs are recognized clinical entities, operational definitions of what constitutes these different forms can get complicated (McCrory et al. 2013; Reith et al. 2015). Since neuropathological evidence is required to confirm CTE, our understanding of how CTE might manifest itself as motor, cognitive, or affective symptoms has emerged retrospectively

from ‘verbal autopsies’, involving interviews of the families of those neuropathologically diagnosed with CTE post-mortem. Stern et al. (2013) conducted next-of-kin phone interviews for 36 deceased men with a diverse history of contact sports, ranging from high school only on up to collegiate and professional sports. The brains from these men, selected from 81 brains neuropathologically confirmed with CTE at the Boston University Center for the Study of Traumatic Encephalopathy brain bank, were free of comorbid brain disorders and the interviews were performed blind to their respective neuropathological results. In addition to documenting changes in cognitive, behavioral, psychological, and motor function, the interviewers also obtained complete histories on demographics, military service, occupation, athletic activity, physical and mental health treatments, daily social habits, and cause of death. Although three of the subjects were asymptomatic, the authors fit the remaining 33 subjects into one of only two CTE variants based on their initial symptoms—behavior/mood or cognition—thereby excluding a motor variant since none of the subjects exhibited motor impairment as the initial symptom. Subjects ascribed to the behavior/mood variant exhibited their initial symptoms at a significantly younger age than those with the cognition variant, but they also died significantly younger. Less than one-third of the subjects ever exhibited motor impairment or Parkinsonism, whereas 94% eventually showed signs of dementia in the form of progressive memory impairment; signs are features that can be verified by an independent observer. Dementia was a more common outcome in the cognition variant. Interestingly, 40.9% of the behavior/mood group had been diagnosed as early-stage CTE (Stages I-II out of IV, (McKee et al. 2013)), in contrast to only 9.1% of the cognition group,

which was primarily late-stage CTE. Behavioral features were manifested as explosivity, verbal and physical violence and impulsivity. Prominent mood changes included primarily depression, hopelessness, suicidal ideation and anxiety. Cognitive dysfunction included memory loss, executive dysfunction, loss of concentration or attention, impaired language and visuospatial difficulties. They added that the behavior/mood variant comprised signs and symptoms that were more stable in contrast to the more progressive features of the cognition variant.

Recognizing the limited external validity inherent in such a small non-random sample from a CTE brain bank comprised of athletes' brains donated by families who may have felt compelled to donate based on the symptoms they had witnessed, the same investigators refined their definitions of CTE variants by expanding the number of neuropathology cases from 36 to 202 athletes (Montenigro et al. 2014). They accomplished this by conducting a systematic review of the published literature of case series that had reported enough information allowing each case to be classified according to Jordan's (2013) clinical criteria of definite, probable or possible CTE neuropathology. Given the vast array of signs and symptoms associated with neuropathologically defined CTE, Montenigro and colleagues resorted to research diagnostic subtyping to clinically define what they called traumatic encephalopathy syndrome (TES). They arrived at four subtypes—a behavioral/mood variant, a cognitive variant, a mixed variant, and TES dementia—requiring that five general criteria be met, at least one of three core clinical features from the cognition, behavioral or mood domains and at least two of nine supportive features. Besides a history of repeated TBI ranging from subconcussive to severe loss of consciousness, other key general criteria include a minimum of 12 months of clinical signs or symptoms and the absence of neurological co-morbidities that could otherwise account for those features. Supportive features included impulsivity, anxiety, apathy, paranoia, suicidality, headaches, motor signs, progressive decline and a delayed onset of at least 2 years post-TBI. Modifiers were applied to identify the clinical course as progressive, stable or unknown/inconsistent, and whether motor signs were manifested. Because they delved back to the earliest CTE-related literature (1928–2010), the proportion of boxers jumped from 8 to 70% of cases, which prompted them to address the perceived divide between 'classic' CTE and the post-2005 phenomenon of 'modern' CTE. A designation of classic CTE was reserved for cases having prominent signs of motor impairment, such as ataxia, dysarthria, Parkinsonism, gait anomalies and tremor, with the clinical domains of cognition, mood, and behavior featuring much less prominently. They attributed the perceived clinical divide as an artefact borne out of the preponderance of boxers in earlier cases. To support this claim, they took a closer look at the 80 brains from athletes

examined by McKee et al. (2013) and determined that 71% of professional boxers presented motor signs compared to only 13% of professional football players. Furthermore, of the CTE Stage IV cases, 83% of the boxers had exhibited cerebellar pathology compared to only 57% of footballers. The biomechanical differences in repetitive head trauma experienced by boxers and football players might explain the patterns observed (Stern et al. 2013; Montenigro et al. 2014). Punches exert powerful torsional forces through the jaw to the brainstem and cerebellum, whereas the accelerative and decelerative forces exerted on the brain during collisions in football are largely linear or transverse. Besides the type of brain injury, clinical researchers also need data on other risk factors such as the number, frequency and severity of TBIs, the age range of exposure, lifestyle choices, and genetic susceptibility (e.g., Apolipoprotein E4). At this time, however, Montenigro and colleagues emphasized that in a clinical setting their research diagnostic scheme sacrifices specificity (avoiding false positives) for high sensitivity (avoiding false negatives). In the future, improving our ability to use a cluster of signs and symptoms as the clinical manifestations that diagnose or predict the underlying neuropathology of CTE will also require a fuller understanding of the risk factors that help transform brain trauma events into a progressive neurodegenerative disease.

38.3 Neuropathology of CTE

38.3.1 Historical Overview

While numerous clinical and neuropathological descriptions of CTE have been reported during the past decades, it remains unclear whether the pathological changes causally lead to the clinical observations given the current lack of epidemiological, longitudinal, cross-sectional and prospective data. Most of our understanding of CTE is based on the retrospective examination of patients at autopsy stages.

The neuropathological features of CTE were first described in a case report of a 51-year-old ex-boxer who developed post-traumatic dementia in 1954 by Brandenburg and Hallervorden (1954). The authors described Alzheimer's disease-like neuropathological changes, including the presence of senile plaques with neurofibrillary tangles (NFTs) in the cortex, basal nuclei, and to a lesser extent, in the cerebellum. This initial neuropathological report was followed by a number of case reports or small cases of boxers with varying degrees of pathologic findings associated with the disorder (Constantinidis and Tissot 1967; Courville 1962; Grahmann and Ule 1957; Mc 1959; Neuburger et al. 1959). Many of these reports described shared pathological abnormalities, such as cerebral atrophy, particularly of the frontal lobes. In 1973, Corsellis and colleagues (1973) performed a detailed

histopathological analysis on the brains of 15 ex-boxers ranging in age from 57 to 91 years. This seminal research outlined the major gross and microscopic neuropathological changes of CTE in boxers, demonstrating a pathologically widened and fenestrated cavum septum pellucidum, enlarged lateral and third ventricles, thinning of the hypothalamic floor, cerebellar and cerebral scarring, marked loss of pigment in the substantia nigra and uniquely distributed NFTs. In 1990, Roberts et al. (1990a), in a well-controlled study re-examining brains from the Corsellis series plus six additional retired boxers using a refined immunohistological staining technique, discovered the presence of β -amyloid ($A\beta$) plaques in nearly all cases. In a separate study (Roberts et al. 1990b), these same authors also examined the neuropathological features of CTE in the first non-boxer case, an elderly woman with a history of domestic violence and repeated blows to the head, revealing neuropathology identical to that seen in boxers. An autopsy study by Hof et al. (1991) of a 24-year-old autistic woman who had a long history of head banging showed the formation of NFTs in layer II and III of the cerebral cortex, especially in the temporal region, and amygdala in the absence of neuritic plaques or $A\beta$ deposits. Geddes et al. (1999), investigating the early neuropathological changes of CTE in the brains of five young men, ranging in age from 23 to 28 years, who had suffered from repetitive head injuries, reported no detectable gross changes to the brain, but demonstrated marked histological changes in all five cases involving formation of phosphorylated tau-positive, neocortical NFTs and neuropil threads (NTs) in striking clusters around intracortical blood vessels. $A\beta$ deposits were not found in any of the cases. The authors suggested that neocortical NFT formation and cytoskeletal abnormalities through damage of blood vessels or perivascular elements may contribute to the pathogenesis of this disease.

Omalu et al. (2005) reported the first case of CTE in a retired NFL player in 2005. Autopsy revealed mild pallor with mild dropout of pigmented neurons in the substantia nigra and mild neuronal dropout in the frontal, parietal, and temporal neocortex despite the apparent absence of cortical atrophy. Microscopic examination showed sparse NFTs and tau-positive NTs with diffuse amyloid plaques in the neocortex. The following year, Omalu et al. (2006) reported a second case of CTE in former NFL players, demonstrating tau-positive NFTs and NTs in all regions of the brain without detectable amyloid plaques and cerebral amyloid angiopathy. The third case of CTE in a former NFL player, characterized by diffuse cerebral tauopathy (NFTs and NTs) without any neuritic amyloidopathy, was reported in 2010 by the same research team (Omalu et al. 2010b). Omalu and colleagues also published neuropathological evidence of CTE in a 40-year-old professional wrestler (Omalu et al. 2010a) and in an Iraqi war veteran (Omalu et al. 2011a, b). Both

cases exhibited wide-spread tau-positive NFTs and NTs without atrophy. In 2009, McKee et al. (2009) carefully reviewed the clinical and neuropathological characteristics of 47 cases of neuropathologically-confirmed CTE in the world literature and also described the clinical and histological findings of CTE from an additional three retired athletes ranging in age from 45 to 80 years, including a former professional football player. The authors summarized the neuropathological features of CTE, including atrophy, ventricular dilation, fenestration of the cavum septum pellucidum, tau-positive NFTs, NTs and astrocytic tangles, and they documented $A\beta$ deposition as an inconsistent pathologic feature of CTE. Later, McKee et al. (2010) identified a widespread TAR-DNA binding protein 43 (TDP-43) proteinopathy in the frontal and temporal cortices, medial temporal lobe, basal ganglia, diencephalon, and brainstem in 10 of 12 examined CTE cases. The largest case study to date is that of McKee et al. (2013), who comprehensively investigated postmortem brains from a cohort of 85 head trauma patients between the ages of 17–98 years and showed neuropathological evidence of CTE in 68 cases. The subjects of this study involve 64 athletes, 21 military veterans and one individual with head-banging behavior. In this study, McKee et al. also defined four stages of CTE based on stereotyped patterns of structural change and p-tau pathology (Fig. 38.1). Furthermore, McKee et al. introduced neuropathological criteria for diagnosing CTE: “(i) perivascular foci of p-tau immunoreactive astrocytic tangles and neurofibrillary tangles; (ii) irregular cortical distribution of p-tau immunoreactive neurofibrillary tangles and astrocytic tangles with a predilection for the depth of cerebral sulci; (iii) clusters of subpial and periventricular astrocytic tangles in the cerebral cortex, diencephalon, basal ganglia and brainstem; and (iv) neurofibrillary tangles in the cerebral cortex located preferentially in the superficial layers”.

38.3.2 Gross Pathological Features

The neuropathological features of modern CTE have been evolving over the last decade (Randolph 2014). Grossly, there are usually no identifiable pathological abnormalities in early-stage CTE, but sometimes a cavum septum pellucidum and mild enlargement of the frontal and temporal horns of the lateral ventricles may be observed. Intermediate and advanced stages of CTE are normally accompanied by generalized brain atrophy with reduced brain weight. Specifically, a marked cerebral atrophy, particularly in the frontal and temporal regions, was commonly reported with advanced CTE (Payne 1968; Corsellis et al. 1973; McKee et al. 2009, 2010, 2013; Mawdsley and Ferguson 1963; Brandenburg and Hallervorden 1954; Neuburger et al. 1959; Grahmann and Ule 1957; Roberts et al. 1990a; Nowak et al. 2009). In addi-

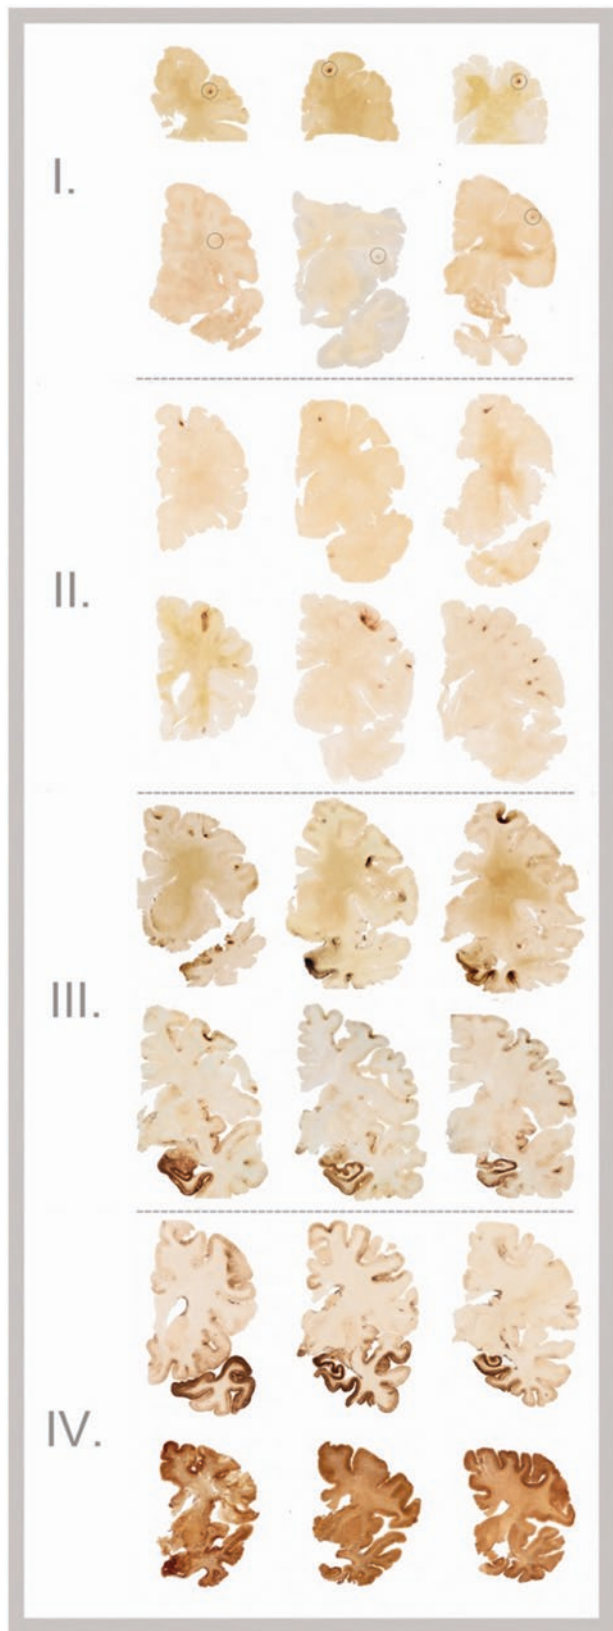

Fig. 38.1 The four stages of CTE. In stage I CTE, p-tau pathology is restricted to discrete foci in the cerebral cortex, most commonly in the superior, dorsolateral or lateral frontal cortices, and typically around small vessels at the depths of sulci (black circles). In stage II CTE, there

tion, atrophy of several other regions of the brain, such as parietal and occipital lobes, cerebellum, hippocampus, thalamus, mammillary bodies, entorhinal cortex and amygdala, has also been reported (Williams and Tannenberg 1996; Grahmann and Ule 1957; McKee et al. 2013). However, brain atrophy is not a significant gross feature in several cases of non-boxing athletes with CTE (Omalu et al. 2005, 2006, 2010a, b, 2011a, b). A second common gross pathological feature, especially in those with a history of boxing, is cavum septum pellucidum, which has been noted in 69% of CTE cases and was accompanied by a fenestrated septum in 49% of cases (McKee et al. 2009). Other gross neuropathology described in recent cases of CTE includes ventricular enlargement, thinning of the corpus callosum, dilation of perivascular spaces and pallor of the substantia nigra and locus coeruleus (McKee et al. 2009, 2013).

38.3.3 Microscopic Pathological Features

Histologically, CTE is characterized by extensive regional occurrence of p-tau-positive NFTs and NTs. In addition, the presence of p-tau-positive astrocytic tangles has been described in the McKee case series (McKee et al. 2009, 2013). The tau-immunoreactive neurofibrillary pathology is commonly found in the frontal, temporal and insular cortices, basal ganglia, brainstem, spinal cord, and diencephalon, and with distinct accumulations around the depths of cortical sulci and perivascular areas. Currently, the significance of this abnormal accumulation of tau around blood vessels is not yet clear, but some researchers hypothesize that damage to blood vessels during neurotrauma causes brain atrophy and the formation of NFTs (Saulle and Greenwald 2012). Although examinations of the brains of AD patients and two boxers with CTE revealed a similar tau isoform ratio and phosphorylation state between two distinct diseases (Schmidt et al. 2001), the abnormal distribution and localized nature of the tau pathology are unique to CTE and distinguish it from other degenerative tauopathies (McKee et al. 2009, 2013). The widespread presence of TDP-43-positive inclusions and

←
Fig. 38.1 (continued) are multiple epicenters at the depths of the cerebral sulci and localized spread of neurofibrillary pathology from these epicenters to the superficial layers of adjacent cortex. The medial temporal lobe is spared neurofibrillary p-tau pathology in stage II CTE. In stage III, p-tau pathology is widespread; the frontal, insular, temporal and parietal cortices show neurofibrillary degeneration with greatest severity in the frontal and temporal lobe, concentrated at the depths of the sulci. Also in stage III CTE, the amygdala, hippocampus and entorhinal cortex show neurofibrillary pathology. In stage IV CTE, there is severe p-tau pathology affecting most regions of the cerebral cortex and the medial temporal lobe, sparing calcarine cortex in all but the most severe cases. All images, CP-13 immunostained 50- μ m tissue sections. [Reprinted in its entirety from McKee et al. (2013) with permission from the Oxford University Press and from the primary author.]

Table 38.2 Proposed supportive neuropathological criteria for CTE

1.	Macroscopic abnormalities of the septum pellucidum, disproportionate dilation of the third ventricles, mammillary body atrophy, or signs of previous brain injury
2.	Abnormal tau-positive neurofibrillary pathology in subcortical nuclei, including the mammillary bodies and other hypothalamic nuclei, amygdala, nucleus accumbens, thalamus, substantia nigra and midbrain tegmentum
3.	Abnormal tau-positive neurofibrillary pathology in superficial layers II and III
4.	Abnormal tau-positive neurofibrillary pathology in the hippocampus, particularly in CA2 and CA4 regions
5.	Tau-immunoreactive thorny astrocytes in the subpial and periventricular regions
6.	TDP-43-positive neuronal inclusions in the hippocampus, anteromedial temporal cortex and amygdala

Table 38.3 Proposed neuropathological criteria to exclude the primary diagnosis of CTE

1.	Prominent cell loss in the cerebellar dentate nuclei, coiled bodies in oligodendroglia and tufted astrocytes as seen in progressive supranuclear palsy (PSP)
2.	Predominant neurofibrillary degeneration of the hippocampal CA1 region with the presence of A β plaques as seen in AD
3.	Prominent lesions in the striatum and pallidum in association with extensive glial plaques in both cortical and subcortical areas as seen in corticobasal degeneration (CBD)
4.	Globular astrocytic inclusions as seen in globular glial tauopathy (GGT)

neurites is another common pathological finding reported in most cases of CTE. TDP-43 immunoreactivity is prominent in the frontal and medial temporal cortices, brainstem, insula, hippocampus, caudate, subcortical white matter, amygdala, putamen and hypothalamus and is occasionally co-localized with p-tau. Recent examinations of the brains of three athletes with CTE even revealed extensive TDP-43-positive inclusions in the anterior horns of the spinal cord (McKee et al. 2010). Deposition of A β -containing plaques, which are found in 40–50 % of individuals with CTE, is not a consistent feature of CTE. Furthermore, unlike AD, A β plaques observed in CTE are less dense and predominantly diffuse (McKee et al. 2009).

Very recently, the National Institutes of Health (NIH) held a consensus meeting to evaluate neuropathological criteria for the diagnosis of CTE. The consensus group agreed that abnormal p-tau pathology in neurons, glia and cell processes, when detected in an irregular, focal, perivascular distribution and at the depths of cortical sulci is sufficient for diagnosing CTE (McKee et al. 2016). Furthermore, they defined a group of supportive neuropathological features (Table 38.2) for diagnosis of CTE. Also, in the presence of co-morbid pathology, the group defined the neuropathological features for ruling out the sole diagnosis of CTE (Table 38.3).

38.4 Relevance to Neuropsychiatric Disorders

Even after a history of repetitive head trauma has been documented, establishing a link between this history and the development of neuropsychiatric sequelae can be problematic. Confounding factors include pre-existing mental traits, substance abuse, education and family dynamics. For instance, people who participate in collision or contact sports may have higher premorbid rates of impulsivity and aggression than the general population, and post-injury changes in personality could reflect exaggerations of pre-morbid traits (Nicholl and LaFrance 2009). CTE, or the syndrome as clinically defined by Montenigro et al. (2014), presents with symptoms and signs in one or more of the four clinical domains: mood, behavior, cognition and motor. Personality changes are not uncommon following traumatic brain injuries, however, the list of psychological and cognitive changes attributed to CTE may be too long to manifest unique clinical-pathological correlations (Randolph 2014). In a retrospective analysis of 60 Finnish patients 30 years post-TBI, Koponen et al. (2002) diagnosed the long-term psychiatric consequences of TBI according to DSM-IV and DSM-III-R criteria. During that 30-year period, they reported that 62 % had developed Axis I disorders, including major depression, alcohol abuse, panic disorder, specific phobias and psychotic disorders, which according to the authors, contrasted with 33 % for the U.S. Epidemiologic Catchment Area (ECA) survey. Furthermore, an Axis II personality disorder had been diagnosed in over 23 % of patients. The prevalence of current disorders among the TBI patients was 40 % compared to <16 % for the ECA. However, it should be noted that their study lacked age-matched controls and their sample was drawn entirely from a clinical psychiatric population. According to McKee et al. (2013), heightened suicidality is associated with mid- to late-stage CTE in former athletes. However, Iverson (2014) emphasized that such a claim is premature, finding little evidence linking suicidality with proteinopathy. Indeed, both Randolph (2014) and Iverson (2014) cite evidence that the risk of suicide for retired NFL players is much less than for same-aged men in the general population. CTE induced by repetitive head trauma has also been linked to neurocognitive deficits. One study of 41 NFL retirees found that they performed more poorly than 41 healthy controls on a battery of neurocognitive tests, however, their pattern of mild cognitive impairment (MCI) was indistinguishable from the scores of 81 amnesic MCI patients with no history of TBI (Randolph et al. 2013). Thus, it remains entirely feasible that the MCI patients and the retired NFL players with MCI shared a similar neuropathological process not dependent on a history of head trauma. Hart et al. (2013) reached a similar conclusion in their study of MCI and depression in retired NFL players, declaring that

none of them met the reported clinical profile for CTE. Hart and colleagues subjected 34 retired NFL players to a battery of psychological and cognitive tests as well as neuroimaging ($n=26$). All but two had a history of concussions, ranging from 1 to 13 episodes, and the group was contrasted with age-matched healthy controls. Also, players diagnosed with cognitive deficits and/or depression were compared to those without. The prevalence of depression and MCI in players was higher than expected in the general population, while the prevalence of dementia was less than expected. When comparing the cognitively impaired and unimpaired and when evaluating neurobehavioral outcomes, the authors failed to detect significant links with either concussion history or the number of years in the NFL (an indirect measure of subconcussive history). Importantly, retired NFL players displayed significantly greater white matter lesion volume than did healthy controls, whereas the lesion volume of symptomatic and asymptomatic players did not differ significantly, which perhaps hints at the influence of subconcussive impacts. A similar pattern emerged from changes in cerebral blood flow and in the distribution of low fractional anisotropy in athletes, indicative of white matter injury, in the temporal, parietal and frontal regions associated with neuropsychological outcomes.

38.5 Relevance to Neurodegenerative Disorders

It remains debatable whether the aggregations formed by hyperphosphorylated proteins are the root cause of neurodegenerative disease or simply a consequence of the disease process. The p-tau now associated with CTE can also be induced by hypoglycemia (Chu-Wan et al. 2013), hypoxia (Gao et al. 2013), cerebral ischemia or stroke (Wen et al. 2004), and heavy metal exposure (Cai et al. 2011; Xiong et al. 2012). Randolph (2014) listed 26 neurodegenerative conditions whose neuropathology includes elevated levels of cerebral tau aggregations. Oddly enough, Davis et al. (2015) produced a different table of 26 tauopathies. Taken together, the combined list of conditions, ranging from Alzheimer's disease to Parkinson's disease to white matter tauopathy with globular glial inclusions, also includes normal aging, thereby complicating any effort to prescribe a unique neuropathological signature to CTE. Indeed, Randolph (2014) postulated that since the overall death rate for retired NFL players was much lower than for men in the general population, then we might see a higher incidence of age-related neurodegenerative disease in these former athletes. Randolph's main argument, which is also championed in more detail by Davis et al. (2015), was that more carefully controlled studies were needed before the presence of p-tau could be causally linked to a specific neurodegenerative disease process or to cogni-

tive or neurobehavioral dysfunction. Puvanna et al. (2016) provide evidence that the presence of p-tau is not an etiologic mechanism induced by repetitive head trauma or other sources of axonal injury, but instead is a marker of chronic neurological dysfunction. They compared CTE-confirmed brains to both severe epileptic brains and healthy control brains. Their findings regarding the distribution pattern of insoluble p-tau in CTE brains corroborated those of others, however, they found the same macroscopic distribution pattern in epileptic brains without a history of neurotrauma. Microscopically, the only difference they discerned between CTE and epileptic brains was that CTE was characterized by the presence of high molecular weight tau tangles, whereas the tau in epileptic brains was mostly low molecular weight, diffuse tau. The authors cautioned that they could not rule out a history of comorbid epileptic seizures in their sample of CTE brains.

Since CTE's clinical presentation can be indistinguishable from Alzheimer's disease (AD), and because brain trauma is known to elevate A β levels in addition to abnormal tau, Stein et al. (2015) compared the patterns of A β deposits in the brains of 114 CTE-confirmed subjects. They also compared these brains with confirmed AD brains and with a large cohort of non-specific brains representing the general population-at-large. Diffuse or neuritic plaque deposits of A β were present in 52 % of CTE brains. However, compared to the nonspecific cohort, A β deposits appeared in CTE brains at a younger age and accumulated at an accelerated rate. Also, CTE brains with A β plaques exhibited more severe tau and Lewy body pathology independent of age. In CTE-AD comorbid subjects, the A β deposits were more common in the sulci than in gyri. Parkinsonian symptoms are also not uncommon in CTE patients displaying pallor substantia nigra (Smith et al. 2013). Gardner et al. (2015) demonstrated in a controlled epidemiological analysis that hospital patients aged 55 and older were at a 44 % increased risk of developing PD in the next 5–7 years if they had been hospitalized due to TBI as opposed to a non-TBI injury; fully 66 % of injuries in both groups resulted from falls. Increasing the potential relevance of their findings to CTE were the facts that greater TBI severity and multiple TBIs further increased the risk of PD. Acosta et al. (2015) investigated the chronic effects of TBI on PD-related pathology 60 days post-TBI in a rat model of controlled cortical impact (CCI). Their immunostaining studies of key markers of PD pathology revealed that the ipsilateral SNpc had been infiltrated by pro-inflammatory activated microglia resulting in an abundant overexpression of alpha-synuclein in the SN culminating in a significant decrease in the number of tyrosine hydroxylase-positive nigral neurons, which are hallmark features of PD. Examinations of some CTE-confirmed brains have also detected widespread TDP-43 proteinopathy, which is more often associated with amyotrophic lateral sclerosis, motor

neuron disease and frontotemporal lobar degeneration. McKee et al. (2010) examined CTE brains of contact sport athletes and found TDP-43 proteinopathy afflicting the frontal and temporal lobes, basal ganglia, diencephalon, brainstem and spinal cord. Presently, since both single and repeated TBI exposures have been linked to multiple neurodegenerative diseases with the abnormal accumulation of multiple proteins, a newly emerging view has been described at length by Washington et al. (2016), who are advancing the notion of polypathology, and recommending that we describe the spectrum of chronic disorders that surface after single or repeated TBI as traumatic encephalopathy or trauma-induced neurodegeneration.

38.6 Model Systems

CTE-related complications are many, ranging from trauma-induced dementia and psychosis to the development of Alzheimer's and Parkinson's diseases. With a greater prevalence of war and contact-sport related injuries, CTE will become more common. While it has been known at least since the 1898 case of Phineas Gage (Damasio et al. 1994; Van Horn et al. 2012; Koponen et al. 2002) that head trauma can lead to the development of neurological and psychological disorders, the pathobiological changes that influence the development of neurological complications are not well understood. Hence in vitro and in vivo models of CTE were developed to better comprehend these changes. Deciphering these pathobiological changes will help us to develop effective medicines to treat or even prevent the occurrence of CTE-related complications.

38.6.1 In Vitro Models of CTE

The advantages of using in vitro models of CTE are the ability to control the experimental conditions to obtain reproducible results without confounding systemic factors. With this, it is possible to understand the development and progression of trauma-induced inflammation and cell death. Various in vitro models of CTE have been developed to study the effects of various modes of brain injury (Morrison et al. 1998b). Among these, the most commonly used models are stretch-injury, liquid shear-stress-induced injury and barotrauma.

Transection: Following a penetrating brain injury, brain tissue at the wound site is often mutilated with microtubule loss and misalignment, contributing to neurodegeneration often seen in patients healing from such injuries (Brizuela et al. 2015; Povlishock et al. 1999). To study such axotomy in vitro, neurons and/or glia are plated on tissue culture plates. Using a blade (Mukhin et al. 1998), plastic stylet

(Tecoma et al. 1989) or rotating scribe (Mukhin et al. 1997), multiple cells are mechanically damaged or removed via transection. Glial activation, cell viability, and other cell-biological assays can then be measured (Tecoma et al. 1989). A micro-transection model was also developed for study of single-cell trauma (Gross et al. 1983). One of the main disadvantages of this model is the lack of standardized protocols regarding the amount of strain and force required to reproduce this model from one lab to another. Clinically speaking, secondary axotomy is a major consequence of CTE rather than primary axotomy. Hence, currently the focus has shifted to other models of CTE. Nevertheless, this technique is still used to test the efficacy of novel pharmacological agents that primarily increase axon growth via microtubule sprouting (Brizuela et al. 2015).

Barotrauma: Along with the transection model, barotrauma is one of the earliest in vitro models of CTE (Lewelt et al. 1982). While the transection model simulates a penetrating head injury, the barotrauma model recreates blast-induced and shockwave-generated neuronal injury. This is achieved by creating a pressurized chamber (≤ 15 atm) where the neuronal cells are kept for a certain duration of time (Murphy and Horrocks 1993). The severity of the injury depends on the overpressure and exposure time. However, because brain tissue is incompressible, the pressures required to cause cell compression are much higher and therefore not clinically relevant. A modification of this model is the weight-drop model where a free-falling weight drops from a specified height onto the cultured cells or brain slice. The force of impact determines if this injury is focal or diffuse. Another modified version of barotrauma is the fluid percussion model. A rapid pulse is delivered by dropping a weight onto a fluid-filled chamber containing neuronal or glial cells. This millisecond change in fluid pressure can cause axotomy of the cells present in the chamber. While this modified version of the barotrauma model provided a more realistic view of pulse pressure-induced injury, the force of pressure required to induce neuronal damage was still much higher than the relevant pressures that induce brain trauma.

Acceleration/deceleration injury (ADI): Being one of the major contributing factors to brain trauma, acceleration/deceleration injury is also one of the most widely studied brain injury models. This injury occurs due to inertial loading. An example of acceleration trauma is a blow to the head, after which the accelerating cranium impacts the stationary brain. Likewise, during an automobile accident, the accelerating brain collides with the stationary skull again leading to brain trauma. This trauma can be focal or diffuse and can lead to shear strain, axotomy and neuroinflammation (Davis 2000; Daneshvar et al. 2015). Various models of ADI have been developed, each recapitulating some aspect of this

complex injury. One of the earliest models of acceleration-induced neuronal injury required a flask of cultured cells to be subjected to a tangential force of 220 x g using an impacting pendulum (Lucas and Wolf 1991). After three consecutive accelerations, neuronal apoptosis occurred. At that time, the magnitude of force generated following ADI was not well known. Around 1990, physical model simulations of head injury were developed along with animal models of CTE (Margulies et al. 1990). It was found that shear strain of 0.10–0.50 produced at a strain rate of 10–50 per sec generated regional brain deformations linked to clinically relevant regional brain injuries.

Stretch injury: One of the major disadvantages of the ADI model was its inability to account for stretch-induced mechanical strain on the axons, usually seen in ADI. During ADI-induced brain trauma, the brain collides with the cranium causing neurons and glia present in various parts of the brain to stretch due to inertial loading. This causes axonal strain leading to axotomy and synapse loss and consequently neuroinflammation and neurodegeneration. To mimic this aspect of neuronal injury, the cell stretch injury model was developed. Ellis et al. (1995) developed the first model of stretch injury by seeding rat cortical astrocytes on commercially available plates having a 2-mm thick silastic well bottom. A cell injury controller was used to apply a rapid positive pressure with known amplitude and duration (in milliseconds). This pulse caused a transient stretching of the Silastic bottom thereby inducing a biaxial stretch of the cells adhered to it. By controlling pulse amplitude and duration, mild, moderate and severe stretch corresponding to 10%, 33% and 50% Silastic membrane displacement could be reproduced. Further modifications by Cargilland and Thiabault (1996) and Morisson et al. (1998a) have resulted in higher strain magnitudes and modifiable strain rates, thus achieving better reproducibility and clinically relevant physical simulations.

As mentioned by Kumaria and Tolia (2008), a major disadvantage of using primary neuronal culture is the harvesting of tissue from embryonic mice or rats, which might limit the modeling of CTE to cultures of developing rather than adult neuronal cells. Another disadvantage of using a monolayer of cells in such models, especially in the stretch injury model, is the lack of tissue architecture. Unlike the single layer of neurons or glia used in these models, the brain architecture is much more complex. To overcome these problems, 3D matrix gels and ex vivo brain slice cultures are currently being used to understand the effect of trauma on tissue architecture. Morrison et al. (2006) designed a stretch injury model using organotypic hippocampal slices where a pulse pressure applied directly to the tissue adhering to the Silastic membrane results in 93% and 86% tissue strain in the x and y dimensions, respectively.

38.6.2 In Vivo Models of CTE

CTE is a complex disease involving primarily mechanical shearing and compression, leading to inflammation, edema and hemorrhaging of brain tissue at the site of injury and possibly the opposing side (e.g., coup-contrecoup). Following this primary injury, various cellular and systemic events also occur, taking place over months or years, leading to permanent brain tissue damage and consequently neurological disorders. While in vitro models provide a simplified model of CTE and can be used to study the molecular and cellular signaling cascades following injury, they do not provide knowledge about systemic events that have been known to occur acutely or even over a prolonged period of time. Also, it is not possible to maintain primary cell cultures or cell lines for a protracted period following injury due to the finite growth of primary cultures or the occurrence of overgrowth of confluent cell lines. Hence, to study the long-term effects of CTE, animal models are widely used to recapitulate the pathobiology of brain trauma, giving researchers the opportunity to understand the biomechanics of injury as well as to test for the efficacy of new drugs (Xiong et al. 2013). As shown in Fig. 38.2, depending on the type of brain trauma the researcher wants to study, four animal models have been developed for addressing the biomechanical aspects of head injury as well as the complex molecular cascades: a) fluid percussion injury (FPI), b) controlled cortical impact (CCI) injury, c) weight-drop impact acceleration injury and d) blast injury.

Fluid percussion injury (FPI) model: In this model, the experimental animal is anesthetized and placed in a stereotaxic frame after the scalp has been incised and the temporal muscles gently moved away from the skull. Once the animal has been secured in the frame, a lateral or medial craniotomy is made exposing the underlying dura mater. Usually a plastic cap is glued to the exposed dura to prevent fracturing of the skull. The FPI device, which is a cylindrical tube containing sterile isotonic saline, fills the interstitial space of the exposed part of the brain. As the pendulum strikes the opposite end of the fluid-filled cylinder, a compression or pressure pulse is delivered to the other end connected to the dura mater causing a brief displacement and deformation of the underlying brain tissue. The severity of this trauma depends upon the force with which the pendulum strikes the cylinder. The FPI model recapitulates the inertial-loading or ADI-induced head trauma without skull fracture. FPI leads to hemorrhaging, edema, neuroinflammation and long-term neurodegeneration similar to the symptoms seen in TBI in humans. One advantage of this model is that the experimenter can study the effect of impact on different regions of the brain depending on where the craniotomy is performed. Thus a researcher can induce

Nature Reviews | Neuroscience

Fig. 38.2 Experimental set ups for the animal models of traumatic brain injury. **(a)** | The fluid percussion injury (FPI) device uses rapid injection of a fluid pulse into the epidural space. **(b)** | The controlled cortical impact (CCI) model uses an air or electromagnetic driven piston to penetrate the brain at a known distance and velocity. **(c)** | The penetrating ballistic-like brain injury (PBBI) involves the transmission of projectiles with high energy of a metal rod or expansion of the

probe's elastic balloon. **(d)** | In the Feeney weight-drop model, a free weight is released directly onto the exposed dura. **(e)** | In the Marmarou weight-drop model, a metal disk is placed over the skull to prevent bone fracture. **(f)** | The blast brain injury caused by primary injury of blast or other mechanisms, e.g., thoracic effect. [Reprinted in its entirety from Xiong et al. (2013) with permission from Nature Publications]

midline FPI (in which the craniotomy is performed around the vertex) (McIntosh et al. 1987), sagittal FPI or parasagittal (lateral) FPI (McIntosh et al. 1989). Lateral fluid percussion injury (IFPI) is commonly used for its ability to produce primary focal trauma along with secondary diffuse neuronal injury. Besides cortical injury, other parts of the brain, including the thalamus and hippocampus, also suffer some percentage of neuronal loss. Over a protracted period of time (months), progressive neurodegeneration occurs in these regions resulting in cognitive, behavioral as well as motor deficits (Schmidt and Grady 1993; Creed et al. 2011; Hamm et al. 1994; Floyd et al. 2002). Since many CTE-related incidences, especially contact sport-related injuries, falls and minor automobile accidents, show a similar injury profile, the FPI model is widely used. In fact, besides using rodents (Perri et al. 1997; Daugherty et al. 2004) as experimental animals, many labs have also used pigs (Armstead and Kurth 1994; Lafrenaye et al. 2015), rabbits (Hartl et al. 1997) and cats (Unterberg et al. 1988; Sullivan et al. 1976). However, this model cannot replicate moderate to severe skull fracture injuries.

Controlled cortical impact (CCI): Using a pneumatic or electromagnetic impact device to generate a controlled impact on the exposed dura of the animal, CCI at one point was considered a superior model to FPI due to its ability to accurately control parameters such as velocity, time and force of impact (Romine et al. 2014). Since the force of impact is controlled, the risk of rebound injury and hence skull fracture is reduced compared to that in the FPI and IFPI models. The impact velocity is typically in the range of 0.5 to 10 m/s. CCI was first developed by Lighthall (1988) where he used a stroke-constrained pneumatic impactor at contact velocities of 2.0–4.0 m/s to produce 2.0–5.0 mm focal cerebral deformations in ferrets. Depending upon the magnitude of impact, mild focal lesions to severe large contusions and secondary diffuse neurodegeneration could be produced. The pathobiology of CCI induces similar sequelae of events as seen in closed-head clinical injuries such as cortical contusion, edema, increased intracranial pressure and hemorrhage as well as systemic and cellular changes and coma (Xue et al. 2015; Whalen et al. 1998; Lighthall et al. 1990). Immediately following cortical impact, the neural tissue below the exposed dura shows edema and cerebral hemorrhage, and the animal may experience temporary movement deficits after recovering from anesthesia. Moderate to severe impacts can lead to hippocampal and thalamic degeneration as well as the animal becoming comatose (Lighthall et al. 1990). Long-term effects of CCI have shown cognitive decline, especially short-term memory loss as well as behavioral changes. Despite the widespread use of rodents as *in vivo* CTE models, obvious differences exist between rodent and human brains. Mainly, brain geometry, degree of lateralization, white to gray ratio and the craniospinal angle differ

between quadrupedal rodents and bipedal humans (Laurer and McIntosh 1999; Fink 1979). Recently, neonatal pigs and piglets have been used in CCI experiments since the tissue density of the pig brain more closely approximates the human brain than does the rodent brain (Mytar et al. 2012; Pesek et al. 2014). Neonatal pigs have been used instead of adult pigs mainly due to space and cost constraints. Hence the findings from neonatal pigs might be more applicable to pediatric rather than adult CTE.

Penetrating CTE model: This model was developed to mimic head injury caused by penetrating objects such as bullets or shrapnel from explosives. This model favors larger animals such as sheep, dogs and rhesus monkeys over rodents since the target area in mice and rats is too small (Crockard et al. 1977; Tan et al. 1998; Finnie 1993). Also, the high projectile speeds result in high mortality rates in rodents. Recently, Plantman et al. (2012) developed a non-fatal rat model of penetrating CTE. According to the authors, the biomechanics of this model enable high rodent survival despite the penetrating injury.

Blast injury models of CTE: With the increased occurrence of armed conflict in many parts of the world, blast-related head trauma is becoming a major concern among both military personnel as well as civilians caught in the crossfire. Upon detonation of an explosive, a high-pressure shock wave blows outward at supersonic speed from the epicenter of the blast. Any individual present in the path of the oncoming blast wave experiences excessive pressure fluctuations along with high velocity wind accompanying the blast wave. Besides traumatizing gas-filled organs such as lungs, intestines or ears, a high-velocity blast wave can also cause brain trauma resulting directly from the shockwave passing through the brain and indirectly as the pressure wave gets propagated from the thoracic cavity via the cerebral vasculature. Edema, hemorrhage and neuroinflammation are seen acutely post-blast (DeWitt and Prough 2009; Kocsis and Tessler 2009). If unchecked, the neuroinflammation leads to loss of white or grey matter leading to neuropsychiatric disorders, cognitive decline and neurodegeneration. Misfolding of proteins such as tau, alpha-synuclein or β -amyloid is also seen in the postmortem brains of some war veterans, leading to the speculation that successive mild blast injuries or a moderate-to-severe blast injury can increase the susceptibility of the patient to accelerated age-related neurological disorders such as Alzheimer's or Parkinson's disease (DeKosky et al. 2013; McKee and Robinson 2014). To recreate different scenarios involved in blast-related injuries, different blast models have been applied.

Open-field blast injury: Earlier studies were conducted mainly on large animals subjected to open-field blasts since they replicated real-life scenarios with large animals being similar in size and tissue density to humans (Richmond et al. 1967; White et al. 1965; Cernak et al. 2011). However the

cost of maintaining these animals, the large amount of explosives needed as well as the lack of reproducibility of the injury profile prompted some researchers to adopt rodent models. Recently, modifications in experimental parameters and explosive devices have led to the development of rodent (Rubovitch et al. 2011) and primate (Lu et al. 2012) animal models of open-field blast injury.

Shock-tube models: A shock-tube comprises two chambers separated by a diaphragm, with the smaller “driver” chamber pressurized with compressed gas, either air or a lighter inert gas, while the larger “driven” chamber houses an anesthetized animal. If the intent of the experiment is to focus only on neurotrauma, then the animal is placed in a protective body shield with only its head exposed to the shock wave. The pressure in the driver chamber receiving the compressed gas increases until the diaphragm ruptures, propagating a shock wave. The shock wave intensity can be altered by varying diaphragm thickness. Various shock-tubes have been developed across many labs, however, as Risling and Davidsson (2012) have expressed, we need a well-documented and calibrated system characterizing all shock tubes to facilitate efforts at replicating results across different labs (Elias and Annas 1987). Currently, a sophisticated shock-tube is being used at the Applied Physics lab at Johns Hopkins University (Cernak et al. 2011). This shock-tube is capable of delivering complex shock-wave profiles as well as real-time measurement of various parameters such as overpressure impulse, total pressure, etc. Clemedson and colleagues (1953, 1954) were one of the first groups to study the effects of blast injury on animals. Initially their research focused on understanding the pathology of blast-induced

respiratory and vasculature defects in pigs. Later, they began to study the relationship between blast overpressure and neurotrauma (Clemedson 1956; Clemedson et al. 1957). Currently, along with large animals, mice and rats are also increasingly being used as experimental animals in various blast models of CTE (Budde et al. 2013). Due to the forces that the blast wave (shock wave plus blast wind) delivers to the animal, small animals used in these experiments suffered high mortality rates. With the introduction of Kevlar vests (flak jackets) that protected the thorax and abdomen in humans, researchers became interested in studying the effects of blast waves on the brain alone (Long et al. 2009; Goldstein et al. 2012). Since blast waves can produce not only head trauma but also systemic injuries that contribute to neurotrauma (DeWitt and Prough 2009), shielding the subject’s body prevented the introduction of compounding factors such as blast-induced hypoxemia and hypotension affecting cerebral blood flow. In an effort to model primary blast injuries induced solely by the shockwave without the confounding mechanical injuries imposed by the blast wind, Shah et al. (2012) developed an open-ended shock tube (Fig. 38.3). The animal is positioned outside the shock tube, just beyond and off-axis from its open end. The magnitude and duration of the blast overpressure experienced by the animal is controlled by adjusting its angle and distance from the shock tube’s open end.

Acceleration/deceleration injury (ADI): Advancing our knowledge of concussive injuries would not be complete without animal models designed to either control for or recapitulate the biomechanical forces that impart angular or rotational acceleration on the neck and head (Gullotti et al.

Fig. 38.3 Compressed Gas Open-ended Shock Tube. This is a computer-controlled system that can be triggered remotely. The 0.3-m long driver section is rapidly pressurized with helium gas until the mylar membrane ruptures, propelling a shock wave down the 3-m driven section. Pressure transducers located in and outside the tube record the internal burst pressure and compression wave parameters outside the tube where the animal is positioned. The shock tube was designed to simulate open-field blast waves for the laboratory study of primary traumatic brain injuries by positioning the animal outside and (a) off-axis to expose animal to a shock wave devoid of blast wind.

The intensity of the shock wave experienced by the animal depends on Mylar thickness, the animal’s distance from the shock tube’s open end and its angle from the tube’s central axis. If necessary, exposure to rotational forces (bobblehead effect) could be introduced by positioning the animal (b) within the blast wave (shock wave & blast wind) at a pre-specified distance from the shock tube. However, this variant would necessitate much lower mylar rupture pressures to avoid overly severe or lethal injuries. [Shock tube schematic adapted in part from Budde et al. (2013)]

2014). As mentioned in the introduction, Goldstein et al. (2012) modeled this ‘bubblehead effect’ in a shock tube by exposing mice to the blast wind. Only mice whose heads were unrestrained exhibited CTE pathology. Recently, Stemper et al. (2015) devised a rotational injury rat model in which the rat’s head rests inside a helmet that can be rapidly accelerated purely in a coronal plane of rotation when an impactor rod drops onto a laterally extended moment arm attached to the rat helmet. This model has the advantage of isolating the effects of one type of rotational force contributing to brain shear seen in many human mild TBIs.

38.7 Therapeutics

As described in previous sections, multiple preclinical models of experimental TBI are being used to cause static or dynamic brain trauma to help us characterize and understand TBI pathobiology and to evaluate potential therapeutic approaches. No single animal model of CTE replicates all of the pathologic events that contribute to progressive chronic neurodegeneration. Due to multidimensional cascades of secondary brain injury leading to impaired sensorimotor, cognitive, biochemical, neurochemical and histological deficits, the pathophysiology of TBI is multi-faceted and rich with pharmacological targets, thereby offering a multitude of therapeutic options. Several neuroprotective agents targeting the neuroinflammatory and neurodegenerative pathways have been tested in preclinical animal models. The therapeutic targets include AMPA-receptor antagonists, anti-inflammatory agents, antioxidants, apoptosis inhibitors, bradykinin receptor antagonists, immunophilin ligands, calcium channel blockers, necrosis inhibitors, neurotrophic factors, neurosteroids, NMDA receptor antagonists, nitric oxide modulators, oxygen carriers, polyethylene glycol, thyrotropin-releasing hormone analogs and others. Several studies have demonstrated the neuroprotective efficacy of progesterone for TBI in preclinical animal models (Schumacher et al. 2016; Lin et al. 2015). In clinical trials, the positive outcomes from Phase 2 safety trials led to multicenter, randomized and placebo-controlled Phase 3 trials, named ProTECT III and SyNAPSE. With more than 2000 TBI patients enrolled, the negative outcomes from these Phase 3 trials came as a big disappointment (Howard et al. 2015). More than 30 human phase III prospective trials of targeted drug therapies that showed promise in preclinical TBI models have failed to generate favorable results under clinical settings (Kabadi and Faden 2014; Xiong et al. 2009), in part due to inadequate single-target therapy. Therefore, any future effective therapy would most likely need to target multiple pathways, which could be partially accomplished by combination therapy. Still, major methodological hurdles exist between preclinical and clinical modeling and evalua-

tion due to a complex and heterogeneous human TBI/CTE population, thereby contributing to the failure of preclinical drugs in clinical trials. Currently, clinical trials are ongoing for at least 25 drugs developed for TBI. Furthermore, at least 50 new drug candidates are undergoing or have completed the preclinical phase and await entry to clinical phase. Recently, preclinical studies revealed E64D, a cathepsin B inhibitor (Hook et al. 2015), and Mdivi-1, a Drp1 mitochondrial division inhibitor 1 (Wu et al. 2016), as promising lead drug candidates and are being considered for clinical trials.

Future therapies: Recently, consensus panels funded by the NINDS/NIBIB defined the neuropathological criteria for CTE as an accumulation of abnormal hyper-phosphorylated tau in neurons and astroglia, non-specific p-tau immunoreactive pretangles, NFTs, extracellular tangles and supportive non-p-tau pathologies including TDP-43 and β -amyloid in immunoreactive neuronal cytoplasmic inclusions and dot-like structures in the NFTs. Therefore, clinical success might be achieved with novel neuroprotective therapies targeting tau phosphorylation and NFT formation.

Another major challenge in developing therapeutics for TBI/CTE is overcoming the blood–brain barrier (BBB) while delivering drugs. Researchers are encapsulating their therapeutics into nanoparticles to carry significant drug loads through the BBB to combat TBI/CTE. We lack FDA-approved therapeutics for mitigating TBI-induced neurodegeneration, thus stem cell therapy, deep brain stimulation (DBS) and transcranial magnetic stimulation (TMS) are all being evaluated in preclinical and clinical trials for treatment of CNS trauma. Recently, Rezai et al. (2015) demonstrated for the first time that DBS was safe, suggesting its potential effectiveness for making behavioral and emotional adjustments, which in turn improved functional independence years after severe TBI. Repetitive TMS (rTMS) is a non-invasive alternative that can influence brain plasticity, cortical reorganization and neuronal excitability. When used as a therapeutic intervention, rTMS has produced positive outcomes in people with motor disorders and psychiatric conditions suggesting that rTMS may be a promising treatment for TBI (Herrold et al. 2014). Stem cell therapy is another innovative treatment strategy against TBI/CTE currently being tested in animal models (Ahmed et al. 2015) to add trophic support to the injury response of CNS repair and regeneration.

Since there are currently no approved therapeutic products, the sector is teeming with opportunities for new entrants as well as stalwarts of the pharmaceutical industry. Some of the notable companies developing therapeutics for TBI/CTE are ALSP Inc, Cognosci, Medicortex, Amarantus BioScience Holdings, Aldagen, NeuroScience Pharmaceuticals and Targacept (<http://www.persistencemarketresearch.com/market-research/traumatic-brain-injury-therapeutics-market.asp>, accessed 29 December 2015). However, it is important that modelling preclinical CTE for future drug discovery

Fig. 38.4 Potential biomarkers for TBI/CTE. Within the neuronal cytoplasm, potential biomarkers include NSE, SBPs and UCH-L1. NF-H becomes phosphorylated in axons. Phospho-tau and TDP-43 are biomarkers of neurofibrillary tangles. Overexpression of amyloid precursor protein and amyloid-β could be markers for amyloid plaques. Astroglia will respond to injury by releasing S100-B and GFAP. Gliosis and injury-induced neuroinflammation upregulates the expression of interleukins and cytokines/chemokines. The ratio of cerebrospinal fluid

(CSF) to serum albumin can be a biomarker for integrity of the blood–brain barrier. Other potentially useful markers for brain injury response are cleaved tau, neurosteroids, spectrin breakdown products, microRNAs, and of course, neuroimaging. Abbreviations: GFAP, glial fibrillary acidic protein; NF-H, neurofilament heavy polypeptide; NSE, γ-enolase; SBPs, spectrin breakdown products; TDP-43, TAR DNA-binding protein 43; UCH-L1, ubiquitin carboxyl-terminal hydrolase isoenzyme L1. [Adapted in part from Zetterberg et al. (2013)]

must address the challenges associated with it and should take into consideration the length of the inter-injury interval and the number, severity, mechanism, age, gender and genetic predisposition at time of impacts (Turner et al. 2015; Goldstein et al. 2012).

38.8 Biomarkers

Biomarkers of neuronal, axonal and astroglial damage could be used to diagnose mild repetitive TBI and aid in medical counselling of at-risk individuals, such as military personnel and concussed athletes. At present, we lack validated biomarkers unique to CTE. Several researchers are actively

pursuing research to find biomarkers to develop diagnostic tests for CTE that could be used during early stages of the disease process (reviewed by Goldstein et al. 2014; DeKosky et al. 2013; Ojo et al. 2016; Yokobori et al. 2013). Currently, physicians are using a battery of neurological and brain-imaging tests. Eventually, the hope is to use a range of neuropsychological tests for determining the pattern of cognitive or behavioral decline as well as brain imaging and biomarkers to diagnose CTE. Furthermore, serial and longitudinal measurements of biomarkers in conjunction with brain imaging during the acute, subacute and chronic phases following primary TBI insult will help in understanding the pathogenesis and clinical course of CTE (McKee et al. 2016). A list of potential biomarkers of TBI/CTE is shown in Fig. 38.4.

38.8.1 Neuroimaging

Neuroimaging of the living brain has become fundamental in the effort to develop diagnostic and prognostic tools for managing TBI. Multiple imaging techniques are currently being evaluated to understand and evaluate the effects of promising therapeutic interventions for TBI in athletes, civilians and military veterans (reviewed by Wilde et al. 2015; DeKosky et al. 2013; Mitsis et al. 2014; Dani et al. 2015; Zhang et al. 2016). Computed tomography (CT), followed by MRI, remains the imaging modality of choice for initial assessments due to its ease of access, rapid acquisition and for its sensitivity (Currie et al. 2016). Structural and functional neuroimaging techniques such as quantitative fluid attenuated inversion recovery (FLAIR), positron emission tomography (PET), susceptibility weighted imaging (SWI), volumetric analysis, diffusion tensor imaging (DTI), magnetization transfer imaging (MTI), magnetoencephalography (MEG), task-based and resting state functional MRI (fMRI), arterial spin labeling (ASL) and magnetic resonance spectroscopy (MRS) are also being evaluated as diagnostic and prognostic tools for TBI/CTE (reviewed in Wilde et al. 2015). Each of these imaging techniques comes with its own advantages and limitations while providing some in vivo evidence of neurological damage such as non-specific atrophic changes (Wilde et al. 2015). Other non-invasive tests include electroencephalography event-related potentials (ERPs), quantitative EEG and single photon emission computerized tomography (SPECT). SPECT is being developed to distinguish different dementia types, such as CTE from AD or other neurodegenerative diseases. FDDNP is the only currently available radiotracer to image NFTs, besides amyloid aggregates, for visualizing AD pathology in living humans. Recently, PET scans performed with the FDDNP ligand revealed higher FDDNP levels in athletes compared to controls in areas that produce tau deposits following trauma. More recently, Pittsburgh compound B62, [18]-florbetapir, the new tau-binding ligand [18F]-T807, and THK523 compounds have been validated against amyloid or tau pathology in live patients by PET (Mitsis et al. 2014; Dani et al. 2015). Better PET ligands for amyloidopathy, tauopathy and synucleinopathy are being developed and evaluated in patients. Since the A β deposits and NFT distribution are different in CTE and AD, the PET ligands should successfully diagnose the different disease conditions.

38.8.2 Fluid Biomarkers

Biomarkers of neuronal, axonal and astroglial damage have been used to diagnose several neurodegenerative disorders, including AD, PD, ALS, etc. These same markers could help diagnose CTE, predict clinical outcomes of patients with head

trauma and provide information for medical counselling of at-risk individuals, such as military personnel and concussed athletes (Zetterberg et al. 2013; DeKosky et al. 2013; Blennow and Zetterberg 2015; Agoston and Elsayed 2012). CSF markers are preferred over peripheral blood markers, owing to their increased proximity to the brain. Biomarkers that are highly expressed within the CNS are also detectable in blood. Although potential peripheral blood markers are currently below detection limits due to sensitivity of the standard assays, detection and quantification of a number of potential CNS markers in peripheral blood is bound to steadily increase as ultrasensitive assays become available.

As shown in Fig. 38.4, several CSF and blood biomarkers of brain injury have been proposed, including proteins that indicate BBB integrity and neuroinflammation, as well as axonal, neuronal and astroglial damage (Zetterberg et al. 2013; DeKosky et al. 2013; Blennow and Zetterberg 2015). Studies have also shown an increase in the CSF:serum albumin ratio in patients with severe TBI associated with a neuroinflammatory response both in the CSF and serum (Zetterberg et al. 2013). Since an acute inflammatory response occurs within the CNS after severe TBI, studies have found increased levels of inflammatory proteins IL-6, IL-8 and IL-10 to a greater extent in CSF than in the serum of TBI patients. Increased levels of tau and neurofilament light polypeptide (NFL), the two well established biomarkers of acute axonal injury, have been found in the CSF and serum of people with possible CTE including boxers. Another marker of acute neuronal injury, γ -Enolase, is also known to increase in the serum and CSF of people with severe head trauma. The S100 protein, a member of the Ca²⁺-binding protein family that helps to regulate intracellular Ca²⁺ levels, is made up of S100-A and S100-B subunits. S100-B and GFAP (marker of astrocytes) protein levels are increased in the CSF and serum of athletes due to astroglial injury. Studies have also shown increased ventricular CSF and serum levels of APP, A β 40 and A β 42 during the first week after head trauma in patients with severe TBI but not with mild TBI. Calpain- and caspase-3-cleaved spectrin breakdown products and UCH-L1 (ubiquitin carboxyl-terminal hydrolase isoenzyme L1), a deubiquitinase, were recently shown to be potential biomarkers for TBI (Zetterberg et al. 2013; DeKosky et al. 2013; Blennow and Zetterberg 2015; Marx et al. 2016). In their studies, the CSF levels of both spectrin breakdown products and UCH-L1 were significantly higher in patients with severe TBI. Levels of these two markers also contributed to clinically relevant prognostic information in addition to that obtained by routine clinical assessments (Zetterberg et al. 2013; Blennow and Zetterberg 2015; Marx et al. 2016). Small non-coding RNAs in peripheral blood mononuclear cells have also been suggested as potential biomarkers for mild TBI (Zetterberg et al. 2013; Pasinetti et al. 2012). More recently, phosphorylated tau and

TDP-43 are being evaluated as biomarkers for TBI and CTE (Smith et al. 2013; Sierra-Rio et al. 2016). Phosphorylated tau and TDP-43 are primary constituents of NFTs and inclusions, the two most prominent neuropathological characteristics of CTE. Increased levels of total tau have been found in CSF after acute TBI, but no data have yet been examined in patients with probable CTE. The prevalence of chronic pituitary dysfunction, caused by the tearing of axons in the pituitary stalk, may be as high as 30–80% in patients 24–36 months after TBI (Dusick et al. 2012; Guerrero and Alfonso 2010). Abnormalities in pituitary hormone levels leading to chronic pituitary dysfunction correlate with the presence of long-term cognitive symptoms after TBI and so abnormal hormone levels could serve as a CTE biomarker and could be treated by hormone replacement therapy. Defining unified neuropathological criteria for the diagnosis of CTE will also facilitate the discovery of novel diagnostic biomarkers (Mez et al. 2015; McKee et al. 2016). Development of ultra-sensitive assays for detection of CNS biomarkers in the blood, clinical studies of serial, advanced brain imaging and longitudinal studies of biomarkers in chronic or progressive symptoms after TBI may help in understanding the pathogenesis and clinical course of CTE.

38.9 Review Questions

1. What are the main gross pathological features of CTE?
2. Briefly describe the major microscopic pathological features of CTE.
3. Please describe the unique features to definitively diagnose CTE.
4. Describe the “Bobblehead Effect” and its relevance to CTE.
5. What is meant by “verbal autopsy” and explain its importance to our current understanding of CTE?
6. What are some of the limitations or potential biases encountered when attempting to define a disease based on the examination of donated brains and verbal autopsies?
7. Why might people with a history of repeated concussions or TBI differ in the degree to which they manifest motor disturbances, behavioral/mood changes, or cognitive impairment?
8. How might researchers determine whether the neuropathology linked to CTE causes the clinical syndrome (behavioral/mood and cognitive) associated with CTE and to rule out comorbidities?
9. What patterns of tau and A β deposition might help discriminate CTE from other neurodegenerative disorders?
10. What major signaling pathways in the brain’s response to TBI/CTE are being investigated for their pharmacotherapeutic targets?
11. Give at least two reasons why drugs targeting TBI/CTE have failed in clinical trials.
12. Describe at least one pharmacological hurdle to the efficacious treatment of TBI/CTE, and then identify the non-pharmacological alternative treatments currently being developed for neurotrauma.

38.10 Answers

1. Grossly, there are usually no identifiable pathological abnormalities in early-stage CTE, but sometimes a cavum septum pellucidum and mild enlargement of the frontal and temporal horns of the lateral ventricles may be observed.
2. Histologically, CTE is characterized by extensive regional occurrence of p-tau-positive NFTs and NTs. In addition, the presence of p-tau-positive astrocytic tangles has been described in the McKee case series.
3. Although examinations of the brains of AD patients and two boxers with CTE revealed a similar tau isoform ratio and phosphorylation state between two distinct diseases, the abnormal distribution and localized nature of the tau pathology are unique to CTE and distinguish it from other degenerative tauopathies.
4. During head trauma, the brain may be subjected to the compressive and shearing forces of rapid acceleration and deceleration. Goldstein et al. (2012) hypothesized that the rapid acceleration-deceleration forces of concussive impact trauma (e.g., the “bobblehead effect”) were key to CTE pathogenesis in both sports- and blast-induced TBI.
5. Since neuropathological evidence is required to confirm CTE, our understanding of how CTE might manifest itself as motor, cognitive, or affective symptoms has emerged retrospectively from ‘verbal autopsies’, involving interviews of the families of those neuropathologically diagnosed with CTE post-mortem.
6. You must recognize the limited external validity inherent in such a small non-random sample from a CTE brain bank comprised of athletes’ brains donated by families who may have felt compelled to donate based on the symptoms they had witnessed.
7. Depending on an individual’s unique history of TBIs and their frequency, the resulting physical brain injuries can range from mild to severe and be either localized contusions in specific brain regions or extensive and diffuse. Other factors include the age range of exposure, genetic susceptibility, pre-existing mental traits, substance abuse, education and other lifestyle choices.
8. Given the current lack of prospective longitudinal and cross-sectional data, this will require both animal and

human studies of CTE based on randomized before-after control-impact studies employing protein-based assays, biofluid-based biomarkers and neuroimaging.

9. Distinct p-tau accumulations localized around the depths of cortical sulci and perivascular areas. Also, A β plaques are not consistently observed in CTE cases (<50%), but when present, they are less dense and predominantly diffuse. Finally, the tau found in CTE is characterized as high molecular weight tau.
10. The therapeutic targets include AMPA-receptor antagonists, anti-inflammatory agents, antioxidants, apoptosis inhibitors, bradykinin receptor antagonists, immunophilin ligands, calcium channel blockers, necrosis inhibitors, neurotrophic factors, neurosteroids, NMDA receptor antagonists, nitric oxide modulators, oxygen carriers, polyethylene glycol, thyrotropin-releasing hormone analogs and others.
11. Due to inadequate single-target therapy. Therefore, any future effective therapy would most likely need to target multiple pathways.
12. One major challenge in developing therapeutics for TBI/CTE is overcoming the blood-brain barrier while delivering drugs. Researchers are encapsulating their therapeutics into nanoparticles to carry significant drug loads through the BBB to combat TBI/CTE.

Abstract

The term “neuroimmune system” emphasizes the fact that nervous and lymphoid tissues constitute a unified system that functions in the maintenance of homeostasis. The conventional division between the two systems has blurred, as well as the distinction between neuropeptides on the one hand, and immune cytokines on the other. Two lines of research have altered our perspective on neuroimmune interactions: (a) the identification of conventional neuropeptides and their receptors, especially those related to the hypothalamic-pituitary-adrenal (HPA) axis, in most lymphoid tissues, and (b) the large body of evidence that cytokines, historically associated with immune system communication, play vital roles in nervous function. The role of the HPA axis in coordinating responses to stressors, and the role of the immune system in mediating the “sickness” response, underscores this reciprocal relationship between the CNS and the immune system. In spite of this nascent state of knowledge, the evidence for hyper-reactivity of the HPA axis and the alterations in cytokine levels observed in both major depressive disorder (MDD) and schizophrenia serve as a foundation for further research establishing a causative relationship between alterations in immune system function and these debilitating psychiatric disorders.

39.1 Introduction

The earliest evidence for neuroimmune interaction and regulation is the classical immune conditioning experiment of Ader and Cohen in 1975 (Ader 1987). Since then, it is well established that the central nervous system (CNS) and the immune system interact and regulate one another's function

(Madden and Felten 1995; Carr and Blalock 1989). This interaction can be particularly important at times of extraordinary stress, whether due to psychological factors or to a physical response to an injury or an infection. The CNS regulates immune system function with classical neurotransmitters acting through the central nervous system and peripherally through the sympathetic nervous system; and with neuropeptides also acting through both the central and peripheral nervous systems. The immune system, in turn, alters CNS function, particularly through the release of cytokines. While this reciprocal regulation between the CNS and the immune system is designed to maintain homeostasis, dysfunction in one can lead to aberrant function in the other, producing a pathological state.

Interactions between the immune and nervous system are complex and attempts to decipher these are still incomplete. One of the first empirical findings in support of an interaction between these systems was the discovery of receptors for neurohormones and neuropeptides on cells of the immune system (Hadden et al. 1970; Wybran et al. 1979; Hazum et al. 1979; Landmann et al. 1981). This implied that immune cells can and do respond to the endogenous ligands for these receptors. Conversely, the demonstration of many cytokine receptors and the cytokines themselves in the CNS suggests not only that these small proteins have a functional role in the CNS, but that cytokines released by the immune system may be able to regulate CNS function (Adler and Rogers 2005; Cartier et al. 2005). Subsequent studies demonstrated that immune cells also synthesize and release many neurohormones and neuropeptides. This provides a mechanism for local control of the physiological effects of these transmitters, in addition to distant control mediated through the peripheral and central nervous systems. This sharing of ligands and receptors in the nervous and immune systems led to the suggestion that this constituted a complete biochemical information circuit and that this interactive communication system provided the basis for the immune system acting as a sensory system and the brain playing an immunoregulatory role (Blalock 1994).

In this chapter we will provide an overview of how the hypothalamic-pituitary-adrenal (HPA) axis, the CNS and the immune system are integrated and regulate each other's activity. While there are many neurotransmitters and neurohormones that act directly and indirectly through the CNS on the immune system, such as serotonin, norepinephrine and gamma-aminobutyric acid (GABA), we will focus on neuropeptides and cytokines found to regulate the immune response. In particular, we will examine HPA axis regulation of CNS function by release of peptides and glucocorticoids in response to stress and inflammation. We will consider opioid-like peptides as well as corticotrophin-releasing hormone (CRH) and related peptides that are synthesized in the immune system as well as the CNS and how they regulate

immune function. We will also discuss cytokines released by the immune system and how they impact CNS function. Finally, we will provide a brief overview of how the neuro-immune system plays a role in psychiatric illnesses such as depression and schizophrenia, a topic explored in more detail in the following two chapters.

39.2 HPA Axis Regulation of CNS Function

The occurrence of physical or psychological events, or “stressors”, that threaten the well-being of an organism can lead to activation of a generalized stress response. The stress response consists of a coordinated activation of adaptive processes (collectively referred to as allostasis) that are designed to return the organism to steady-state conditions, i.e. homeostasis. This coordinated response is mediated by components of the central nervous system (CNS), the peripheral nervous system (PNS), and the endocrine system. The hypothalamic-pituitary-adrenal (HPA) axis defines the classical core of the neuro-endocrine stress response system. The HPA axis coordinates the component processes of the stress response by serving as the major communication route between the CNS, the PNS and the endocrine system. The HPA axis consists of three major components: the hypothalamic paraventricular nucleus (PVN), corticotrophs in the anterior pituitary gland, and the adrenal cortex. The hypothalamus is situated at the anterior-most end of the brainstem and serves as the final common pathway for regulation of visceromotor and endocrine functions by the CNS. The PVN, situated bilaterally along the midline of the anterior hypothalamus, coordinates endocrine functions via the pituitary gland and visceromotor functions via pathways to the brainstem. The pituitary corticotrophs are one of several distinct cell types in the anterior pituitary, each serving as an interface between the central nervous system and the endocrine system to control some aspect of metabolism or sexual behavior. The adrenal cortex comprises the outer layers of the adrenal gland, which plays a major role in responses to stress, through its innervation by the sympathetic nervous system and via circulating hormones.

The activation of a stress response begins with the appraisal of stressors by the distributed CNS network commonly known as the limbic system. The concept of the limbic system, which was originally defined anatomically, has taken on a functional connotation and now typically refers to CNS systems which modulate the hypothalamus. These brain areas include the hippocampus, the amygdala, and regions in medial prefrontal cortex. The components of the limbic system all influence hypothalamic output, and constitute a distributed system that regulates affective state and is critically involved in the appraisal and response of the organism to stressors. In general, the hippocampus and the anterior

cingulate / prelimbic regions of prefrontal cortex inhibit HPA axis output, while the amygdala and the infralimbic region of prefrontal cortex potentiate HPA axis activity. Thus, different regions of the limbic system modulate the output of the HPA axis in a reciprocal fashion to coordinate the temporal sequence of the stress response, controlling the initiation, propagation, and termination of distinct processes.

39.2.1 Hormones Released by the HPA Axis

Two neuropeptides, corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP) are released from parvocellular neurons in the hypothalamic PVN to initiate a stress response. The terminal endings of these neurons, located in the median eminence of the hypothalamus, release CRH and AVP into the hypothalamic-hypophyseal portal vessel system, where they travel to the anterior pituitary. The two neuropeptides act synergistically on pituitary corticotrophs to activate the synthesis of pro-opiomelanocortin (POMC). This peptide, discussed in detail below, is processed to produce several peptides including adrenocorticotrophic hormone (ACTH), or corticotropin. ACTH released from corticotrophs travels via the bloodstream to act on cells in the zona fasciculata layer of the adrenal cortex, stimulating the synthesis and release of the glucocorticoids, cortisol (in humans) or corticosterone (in rodents).

In addition to regulating the synthesis and release of ACTH from the pituitary, neurons in the PVN also project to areas in the brainstem that control the output of the sympathetic branch of the PNS. Activation of PVN neurons at the onset of a stress response thus leads to increased sympathetic outflow, resulting in release of norepinephrine from sympathetic nerve terminals and epinephrine from the adrenal medulla. The effects of these catecholamines are responsible for the behavioral syndrome known as the "fight-or-flight" response.

The effects of the neuropeptides and glucocorticoids associated with the HPA axis are mediated through distinct receptor subclasses. Two classes of CRH receptors have been identified, type 1 and type 2, with distinct but overlapping distributions in the CNS (Hsu and Hsueh 2001; Reyes et al. 2001). It is currently thought that CRH acts through type 1 receptors (CRHR1), while novel ligands have been identified for the related type 2 receptors (CRHR2). These ligands, urocortin II (Reyes et al. 2001) and urocortin III (Lewis et al. 2001), play a role in the regulation of appetitive behaviors and are thought to play a role in the adaptive (slow) phase of the stress response (de Kloet et al. 2005) as discussed below. Expression of mRNA for the urocortins has been demonstrated in the hypothalamus, brainstem, and amygdala (Hsu and Hsueh 2001). Interestingly, the CNS distributions of the CRHR1 and CRHR2 receptors correspond to the CRH and urocortin terminal fields, respectively.

The effects of the glucocorticoids are also mediated through two distinct subclasses of cytosolic steroid receptors. Glucocorticoid receptors (GRs) are found throughout the brain, but GR density is highest in the hypothalamic PVN, ascending aminergic pathways, and in limbic brain regions (Herman et al. 2003). Mineralocorticoid receptors (MR) are named for their primary ligand, the steroid aldosterone, which is produced by the outer zona glomerulosa layer of the adrenal cortex and regulates sodium balance. However, MRs in the brain have a ten-fold higher affinity for glucocorticoids than GRs and thus respond to lower levels of these hormones during the initial phase of a stress response. MRs are also expressed at high levels in limbic brain regions; thus there is considerable overlap between these two receptors in key brain areas that regulate the HPA axis.

39.2.2 The Role of HPA Axis in Response to Stress

Under resting conditions, CRH and AVP are released from the hypothalamus in a pulsatile fashion with a frequency of 2–3 episodes per hour (Engler et al. 1989). The amplitude of the neuropeptide pulses normally increases in the morning, resulting in a circadian fluctuation in ACTH and cortisol levels. This daily rhythm is modulated by feeding and activity schedules, but is particularly perturbed by stressful stimuli originating internally (e.g., anxiety or systemic infection) or externally (e.g., threatening situations). Thus, acute stressors lead to activation of the stress response.

39.2.2.1 Modes of the Acute Stress Response

The stress system is characterized by two modes of operation, a fast phase that serves to mobilize and activate, and a slow phase that promotes recovery and adaptation. Each mode is associated with characteristic behavioral changes that are mediated by distinct cellular and molecular mechanisms.

The initial fast phase is manifested behaviorally by increases in vigilance and arousal, and alterations in attention. This phase is associated with the release of CRH and AVP from the hypothalamic PVN, activation of sympathetic outflow and release of catecholamines from the adrenal medulla, and rising blood levels of cortisol. The effects of CRH in the fast phase are mediated through type 1 receptors (CRHR1), which are responsible for activation of the HPA axis and the sympathetic nervous system. Levels of cortisol rise rapidly due to release of ACTH from the pituitary, and serve in the periphery to mobilize metabolic resources and alter immune system responses (discussed below). The effects of cortisol on brain structures, and thus behavior, in the fast phase are mediated primarily by the higher-affinity MRs, which respond to the rising levels of cortisol at the initiation of a stress response. An important aspect of MR-induced

changes involves their role in the appraisal of environmental stimuli in this phase of the response. The alterations in neuronal function mediated by the interaction of cortisol with MRs lead to increases in arousal level, heightened vigilance and alertness, and enhancement of attention.

The slow phase of the stress system is characterized by processes that promote recovery from, and adaptation to, the stressful conditions that prompted the response. At the level of the hypothalamus, this phase is probably mediated by the urocortins acting through CRHR2 receptors (Reul and Holsboer 2002; de Kloet et al. 2005). In contrast to the fast phase, the slow phase is associated with activation of the parasympathetic nervous system, which promotes the appetitive and metabolic functions which help to restore homeostasis. As cortisol levels peak and then slowly subside during the slow phase, the lower-affinity GRs are activated and lead to transcriptional changes in target organs that promote recovery. In the brain, GR activation-induced transcriptional changes may be crucial for the consolidation of memory traces involving the association of stressors with sensory stimuli (in the amygdala) (Roosendaal and McGaugh 1997) and environmental context (in the hippocampus) (Oitzl and de Kloet 1992).

At all levels of the HPA axis, feedback mechanisms exist that control the output of neuropeptides and circulating hormones. These mechanisms regulate the levels of these factors during normal diurnal cycles, but also act to limit the magnitude of the stress response and terminate its effects. These feedback mechanisms consist of both "short" loops, where each factor acts to inhibit its own secretion, and "long" loops, whereby ACTH acts on PVN neurons to inhibit the secretion of CRH, and cortisol acts on the PVN and the pituitary to inhibit the secretion of CRH and ACTH, respectively (de Kloet et al. 2005).

39.2.2.2 Modes of the Chronic Stress Response

It is important to distinguish between the response of the HPA axis to acute stressors, and the response to chronic stress. While the HPA response to acute stressors can clearly be seen as an adaptive response that serves to maintain or re-establish homeostasis, the response to chronic stress can lead to maladaptive conditions, especially in "vulnerable" individuals, that may initiate or facilitate CNS disease processes, as discussed below.

39.2.3 Role of HPA Axis in Inflammation

The activation of the stress systems affects all tissues of the organism, and the peripheral immune system is no exception. These effects are mediated through at least two pathways: via the HPA axis and by virtue of the innervation of lymphatic tissues by autonomic nerve fibers, especially from

the sympathetic nervous system. All lymphoid tissues, primary (bone marrow and thymus) as well as secondary (spleen, lymph nodes, and gut-associated lymphoid tissue) are innervated by sympathetic nerve fibers. As discussed above, most lymphoid cells express catecholamine receptors, including B-lymphocytes, CD4- and CD8-positive T cells, dendritic cells, monocytes, and macrophages. The HPA axis also directly affects peripheral immune functions via receptors for CRH, ACTH and cortisol.

39.3 Neuropeptides as Modulators of the CNS and Immune Function

There is differential expression of neurotransmitter and neurohormonal receptors among the various cell types of the immune system. This suggests that particular neurohormones produce specific and differential effects on immune cells, and hence on immune function. It also suggests that the pharmacology of immune cells will vary from cell type to cell type and that these pharmacological differences represent potential drug treatment strategies in coping with various pathological states. There is still a great deal of work to be done in this field since there is debate in the literature on receptor expression, i.e., which cells consistently express which subset of receptors, and whether and how receptor expression is regulated by the changing milieu.

For example, functional activities of β 2-adrenergic, prostaglandin and histamine receptors are increased in T lymphocytes activated by IL-2 (Dailey et al. 1988). This takes place in an apparently coordinated manner even though the prostaglandin receptors are clearly dominant in regulation of signal transduction in resting cells. The change in functional activity is presumably due to up-regulation of receptor expression. These and other studies indicate that receptor expression is a dynamic aspect of immune system function and it that implies alterations in receptor function are important for immune system activities, in this particular case cellular proliferation.

39.3.1 Peptides Derived from Proenkephalin

Two of the most abundant endogenous opioid peptides, methionine-enkephalin (Met-enk; Tyr-Gly-Gly-Phe-Met) and leucine-enkephalin (Leu-enk; Tyr-Gly-Gly-Phe-Leu) are derived from the precursor protein, proenkephalin (PENK). PENK is a 267 amino acid precursor that contains 6 copies of Met-enk, two of which are extended forms (Tyr-Gly-Gly-Phe-Met-Arg-Phe and Tyr-Gly-Gly-Phe-Met-Arg-Gly-Leu) and one copy of Leu-enk. This ratio is essentially the same as the ratio of these peptides found in brain and adrenal chromaffin cells. The fact that there are two distinct

peptides closely related in structure and function proved to be a major obstacle that slowed their discovery (Kosterlitz and Hughes 1977).

The first two opioid peptides were isolated from pig brain and shown to be active in bioassay systems by Hughes and Kosterlitz in 1975 (Hughes et al. 1975). It was some time later, though, that the precursor proteins for these small peptides were discovered. The first of these to be identified was proopiomelanocortin (POMC). It was not until 1982 that PENK was identified and sequenced in multiple species (Udenfriend and Kilpatrick 1983). Hypothalamic neurons containing POMC have been extensively studied in their role regulating food intake.

As mentioned above, PENK contains not only both pentapeptide enkephalins, but also a hepta- and octapeptide enkephalin. This structure is maintained across species (Noda et al. 1982; Comb et al. 1982; Gubler et al. 1982). The processing of PENK into smaller peptides, even for an extended period of time, maintains this assortment of four distinct peptides (Fleminger et al. 1983), indicating that all are active products of PENK and that the longer peptides are not simply alternate precursors for Met-enk. Interestingly, while a great deal of attention has been paid to the role of the pentapeptides, Met-enk and Leu-enk, knowledge of the physiological role of the hepta- and octapeptides is still very limited.

There is evidence PENK is not processed in the same way in all tissues and the suggestion has been made that alternative processing may occur in immune system cells containing PENK, compared to processing in neurons. This would open the possibility that differential processing may lead to release of enkephalin-like peptides from the immune system that would have a different spectrum of activities, at least to some extent, than those derived from neural tissues. This, in turn, would provide the opportunity for differential regulation of components of the immune system, depending on the source of the enkephalin-like peptide release.

39.3.1.1 Expression of Enkephalins in the Immune System

PENK is distributed widely throughout the brain (Wamsley et al. 1980; Finley et al. 1981; Harlan et al. 1987), indicating involvement of the enkephalins in a variety of physiological functions. The first suggestion that peptides derived from PENK were involved in immune system function came from the work of Wybran (Wybran et al. 1979), which demonstrated specific binding of both Met-enk and morphine to lymphocytes. Early studies also demonstrated that the enkephalins are concentrated in leukocytes compared to other blood components, supporting the idea that immune cells can synthesize the opioid peptides. Since these initial observations, a large body of evidence has provided more detail supporting the idea that the enkephalin peptides are

produced by and have important actions in cells of the immune system.

Determination of which PENK products are formed by different immune cells has been difficult because of the lack of antibodies specific to the various peptides. For instance, many studies use readily available antibodies to Met-enk, but the possibility is strong that these antibodies can also react with larger peptides containing Met-enk. In addition, the variations in results reported in the literature are probably due to differences in cell types as well as the inducing signal. For instance, Th2 cytokines, such as IL-4, IL-6 and TGF- β , produce many-fold increases in PENK mRNA in human thymocytes. On the other hand, Th1 cytokines have variable (IL-1 β) or no (IFN- γ) effect (Kavelaars and Heijnen 2000). Further, Th2 cytokines lead to a 4- to 5-fold increase in Met-enk-like protein in thymocytes, whereas Th1 cytokines produce no such effect. It appears, moreover, that the induced Met-enk itself is not released by thymocytes; rather, larger peptides containing Met-enk are released.

Similar results have been found in T cells. PENK is synthesized in T cells and both synthesized and processed into smaller peptides in macrophages and activated monocytes, but not in inactivated monocytes. Paradoxically, in many cases it has been very difficult to demonstrate release of PENK products. For example, T cells do not appear to secrete detectable levels of PENK-derived peptides whereas monocytes do. On the other hand, under some conditions T cells have been shown to secrete intermediate products of prepro-enkephalin, the precursor to PENK. These intermediate products appear to inhibit proliferative capacity via unidentified, i.e., non-opioid, binding sites. The larger peptides eventually are processed into Met-enk (and Leu-enk) in some cases, whereas in others the larger peptides are probably the active products themselves (Dillen et al. 1993; Hiddinga et al. 1994). There are many questions yet to be answered in this area. To compound the problems of determining if the products of PENK are released and are active, the quantity of material provided by the tissues is sometimes small enough to make consistent quantitative data difficult to obtain. This leads to further confusion and contradictions in the literature.

39.3.1.2 Function of the Enkephalins in the Immune System

Met-enk, the most abundant of the enkephalin peptides, produces effects on its target cells that are both concentration-dependent and modified by the presence of other stimuli. The concentration-dependent effects can be bimodal, with low concentrations producing effects opposite those of high concentrations (Oleson and Johnson 1988). An example is the differing effects of varying concentrations of enkephalins on the production of reactive oxygen species (ROS) by polymorphonuclear leukocytes.

ROS production is enhanced by low enkephalin concentrations and suppressed by high concentrations (Roschetti et al. 1988; Marotti et al. 1992). In a similar manner, Met-enk inhibits antibody production by B cells whereas slightly larger peptides also derived from PENK stimulate B cell antibody production (Hiddinga et al. 1994; Das et al. 1997). One possible explanation of these paradoxical data is that opioid peptides may play a role as modulators of immune system function, fine tuning the current state of activity, rather than being the primary drivers or determinants of function. As such, the effects of these peptides would be highly dependent on the current status of the immune system, whether activated or inactive, and on which other regulatory factors were present and what their overall effects are. In this sense, the endogenous opioids would act more to maintain homeostasis rather than to specifically activate or inhibit the immune system.

The exact role of Met-enk and related peptides derived from PENK remains controversial since there are many studies with seemingly contradictory results. Many of these studies were carried out in vitro and how well the results translate to in vivo conditions is not clear at present. In addition, relatively few of these studies used experimental conditions that were the same or even similar to those used in other studies, making comparison and resolution of differences difficult.

39.3.2 Peptides Derived from Prodynorphin

A second major source of endogenous opioid peptides is derived from prodynorphin (pDYN), the product of a single gene that contains four exons (Gein 2014) with seven splice variants in humans. The processing of the pDYN peptide appears to be differentially regulated in CNS regions (reviewed in Schwarzer 2009). Of several peptide fragments generated, the major components appear to be dynorphin A and dynorphin B, separately derived from pDYN. Dynorphins make up a family of opioid peptides that appear to act primarily at kappa opioid receptors in the central and peripheral nervous system, with dynorphin A (amino acids 1-17) having the highest affinity for this opioid receptor (James et al. 1984) and is produced and contained within immune cells. Evidence suggests that opioids modulate innate and acquired immune responses (McCarthy et al. 2010). The endogenous opioid system consists of three peptide precursors that encode for dynorphins, enkephalins, β -endorphins and proopiomelanocortin (POMC) (Kieffer and Gavériaux-Ruff 2002). In addition, opioid peptides generated from proenkephalin A act as cytokines that are capable of regulating granulocytes and mononuclear cell function (Sharp et al. 1998).

39.3.2.1 Expression of Dynorphins in the CNS and Immune System

Within the central nervous system, dynorphins are primarily localized to the hippocampus, amygdala, striatum and the spinal cord. Through the nervous system, dynorphins control memory, learning, emotions and reactions to stress. However, dynorphins, like other opioids, are locally synthesized in various tissues including tissues of the immune system (Gein 2014). Dynorphins are known to be present within immune cells and nerve fibers with inflamed tissues (Hassan et al. 1992). Aside from dynorphin expression, opioid receptor expression has been shown on a variety of immune cells, which allow for direct and dynamic effects on immune function (Bidlack 2000). Specifically, k-opioid and δ -opioid receptors are found to be present on lymphocytes and there is further evidence for both neural and non-neural opioid receptors on immune cells (Bidlack 2000). Depending on the site of their production, dynorphins have different physiological actions, indicating that dynorphins have a wide variety of functions regarding the human immunological response.

39.3.2.2 Function of Prodynorphin Derivatives in the CNS and Immune System

The immunomodulatory function of dynorphins is determined by the expression levels of kappa receptors. The dynamic effects are thought to be due to the complicated pro-opioid system and its multiple receptors. Through k-opioid receptors, dynorphins regulate proliferation, as well as the production of antibodies. Dynorphins also regulate anti-inflammatory activity as well as pro-inflammatory activity. In addition, dynorphin peptides are capable of directly modulating lymphocytes and other cells involved in immunity (Bidlack et al. 2006). Dynorphins are thought to contribute to the pathophysiology of depression, schizophrenia, epilepsy and addiction (Schwarzer 2009). Stress, which is known to be associated with aversive mental states, is known to induce the release of dynorphins, rapidly activating k-opioid receptors. Prolonged k-opioid receptor activation can lead to characteristic depressive disorders (Knoll and Carlezon 2010). The use of dynorphin antagonists has been shown to alleviate depressive behaviors (Shirayama et al. 2004), providing evidence that therapeutic effects may be induced by preventing the over-activation of k-opioid receptors by dynorphin.

39.3.3 Peptides Derived from Proopiomelanocortin (POMC)

Another major source of endogenous opioid peptides as well as non-opioid peptides is proopiomelanocortin (POMC).

This large peptide contains the sequences of, and is processed into, a number of smaller peptides, including ACTH, β -endorphin, β -lipotropin, α -MSH, β -MSH and γ -MSH. Which products are derived from POMC depends upon the cell in which the processing takes place. In the anterior lobe of the pituitary POMC is processed into ACTH and β -lipotropin. In the neurointermediate lobe the major products are β -endorphin, α -MSH and γ -MSH. POMC was the first of the peptide precursors for which such cell-dependent processing was demonstrated.

39.3.3.1 Expression of POMC in the Immune System

The discovery by Blalock and colleagues that POMC was also produced by immune cells was a major event in the developing recognition of interactions between the immune and nervous systems (reviewed in Blalock 1999). These studies indicated that not only do neurohormones derived from the nervous system alter immune system activity, but also similar or identical hormones can be released from immune cells to regulate the nervous system as well as the immune system itself.

Similar to what was found with the PENK-derived enkephalins, peptides derived from POMC frequently have biphasic dose-response curves, i.e., low doses stimulate immune system function whereas high doses usually suppress function. Again, it appears the system is designed to maintain homeostasis in response to a wide range of conditions.

The finding that the immune and neuroendocrine systems both express receptors for opioids and for ACTH and that both systems can synthesize and release peptides active at these receptors, led to the suggestion that the immune system functions as a sensory organ (Blalock 1984, 1999) and that this forms the basis for the interaction between the two systems. It is well known that the nervous system responds to a variety of stimuli and, when appropriate, releases neurotransmitters and hormones that enable an appropriate reaction to these stimuli or stresses. This can include changes in immune system function. Blalock proposed that the immune system also responds to particular stimuli, in this case environmental changes that would not be readily detected by the nervous system, such as the presence of bacteria or viruses. In response, the immune system releases a variety of compounds, including peptide hormones that will alter both immune and nervous system function.

39.3.3.2 Function of POMC Derivatives in the CNS and Immune System

Beta-Endorphin

A locally induced inflammation followed by cold-water swimming, a stress that is known to activate intrinsic opioid

systems, produces an antinociceptive effect localized to the area of inflammation (Stein et al. 1990a). Through a series of experiments it became apparent that the agent producing this effect was β -endorphin and that it was localized to the area of inflammation; i.e., it was not a systemic effect of the peptide. This provided strong evidence that localized release of endogenous opioid peptides in areas of inflammation could play an important role in regulating inflammation and nociception. Subsequent experiments using this same model demonstrated significantly increased levels of both β -endorphin and Met-enk localized to the area of inflammation, although it appeared that β -endorphin was responsible for the antinociceptive effect (Stein et al. 1990b). These studies indicated that localized release of these opioid peptides from immune cells was responsible for the reduction in pain. Further support for the involvement of immune cells in this antinociceptive action came from suppression of the immune system with cyclosporin A, which resulted in the loss of the antinociceptive effects of the endogenous opioids. Interestingly, Met-enk did not play an important role under this experimental paradigm and it was not clear whether Met-enk was released from immune cells, even though it was definitely present in the cells. The paradoxical synthesis of two opioid peptides and the release of only one to produce antinociception leaves many unanswered questions, such as why is Met-enk synthesized in the first place? This and many other questions remain.

α -MSH

The tridecapeptide, α -MSH, is also derived from POMC. While originally discovered through its effects on the skin, α -MSH can alter immune system function. Understanding the role of α -MSH in neuroimmune modulation is still in the early stages (Luger et al. 2003). α -MSH acts through melanocortin-1 receptors (MC-1R), which are expressed by immune cells, including macrophages and monocytes. Both β -MSH and γ -MSH, also products of POMC, act through other melanocortin receptors and these receptors have not been found on immune cells to date. This indicates that α -MSH may be the only of these three to be involved in regulating immune function.

Most studies to date suggest that α -MSH modulates or reduces inflammation, down-regulating proinflammatory cytokines and other proinflammatory molecules (Luger et al. 2003). These effects are produced, at least in part, by inhibition of NF κ B activity. There is some evidence that α -MSH may have biphasic effects in this regard since low concentrations increase antibody production by B cells whereas higher concentrations reduce production.

As discussed above, several other peptides may be derived from POMC in a cell-specific manner, dependent upon processing within each cell type. The role of ACTH in nervous

system-immune system interactions is discussed elsewhere in this chapter. At present a neuroimmune function for the other POMC peptides has not been demonstrated.

39.3.4 Corticotropin Releasing Hormone

Corticotropin Releasing Hormone (CRH; corticotropin releasing factor; CRF) plays a major role in CNS regulation of the immune system. In particular, CRH released from the hypothalamus is the first point in HPA axis regulation of immune function. As a critical player in the response to stress, the HPA axis is a primary point of coordination in the neural-immune interaction. This is discussed in Sect. 39.2 of this chapter. CRH also plays an important role in many CNS functions, including regulation of the autonomic nervous system and endocrine function. CRH is involved in the central response to anxiety and stress, and hence affects immune system function via that route. There is also convincing evidence that CRH can play a role in depression. The central role of CRH has been reviewed (Dunn and Berridge 1990; Heim and Nemeroff 1999). Beyond these well-known roles for CRH, this neuropeptide hormone is also synthesized in immune cells and so appears to play an even more widespread role than originally thought.

Early studies demonstrated a role for CRH in augmenting function of immune cells, such as natural killer cells (Carr et al. 1990). The localization and the synthesis of CRH in the immune system and in immune cells were initially suggested by finding mRNA for CRH in leukocytes (Stephanou et al. 1990) and significant concentrations of CRH in areas of inflammation (Karalis et al. 1991). This suggested CRH was produced locally, i.e., in the periphery in areas of inflammation, probably in part by immune cells. Further studies supported these ideas. In Lew/N rats, which are deficient in hypothalamic CRH responses to inflammatory stimuli, there are high levels of CRH in inflamed joints (Crofford et al. 1992). These data suggested that CRH plays the role of an autocrine or paracrine inflammatory factor. The obvious paradox is that CRH plays a powerful anti-inflammatory role as the primary CNS activator of the HPA axis, yet in local peripheral sites it has just the opposite effect. Thus, CRH expression and function with respect to inflammation is site specific.

CRH had been shown to have important effects in areas of inflammation, such as augmentation of analgesia by endogenous opioid peptides. It has been further demonstrated that the effects were blocked by local administration of a CRH antagonist, a CRH antibody or by antisense oligonucleotides directed against CRH. This implies that local production and release of this hormone by immune cells do, in fact, occur and are physiologically important (Schafer et al. 1996). It was found that systemic administration of these same various

antagonists of CRH action, an approach directed against CRH released from a distant site, was either ineffective or several orders of magnitude less potent than local administration, bolstering this argument.

It proved difficult to definitively demonstrate CRH synthesis from immune cells, although numerous studies provided evidence this does happen (Aird et al. 1993; Ekman et al. 1993). Eventually it became clear that regulation of CRH synthesis and release in immune cells differs from that in hypothalamic neurons. While immune cells may synthesize and release much smaller concentrations of CRH and other neuroimmune peptides, and although their release may require *de novo* synthesis, an inherently slow process, the fact that immune cells release these hormones locally in the target area compensates for both of these factors to some extent. These data indicating site and tissue specific effects of CRH, sometimes even contradictory effects, point to the complex interrelationship between the nervous, endocrine and immune systems, an interaction that has yet to be deciphered completely.

39.3.5 Tachykinins

Tachykinins are a family of neuropeptides that are intensively studied. In fact, tachykinins are the largest family of neuropeptides present within mammals and amphibians. They make up a group of structurally related peptides all derived from *tac* genes, in alternating sequences (Steinhoff et al. 2014). *Tac* genes encode preprotachykinins, precursor proteins, which get chopped into smaller peptides, forming tachykinins. Tachykinins interact with three types of G protein-coupled receptors known as neurokinins. In mammals, substance P, neurokinin A and neurokinin B are the most well-known and studied tachykinins (Pinto et al. 2004). However, new tachykinins are still being discovered. Hemokinin 1, for example, is preferentially expressed in peripheral tissues and may have functions outside of the well-defined functions of tachykinin peptides as neurotransmitters. It has been suggested that aside from neurotransmitter like actions, tachykinins can have profound influences on inflammatory responses, effecting immune cell function in many different ways (Zhang et al. 2006).

39.3.5.1 Expression of Tachykinins in the CNS and Immune system

Tachykinins show broadly distributed expression within human tissues. It has been observed that tachykinin peptide expression is mainly found within neuronal tissues (Otsuka and Yoshioka 1993; Severini et al. 2002); however recent findings have also identified tachykinin expression in a variety of peripheral tissues. Substance P and neurokinin A, for example, are found to be expressed throughout the CNS

and within primary afferent neurons that innervate peripheral tissues. Substance P and neurokinin A have also been found to be expressed in non-neural tissues, like endothelial cells, immune cells and inflammatory cells (Linnik and Moskowitz 1989; Lecci and Maggi 2003). Further, neurokinin B has been discovered to be expressed solely in the CNS, while its function remains largely unknown (Moussaoui et al. 1992; Patacchini et al. 2000). Tachykinin expression has also been reported in pulmonary arteries and veins, suggesting its potential role in lung physiopathology (Pinto et al. 2004). More recently, hemokinin 1 expression in peripheral tissues has led to the great importance of determining new tachykinin peptide expression and function. Understanding the interactions of tachykinins and immune cells may provide advancements in new therapies for inflammatory and immune-related diseases.

39.3.5.2 Function of Tachykinins in the CNS and Immune System

Tachykinins participate in physiological regulation of the nervous, immune, gastrointestinal, urogenital, respiratory and dermal systems. They play a role in inflammation, nociception, proliferation and epithelial secretion (Steinhoff et al. 2014). In addition, regulation of neuronal survival and degeneration has also been suggested as roles of tachykinins.

Due to the variety of expression levels throughout the mammalian body, it has been found that different tachykinin expression levels, in different areas, can lead to different physiological regulations. For example, activation of substance P receptors in the spinal cord regulates synaptic transmission in response to noxious stimuli, while activation of central receptors for substance P regulates cardiovascular and respiratory functions, and is responsible for emetic reflex activation (Marriott 2004). Recently, tachykinins have been discussed as targets for a variety of different therapeutic drugs for a wide variety of disorders. It has been shown that substance P and neurokinin A elicit the production of cytokines through malignant glial cells within brain tumors. In addition, increased proliferation rates of malignant glial cells have been correlated with substance P and neurokinin A levels (Marriott 2004). These findings suggest that tumor proliferation and growth could be due to the interaction of substance P with receptors capable of producing cytokines downstream. On the other hand, substance P and neurokinin A play a role in the secretion of ions and fluid, as well as motor activity of the gastrointestinal tract. For this reason, they have been implicated in gastrointestinal disorders and have recently become ideal targets for pharmacotherapy of gastrointestinal disorders (Holzer 1998). These results suggest that through targeting tachykinins, therapeutic drugs for a variety of disorders may prove beneficial. In addition, it is important to note that when tachykinins are not tightly regulated, a variety of disorders can arise.

39.4 The Role of the Neuroimmune System in Psychiatric Disorders

39.4.1 Overview of the Immune System in Major Depression

In recent years there has been increased investigation of potential links between immune function and depression. Two large meta-analyses of multiple studies found that patients with major depression show reliable changes in immune function (Herbert and Cohen 1993; Irwin 1999), including lowered proliferative response of lymphocytes to mitogens, lower NK cell activity and changes in white blood cell populations. Data suggest that major depressive disorder (MDD) can alter immune function and this is most likely to occur in patients with severe depression (Herbert and Cohen 1993; Irwin 1999; Maes 1999; Frank et al. 2002). While the initial thought was that immune function was depressed in MDD, more recent evidence has suggested that many aspects of the immune system are likely to be activated. Both stress and major depression, two disorders that share many features, can be characterized by activation of some immune capacities and suppression of others (Raison and Miller 2001).

The mechanisms for these interactions are not well defined, although numerous hypotheses have been advanced. It should be noted at the outset that attempts to determine the relationship between depression and altered immune function are confounded by the multiplicity of factors known to be associated with both and that may alter the interrelationship. Examples include age, gender, sleep status, the likelihood that depression represents a complex of disease states with varying involvement of the immune system, and the frequent presence of other psychiatric or physical disorders which can affect both psychological status and immune function. A detailed review of this topic has been published (Irwin 2001). Indeed, it has been pointed out by Irwin that current data suggest immune changes in MDD specifically correlated with the disorder are also seen with stress and other psychiatric disorders, suggesting some common characteristic(s) shared by these problems (Irwin 2001).

In addition, the likelihood that depression represents a complex of disease states with varying involvement of the immune system supports the idea that there is a subgroup of depressed patients who have associated alterations in immune function. Indeed, data suggest that different types of depression display distinct, and even opposite, changes in neuroimmune functions (Antonijevic 2006). As a result of multiple issues, there are contradictory, or at least inconsistent, findings in the literature. This is characteristic of most types of studies of depression, again probably because depression represents multiple disease states.

There is increasing evidence that aberrations in immune system function induce or at least support the development

of MDD. Activation of some aspects of the immune system is generally associated with MDD, even in patients who are otherwise quite healthy. Many studies support this idea (Raison et al. 2006). Proinflammatory cytokines, such as IL-6 and TNF- α , are increased in plasma and in the CNS. There also are increases in the level of chemokines and adhesion molecules.

Several studies have shown increased plasma levels of IL-6 in patients with MDD. In a more extensive study, Alesci and colleagues found that IL-6 levels were increased in MDD patients throughout the circadian cycle (Alesci et al. 2005). There was a 12-h shift in the circadian rhythm of IL-6 plasma levels and its complexity was reduced. Even though IL-6 is a known activator of the HPA axis, cortisol levels were not consistently changed in MDD patients compared to controls. Additionally, it was found that IL-6 levels, with their altered rhythm, correlated significantly with mood ratings. IL-6 also induces a “sickness” behavior very similar to depression. These data suggest a direct relationship between IL-6 and depression.

A related example is the effects of interferon- α (IFN- α) on mood and, specifically, its ability to produce significant depression (Trask et al. 2000; Raison et al. 2006). IFN- α is used to treat several serious disorders, including malignant melanoma and hepatitis C. A major side effect of prolonged or high dose therapy with this agent is major depression, even to the point, though rare, of suicidality. Estimates are that this occurs in as many as 30–50% of patients undergoing IFN- α treatment. A history of psychiatric symptoms is considered a relative contraindication to the use of IFN- α , and a psychiatrist should closely monitor treatment of such patients using this drug. Further indications that the syndrome produced by IFN- α is depression are that it is responsive to treatment with antidepressants and that there are indications of changes in serotonin and possibly norepinephrine metabolism centrally. Alterations in both of these neurotransmitters are associated with depression. It is also interesting that IFN- α is a potent inducer of IL-6, which may be associated with the induction of depression.

As indicated by this brief overview there is considerable evidence for a close relationship between changes in the immune system and depression, particularly MDD. Whether there is a clear cause and effect relationship between these is not known in most cases, although there are strong data in the case of IL-6 and IFN- α , as noted. It will be important to determine more clearly the exact relationship between depression and immune system alterations. There is also a need to determine which of the immune alterations that are found are clinically important (Irwin 2001).

39.4.1.1 Impact of HPA Axis on Major Depression

The hyper-reactivity of the HPA axis that occurs with chronic stress is also often observed in depressed patients (Owens and Nemeroff 1991). In animal models, intracerebroventricular

injection of CRH induces anxiety and a depression-like phenotype (Heinrichs and Koob 2004), and CRHR1 antagonists decrease the signs and symptoms of depression. In contrast, the urocortins, thought to act via the CRHR2 system and potentially involved in the adaptive phase of the stress response, seem to have anxiolytic properties (Heinrichs and Koob 2004). The hypercortisolemia resulting from chronic stress perturbs monoaminergic systems as observed in depression, and causes dysregulation of anxiety and aggressive behavior. Using neuroendocrine tests in longitudinal studies, it has been shown that depressed patients do not respond well to anti-depressant treatment if HPA axis disturbances persist; further, patients showed higher rates of relapse when HPA axis disturbances returned (Zobel et al. 2001). In line with these clinical studies, it is interesting to note that chronic treatment of rats with the anti-depressant amitriptyline resulted in changes in limbic MR and GR that occurred in parallel with HPA axis normalization (Reul et al. 1993). In sum, these observations make a strong case for a major role for the HPA axis in the etiology of depression. An important aspect of research in depression addresses the role of genetic predispositions and developmental events as causative factors. Based on studies of twins, it is estimated that depression has a heritability of 40% (Sullivan et al. 2000).

39.4.1.2 Neuropeptides on Major Depression

A large body of research has aimed at identifying neuropeptides that are dysregulated within patients diagnosed with MDD. Of this body of research, three neuropeptides have been readily identified as being changed in individuals with the disorder, those being substance P, corticotrophin-releasing hormone and vasopressin. Substance P is thought to play a role in the pathophysiology of depression and may be a key target of antidepressants (Bondy et al. 2003). In addition, Bondy et al. (2003) found a subpopulation of individuals with MDD to have elevated serum levels of substance P, suggesting elevated levels of substance P may play a role in the pathophysiology in a subpopulation of patients with the disorder. In addition to substance P, CRH has been identified as an abnormal neuropeptide within the disorder. CRH induces release of ACTH, which is potentiated by vasopressin (Raadsheer et al. 1994). As noted above, CRH has activated the HPA axis (Raadsheer et al. 1994, 1995). Further, studies have identified increased levels of CRH expressing neurons and mRNA levels within the hypothalamic paraventricular nucleus (Raadsheer et al. 1995). Although elevated mRNA levels have been observed, the same has also been reported in cerebral spinal fluid of patients with MDD (Nemeroff 1988). The hyperactivity of CRH has been suggested to be causally related to the symptomology present within the disorder (Raadsheer et al. 1995; Holsboer 2003). Taken together, depression can be characterized by hyperactive CRH systems and HPA axis hypoactivity (Kasckow et al. 2001). Arginine vasopressin, another commonly associated neuropeptide, has

been associated with increased HPA axis activity in MDD (Bondy et al. 2003). Elevated plasma concentrations of arginine vasopressin have been identified in patients with the disorder (Müller et al. 2000; van Londen et al. 1997) and it has been suggested that chronically active vasopressin may play a role in depressive symptomology by influencing the HPA axis (Bondy et al. 2003; van Londen et al. 1997; Müller et al. 2000). Further, antagonizing vasopressin receptors may have a promising role in treatment for major depression (Pariante and Lightman 2008). Targeting of neuropeptide dysregulation in patients with bipolar disorder may prove a promising candidate for treatment of the disorder.

39.4.1.3 Impact of Immune System Cytokines in Major Depression

A large number of studies have demonstrated increases in several pro-inflammatory cytokines in patients diagnosed with MD. It is interesting to note that all of these cytokines are associated with activation of the HPA axis. Thus, elevations in IL-6 have been consistently associated with clinically diagnosed depression (Alesci et al. 2005; Lanquillon et al. 2000; Maes et al. 1997; Musselman et al. 2001; Sluzewska et al. 1995). The circadian pattern of IL-6 secretion is shifted 180° out of phase in depressed patients (Alesci et al. 2005), and IL-6 levels are significantly correlated with severity of depression (Musselman et al. 2001). Prior to administration of antidepressant medication, levels of IL-6 were elevated in patients who did not respond to the treatment, whereas responders showed normal levels before treatment, suggesting that IL-6 levels could be used to predict treatment outcome (Lanquillon et al. 2000). Depression has also been associated with increases in IL-1 (Owen et al. 2001; Thomas et al. 2005) and TNF- α (Hestad et al. 2003; Tuglu et al. 2003). These studies support a role for pro-inflammatory cytokines in MDD, and suggest a novel strategy for treatment of the disease (Raison et al. 2006).

39.4.2 Overview of the Neuroimmune System in Schizophrenia

The involvement of the immune system in schizophrenia (SZ) is an even more complicated issue compared to involvement with depression. There have been suggestions for many decades that schizophrenia is associated with immune dysfunction (Vaughan et al. 1949). However, it is only recently that substantial evidence relating to this idea has begun to appear and this is even less definitive than data supporting a link between the immune system and depression. Analogous to depression, there are multiple problems with dissecting a role for the immune system in schizophrenia, including the multiplicity of the disease etiology and the difficulty in controlling for the many factors that are frequently associated with schizophrenia and that also alter immune function themselves.

These include age, gender, sleep status, the likelihood that schizophrenia represents a complex of disease states, and the frequent presence of other psychiatric or physical disorders which can affect both psychological status and immune function. The difficulties with such studies have been set forth by Keller and colleagues (2013).

Nevertheless, despite the difficulties, there are intriguing findings that have strengthened the hypothesis that neuro-immune interactions are altered in schizophrenia patients. One argument for an association between immune function and schizophrenia is that epidemiological data show a linkage between prenatal viral infections and subsequent appearance of schizophrenia. There have also been studies that show an acute exacerbation of schizophrenia can occur in response to immune system dysfunction. These have been reviewed (Keller et al. 2013). The most extensively examined idea is that schizophrenia is associated with autoimmune diseases or that schizophrenia may, in certain instances, be associated with a lack of normal autoimmune function (Gaughran 2002; Jones et al. 2005; Kipnis et al. 2006).

Autoimmune diseases are associated with some schizophrenia-like symptoms. There are also associations between the appearance of several autoimmune diseases and schizophrenia, although these are both positive and negative correlations. It has been proposed that there is a genetic linkage between schizophrenia and autoimmune diseases. Again, there are both positive and negative associations. Many of these correlations have been refuted by later data. The extensive literature documenting multiple changes in immune system markers and function in the schizophrenic population has been reviewed extensively (Gaughran 2002).

An interesting hypothesis advanced recently is that schizophrenia is, at least in some cases, due to loss of a specific aspect of autoimmunity due to prenatal loss of a specific subset of T cells (Kipnis et al. 2006). This idea is based on a series of studies from the Schwartz lab that indicate autoimmune T cells in the CNS play a fundamental physiological role, exerting a protective effect on neurons when they are subjected to stress. The hypothesis is that there is a prenatal loss of the relevant autoimmune clones so that when stress appears later in life, the neuroprotective effects are lost or at least diminished, and ultimately neurodegeneration occurs, leading to schizophrenia. This idea is consistent with a number of characteristics of schizophrenia. The dopamine hypothesis posits abnormally high levels of dopamine in schizophrenia. Dopamine release is increased centrally in response to stress and this normally suppresses regulatory T cells, leading to increased activity in protective autoimmune T cells. In schizophrenia, however, there is a loss of autoimmune protection, consistent with a lack of protective autoimmune T cells. This would result in lack of neuroprotection and greater neurodegeneration. It is generally accepted that schizophrenia is a developmental disorder. There are also considerable data indicating schizophrenia is often associated with maternal

inflammation or viral infection. Both of these could lead to loss of immune cells prenatally, perhaps to a specific loss of protective autoimmune clones. There is a great deal of work to be done to support or disprove this hypothesis, but it does bring together several aspects of schizophrenia and it provides a framework for investigating a potential role of autoimmunity in schizophrenia.

39.4.2.1 Impact of HPA Axis on Schizophrenia

Hyperactivity of the HPA axis has been implicated in the pathology of schizophrenia (Walker et al. 2008). Others have suggested that the hyper-activation of the HPA is due to the hyper-secretion of CRH. In line with this hypothesis, elevated levels of cerebrospinal fluid CRH have been observed in patients with SZ. Others have observed abnormal cortisol levels in patients with SZ (Kaneko et al. 1992), and augmentation of these levels may exaggerate psychotic symptoms (Walker et al. 2008). Interestingly, antipsychotics have been shown to reduce HPA activity, alleviating symptoms associated with the disorder (Walker et al. 2008). In addition, Kaneko et al. (1992) have even been able to link HPA dysfunction with negative symptoms of the disorder. Although it is well known that the HPA axis is hyperactive in individuals with schizophrenia, further research is needed to identify how the HPA axis dysregulation gives rise to symptoms seen within the disorder.

39.4.2.2 Neuropeptides on Schizophrenia

Similar to other disorders, neuropeptides within schizophrenia have found to be dysregulated. Perhaps the most commonly studied neuropeptide in regards to schizophrenia, neuropeptide Y levels have been shown to be reduced in patients with SZ (Frederiksen et al. 1991; Gabriel et al. 1996; Itokawa and Yoshikawa 2003). In addition, neuropeptide YY has also been shown to be reduced in SZ (Widerlöv et al. 1988). In combination, neuropeptide Y and neuropeptide YY may be useful trait markers in identifying patients with the disorder (Widerlöv et al. 1988). Through the use of post-mortem studies, neuropeptide Y, arginine vasopressin, neuropeptide YY and galanin levels have all found to be decreased in the temporal cortex of patients with schizophrenia (Frederiksen et al. 1991). Other studies have also found decreased levels of somatostatin in temporal and frontal lobes (Gabriel et al. 1996) and mRNA levels were decreased in the dorsolateral prefrontal cortex (Morris et al. 2008). Similarly, decreased levels of somatostatin-like immunoreactivity in the cerebrospinal fluid have been observed (Bissette et al. 1986; Reinikainen et al. 1990). Interestingly, vasoactive intestinal polypeptide levels are decreased in patients with schizophrenia (Vacic et al. 2011; Gabriel et al. 1996), and are suggested to be a potential target for development of antipsychotic drugs (Vacic et al. 2011). It is of note

that antipsychotic treatment has been shown to have beneficial effects on neuropeptide Y and somatostatin cortical levels increasing levels back to normal (Sakai et al. 1995), suggesting that antipsychotics may have therapeutic effects by targeting neuropeptides. Much work remains to be done in order to identify all neuropeptides dysregulated within the disorder, however therapeutic effects may prove beneficial by targeting dysfunctional neuropeptides of the disorder.

39.4.2.3 Impact of Immune system Cytokines in Schizophrenia

While the etiology of schizophrenia is essentially unknown, it is generally accepted that the disease complex is caused by the abnormal development of limbic system structures that are assembled mainly in the third trimester of human gestation (Weinberger 1987; Waddington 1993). Additionally, the hypothesis is gaining support that the disease is precipitated by environmental stressors around the period of final maturation of these limbic structures. This “two hit” idea has led to research directed at two potential targets for cytokine action: the effects of cytokines on the development of the nervous system, and the acute effects of cytokine administration in generating psychotic symptoms.

A number of environmental factors have been correlated with the development of schizophrenia including birth trauma, maternal viral infection, and season of birth (reviewed in Nawa et al. 2000). Prolonged labor results in abnormally elevated serum IL-6 levels (De Jongh et al. 1997), suggesting a possible link between immune system activation and the perinatal complications associated with the development of schizophrenia. Given the role of proinflammatory cytokines in repair of tissue damage and infection, it is interesting that TGF- α and IL1- β can suppress the normal expression of brain-derived neurotrophic factor (BDNF), a neurotrophin that is a key regulator of neuronal and synaptic development, in the hippocampus (Lapchak et al. 1993). Conversely, IL1- β causes up-regulation of nerve growth factor (NGF), another factor that regulates growth and development of central neurons, in microglial cells (Heese et al. 1998). These findings compel further research into the interactions between cytokines and the brain-derived trophic factors that may lead to abnormal development of brain regions that ultimately result in the manifestation of schizophrenia in the mature brain.

Several reports of persistent psychosis following the administration of interferon- α (Tamam et al. 2003; Thome and Knopf 2003; Telio et al. 2006) or high doses of IL-2 (Denicoff et al. 1987) demonstrate that cytokines could conceivably mediate some aspects of cognitive impairment observed in schizophrenic patients. These studies are interesting in light of the fact that evidence for abnormal levels of cytokines in schizophrenic patients is accumulating

(Malek-Ahmadi 1996; Prolo and Licinio 1999). However, further studies are needed to show a causative relationship between cytokine levels in patients and the precipitation of psychotic episodes.

39.4.3 Bipolar Disorder

39.4.3.1 Impact of HPA Axis on Bipolar Disorder

The HPA axis remains less studied in bipolar disorder (BD) than in major depression and schizophrenia, however it is suggested that patients with BD show similar HPA axis dysfunction (Watson et al. 2004). Recent studies provide robust evidence demonstrating HPA axis abnormalities in BD. Due to HPA axis dysregulation, ACTH and cortisol levels have been reported to be dysregulated in patients with BD (Daban et al. 2005). Hypercortisolism is thought to play a central role in the pathogenesis of cognitive deficits and depressive symptoms of BD, which may result from neurocytotoxic effects of heightened cortisol levels. In fact, increased ACTH and cortisol levels may precede manic episodes giving rise to these symptoms. It has also been reported that patients with BD have a higher degree of HPA axis dysfunction than those with unipolar disorder (Rybakowski and Twardowska 1999). Compared to individuals with unipolar disorder, patients with BD exhibit significantly higher concentrations of cortisol in acute episodes and during remission (Rybakowski and Twardowska 1999). Interestingly, HPA dysregulation has not been linked to particular episodes of depression or during mania within BD (Schmider et al. 1995).

Pituitary gland volume has also become an indicator of HPA axis dysfunction (Sassi et al. 2001), and has become an indicator of HPA axis dysfunction in patients with BD. Patients with BD have shown a consistent decrease in pituitary gland volume compared to healthy individuals.

Due to the consistent findings of HPA axis dysregulation in patients with BD, it has become a trait marker for BD and may be indicative of pathophysiological processes within the illness. Further, HPA axis manipulation (i.e. drug targeting) has been shown to have therapeutic effects within patients with the disorder (Daban et al. 2005). Interestingly, therapeutic approaches targeting HPA axis dysregulation may prove beneficial for BD treatment regimes.

39.4.3.2 Neuropeptides on Bipolar Disorder

Early reports suggest alterations in the neuropeptides vasopressin (Gold et al. 1978), somatostatin (Gerner and Yamada 1982), and endorphins (Verebey et al. 1978) and in patients with BD compared to healthy individuals. Studies have also suggested decreased levels of neuropeptide Y in the prefrontal cortex of individuals with bipolar disorder (Caberlotto

and Hurd 1999; Kuromitsu et al. 2001). The decreased levels of NPY seen in patients with bipolar disorder have been shown to be similar to individuals with schizophrenia (Kuromitsu et al. 2001), suggesting a common pathology between the two disorders. Much research is still needed to identify other neuropeptide differences between BD and healthy individuals before treatment can be conducted.

39.4.3.3 Impact of Immune system Cytokines in Bipolar Disorder

Evidence suggests a bidirectional link between inflammation and mood disorders (Rosenblat et al. 2014). This is supported by studies showing that emotional, psychological or physical stress could induce stress responses (Miller et al. 2013; Raison and Miller 2013). Indeed, elevated IL-1, IL-6, TNF- α and CRP have been observed following the application of psychological stress alone (Steptoe et al. 2007). In patients with bipolar disorder, numerous studies have correlated elevation of inflammatory markers (prostaglandin E2 (PGE2), CRP, TNF- α , IL-1- β , IL-2, IL-6) with increased incidence of mood symptoms and mood episodes (reviewed in Rosenblat et al. 2014). Two recent meta-analyses of cytokine changes in bipolar patients found consistency in elevated soluble IL-2R, TNF- α , and soluble IL-6R compared to control patients (Munkholm et al. 2013; Miller et al. 2013).

One postulated mechanism to explain how pro-inflammatory cytokines can induce depressive symptoms is through regulation of tryptophan metabolism. Tryptophan is a precursor of serotonin, melatonin, and other bioactive metabolites. Impairment of serotonin neurotransmission underlies one theory explaining the etiology of mood disorders including major depression and bipolar disorder (Arango et al. 2002; Barton et al. 2008; Rosa-Neto et al. 2004; Anderson et al. 2014). Indeed, depletion of brain tryptophan levels can induce depressive symptoms in individuals who are sensitive to major depression (Young et al. 1985; Booij et al. 2002; Smith et al. 1997; Delgado et al. 1990). Moreover, inhibition of tryptophan hydroxylase, the first step in the pathway of serotonin synthesis, can induce a relapse of depression in remitted depressive patients (Smith et al. 1997; Delgado et al. 1990). Limiting tryptophan availability in the brain by shunting of tryptophan down non-serotonin-producing metabolic pathways may also limit the capacity to produce serotonin (Jaronen and Quintana 2014). In addition to metabolism by tryptophan hydroxylase, tryptophan is also metabolized by indolamine 2,3-dioxygenase (IDO) to kynurinine. IDO activity is upregulated, at least in part, by inflammatory cytokines such as interferon- α , IFN- γ (the major inducer), IL-2, TNF- α and IL-6 (Capuron et al. 2001; Anderson and Maes 2015). Kynurinine, kynurenic acid and quinolonic acid are all tryptophan metabolites, and

each has been shown on their own to induce depressive symptoms (Maes et al. 2011). Proinflammatory cytokines, such as IL-1, IL-6 and TNF- α , have also been shown to activate the HPA axis leading to increased circulating cortisol levels. Cortisol, in turn, drives higher IDO activity and tryptophan depletion (Hoes and Sijben 1981; Maes et al. 2011; Wolf 1974). Finally, the elimination of serotonin from the brain is initiated by its conversion to 5-hydroxyindoleacetic acid, a process that is enhanced by IL-6 and TNF- α (Wang and Dunn 1998; Zhang et al. 2001). Many studies have examined how cytokines vary in bipolar disorder compared to healthy individuals. A meta-analysis, consisting of 30 studies evaluating levels of cytokines in patients with BD have revealed consistent elevations in pro-inflammatory, anti-inflammatory and regulatory cytokines (Modabbernia et al. 2013). Increases in IL-6 and TNF- α serum levels have been consistently observed in patients with BD (Kupka et al. 2002; Kim et al. 2007; Ortiz-Domínguez et al. 2007; Brietzke and Kapczinski 2008). In contrast, other cytokines have been revealed to have different levels during the different manic and depressive phases of BD. During manic episodes, elevated serum levels of IL-6 (Kim et al. 2007; Ortiz-Domínguez et al. 2007), TNF- α (Kupka et al. 2002; Kim et al. 2007; Ortiz-Domínguez et al. 2007; Brietzke and Kapczinski 2008) and IL-4 (Ortiz-Domínguez et al. 2007) have been observed; During depressive phases of the illness, IL-6 and TNF- α show elevated levels, while IL-2 show decreased serum levels (Ortiz-Domínguez et al. 2007). These studies suggest that serum levels of cytokines may vary depending on the phase of the illness. The most consistent finding in regards to cytokine levels is the elevated levels of TNF- α seen within both phases of the illness. These studies suggest that therapeutic targets on the TNF- α pathway may prove beneficial in the treatment of bipolar disorder. In addition, inflammatory cytokines have been implicated in reducing anti-depressive levels of serotonin in the brain and increasing pro-depressive levels of alternate tryptophan metabolites.

39.4.4 Post-Traumatic Stress Disorder (PTSD)

39.4.4.1 Impact of HPA Axis on PTSD

Posttraumatic stress disorder is often experienced after traumatic experiences (i.e. war or life-threatening experience) and is generally accompanied with acute and chronic alterations in stress responses. Traumatic stress responses include intense fear, helplessness and horror (Brewin et al. 2000). Further, it is known that 8–18% of individuals exposed to traumatic events develop PTSD (Breslau et al. 1998; Kessler et al. 1995; Sledjeski et al. 2008). Individuals who develop PTSD show symptoms such as hyperarousal and symptoms are thought to be accompanied by or lead to alterations in biological stress responses (de Kloet et al. 2006).

Like other disorders (e.g. anxiety disorder and major depressive disorder), individuals with PTSD show alterations in stress response and hypothalamic-pituitary-adrenocortical (HPA) function. However, inconsistencies have been seen in studies linking HPA function and PTSD (Morris et al. 2012). The HPA axis is one of the three systems activated in response to stress (Teicher et al. 2002). Exposure to stress triggers emotional responses, including activation of the limbic system that initiates HPA activity. Some studies have reported PTSD patients to have high levels of CRH in cerebrospinal fluid (CSF) (Baker and Shalhoub-Kevorkian 1999; Bremner et al. 1997), while diurnal plasma cortisol levels are decreased (Yehuda et al. 1994). The combination of low diurnal plasma cortisol levels and high levels of CRH in CSF has been attributed to enhance HPA-axis feedback regulation.

Recently, researchers have posited an “attenuation hypothesis” of HPA axis functioning in PTSD. This hypothesis states that low cortisol levels seen in individuals with PTSD may be explained by allostasis, the body’s adaptive efforts to maintain homeostasis. In normal individuals, stress leads to HPA axis activation and release of cortisol to allow for adaptive coping that may have protective effects of neuroendocrine processes and blunt the impact of physiological and psychological stressors. In the case of PTSD, it is hypothesized that stress and trauma are prolonged, unpredictable or overwhelming and the demand of the HPA axis may be excessive, leading to allostatic overload. This allostatic overload may decrease the body’s ability to mediate stress and increase the vulnerability for PTSD pathology (Jones and Moller 2011).

The most significant observation in regards to PTSD is the low cortisol levels consistently found in patients. Due to these findings, novel therapeutic approaches to treat PTSD are being developed to target low levels of cortisol (Yehuda 2006).

39.4.4.2 Neuropeptides on PTSD

Neuropeptide Y dysregulation following exposure to stress is thought to give rise to behavioral consequences (i.e. problems regulating emotion) (Heilig 2004) and is thought to act as a biological mediator of these negative actions (Yehuda 2006). Recently, there has been increased evidence for the role of neuropeptide Y (NPY) as a protective stress factor. Recently, many studies have implicated decreased levels of NPY in patients with PTSD (Sah et al. 2009; Rasmusson et al. 2000; Yehuda 2006). Decreased levels of NPY have been observed in plasma (Rasmusson et al. 2000; Sah et al. 2014) and in cerebrospinal fluid (Sah et al. 2009) of patients with PTSD. Rasmusson et al. (2000) have suggested this decrease in plasma NPY to contribute to PTSD symptoms (hyperarousal, exaggerated alarm reactions and anxiety), and may mediate the noradrenergic system hyperactivity. In

addition, Sah et al. (2014) have also suggested that NPY may regulate PTSD symptomology. For these reasons, many studies have proposed that NPY may be a promising clinical target and diagnostic measure. Interesting, recently derived anti-depressants, used to treat PTSD, have been shown to increase levels of NPY (Yehuda 2006), which helps alleviate some symptoms seen within the disorder.

39.4.4.3 Impact of Immune System Cytokines in PTSD

Within patients with PTSD, increased levels of pro-inflammatory cytokines have been observed (Hoge et al. 2009; Tucker et al. 2014; Spivak et al. 1997; von Känel et al. 2007; Baker et al. 2001). Some studies have shown increased levels of IL-1 β , IL-6 and TNF- α in PTSD by isolated peripheral blood mononuclear cells; this suggests evidence for low grade inflammation in PTSD. Other have shown increases in plasma IL-1 β (Tucker et al. 2014; Spivak et al. 1997), IL-6 (Maes 1999) and TNF- α (von Känel et al. 2007; Gola et al. 2013). In addition, elevated levels of IL-6 have been detected in cerebrospinal fluid of patients with PTSD (Baker et al. 2001). Interestingly, some studies have correlated increased levels of TNF- α with PTSD symptom severity (Gola et al. 2013; Gola et al. 2013; Gola et al. 2013). It has been shown that pro-inflammatory cytokines, like IL-6, TNF- α and others are indicative of HPA disruption and physical response (Biffi et al. 1996; Hisano et al. 1997; Hirano et al. 1990). Interactions between cytokines and the HPA axis have effects at the pituitary, allowing for physiological and psychological disturbances following traumatic experiences and injuries, like those seen in PTSD (Sutherland et al. 2003). Much evidence suggests elevated cytokine levels in patients with PTSD and may suggest potential treatments of the disorder. However, much research remains to be conducted to understand the full effects of cytokine dysregulation in PTSD.

39.4.5 Anxiety Disorder

39.4.5.1 Impact of HPA Axis on Stress and Anxiety Disorders

Homeostasis is dependent on the maintenance of the complex dynamic equilibrium of the constantly changing external and internal factors present in everyday life. This proper balance is however dysfunctional in cases of increased and prolonged stress and anxiety. In fact, early life stress, such as neglect and childhood abuse, has been linked to later life anxiety disorders (Arborelius et al. 1999). HPA hyper-activation has been shown in patients with anxiety and stress disorders (Holmes et al. 2003). Some studies have shown increased levels of cortisol to correlate with high anxiety levels (Granger et al. 1994; Coplan et al. 2002), in turn increasing basal HPA axis activity (Feder et al. 2004). Further, increased levels of CRH have

been observed in human and animal models of anxiety disorder (Dunn and Berridge 1990).

39.4.5.2 Neuropeptides on Stress and Anxiety Disorders

Similar symptoms of anxiety and depression commonly co-exist. Therefore, changes in neuropeptides are similar to those seen in major depression. Like other disorders previously discussed, substance P, CRH, vasopressin, NPY and galanin neuropeptide changes have been shown to alter anxiety and depressive behaviors (Holmes et al. 2003). Studies have shown reduced concentrations of NPY in cerebrospinal fluid and plasma in depression and anxiety (Westrin et al. 1999; Widerlöv et al. 1988). Further, NPY injections in animal models have been shown to have anxiolytic effects (anxiety alleviating) (Griebel 1999), while CRH injections have anxiogenic-like (anxiety causing) effects (Radulovic et al. 1999). These observations may correlate with the previous findings of decreased NPY levels and increased CRH levels in individuals with high stress and anxiety. Currently, clinical trials are ongoing testing the efficacy of substance P antagonists. Preliminary studies show promising results for future treatment of stress, anxiety and depression (Holmes et al. 2003). It could be hypothesized that other neuropeptide antagonists could prove beneficial for treatment of these disorders.

39.4.5.3 Impact of Immune system Cytokines in Stress and Anxiety Disorders

Little work has been dedicated towards identifying the role of cytokines in anxiety and stress disorders. Of studies conducted, changes have been reported in production of TNF- α , IL-6, IL-1 receptor antagonist, INF- γ and IL-10 in stress. In addition, increased levels of INF- γ and decreased levels of IL-10 and IL-4 have been reported in anxiety disorders (Maes 1999). Further, preliminary results suggest an increase in IL-2 levels in patients with anxiety disorder (Rapaport and Stein 1994). Overall, it can be concluded that stress and anxiety disorders lead to changes in TNF- α , IL-6, INF- γ , IL-10 and IL-4. These changes in cytokines may lead to the pathophysiology of stress and anxiety disorders and in turn may prove valuable as beneficial treatment candidates.

39.5 Review Questions

1. Name three of the four peptides for which proenkephalin is the precursor.
 - (a) methionine-enkephalin
 - (b) leucine-enkephalin
 - (c) methionine-enkephalin-Arg-Phe
 - (d) methionine-enkephalin-Arg-Gly-Leu

Answer: Any combination of the 3 listed above

2. The major physiological role of the enkephalins in regulating immune function appears to be
 - (a) stimulation of all immune cells
 - (b) inhibition of all immune cells
 - (c) maintenance of homeostasis
 - (d) increased expression of regulatory T cells
 - (e) decreasing reactive oxygen species production

Answer: (d) increased expression of regulatory T cells

3. Name the three products derived from proopiomelanocortin (POMC) for which evidence is the strongest supporting involvement in regulating immune system function.

Answer: β -endorphin; α -MSH and γ -MSH

4. The site of action for α -MSH is
 - (a) mu opioid receptors
 - (b) melanocortin-1 receptors
 - (c) glucocorticoid receptors
 - (d) melatonin receptors
 - (e) ACTH receptors

Answer: (b) melanocortin-1 receptors

5. Local release by immune cells of which neuropeptide plays the most important role in nociception produced in areas of inflammation by the immune system?
 - (a) methionine-enkephalin.
 - (b) α -MSH
 - (c) ACTH
 - (d) β -endorphin
 - (e) urocortin-1

Answer: (d) β -endorphin

6. Which neuropeptide is anti-inflammatory when activating the HPA axis but is proinflammatory when released locally by immune cells?
 - (a) ACTH
 - (b) CRH
 - (c) β -endorphin
 - (d) nociceptin
 - (e) γ -MSH

Answer: (b) CRH

7. Which cytokine has been found to induce major depressive disorder in a high percentage of patients when used to treat malignant melanoma or hepatitis C?
 - (a) IL-6
 - (b) TNF- α
 - (c) IL-4
 - (d) interferon- α
 - (e) IL-10

Answer: (d) interferon- α

8. The neuropeptide synthesized and released from the CNS, particularly the hypothalamus, as well as from immune cells is
 - (a) ACTH
 - (b) urocortin-1

- (c) CRH
- (d) TNF- α
- (e) insulin

Answer: (c) CRH

9. The proinflammatory cytokine found to have increased levels in plasma and CNS in major depressive illness and whose levels correlate significantly with mood rating is
 - (a) IL-6
 - (b) TNF- α
 - (c) CRH
 - (d) IL-2
 - (e) β -endorphin

Answer: (a) IL-6

10. Hyper-activation of the HPA axis in schizophrenia is thought to be due to hyper-secretion of what neuropeptide?
 - (a) CRH
 - (b) IL-6
 - (c) IL-2
 - (d) ACTH
 - (e) IL-10

Answer: (a) CRH

Abstract

Autism spectrum disorders (ASD) are characterized by deficits in sociability and communication, as well as severe anxiety and stereotypic movements. Moreover, over 50 % of children with ASD experience atopic symptoms indicative of mast cell (MC) activation (asthma, eczema, food allergies and/or intolerance) which correlate with the presence of brain auto-antibodies. ASD pathogenesis is unknown preventing the development of effective treatments. As a result, more than 70 % of children with ASD are prescribed psychopharmacologic agents that often have little benefit and serious adverse effects. Increasing evidence indicates that local brain inflammation is involved in ASD. In particular, there is activation and proliferation of microglia, which communicate with MCs, located perivascularly primarily in the thalamus and hypothalamus, as well as the lining of the ventricles. MCs are stimulated by corticotropin-releasing hormone (CRH) and neurotensin (NT) secreted from the hypothalamus under stress; these peptides can also induce each other's surface receptors leading to autocrine and paracrine effects. Stimulated MCs release inflammatory and neurotoxic mediators that disrupt the blood-brain barrier (BBB), activate microglia and cause focal inflammation. CRH and NT are significantly increased in serum of ASD children compared to normotypic controls. Addressing the "allergic" and anxiety symptoms would not only improve the health of the patients, but could also potentially reduce the core symptoms of ASD. Use of the natural anti-inflammatory flavonoid luteolin, in an olive fruit oil preparation to increase oral absorption, appears to provide significant benefit and should be investigated further. Treatment approaches targeting brain inflammation could have a great benefit.

40.1 Introduction

Autism spectrum disorders (ASD) are pervasive neurodevelopmental disorders characterized by varying degrees of deficiencies in communication and social interactions, as well as the presence of stereotypic behaviors (Fombonne 2009; Lai et al. 2014). Many ASD children regress at about age 3 years implying the importance of some environmental (Vijayakumar and Judy 2016) and epigenetic trigger (Herbert 2010). Although these could include vaccination (Delong 2011), infection (Hsiao et al. 2012), trauma (Blenner et al. 2011), toxin exposures (Deth et al. 2008) and stress (Lanni et al. 2012) none have, to date, been shown causal for disease. The prevalence of ASD has been increasing globally (Perou et al. 2013; Elsabbagh et al. 2012). Recent results indicate that as many as 1 in 68 children have ASD (Developmental Disabilities Monitoring Network Surveillance Year 2010 Principal Investigators Centers for Disease Control and Prevention (CDC) 2014). The diagnosis and definition of ASD (Erturk et al. 2015) has evolved since the original description of Dr. Kanner (Volkmar and McPartland 2014). The American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (DSM-5) changed the classification in 2013 and abandoned the previous designations of autism disorder, pervasive development not otherwise specified (PDD-NOS) and Asperger’s syndrome for ASD with mild, moderate and severe symptoms (Volkmar and McPartland 2014). The lack of uniformity of symptoms across ASD and the lack of reliable biomarkers (Ruggeri et al. 2014; Subramanian et al. 2015) has made diagnosis even more challenging. Moreover, the existence of subgroups within ASD (Table 40.1) and the lack of agreement of the use of intelligence have even prompted patients and families to reject the stereotypic and categorical term “autistic” (Volkmar and McPartland 2014). Certain interactive instruments such as Childhood Autism Rating Scale (CARS) and Aberrant Behavior Checklist (ABC) may be suggestive of ASD, but diagnosis typically depends on the use of Autism Diagnostic Observation Schedule (ADOS-G) or ADI-R or fulfillment of DSM-V criteria (Volkmar and McPartland 2014; McPheeters et al.

2016). ASD are more common in boys than girls (approximately 4:1), but there is no plausible explanation for this difference. In spite of the fact, that ASD have been considered to affect individuals for life, recent studies have shown that many cases may be preventable or reversible (Beaudet 2012).

ASD have emerged as one of the most complex behavioral disorders, which in spite of great advances a possible etiology, remains poorly understood (Yoo 2015a; Ziats et al. 2015). Studies have shown that for “strict” autism probandwise concordance for male twins was 0.58 for monozygotic and 0.21 for 31 dizygotic pairs; this penetrance increased for ASD to 0.77 and 0.31 respectively leaving room for epigenetic influences (de et al. 2016; Loke et al. 2015). In spite of the discovery of numerous gene mutations in ASD (Yoo 2015) they do not account for more than 5% of the cases with the exception of Fragile X, Tuberous Sclerosis and Rett Syndromes. This risk may be further increased if children have mutations leading to decreased phosphatase and tensin homolog (PTEN) (Aldinger et al. 2011), which is an upstream inhibitor of the mammalian target of rapamycin (mTOR) (Aldinger et al. 2011).

These problems, coupled with the lack of biomarkers and specific pathogenesis, have increased the estimated annual economic burden of ASD from \$242 billion in 2014 (Buescher et al. 2014) to \$268 billion in 2015 and \$416 billion in 2025 (Leigh and Du 2015). To make matters worse, there are no reliable animal “models” of ASD (Ruhela et al. 2015), creating an urgent need for representative experimental animal models for ASD (Ruhela et al. 2015). In fact, mouse “models” are increasingly considered unreliable with respect to human inflammatory diseases (Seok et al. 2013).

There may be preventable forms of ASD (Beaudet 2012), but it is critical that one identifies and targets a specific pathogenetic mechanism in order to succeed (Ghosh et al. 2013). It is quite encouraging that the European Union started a unique program, “European Autism Interventions-A MultiCentre Study for Developing New Medications (EU-AIMS) Initiative (Ecker et al. 2013).

40.2 Perinatal Conditions Associated with Increased ASD Risk

Increasing evidence indicates that brain inflammation is important in the pathogenesis of neuropsychiatric disorders (Beumer et al. 2012; Hagberg et al. 2012; Jones and Thomsen 2013; Munkholm et al. 2013; Schmidt et al. 2007; Theoharides and Zhang 2011). Inflammation during fetal and neonatal life has been associated with subsequent neuropsychiatric disorders (Hagberg et al. 2012). Exposure to mold was associated with decreased cognitive function in six-year old children (Jedrychowski et al. 2011) and cognitive dysfunction has been linked to toxigenic fungi exposure (Gordon et al. 2004).

Seizures

^aPediatric autoimmune neuropsychiatric disorders associated with streptococcal infections

Prenatal exposure to common environmental triggers affected brain lipid composition and increased the risk of ASD (Wong et al. 2015). A recent study reported associations between higher ASD prevalence and proximity to industrial facilities emitting air pollutants (Dickerson et al. 2015). In fact, a cross-sectional study reported significant correlation between hair mercury content and ASD (Fido and Al-Saad 2005; Geier et al. 2012). Chemical intolerant mothers were three times more likely to report having a child with ASD (Heilbrun et al. 2015); moreover, these mothers reported that their children were more prone to allergies, food cravings and sensitivity to odors (Heilbrun et al. 2015).

Exposure to air pollutants (Suades-Gonzalez et al. 2015) and interactions between chemical irritants and pathogens from sewage sludges (biosolids) may also be important (Lewis et al. 2002). Use of antidepressants, especially serotonin-specific reuptake inhibitors (SSRIs) (Boukhris et al. 2015; Sorensen et al. 2013) during pregnancy was associated with higher risk of delivering children with ASD (Rais and Rais 2014), while other studies showed an increased association with ADHD, but not ASD (Clements et al. 2015). Prolonged oxytocin use to induce labor was associated with increased risk of delivering children who developed ASD (Gregory et al. 2013). Use of acetaminophen during pregnancy was also associated with increased risk of ASD but only the type accompanied by hyperkinetic symptoms (Liew et al. 2015).

An analysis of 30,942 cases of ASD concluded that very young or old parents, and primarily the bigger the age difference between the couples, was associated with higher risk of having children with ASD (Sandin et al. 2015).

ASD was associated in women with childhood sexual or physical abuse (Roberts et al. 2015; Weisman et al. 2015), and in 0–9 years old boys with ritual circumcision (Frisch and Simonsen 2015). In both setting, the precipitating factor may have been stress. Prenatal stress has been linked to increased risk of ASD (Beversdorf et al. 2005; Ronald et al. 2010). A meta-analysis showed a strong correlation between the presence of anxiety disorders and ASD (van Steensel et al. 2011). ASD patients were prone to stress (Gillott and Standen 2007; Vasa and Mazurek 2015) and anxiety was also strongly correlated with repetitive behaviors with children with ASD (Rodgers et al. 2012). Children with ASD, especially those with GI problems; had significantly higher rate of both anxiety and sensory over-reactivity (Mazurek et al. 2013). Anxiety in children with ASD was consistent with sympathetic over-arousal and parasympathetic under-arousal (Kushki et al. 2013). Heightened response to stress and comorbid anxiety disorders may be due to maladaptive psychological responses in children with ASD (Hollocks et al. 2014).

Paternal stress altered sperm micro RNA and reprogrammed the offspring stress response (Rodgers et al. 2013).

Amazingly, prereproductive stress in female rats alters of corticotropin-releasing hormone (CRH) expression in ova as well as CRH-1 receptor expression in the brain of the offspring (Zaidan et al. 2013). Prenatal negative life events increased cord blood immunoglobulin E (IgE) (Peters et al. 2012) and the risk of atopy (Sternthal et al. 2009; Andersson et al. 2016). Moreover, neonatal maternal deprivation stress induced long-term interactions in rats between colonic nerve-MCs (Barreau et al. 2008).

Acute stress can exacerbate inflammatory disorders, such as migraines (Theoharides et al. 2005) and multiple sclerosis (Karagkouni et al. 2013; Mohr et al. 2000). Stress activates MCs through CRH and leads to BBB disruption in rats (Esposito et al. 2002). CRH is also responsible for disruption of the gut-blood barrier through MC stimulation (Vanuytsel et al. 2014). Restraint stress resulted in activation of brain MCs and elevation of rat MC protease levels in cerebrospinal fluid (CSF), effects abolished by pretreatment with polyclonal antiserum to CRH (Theoharides et al. 1995) or pretreatment with the CRH-1 receptor antagonist Antalarmin (Theoharides et al. 1995). CRH can actually be secreted from MCs (Kempuraj et al. 2004) and could have autocrine and paracrine effects.

40.3 Immune Dysregulation

It is now recognized that ASD are associated with some immune dysfunction (Derecki et al. 2010; Onore et al. 2012; Rossignol and Frye 2012a; Theoharides et al. 2012a; Zimmerman et al. 2005), autoimmunity (Ashwood and Van de Water 2004; Theoharides et al. 2013a), and/or an neuro-immune component (Theoharides et al. 2009). In fact, recent reviews stress neuroinflammation in the pathogenesis of ASD (Estes and McAllister 2015; Volkmar and McPartland 2014; Gottfried et al. 2015; Theoharides and Zhang 2011; Kern et al. 2015).

Maternal and autoimmune diseases, especially asthma and psoriasis have been reported to increase the risk of ASD in the offspring (Chen et al. 2016). Circulating auto-antibodies directed against fetal brain proteins have been reported in about 30% of mothers of children with ASD and ASD patients (Braunschweig and Van de Water 2012; Rossi et al. 2011; Wills et al. 2009) implying BBB break neonatally. Another study reported that 42% of 3-year old children with ASD had plasma autoantibodies against GABAergic cerebellar neuronal proteins (Rossi et al. 2011). A recent paper described a strong statistical correlation between the presence of brain autoantibodies and allergic symptoms (Mostafa and Al-Ayadhi 2013).

The markers of inflammation identified in the brain and CSF of many ASD patients include tumor necrosis factor

(TNF), IL-6 and monocyte chemoattractant protein-1 (MCP-1) (Li et al. 2009b), the latter of which also is chemotactic for MCs (Theoharides et al. 2010b). In fact, elevated MCP-1 in amniotic fluid was strongly correlated with increased risk for infantile autism (Abdallah et al. 2012). A recent review reported that MCP-1 was elevated in archived neonatal blood specimens (Zerbo et al. 2014). Maternal immune activation (MIA) in mice led to increased serum IL-6 and IL-17, and contributed to immune dysregulation and autism-like behaviors in the offspring (Dahlgren et al. 2006; Hsiao et al. 2012; Smith et al. 2007). Another study showed that MIA also led to increased levels of IL-1 β , IL-33, MCP-1 and VEGF in the fetal brain (rrode-Bruses G and Bruses 2012). We had shown that acute stress significantly increases serum IL-6 in mice that was entirely dependent on MCs as it was absent in MC-deficient W/W^v mice (Huang et al. 2003). We later showed that the MIA model of autism could not develop in these mice (unpublished). Nevertheless, a recent study reported that TNF and IL-1 β were not increased, while IL-8 was elevated in the plasma of children (mean age 9.3 \pm 0.7 years) with ASD (n=15) compared to healthy controls (n=20) (Tonhajzerova et al. 2015). Two studies showed increased TNF (Zimmerman et al. 2005) levels in CSF of patient with ASD (Chez et al. 2007). We recently reported that TNF and IL-6 are increased in a subgroup of patients with ASD who improved significantly concomitant to lower cytokine levels after treatment with a flavonoid containing supplement (Tsilioni et al. 2015).

Other studies showed that stimulated peripheral blood mononuclear cells (PBMCs) from patients (n=23) with ASD produced twice as much TNF as those from controls (n=13) (Jyonouchi et al. 2001). This finding was confirmed later where stimulated PBMCs from patients with ASD (n=66) produced more TNF and IL-13 than controls (n=73) (Ashwood et al. 2011). It was uniquely interesting that these PBMC produced more TNF also in response to common dietary proteins such as gliadin, cow's milk protein and soy (Jyonouchi et al. 2002). Given that TNF is produced following activation of NF κ -B, it is important that NF κ -B DNA binding activity was twice as much in peripheral blood from patients with ASD than controls (n=29) (Naik et al. 2011). Moreover another study identified signaling through NF κ -B was prominent in interacting gene networks constructed from brains of ASD patients (Ziats and Rennert 2011).

IL-6 and TNF could disrupt the BBB (Theoharides and Doyle 2008) and cause "focal encephalitis" in specific brain areas, thus contributing to the pathogenesis of ASD (Theoharides et al. 2008; Theoharides 2013).

Epidemiological studies have shown that allergic diseases are associated with psychological and behavioral problems in preschoolers (Tsai et al. 2013). In particular, one study showed that infant atopic eczema was associated with attention-

deficit-hypersensitivity disorder (ADHD) (Genuneit et al. 2014) and another large epidemiological study reported a strong correlation between eczema and both ADHD and ASD (Yaghmaie et al. 2013). Another study of 14,812 atopic subjects younger than 3 years old and 6944 non-atopic subjects (followed from 1997 to 2010) showed a dose-dependent relationship between atopy and greater risk of ASD and ADHD (Chen et al. 2014a). Many ASD patients suffer from food allergies (Jyonouchi 2010) and "allergic-like" symptoms (Angelidou et al. 2011; Kogan et al. 2009), indicating MC activation (Kempuraj et al. 2010; Theoharides et al. 2012a). The suggestion was, therefore, made that a subtype of ASD may be "Allergy of the brain" (Theoharides 2013). A recent publication actually reported neurochemical changes and autistic-like behavior in a mouse model of food allergy (de Theije et al. 2014). A recent case control study among members of Kaiser Permanente Northern California (1980–2003) reported that allergies and autoimmune disorders were diagnosed more often, with psoriasis occurring more than twice as often in ASD patients than controls (Zerbo et al. 2015). Asthma was also 35 % more common in ASD (Heilbrun et al. 2015).

Interestingly, children with mastocytosis, characterized by an increased number of MCs (Theoharides et al. 2015c) appear to have a five to tenfold higher risk of developing ASD than the general population (Theoharides 2009).

40.4 Mast Cells and Microglia

During healthy brain development, microglia may "prune" neural circuits through a complement-dependent manner (Schafer et al. 2012) and provide neuroprotection (Chen and Trapp 2015). Microglia are innate brain macrophages that sensitize the brain for damage; then both establish and resolve inflammation (Shemer et al. 2015). However, abnormal microglia activation and proliferation could lead to focal inflammation and "choking" of normal synaptic traffic (Felger et al. 2015). Neuroglial activation and proliferation has been reported in brains of patients with ASD (Morgan et al. 2012; Rodriguez and Kern 2011; Vargas et al. 2005). A recent study of the transcriptomes from 104 human brain cortical tissue samples from patients with ASD showed an inverse relationship between increased M2-microglia activation and decreased neuronal activity (Gupta et al. 2014). As a result of these studies, microglia are now considered an important component of the pathogenesis of ASD (Takano 2015) and other neuropsychiatric disorders (Kritas et al. 2014b; Theoharides et al. 2015e). MCs (Nelissen et al. 2013) and MC-microglial interactions are increasingly involved in neuroinflammatory diseases (Ohnmacht and Voehringer 2010; Skaper et al. 2012; Theoharides et al. 2013b) and MC-derived tryptase can activate microglia (Zhang et al.

2012c), as does histamine (Rocha et al. 2014; Zhu et al. 2014; Hakim-Rad et al. 2009). In fact, suppression of brain MC degranulation inhibited microglia activation and inflammation of the brain (Dong et al. 2016).

MCs derive from bone marrow progenitors, mature in tissues and are critical for allergic reactions (Theoharides et al. 2015d). MCs are also implicated in immunity (Kalesnikoff and Galli 2008) and inflammation (Theoharides et al. 2010a), but may have additional immunomodulatory functions (Galli et al. 2008; Kalesnikoff and Galli 2008).

MCs are located perivascularly in close proximity to brain neurons especially in the leptomeninges (Rozniecki et al. 1999), as well as thalamus and hypothalamus (Pang et al. 1996) where they contain most of the brain histamine (Alstadhaug 2014). Increasing evidence indicates that brain histamine is involved in the pathogenesis of neuropsychiatric diseases (Haas et al. 2008; Shan et al. 2015) and in the disruption of the blood-brain-barrier (BBB) (Banuelos-Cabrera et al. 2014), through MC activation (Esposito et al. 2001, 2002; McKittrick et al. 2015). In fact, MCs are located adjacent to CRH-positive neurons in the rat median eminence (Theoharides et al. 1995). MCs and CRH regulate the permeability of the gut-blood (Vanuytsel et al. 2014) and blood-brain (Esposito et al. 2002) barriers. Interestingly, the presence of commensal house dust mite allergen in the human gut was recently shown to contribute to intestinal basic dysfunction (Tulic et al. 2015). MCs are typically stimulated by specific IgE and antigen (Blank and Rivera 2004), but also by bacterial and viral products through toll-like (TLR) receptors (Sandig and Bulfone-Paus 2012), which are important in the development of innate immunity (Abraham and St John 2010). We showed that stimulated MCs can secrete mitochondrial particles (Zhang et al. 2011) and mitochondrial ATP and DNA (Zhang et al. 2012a) extracellularly. These mitochondrial components could augment MC activation and inflammation (Asadi and Theoharides 2012) since they are mistaken by the body as “innate pathogen” and induces a strong auto-inflammatory response (Zhang et al. 2012a). In fact, we showed that serum of young autistic children had increased levels of extracellular mitochondrial DNA (Zhang et al. 2010). A recent review connected mitochondrial dysfunction to oxidative stress and inflammation in children with ASD (Rossignol and Frye 2012b).

Nucleic acids derived from such stimulated MCs, as well as from damaged cells or micro-organisms, can lead to chronic inflammation and autoimmunity (Rubartelli and Lotze 2007). In fact, DNA released from dying host cells mediates the adjuvant activity of aluminum (Marichal et al. 2011; McKee et al. 2013), which has replaced thimerosal in many vaccines, and has shown a significant correlation with ASD (Tomljenovic and Shaw 2011).

Neuropeptides such as substance P (SP) (Zhang et al. 2011), NT (Donelan et al. 2006) and nerve growth factor

(NGF) (Kritas et al. 2014a) also stimulate MCs, an action augmented by IL-33 (Theoharides et al. 2010c). IL-33 acts through MCs to alert the innate immune system (Enoksson et al. 2011; Moussion et al. 2008) and has recently been linked to brain inflammation (Chakraborty et al. 2010). MCs are also triggered by many other cationic substances, sometimes called “basic segregates” in what have been termed “pseudo-allergic reactions” through a recently identified MRGPRX2 receptor (McNeil et al. 2015; Grimbaldston 2015).

We reported that NT was increased in the serum of young children with ASD (Angelidou et al. 2010) and so was serum levels of CRH (Tsiloni et al. 2014a). NT and NTR immunoreactivity have been identified in the rat hypothalamus (Goedert et al. 1985). Microglia expresses the neurotensin receptor 3 (NTS3), activation of which leads to their proliferation (Martin et al. 2003). NT is a brain peptide involved in inflammation (Mustain et al. 2011). NT and CRH synergistically stimulate MCs, leading to increase vascular permeability (Donelan et al. 2006) and contribute to BBB disruption (Theoharides and Konstantinidou 2007). Microglia also expresses CRH-R1 (Wang et al. 2002). NT also induces expression of CRH-1 receptor (Zhang et al. 2012a), activation of which by CRH increases allergic stimulation of human MCs (Asadi and Theoharides 2012). NT is neurotoxic (Ghanizadeh 2010) and can facilitate *N*-Methyl-D-aspartate (NMDA)-induced excitation of cortical neurons (Antonelli et al. 2004). NT may also stimulate basal pathway neurons (Boules et al. 2014).

Stimulated MCs secrete numerous vasoactive, neurosensitizing and pro-inflammatory mediators: a) the preformed histamine, serotonin, kinins, proteases as well as (b) newly synthesized, leukotrienes, prostaglandins, chemokines (CCXL8, CCL2), cytokines (IL-4, IL-6, IL-1, TNF) and vascular endothelial growth factor (VEGF), which increase blood-brain barrier (BBB) permeability (Theoharides et al. 2008; Theoharides and Konstantinidou 2007). MCs are the only cell type that stores pre-formed TNF in secretory granules (Olszewski et al. 2007) from which it can be released rapidly (Zhang et al. 2012b) and superactivate T cells (Kempuraj et al. 2008; Nakae et al. 2006). In fact, purified brain MCs were reported to synthesize and release TNF (Cocchiara et al. 1999).

MCs can release some mediators, such as IL-6 selectively (Theoharides et al. 2007). We showed that IL-1 can stimulate selective release of IL-6 (Kandere-Grzybowska et al. 2003) and CRH can stimulate selective release of VEGF (Cao et al. 2005). IL-6 could affect brain function (Theoharides et al. 2004) and activate the HPA axis (Kalogeromitros et al. 2007). MC-derived IL-6 and TGF β drive the development of Th-17 cells (Nakae et al. 2007) involved in autoimmunity and MCs secrete IL-17, themselves (Nakae et al. 2007). IL-17 was shown to be increased in the serum of children

with ASD (Al-Ayadhi and Mostafa 2012). The maternal IL-17 pathway was recently shown to promote autism-like behavior in the offspring (Choi et al. 2016). MCs can also secrete exosomes that can deliver microRNAs (Bryniarski et al. 2013) and could be involved in brain pathology (Kawikova and Askenase 2014; Tsilioni et al. 2014b).

Stimulation of mTOR (Lee 2015), especially in subjects with low PTEN, leads to microglia and MC proliferation (Theoharides et al. 2015b). Atopic diathesis, plus increased CRH and NT released under stress could contribute to stress-induced neuroinflammatory diseases (Theoharides and Cochrane 2004) and increase the risk of developing ASD (Theoharides et al. 2016).

40.5 Treatment

40.5.1 Subgroups

Unfortunately, there are no approved effective treatments for the core symptoms of ASD (Broadstock et al. 2007; Parikh et al. 2008; Rogers and Vismara 2008). The existence of ASD subgroups (Table 40.1) makes a unified approach to treatment of ASD difficult (Angelidou et al. 2012). Moreover, placebo responses in neuropsychiatric diseases (Weimer et al. 2015) including ASD (Masi et al. 2015) tend to be high. In fact, an integrative approach (Klein and Kemper 2016) or better yet personalized treatment of ASD is probably the best approach (Molteni et al. 2014) making the need for randomized, placebo-control, trials rather anachronistic (Peck 2016).

40.5.2 Behavioral and Social Interventions

Numerous studies have shown that early behavioral intervention, especially with speech, exercise, music and occupational therapy can significantly improve children with ASD (Rogers et al. 2014; Kasari et al. 2014). In particular, two interventions that have been well established include applied behavior analysis (ABA), developmental social-pragmatic (DSP) or both (Smith and Iadarola 2015). A recent systematic review and meta-analysis concluded that there was strong support for joint attention interventions, even though it was not clear which children most benefit from which type of intervention (Murza et al. 2016).

40.5.3 Psychotropic Medications

A recent review concluded that the percentage of youth receiving outpatient mental health service increased from 9.2% in 1996 to 17.3% in 2012, with those with no or mild impairment accounting for most of the absolute increase

(Olfson et al. 2015). Most children with ASD are prescribed multiple psychotropic medications, primarily antipsychotics (Schubart et al. 2014; Spencer et al. 2013; Wong et al. 2014). A recent publication on psychotropic drug use in children with ASD in 30 countries reported heavy use of antipsychotics, followed by antidepressants and anxiolytics even though they only address aggressive behaviors and not the core symptoms of the ASD (Wong et al. 2014). As a result, there is increased polypharmacy and risk of unwanted drug interactions (Theoharides and Asadi 2012). The antipsychotic agents risperidone and aripiprazole are approved for use in children with ASD (Lake et al. 2014; Spencer et al. 2013). Additional studies have cast doubt on the benefit of psychotropic agents, especially antipsychotics (Mohiuddin and Ghaziuddin 2013; Sochocky and Milin 2013), given frequent adverse effects that include weight gain, sedation, tremor and drooling (Ching and Pringsheim 2012). Two meta-analyses showed that use of psychotropic drugs in children with ASD were not helpful (Sochocky and Milin 2013; Williams et al. 2010). In particular, a double-blind, placebo-controlled trial using the antidepressant citalopram showed there was no benefit and actually worsened ASD symptoms (King et al. 2009; Volkmar 2009). A recent review also concluded that selective serotonin reuptake inhibitors (SSRIs) are not effective in ASD and frequently have adverse effects leading to hyperactivation (Young and Findling 2015). In fact, hyperserotonemia is present in about 25% of children with ASD (Muller et al. 2016) (Table 40.3).

40.5.4 Complementary and Alternative Approaches

Complementary and alternative medicines are more frequently used in children with ASD than in children with other conditions (Marti 2014; Hendren 2013) regardless of ethnic origin (Valicenti-McDermott et al. 2014). However, most supplements and vitamins tried did not have any significant benefits (Adams et al. 2011; Frye et al. 2013; Marti 2014). In contrast, gluten-free and casein-free diets resulted in significant positive changes in communication, attention and hyperactivity (Sanders and Aziz 2012).

A number of children have been shown to have antibodies against the folate receptor alpha (FR α) or low CSF N5-methyltetrahydrofolate (MTHF) and may benefit from treatment with folinic acid (Ramaekers et al. 2016). A small size, double-blind, placebo-controlled, 16-week study showed that supplementation with arachidonic acid (40 mg) and docosahexaenoic acid (40 mg) administered as 6 capsules (240 mg daily) significantly improved the ABC-social withdrawal and social responsiveness scales (Yui et al. 2012).

A recent double-blind, placebo-controlled, study using broccoli-derived sulforaphane ($n=40$, 13–17 years old for 18 weeks) showed significant improvement in social interaction and communication (Singh et al. 2014). However, participants in this study were older and were selected for their unusual history of reduced ASD symptoms during febrile episodes (Curran et al. 2007); moreover, the apparent significance was due to an uncharacteristically low placebo effect (3.3 %).

A number of studies have shown that N-acetyl cysteine (NAC) at this doses (>600 mg/day) can reduce irritability, but does not affect the core symptoms of ASD (Deepmala et al. 2015; Nikoo et al. 2015).

40.5.5 Hormonal Therapy

A number of studies have shown that the posterior pituitary hormone oxytocin can improve eye gaze and emotion recognition (Anagnostou et al. 2014; Bakermans-Kranenburg and van IJM 2013; Preti et al. 2014). However, the current evidence remains limited (Guastella and Hickie 2016).

There is no evidence that single or multiple doses of intravenous secretin have any benefit in ASD (Williams et al. 2012). The clinical experience from the use of the NMDA inhibitor memantine is too limited at present (Hosenbocus and Chahal 2013) and can be associated with neurologic adverse effects such as anxiety, confusion, insomnia, hallucinations and reversible neurological damage, all of which could present as worsening of ASD symptoms requiring even more medication.

40.5.6 Anti-Histamine and Anti-Allergic Agents

Food elimination diets, especially for casein and gluten, may be useful for those children shown to have allergy or food intolerance to these or other food substances (Rossignol 2009). Common allergic symptoms can be largely addressed through administration of histamine-1 (H-1) and H-2 receptor antagonists. However, in the case of ASD, sedating H-1 receptor antagonists may be preferred because they enter the brain and could have a beneficial function there, too. These include diphenhydramine and/or hydroxyzine, especially since the latter is also anxiolytic. The dual H-1 and serotonin receptor antagonist cyproheptadine could be useful for patients with GI symptoms and/or headaches. H-2 receptor antagonists, such as famotidine and ranitidine, are also helpful particularly in patients with GI symptoms or gastroesophageal reflux.

Ketotifen (Schoch 2003) and rupatadine (Alevizos et al. 2013; Vasiadi et al. 2010) are H-1 receptor antagonists (actually reverse agonists), but also have mast cell activation-inhibitory effects. Rupatadine also has platelet activation factor (PAF) blocking actions (Mullol et al. 2015).

In certain cases, especially if asthma is also present, the anti-leukotriene drug montelukast may be helpful. It should be noted however, that none of these drugs have been investigated in ASD specifically.

Certain physicians have been advocating treatment with dog pin worms on the grounds that they shift the immune response in the intestine (Wammes et al. 2014); however, even though animal data were promising, clinical trials in humans have shown no benefit (Evans and Mitre 2015).

40.5.7 Anti-Inflammatory Agents

Glucocorticoids are powerful anti-inflammatory agents, but are not likely to be used in children because of serious limitations, especially growth retardation.

Recent reviews have discussed the potential use of flavonoids for the treatment of neuropsychiatric (Grosso et al. 2013; Jager and Saaby 2011) and neurodegenerative (Jones et al. 2012; Solanki et al. 2015) diseases including Alzheimer's disease (Baptista et al. 2014; Mecocci et al. 2014; Sheikh et al. 2012; Vauzour 2014), and brain "fog" (Theoharides et al. 2015a).

Flavonoids are naturally occurring compounds mostly found in green plants and seeds (Middleton et al. 2000). Many of the flavonoids can suppress TNF-dependent inflammatory pathways (Gupta et al. 2014b). Luteolin (5,7, 3', 4'-tetrahydroxyflavone) is structurally closely related to 7, 8-dihydroflavone, which was shown to have brain-derived neurotrophic factor (BDNF) activity (Jang et al. 2010b). In fact, absence of BDNF was associated with autistic-like-behavior in mice (Scattoni et al. 2013) and 7, 8-dihydroflavone reduced symptoms in a mouse model of Rett syndrome, which is associated with ASD (Johnson et al. 2012). Luteolin induced the synthesis and secretion of neurotrophic factors in cultured rat astrocytes (Xu et al. 2013). Moreover, the related flavonoids 4'-methoxyflavone and 3', 4'-dimethoxyflavone were shown to be neuroprotective (Fatokun et al. 2013).

Luteolin inhibits IL-6 release from microglia (Jang et al. 2008) and from astrocytes, (Sharma et al. 2007), microglial activation and proliferation (Chen et al. 2008; Dirscherl et al. 2010; Kao et al. 2011) and microglia-induced neuron apoptosis (Zhu et al. 2011) (Table 40.2). Luteolin inhibits MCs

Table 40.2 Useful treatment approached for ASD

• Introduce behavioral interventions
• Treat any comorbid conditions, especially allergies
• Eliminate food triggers, especially casein and gluten
• Minimize phenol containing substances, especially chocolate and acetaminophen
• Address gastrointestinal symptoms, especially constipation
• Limit sensory overload
• Reduce inflammation

Table 40.3 Categories of drugs and supplements used for ASD

Drugs
<i>OCD and Disruptive Behavior</i>
• Aripiprazole
• Risperidone
<i>Hyperactivity</i>
• Hydroxyzine
• Propranolol
Supplements
<i>Hyperactivity</i>
• N-acetyl cysteine (NAC)
• S-adenosyl methionine (S-AMe)
• Valerian/Paciflora extract
<i>Oxidative Stress</i>
• Broccoli extract
• Fish oil
• Glutathione
<i>Inflammation</i>
• Luteolin/berberin (BrainGain)
• Luteolin/quercetin (NeuroProtek)
<i>Neuroprotection</i>
• Methyl B12
• Biotin, hydroxytyrosol, selenium

(Asadi et al. 2010; Kempuraj et al. 2005; Kimata et al. 2000), MC cytokine release (Asadi and Theoharides 2012) and thimerosal-induced inflammatory mediator MC release (Asadi et al. 2010). Luteolin also protects mitochondria against methylmercury-induced damage (Franco et al. 2010) and dopaminergic neurons from inflammation (Chen et al. 2008). Luteolin also inhibits auto-immune T cell activation (Kempuraj et al. 2008; Verbeek et al. 2004).

Luteolin improved spatial memory in a scopolamine-induced model (Yoo et al. 2013) and in amyloid β -peptide-induced toxicity (Liu et al. 2009) in rats. Luteolin also attenuated diabetes-associated cognitive decline in rats (Liu et al. 2013b), cognitive dysfunction induced by chronic cerebral hypoperfusion in rats (Fu et al. 2014; Hagedorn et al. 2010) and high fat-diet-induced cognitive dysfunction in mice (Liu et al. 2014). Furthermore, luteolin (Jang et al. 2010a; Liu et al. 2009; Yoo et al. 2013) increased memory and inhibited autism-like behavior in a mouse “model” of autism (Parker-Athill et al. 2009).

Luteolin further inhibits release of the excitatory neurotransmitter glutamate, (Lin et al. 2011), while it activates receptors for the inhibitory neurotransmitter γ -amino butyric acid (GABA) independent of GABA, suggesting it may also have an anxiolytic effect (Hanrahan et al. 2011). In fact, benzodiazepines that act by activating GABA receptors were shown to bind to MCs (Miller et al. 1988). Flavonoids can also inhibit acetylcholinesterase (Boudouda

Table 40.4 Beneficial effects of luteolin

• Reduces oxidative stress
• Inhibits inflammation
• Inhibits mast cell activation
• Inhibits microglia activation
• Inhibits neurotoxicity
• Increases memory
• Mimics BDNF
• Inhibits acetylcholinesterase
• Inhibits demethylase
• Prevents autism-like behaviour in mice
• Improves attention and sociability in children with ASD

et al. 2015; Tsai et al. 2007), which will increase acetylcholine and improve memory (Tables 40.1 and 40.4). Moreover, polyphenols inhibit lysine-specific demethylase-1 (Abdulla et al. 2013), an action that may be relevant since ASD have been associated with methylation defects (Trivedi and Deth 2012).

The luteolin structurally related flavonol quercetin (5,7,3',4',11-pentahydroxyflavonol), also inhibits histamine, IL-6, IL-8, TNF- α and tryptase release from human MCs (Kempuraj et al. 2005; Park et al. 2008) protected against amyloid β -induced neurotoxicity (Liu et al. 2013a; Regitz et al. 2014) and improved cognition in a mouse “model” of Alzheimer’s disease (Wang et al. 2014). In fact, quercetin-o-glucuronide reduced the generation of β -amyloid in primary cultured neurons (Ho et al. 2013). Quercetin reversed acute stress-induced autistic-like behavior and reduced brain glutathione levels in mice (Kumar and Goyal 2008).

In one case-series (Theoharides et al. 2012b) and one open-label study (Taliou et al. 2013) a luteolin and quercetin containing formulation significantly improved attention and behavior in children with ASD. This dietary supplement contains 100 mg luteolin and 70 mg quercetin per softgel capsule, >98 % pure) formulated in olive fruit extract, which increases oral absorption. We recently showed that those patients who most improved with this formulation were those who had high serum TNF at the beginning and decreased at the end of the treatment (Tsilioni et al. 2015), suggesting these are distinct subgroups.

Olive fruit extract contains hydroxytyrosol, which has been reported to protect against brain hypoxia (Gonzalez-Correa et al. 2008). It also contains oleocanthal, which inhibits fibrilization of tau proteins (Li et al. 2009a) and reduces aggregation of A β oligomers (Pitt et al. 2009) implicated in Alzheimer’s disease. Moreover, olive oil (Mohagheghi et al. 2010) and olive leaf extract (Mohagheghi et al. 2011) protected the brain by reducing BBB permeability. In fact, use of olive oil increased memory in rodents (Farr et al. 2012; Martinez-Lapiscina et al. 2013; Tsai et al. 2007).

Flavonoids, especially quercetin and luteolin (they differ by one hydroxyl group) are generally considered safe (Corcoran et al. 2012; Harwood et al. 2007; Kawanishi et al. 2005; Seelinger et al. 2008; Theoharides et al. 2014).

However, dietary supplements containing flavonoids (e.g. bioflavonoids, soy flavonoids, citrus flavonoids) often state “proprietary formula” or “complex” without listing the exact type or amounts of the flavonoids. Moreover, most supplements do not list the sources of flavonoids that are commonly peanut shells and fava beans; these may lead to anaphylactic reactions or hemolytic anemia to allergic and G6PD-deficient individuals, respectively. Less than 10% of orally ingested flavonoids are absorbed (Passamonti et al. 2009; Thilakarathna and Rupasinghe 2013) and are extensively metabolized to inactive ingredients in the liver (Chen et al. 2014b), primarily through glucuronidation, methylation and sulfation (Hollman et al. 1995; Hollman and Katan 1997). Therefore, flavonoids (especially, over 1000 mg/day) must be used with caution when administered with other natural polyphenolic molecules (e.g. curcumin, resveratrol) or drugs metabolized by the liver as they may affect the blood levels of themselves or of other drugs (Theoharides and Asadi 2012).

A methylated luteolin analogue (6-Methoxyluteolin) was shown to inhibit IgE-stimulated histamine release from human basophilic KU812F (Shim et al. 2012). Moreover, we recently showed that tetramethoxyluteolin is a more potent inhibitor of human MCs than luteolin (Weng et al. 2014). Methylated flavonoids are less likely to affect liver metabolism, are more stable (Walle 2007) and have better bioavailability (Wei et al. 2014).

40.5.8 Other Immune Modulators

Intravenous immunoglobulin G (Ig) is often used when one suspects an autoimmune component and all other treatment approaches have failed (Wong and White 2015). A few case studies showed significant benefit (Wong and White 2015a; Gupta et al. 2010; Plioplys 1998; Giudice-Asch et al. 1999; Melamed et al. 2015). Nevertheless, Ig may be helpful especially in children with frequent infections or Pediatric Autoimmune Neuropsychiatric Disorders associated with Streptococcal Infections (PANDAS).

40.5.9 Chelation

A recent comprehensive review concluded that pharmaceutical chelation was not effective and was associated with potential serious adverse effects (James et al. 2015).

40.6 Conclusions

Addressing allergic symptoms and anxiety, as well as reducing brain inflammation can provide significant benefit both for the core and ancillary symptoms of ASD. Luteolin analogues with better bioavailability and BDNF activity should be investigated further.

40.7 Review Questions

1. Do patients with ASD experience nonpsychiatric symptoms?
2. Does the risk for ASD increase with any maternal or childhood conditions?
3. Is there any evidence of brain inflammation in children with ASD?
4. Could mast cell activation contribute to ASD?

40.8 Answers

1. Up to 60% of patients have intolerance to foods (e.g. gluten, casein) allergies and gastrointestinal complaints, while 20–30% of patients have mitochondrial dysfunction, seizures or repeated infections.
2. There is strong statistical association with increased risk of ASD and maternal stress, psoriasis, asthma, allergies, use of psychotropic agents and excessive use of oxytocin for labor induction. There is also strong association with prematurity, small gestational weight, food intolerance and toxic exposures.
3. Biochemical and pathological studies have shown increased expression of the cytokines IL-6 and TNF as well as, the chemokines IL-8 and MCP-1. There is also increased proliferation and activation of microglia in key brain regions.
4. Mast cells both outside and inside the brain can secrete vasodilatory, inflammatory and neurosensitizing molecules that could: (a) disrupt the blood-brain-barrier, (b) activate microglia, (c) focal inflammation especially in the diencephalon.

Abstract

Opioids and cannabinoids have been shown to modulate many different parameters of immune responses. In general, opioids and cannabinoids have been found to be immunosuppressive, both in vitro and in vivo in a variety of assays, including response of lymphocytes to mitogens, antibody formation, activation of T-cells, Natural Killer Cell activity, and phagocytosis by macrophages and neutrophils. Drugs in these two classes have also been shown to inhibit migration of cells from the circulatory system to areas of inflammation, including passage across the blood-brain barrier. Opioids and cannabinoids have both been shown to sensitize mice to a variety of infectious agents, which is commensurate with an immunosuppressed state. In specialized rodent models and in monkeys, opioids sensitized to HIV and SIV, possibly related to their ability to cause heterologous desensitization of chemokine co-receptors for these viruses. The literature covered in this chapter supports the existence of a robust neural-immune interaction.

41.1 Introduction**41.1.1 Opioid and Cannabinoid Receptors are on Cells of the Immune System****41.1.1.1 Opioid Receptors**

There is now indisputable evidence of natural physiological connections between the neural and immune systems. Much of the evidence supporting this link has come from studies of

opioids and cannabinoids and their effects on immune responses. Opioid receptors were first demonstrated biochemically in brain in the early 1970s. Three distinct receptors were discovered in neural tissue and were designated mu, kappa, and delta (Simon 1991). Their respective natural ligands were found to be the neuropeptides, β -endorphin (predominantly mu), dynorphin (kappa) and methionine-enkephalin (delta) (Akil et al. 1984), although there is considerable cross-reactivity. Alkaloid opioids, including morphine and heroin, bind primarily, but not exclusively, to the mu receptor. Morphine is extracted from opium produced by the poppy plant, and heroin is synthetically diacetylated morphine. In vivo, the major metabolite of heroin is morphine. Most laboratory studies employ morphine because it is less lipophilic than heroin, is used therapeutically, and is easier to dissolve. Since the mu receptor is the major target of both compounds, results obtained with morphine are believed to be directly translatable to heroin abuse, although there is some evidence for unique biologically active heroin metabolites (Rossi et al. 1996).

Credit for recognition of the potential existence of receptors for opioids on cells of the immune system is given to Joseph Wybran in the laboratory of Govaerts. In 1979 he reported modulation of the function of human T-cells, purified from normal peripheral blood, by exogenous and endogenous opioids (Wybran et al. 1979). He observed that if morphine was added to human T-cells in culture, they lost the ability to rosette with sheep red blood cells (SRBCs), a fortuitous property that was used before flow cytometry to enumerate T-cells. In contrast, when the opioid neuropeptide, met-enkephalin, was added to the T-cells, rosetting increased. The actions of both opioids were blocked by naloxone, an antagonist for all types of opioid receptors, showing pharmacological specificity of the effects. Wybran proposed that, "normal human blood T lymphocytes bear surface receptor-like structures for morphine and methionine-enkephalin". He concluded that, "Such findings may provide a link between the central nervous system and the immune system." This paper was seminal because it presented strong pharmacologic data to support the existence of opioid receptors on cells of the immune system. However, it has been very difficult to demonstrate opioid receptors routinely by binding studies using cells of the immune system, although scattered reports of positive results are published (Sharp et al. 1998; Sibinga and Goldstein 1988). The difficulties may be due to low receptor numbers on cells of the immune system, to inability to obtain enough purified subsets of immune cells to do adequate binding studies, or to a need to activate immune cells before the receptors are expressed. With the advent of cloning of the opioid receptors from brain tissue, mRNA transcripts have been detected in primary cells of the immune system or lymphoid or monocytic cell lines for all three classes of opioid receptors (Loh and Smith 1990; McCarthy et al. 2001; Sharp et al. 1998).

41.1.1.2 Cannabinoid Receptors

Cannabinoid receptors were identified and cloned several years after the opioid receptors. Cannabinoids, like the psychotropic active ingredient extracted from marijuana, Δ^9 -tetrahydrocannabinol (Δ^9 -THC), were initially believed by some to simply interdigitate into cell membranes. Subsequently, a cannabinoid receptor was cloned from neural tissue (Zhu et al. 1993). When lymphoid tissue was probed for cannabinoid receptor transcripts, a second receptor (designated CB2) was discovered that is primarily expressed in the immune system and has only 44% homology to the first receptor (designated CB1) (Munro et al. 1993). Cells of the immune system express predominantly CB2 receptors, although mRNA for CB1 had also been detected. The brain expresses predominantly CB1 receptors, although there are a few reports of CB2 expression and functional activity. mRNA for CB2 is expressed by B-cells>natural killer cells>monocytes>neutrophils>T-cells in rat, mouse, and human tissues

and cells (Bouaboula et al. 1993; Galiegue et al. 1995). Endogenous cannabinoid ligands have also been discovered, but they are not peptides like the opioids. Anandamide, or arachidonylethanolamide, is a polyunsaturated N-acylethanolamine (Devane et al. 1992), as is 2-arachidonoyl-glycerol (Di Marzo and Deutsch 1998; Mechoulam et al. 1995). Radiolabeled cannabinoids have been shown to bind to mouse spleen cells and human T-cell lines (Kaminski et al. 1992; Schatz et al. 1997). Δ^9 -THC and endogenous cannabinoids all bind to both CB1 and CB2 receptors. However, it is becoming increasingly apparent, using selective CB1 and CB2 antagonists, as well as cannabinoid receptor knock-out mice, that most of the immunomodulating effects of these compounds on the immune system are mediated via the CB2 receptor.

41.1.1.3 Summary

It is now widely accepted that immune cells express receptors for opioids and cannabinoids. This conclusion is based on an impressive body of literature demonstrating immune modulation by exogenous and endogenous opioids and cannabinoids. Evidence from in vitro experiments suggests that effects of these drugs on the cells of the immune system occur, at least partially, by binding of opioid and cannabinoid receptors on these cells. Cocaine has also been found to affect immune function, but the mechanisms have not been defined. Other commonly used and abused drugs include nicotine and alcohol, both of which have marked effects on the immune system, and are frequently part of the panoply of artificial substances used by addicts. In addition, methamphetamines can alter immune status. Due to space limitations the reader is referred to key papers on these subjects (Molina et al. 2010; Soporì 2002).

41.1.2 Mechanisms by Which Drugs of Abuse can Affect Cells of the Immune System

Testing of whether drugs of abuse can alter immune function has been carried out by in vivo administration of the drug, with assessment of in vivo or ex vivo immune function, or alternatively, by harvesting immune cells from a drug naïve (normal) host and exposing them to the drug in vitro. If a drug is given in vivo, there is the possibility that effects on the immune system are not due to a direct interaction of the drug with cells of the immune system, but that immunomodulatory effects are instead mediated by additional systems in the body. For example, opioids, cannabinoids, and other drugs of abuse, can modulate the Hypothalamic-Pituitary-Adrenal (HPA) axis, which can lead to release of immunosuppressive corticosteroids or to activation of the sympathetic nervous (SNS) system, resulting in downstream alterations in immune function. Effects on immune function could thus

be a combination of indirect and direct effects if the drug is given *in vivo*. An additional and important consideration is that both the neural system and cells of the immune system produce opioid peptides, which could lead to complicated interacting pathways, especially *in vivo* (Carr 1991). In evaluating the studies discussed in this Chapter, it should be recognized that most immune responses were assessed 2–3 h after a single injection of a drug. For studies testing longer exposure to morphine, the drug is frequently delivered by subcutaneous implantation of a pellet that slowly releases the drug over a period of a week. Alternatively, mini-pumps dispensing drugs can be implanted. In the case of morphine or other addictive opioids, these methods are used to avoid episodes of withdrawal, which have their own immunomodulatory effects on immune function. In fact, a complication of studies with opioids is that repeated administration can result in tolerance to their analgesic effects, and in many, but not all, cases tolerance to the effects of the drugs on the immune system (Eisenstein et al. 2006). There are a limited number of studies that have addressed the effects of tolerance and of withdrawal from morphine on immune responses (Eisenstein et al. 2006).

41.2 Functional Consequences of Drugs of Abuse on the Immune System

41.2.1 Effects on Innate Immunity and the Inflammatory Response

41.2.1.1 Cells and Molecules of the Innate Immune Response

It is well established that drugs of abuse are involved in a wide range of immunomodulatory activities. Among the areas in immune system function in which these alterations have been observed is innate immunity. This arm of the immune system does not exhibit specificity in recognizing foreign pathogens. It encompasses Natural Killer (NK) cells and the ‘professional’ phagocytic cells that are the first responders to inflammation or infection. Natural Killer cells are lymphocytes that are involved in recognition and killing of mammalian cells that express foreign antigens, such as tumor antigens or viral antigens, or which fail to express histocompatibility antigens of the host. They also produce cytokines (small proteins produced by immune cells that act in an autocrine, paracrine, or endocrine fashion) that can activate the mononuclear phagocytic cells. The phagocytic cells engulf microbes invading the host and include neutrophils, monocytes, and macrophages. Monocytes are formed in the bone marrow and released into the peripheral blood. They are mature, but unactivated cells. When they are stimulated in various ways they can develop into macrophages *in vivo* or *in vitro*. Macrophages have several states of activation that

are characterized by their production of cytokines and by their levels of microbicidal compounds, including reactive oxygen intermediates (ROIs) and reactive nitrogen intermediates (RNIs). Macrophages also play an important role in the acquisition and presentation of foreign antigens to lymphocytes, which triggers the adaptive immune response.

41.2.1.2 Effects of Opioids, Cannabinoids, and Cocaine on Natural Killer (NK) Cells

In the cellular repertoire of the innate immune system, NK cells have the unique ability to kill infected target cells in a manner independent of antigen recognition. Alteration in NK cell function was among the earliest, and has been one of the most consistently observed, effects of drugs on the immune system. Many studies have shown that administration of opioids to rodents results in the suppression of NK cell activity. Leibeskind’s laboratory (Shavit et al. 1986a) was the first to show that morphine given to rats subcutaneously for 4 days suppressed NK cell activity. They later concluded that this effect was not directly on the NK cells in the periphery, because N-methylmorphine, which does not pass the blood-brain barrier, did not depress NK function (Shavit et al. 1986b). Subsequently, Weber and Pert (Weber and Pert 1989) reported that injection of morphine into the periaqueductal gray region of the brains of rats resulted in suppression of NK cell activity in the spleens of these animals 3 h later. Morphine administered into 5 other brain sites was without effect. Moreover, the opioid specific antagonist, naltrexone, blocked the effects in the studies by both groups, implicating the involvement of classic opioid receptors in modulating NK cell activity. Studies have also been carried out in which morphine has been given to normal human subjects under controlled conditions. The results show that peripheral blood NK cell activity is depressed 24 h after morphine administration (Yeager et al. 1995). The exact mechanism by which engagement of opioid receptors in certain regions of the brain alters peripheral functional capacity of NK cells is not known. However, more recent work implicates a neural pathway involving dopamine in modulating NK activity (Saurer et al. 2006). Nonetheless, the mu opioid receptor (MOR) is certainly involved in the effects on NK cell activity, as mice with a genetic deletion of MOR do not respond to morphine with depressed NK cell activity (Gavériaux-Ruff et al. 1998).

The cannabinoids represent another class of abused drugs affecting immune cell function. Although fewer studies have explored the effects of cannabinoids on NK cells, the literature to date shows that the activity of splenic NK cells is suppressed following *in vivo* injection of Δ^9 -THC into rats and mice (Klein et al. 1987; Patel et al. 1985), and also after *in vitro* treatment of human peripheral blood NK cells (Specter et al. 1986). Δ^9 -THC has also been shown to block proliferation of NK cells in response to the cytokine, IL-2, by down-regulating the IL-2 receptor (Zhu et al. 1993).

There are a limited number of reports of immunomodulation by cocaine. In vivo administration of cocaine i.v. to humans elevated NK cell activity in peripheral blood, but exposure of leukocytes to the drug in vitro had no effect (Van Dyke et al. 1986). It was hypothesized that the in vivo effects occurred via release of epinephrine from the SNS (Van Dyke et al. 1986). Contradictory results have been reported for the effect of cocaine on NK activity in rats, with no effect in vivo (Bayer et al. 1996) or suppression of activity after acute or chronic in vivo administration (Pacifici et al. 2003).

41.2.1.3 Drugs of Abuse Alter Functions of Neutrophils and Monocytes/Macrophages

Opioids given in vivo have been demonstrated to inhibit ex vivo phagocytic cell activity (Tubaro et al. 1983). Opioids selective for all three classes of opioid receptors (mu, kappa, and delta), when added to mouse peritoneal macrophages in vitro, inhibited phagocytosis of the yeast *Candida albicans*, and the effects were blocked by the respective receptor selective antagonists (Szabo et al. 1993). Others have shown that mu and delta agonists inhibited Fc-mediated phagocytosis of antibody-coated sheep red blood cells by mouse peritoneal cells exposed in vitro to morphine (Tomassini et al. 2004). These results showed that the activation of each of the opioid receptors resulted in reduced phagocytic activity. More recent studies have provided a mechanism by which phagocytosis is inhibited by morphine, namely through disruption of actin polymerization resulting from an increase in intracellular cAMP, activation of phosphokinase A and inhibition of Rac1-GTPase, and p38 mitogen-activated protein kinase (MAPK) (Ninković and Roy 2012). In addition, morphine given in vivo by slow release pellet, or when added to murine bone marrow cells in vitro, blocked the maturation of stem cells into more mature macrophages (Roy et al. 1991). Morphine pellets also inhibited adhesion of leukocytes to vascular endothelium, thus reducing inflammation (Ni et al. 2000). Further work has shown the morphine also inhibited the ability of phagocytic cells to produce superoxide and peroxide (Peterson et al. 1987a), two metabolites that have strong anti-microbial activity. Peterson and colleagues (Chao et al. 1992) have shown that the inhibitory effects of morphine on phagocytic cell activity are dependent on the production of Transforming Growth Factor (TGF)- β . Reactive oxygen intermediates (ROI), such as superoxide, contribute to the microbicidal activity of phagocytes, so impairment of their production would be consonant with reduced capacity to kill ingested yeast or other microbes. Macrophages taken from mice exposed to morphine can undergo apoptosis (Nair et al. 1997; Yin et al. 1999), and evidence supports a role of ROI and nitric oxide (NO) in this process (Bhat et al. 2004; Singhal et al. 1998). Usually depression of NO is associated with decreased macrophage function, so these findings are

dichotomous with the other evidence on effects of opioids on these cells.

Morphine treatment has been reported to result in reduced recruitment of both neutrophils and macrophages to growing tumors, using a murine Lewis Lung Carcinoma model system (Koodie et al. 2014). Chronic morphine administration has also been shown to inhibit the migration of neutrophils and monocytes that are a part of the process of wound healing (Clark et al. 2007; Martin et al. 2010a, b). The attenuated recruitment of neutrophils was attributed to morphine-induced inhibition of the expression of the chemokines CXCL3 and CCL2 (Martin et al. 2010a).

Δ^9 -THC is also reported to decrease the phagocytic activity of human peripheral blood monocytes and mouse peritoneal macrophages (Lopez-Cepero et al. 1986; Specter et al. 1991a). Long-term use of Δ^9 -THC in non-human primates has also been associated with depressed macrophage function (Cabral et al. 1991). Alveolar macrophages of marijuana smokers exhibited decreased microbicidal activity against *Staphylococcus aureus*, which was associated with decreased production of NO (Roth et al. 2004). Δ^9 -THC also affects macrophage processing of exogenous protein antigens through the CB2 receptor, as shown pharmacologically and using CB2-deficient mice (Buckley et al. 2000; McCoy et al. 1999).

Cocaine, like Δ^9 -THC and morphine, has been reported to decrease the antimicrobial activity of alveolar macrophages obtained from chronic crack cocaine smokers (Roth et al. 2004) and to decrease parameters of mouse macrophage activation (Ou et al. 1989; Pacifici et al. 1993). However, in contrast to the effects of opioids, cocaine has been shown to increase the activation of neutrophils in human subjects, as evidenced by increased killing of *Staphylococcus aureus* (Baldwin et al. 1997).

41.2.1.4 Effects of Drugs of Abuse on the Production of Cytokines and Chemokines

One mechanism by which drugs of abuse modulate immune function is through effects on expression of cytokines and chemokines, or on the functional capacity of their receptors. These proteins act as messengers to direct appropriate cellular activation and differentiation (cytokines) and coordinate the migration of cells to particular sites of inflammation or infection (chemokines). Cytokines have a number of functions. They may alter the innate immune response, act as a bridge to influence the type of adaptive immune response, and can also amplify adaptive immune responses. Chemokines can participate in innate immunity, and also influence adaptive immunity by orchestrating the type of cells that migrate to a pathological site. In addition, some of the chemokines can act as co-activators of immune cell function. Pro-inflammatory and anti-inflammatory cytokines, and also chemokines, which are part of the innate immune

response, mediate generalized symptoms of inflammation including fever (IL-1), organ damage (tumor necrosis factor (TNF)- α), and migration of phagocytic cells (IL-8, CCL2), or dampen these responses (IL-10).

Morphine and other ligands for the mu receptor have been shown to modulate the production of both cytokines and chemokines, although the results have been complex. For example, treatment of stimulated peripheral blood mononuclear cells with morphine decreased IFN- γ production (Peterson et al. 1987b), but increased TGF- β expression (Chao et al. 1992). Since TGF- β can be immunosuppressive, it is possible that the up-regulation of TGF- β may be responsible for the depressed IFN- γ expression. A biphasic dose-response relationship was shown for release of pro-inflammatory cytokines from stimulated mouse peritoneal macrophages treated with morphine in vitro, with increased release of IL-6 and TNF- α and reduced production at high doses (Roy et al. 1998b). In contrast, when mice were treated with relatively high doses of morphine in vivo and their peritoneal macrophages were stimulated ex vivo, they showed increased production of IL-12 and TNF- α (Maldonado et al. 1992).

The pattern of pro-inflammatory cytokines produced has implications for the character of the adaptive immune response that will occur if the host is exposed to a foreign antigen. A T-helper type 1 (Th1) cytokine profile polarizes the immune response towards a more pro-inflammatory cellular immune response, whereas a T-helper type 2 (Th2) profile favors certain types of antibody responses (Mosmann and Coffman 1987). IFN- γ is often considered a marker of a Th1 response, and IL-4 is indicative of a Th2 response. There is evidence that morphine given in vivo biases the immune response toward a Th2 response (Roy et al. 2004). In addition, recent studies of the murine immune response to *Acinetobacter baumannii* and to pulmonary *Streptococcus pneumonia* infection show that chronic morphine administration inhibits the development of T-helper type 17 (Th17) immunity, and decreases the production of the Th17-associated cytokines IL-17 and IL-23 (Breslow et al. 2011b; Ma et al. 2010; Wang et al. 2011). The consequences of this apparent shift toward Th2-type immunity are not clear, since other studies show that antibody production is suppressed in animals treated similarly with morphine (Bussiere et al. 1993). These results will be discussed in greater detail below.

In regard to chemokines, exposure of peripheral blood mononuclear cells (PBMCs) to DAMGO, a synthetic peptide selective for the μ -opioid receptor, has been shown to increase the expression of pro-inflammatory chemokines CCL2, CCL5, and CXCL10 (Wetzel et al. 2000), and the chemokine receptors CXCR4 and CCR5, the major HIV-1 co-receptors (Choi et al. 1999; Steele et al. 2003), the latter leading to increased replication of HIV. More recent work has shown that morphine and other μ -opioid agonists induce CCL2 expression by inducing NF- κ B activation (Happel

et al. 2011). It is difficult to reconcile some of these in vitro observations with the in vivo studies cited above showing that morphine inhibits migration of neutrophils and monocytes that are a part of the process of wound healing through inhibition of chemokine expression (Clark et al. 2007; Martin et al. 2010a, b). Thus it appears that opioids can exert both pro- and anti-inflammatory effects on the immune response.

A major and important finding concerning opioids and chemokines is that there is heterologous desensitization between certain opioid and chemokine receptors (Adler and Rogers 2005). Heterologous desensitization of G-Protein Coupled Receptors (GPCRs) is a process in which engagement of one receptor leads to the inactivation of a second receptor (in the absence of the agonist for the second receptor) to function. This process is mediated by initiation of a signaling pathway which leads to the cross-phosphorylation of the second receptor (Chen et al. 2004; Szabo et al. 2002, 2003), reviewed in (Steele et al. 2002). These studies show, for example, that activation of MOR leads to the cross-desensitization of CCR1, CCR2 and CCR5, and these cross-talk interactions are bi-directional (Fig. 41.1). Heterologous desensitization of chemokine receptors by opioids blocks chemotaxis of human peripheral blood mononuclear cells (Grimm et al. 1998; Szabo et al. 2002) and also blocks HIV infection of primary human monocytes in vitro (Szabo et al. 2003). Moreover, studies conducted in vivo show that pre-treatment of rats with CCL5 or CXCL12 in the periaqueductal gray (PAG) region of the brain, blocks the antinociceptive effects of morphine similarly administered (Szabo et al. 2002). These results are consistent with cross-talk between the chemokine receptors CCR5 or CXCR4, respectively, and MOR. More recent work has shown that at least 90% of neurons in the rodent PAG co-express CXCR4 and MOR (Heinisch et al. 2011; Patel et al. 2006). These results are very important since the process of heterologous desensitization requires that the receptors must be co-expressed in order for the cross-phosphorylation to take place (Steele et al. 2002). More recent work has demonstrated cross-talk between a number of chemokine receptors and MOR in the brain, and these results have potential clinical relevance since MOR plays an important role in the sensitivity to pain. (reviewed in Parsadaniantz et al. 2015).

There are striking parallels between the effects of opioids and cannabinoids on cytokine production. Δ^9 -THC has also been shown to suppress pro-inflammatory cytokines crucial in host defense, such as TNF- α (Fischer-Stenger et al. 1993). Further studies showed a biphasic dose response to cytokine production by Δ^9 -THC on human PBMCs, but it was the opposite of that observed with morphine, with low doses inhibiting TNF- α , IL-6 and IL-8, and high doses increasing these cytokines (Berdyshev et al. 1997). In a mouse model of Legionnaires' Disease, Δ^9 -THC blocked IFN- γ , IL-12, and

Opioid-Induced Heterologous Desensitization of CCR5

Fig. 41.1 Heterologous desensitization of chemokine receptors following activation of the MOR. The activation of MOR by either morphine or a MOR-selective agonist such as DAMGO leads to the induction of a cross-desensitization pathway which rapidly leads to the inactivation of some the chemokine receptors, including CCR5. At this point the cell is unresponsive to CCR5-selective chemokines such as

CCL3, 4 or 5. However, the MOR-induced cross-desensitization does not effect all chemokine receptors. For example, CXCR4 remains fully responsive to activation by the CXCR4-specific chemokine CXCL12. The cell is also protected from infection with an R5 strain, but not an X4 strain, of HIV-1

IL-12 receptor expression and increased IL-4 levels, reflecting a polarization of the immune response towards a Th2 phenotype (Klein and Cabral 2006; Perez-Castrillon et al. 1992). In an immune assay of graft rejection, Δ^9 -THC added into the cultures depressed IFN- γ production by human peripheral blood T-cells (Yuan et al. 2002). When lymph node cells of mice were stimulated with Staphylococcal enterotoxin B, histone methylation and acetylation patterns were consistent with up-regulation of Th2 cytokine genes and parallel down-regulation of Th1 genes (Yang et al. 2014). These results are interesting given the ability of Δ^9 -THC to induce elevated expression of the anti-inflammatory cytokines IL-10 and TGF β in tumor bearing mice (Zhu et al. 2000). Work with the endocannabinoid, anandamide, has demonstrated an inhibitory effect on the production of the pro-inflammatory cytokines IL-12 and IL-23, with a modest up-regulation of the anti-inflammatory cytokine IL-10 in microglial cells (Correa et al. 2009, 2010).

Like morphine, cannabinoids have also been shown to increase the mRNA for the chemokines CCL2, and also for IL-8, in a monocytic cell line transfected with the CB2 receptor (Jbilo et al. 1999). Further, the cannabinoids are reported to be chemotactic for macrophages (and microglial cells), which suggests that the CB2 receptor mediates activation of the cell migration machinery (Derocq et al. 2000; Walter et al. 2003). In contrast and somewhat anomalously, several reports have shown that treatment with Δ^9 -THC or CB2

agonists depressed the capacity of macrophages or microglial cells to migrate in response to certain chemokines, including CCL2, CCL3 and CCL5 (Fraga et al. 2011; Montecucco et al. 2008; Raborn et al. 2008; Romero-Sandoval et al. 2009). Treatment with high doses of CB2 agonists has been reported to attenuate the response of human T-cells to CXCL12 (Ghosh et al. 2006), and taken together these results suggest that CB2 cannabinoids can inhibit leukocyte traffic. This would be consistent with studies that have shown that CB2 agonists inhibit leukocyte adhesion to brain vascular endothelium, and reduce the migration of monocytes across the blood-brain barrier (Persidsky et al. 2015; Ramirez et al. 2012; Rom et al. 2013).

Cocaine is also reported to modulate the production of cytokines and chemokines. Analysis of in vitro cocaine treatment on cytokine and chemokine expression by mouse and human cells has revealed a decreased ability of stimulated immune cells to produce INF- γ , TNF- α , IL-1, and IL-8 (Shen et al. 1994; Watzl et al. 1992). Other studies did not agree, and reported an increase in TNF- α , IL-8, IL-2 and other chemokines (Wang et al. 1994; Zhang et al. 1998). Interestingly, in vivo infusion of cocaine showed an increase in IFN- γ and a decrease in the anti-inflammatory cytokine, IL-10 (Gan et al. 1998). The lack of concordance between in vitro and in vivo studies again suggests that drugs may have complex effects in vivo, partly because they can engage mediators from other systems that might affect immune function.

41.2.2 Effects on Adaptive Immunity

41.2.2.1 Humoral Immunity (Antibody Responses)

Morphine given by slow-release pellet has been shown to block the capacity of mouse spleen cells to mount an *ex vivo* antibody response to the artificial antigen, sheep red blood cells, and a naltrexone releasing pellet blocks the effect of the opioid (Bussiere et al. 1992). Serum antibody responses to tetanus toxoid (Eisenstein et al. 1990) and to trinitrophenylated bovine serum albumin (Weber et al. 1987) were also suppressed in mice by morphine given *in vivo*. Morphine, U50,488H (kappa agonist) and deltorphin II (delta₂ agonist) have all been shown to be immunosuppressive when administered by osmotic mini-pump. All three agonists gave inverted U-shaped dose response curves over a dose range of 0.1–10 mg/kg/day, with maximal immunosuppression between 0.5 and 2 mg/kg/day (Rahim et al. 2001). It has been suggested that part of the suppressive effect of morphine pellets on humoral immune responses is due to activation of the HPA-axis (Pruett et al. 1992). However, all of the effects of opioids on the capacity to mount an antibody response cannot be mediated, since spleen cells taken from normal animals that were never exposed to opioids *in vivo*, have depressed capacity to make antibodies to sheep red blood cells when treated with various opioid agonists *in vitro* (Eisenstein et al. 1995; Taub et al. 1991). Also, quaternary naloxone, which does not pass the blood-brain barrier, blocks the immunosuppressive effect of a kappa agonist given *in vivo* (Radulovic et al. 1995), suggesting that the drug is acting in the periphery. The suppressive effects of morphine and U50,488H *in vivo* and *in vitro* appear to result from individual effects on T-cells and macrophages (Bussiere et al. 1993; Guan et al. 1994) which are needed to cooperate with B-cells to generate antibody production. Morphine has also been shown to have an effect on the mucosal antibody response. Cultured ileal segments from mice receiving morphine and given cholera toxin orally were suppressed in their ability to produce IgA specific for cholera toxin compared with mice receiving placebo (Peng et al. 2001). The effect of chronic administration of morphine and withdrawal from the drug have been examined for effects on responses to a B-cell mitogen (LPS) (Bryant et al. 1987) and on antibody responses (Rahim et al. 2002). Exposure to morphine from slow-release pellets for 3 to 4 days led to tolerance to the immunosuppressive effects in both assays, and withdrawal led to renewed immunosuppression. Extensive investigation into the mechanisms of withdrawal-induced immunosuppression showed that there was a deficit of macrophage function (Rahim et al. 2003, 2005). In contrast, other data suggest that withdrawal biases the immune response to a Th2 cytokine phenotype (Kelschenbach et al. 2005). At present it is not known how to reconcile these observations.

Δ⁹-THC, like morphine, has been shown to suppress *in vitro* antibody formation by mouse spleen cells (Eisenstein et al. 2007; Kaminski et al. 1992, 1994). Interestingly, Δ⁹-THC is reported to increase IgG1 responses to *Legionella* in drug-treated animals, presumably by polarizing the immune response towards a Th2 phenotype (see below under T-cell responses) (Newton et al. 1994).

Cocaine has been investigated for capacity to alter antibody responses and has been found to be immunosuppressive for some antigens, but not others (Havas et al. 1987; Ou et al. 1989; Watson et al. 1983).

41.2.2.2 T-Cell Responses

Morphine given by slow-release pellet also inhibits the ability of splenic T-cells to respond to mitogens (plant products that cause nonspecific proliferation of immune cells). Thus, at 72 h after pellet implantation splenic murine T-cells had a marked inhibition of replication when exposed to Concanavalin A (Con A) (Bryant et al. 1987). Reduction in response to Con A has also been observed using peripheral blood T-cells of rats 2 h after a single subcutaneous injection of morphine (Bayer et al. 1990). Morphine has also been reported to inhibit thymocyte and lymph node derived T-cell proliferation when added to the cells *in vitro* (Roy et al. 1997; Wang et al. 2001). Other measures of T-cell function relate to adaptive immunity in the cellular arm of the immune system. Several studies have shown that chronic morphine exposure inhibits development of delayed-type hypersensitivity (DTH) in rats, mice, and pigs (Bryant and Roudebush 1990; Molitor et al. 1992; Pellis et al. 1986), and cytotoxic T cells in mice (Carpenter and Carr 1995).

Δ⁹-THC has also been shown to inhibit responses to Con A in a protocol which exposed mouse spleen cells *in vitro* to the drug (Klein et al. 1985). Further, Δ⁹-THC and CB2 selective agonists have been shown to inhibit T-cell responses to foreign tissues in an *in vitro* assay of graft rejection called the Mixed Lymphocyte Reaction (MLR) (Robinson et al. 2013). A major mechanism of this immunosuppression was found to be by inhibition of IL-2, a critical autocrine growth factor for T-cells (Robinson et al. 2013). The CB2 receptor has also been studied in murine models of a number of autoimmune diseases including Experimental Autoimmune Encephalitis (EAE), colitis, inflammatory bowel disease, and autoimmune uveoretinitis (Maresz et al. 2007; Singh et al. 2012; Storr et al. 2009; Xu et al. 2007; Zhang et al. 2009). Use of synthetic cannabinoids with selectivity for this receptor (as opposed to CB1) and use of CB2 receptor k/o mice demonstrated that CB2 activation has marked activity in depressing the T-cell responses in these autoimmune models. Other effects of the CB2 system were to depress T-cell trafficking by depressing adhesion molecule expression (Xu et al. 2007; Zhang et al. 2009) and by up-regulating the immunosuppressive cytokine, IL-10 (Storr et al. 2009).

Cannabinoids have been studied for their ability to polarize T-cells toward Th1 or Th2 responses. It has been reported that Δ^9 -THC given to mice that are subsequently infected with *Legionella* suppressed IL-12R β 2 expression by a CB1 mediated mechanism and increased GATA3 mRNA via CB2 signaling (Klein et al. 2004). The IL-12 receptor participates in Th1 responses and GATA3 biases towards a Th2 response, leading to the conclusion that cannabinoids can polarize T cell responses towards a Th2 phenotype. Evidence from exposure of activated human peripheral blood T cells to Δ^9 -THC also supports a Th2 polarization (Yuan et al. 2002). Δ^9 -THC has also been shown to suppress cytotoxic T cell activity against both allogeneic cells (Klein et al. 1991) and virus-infected cells (Fischer-Stenger et al. 1992).

An acute i.v. dose of cocaine has been reported to have an effect similar to that of morphine in suppressing proliferation of T cells in the peripheral blood of rats exposed to Con A 2 h after injection of the drug (Bayer et al. 1996). Cocaine has been shown to inhibit production of Th2 cytokines which would be expected to reduce antibody responses (Wang et al. 1994). Cocaine given orally also suppressed DTH responses in mice (Watson et al. 1983).

41.3 Effects of Drugs of Abuse on Infection

41.3.1 Overview

The majority of publications cited above concluded that the various drugs of abuse were immunosuppressive. A logical conclusion from these observations would be that exposure to the drugs would sensitize to infection. Clinical observations of intravenous drug using (IVDU) populations have long noted an increased incidence of bacterial infections (Honarvar et al. 2013; Risdahl et al. 1996). However, it has not been possible to determine whether more infection occurs in this group because of unsanitary use of needles or because the drugs render the person more susceptible. For example, there have been recent outbreaks of injection-associated anthrax and botulism in IVDUs in Europe, which have been attributed to needle contamination (Berger et al. 2014; MacDonald et al. 2013). This question was important in regard to Human Immunodeficiency Virus (HIV) infection, since in the United States, at the beginning of the epidemic, one third of all cases of HIV occurred in IVDUs (CDC 2000), and estimates suggest that approximately 20 % of global IVDUs are infected with HIV (Mathers et al. 2010; Vlahov et al. 2010). The current estimate in the United States is that 11 % of HIV cases occur in IVDUs (Spiller et al. 2015). Epidemiologic studies have been compromised because drug abusers usually abuse more than drug, and also smoke and abuse alcohol. Studies have not adequately teased apart these factors, nor controlled for drug dosage or fre-

quency of drug use. Several other reviews explore these issues in depth (Kapadia et al. 2005; Rogers et al. 2005). Laboratory studies using animal models of infections can more definitively clarify whether drugs of abuse can be cofactors in susceptibility to infection. Yet, surprisingly there are only a limited number of studies on drugs of abuse and experimental infections of any type.

41.3.2 Effects of Drugs of Abuse on Infections Other Than HIV

41.3.2.1 Effects of Morphine on Infection

There is clinical literature documenting increased incidence of infection in opioid abusers (Haverkos and Lange 1990; Hussey and Katz 1950; Louria et al. 1967; Scheidegger and Zimmerli 1989), and in a hospital setting where controlled doses of opioids were administered to burn patients (Schwacha et al. 2006). As mentioned in the introduction to this chapter, these correlations do not prove causality. In laboratory studies, morphine has been shown to sensitize mice to fungal, bacterial, parasitic and viral infections. In a seminal paper, morphine was shown to increase replication of the fungus, *Candida albicans*, apparently at least partly due to decreased phagocytosis and killing of the organism by neutrophils (Tubaro et al. 1983). Other early laboratory studies showed that morphine pretreatment led to a shock-like syndrome when mice were injected with the parasite, *Toxoplasma gondii* (Chao et al. 1990). In a murine model of *Leishmania donovani* infection, morphine was found to have a biphasic dose response effect, with low doses affording increased protection, and high doses sensitizing to infection (Singh and Singal 2007). Further, morphine and withdrawal from morphine were reported to induce sepsis through increased permeability of the intestinal epithelial barrier, and to enhance sensitivity to bacterial LPS (Hilburger et al. 1997; Roy et al. 1998a), as well as sensitize to oral *Salmonella* infection (Feng et al. 2005; MacFarlane et al. 2000). Morphine has been reported to increase the virulence of *Pseudomonas aeruginosa* in the mouse intestinal tract by a direct effect on the microbe (Babrowski et al. 2012). Epidemiology studies link use of opioid analgesics to increased risk of infection with *Clostridium difficile* (Mora et al. 2012). Thus, morphine seems to have a significant effect on intestinal microbes, possibly through its well known action as an inhibitor of gastrointestinal transit (Feng et al. 2006). Sensitization to infection could also occur by decreasing innate immune responses. As mentioned previously, morphine inhibits phagocytosis of *Candida*, which is one mechanism for potentiating infection (Szabo et al. 1993; Tubaro et al. 1983). Inhibition of neutrophil mobilization by morphine was shown to be a factor in sensitizing to infection with *Streptococcus pneumoniae* and *Acinetobacter*

baumannii infections (Breslow et al. 2011a; Ma et al. 2010). In the case of the pneumococcal infection, depression of the IL-17/IL-23 pathway by the opioid was found to be a mechanism for impaired neutrophil responses (Ma et al. 2010), but IL-17 was not found to be important in sensitization to *Acinetobacter* (Breslow et al. 2011b). For the pneumococcus, morphine was also shown to decrease macrophage signaling through Toll-like receptor-9 (TLR-9), which would dampen the protective inflammatory response (Wang et al. 2008, 2011). Several papers also support an effect of morphine on the adaptive immune response. Meningitis is a devastating manifestation of tuberculosis. Morphine has been shown to depress microglial functions that are necessary for initiating T-cell responses to *Mycobacterium bovis* (Olin et al. 2011). This opioid has also been shown to inhibit secretory antibody formation to cholera toxin in the gastrointestinal tract (Peng et al. 2001), which could be a mechanism of sensitization to gastrointestinal infections. Further, morphine was found to potentiate the development of Herpes simplex virus, type 1 encephalitis in a murine model of Herpes simplex virus, type 1 (Liroy et al. 2006), and to potentiated systemic infection with this virus by decreasing IFN- γ and IL-12 levels, and inhibiting cytotoxic T-lymphocyte responses (Mojadadi et al. 2009).

41.3.2.2 Effects of Δ^9 -THC on Infection

Δ^9 -THC has been shown to sensitize to bacterial, viral and parasitic infections. The first observations were in guinea pigs showing that the cannabinoid augmented infection with herpes simplex virus (Cabral et al. 1986). In addition, Δ^9 -THC administration has been shown to lead to greater viral replication and disease severity in murine models of Friend Leukemia Virus (Specter et al. 1991b), influenza infection (Buchweitz et al. 2007), vaccinia infection (Huemer et al. 2011) and Kaposi's sarcoma virus (KSV) (Zhang et al. 2007). At least one mechanism of viral potentiation was decreased influx of T-cells and macrophages into the lungs of influenza infected animals (Buchweitz et al. 2007). In contrast, treatment with Δ^9 -THC has been shown to depress the reactivation of KSV or Epstein Barr virus in an immortalized B-lymphocyte line (Medveczky et al. 2004). In regard to bacterial infections, Δ^9 -THC sensitized to *Listeria monocytogenes* (Morahan et al. 1979), and inhibited the adaptive immune response to *Legionella pneumophila*. It was found that if the cannabinoid was given 18 h prior to a primary sublethal infection, it sensitized to a secondary challenge with *Legionella* (Newton et al. 1994). Mechanistic studies showed that Th1 responses, which are necessary for host defense to *Legionella*, were depressed by Δ^9 -THC (see above section on cannabinoids and T-cell responses), and the antibody response was shifted from an IgG2a to an IgG1 isotype, indicative of a switch from a Th1 to a Th2 response (Klein et al. 2000; Newton et al. 2009). Δ^9 -THC has also been

reported to sensitize mice to encephalitis with the parasite, *Acanthamoeba castellanii*, by inhibiting the anti-microbial functions of microglia (Cabral and Marciano-Cabral 2004).

41.3.3 Effects of Drugs of Abuse on HIV or Related Infections

There are several papers showing that opioids up-regulate HIV replication when added to infected human peripheral blood cells or microglia in vitro (Li et al. 2002; Peterson et al. 1990, 1994). As mentioned above in Sect. 41.2.1.4. on cytokines and chemokines, the effects of opioids on HIV infection may be related to drug-induced alterations in cytokine or chemokine production or on expression of chemokine receptors (Li et al. 2002; Peterson et al. 1994; Steele et al. 2003). Proinflammatory cytokines, particularly TNF- α , can activate T-cells and lead to increased HIV replication, and chemokine receptors are co-receptors for the virus. It is to be expected that modulation of chemokine and/or chemokine receptor levels can alter HIV infectivity by increasing the pool of infectable cells or by altering availability of the number of co-receptors.

Similar immunodeficiency syndromes may result in monkeys and cats infected with SIV (simian immunodeficiency virus) and FIV (feline immunodeficiency virus), but studies with these viruses have not provided a clear indication of the influence of opioids on the development of these immunodeficiency diseases. In one study monkeys maintained on morphine had a slower progression of the SIV infection, although temporary withdrawal augmented viral load (Donahoe et al. 1993), but in two other studies, viral progression was more rapid (Chuang et al. 1997; Kumar et al. 2006). Neither acute or chronic morphine, nor morphine withdrawal, altered FIV infection in cats, but the number of animals was small and the variance in FIV load large (Barr et al. 2003).

Morphine administration has been reported to exacerbate the recruitment of leukocytes to the CNS during an inflammatory response (Olin et al. 2012). A number of studies have shown that opiate administration promotes the neuroinflammatory and neurodegenerative influences associated with HIV infection. Morphine promotes the cytotoxicity of HIV viral products by a variety of mechanisms including the up-regulation of proinflammatory cytokines, oxidative stress, and other processes (Ellis et al. 2007; Mahajan et al. 2008; Turchan-Cholewo et al. 2009). Furthermore, morphine exacerbates the response of astrocytes to HIV viral proteins, leading to an increase in the production of proinflammatory cytokines and chemokines which lead, in turn, to the recruitment of additional inflammatory cells to the CNS (El-Hage et al. 2005, 2006; Hauser et al. 2012).

Cannabinoids have also been investigated for their effects on HIV and related retroviruses. The humanized severe

combined immunodeficient mouse treated with Δ^9 -THC was found to have a 50-fold increase in viral load of an engineered HIV reporter virus (Roth et al. 2005). Studies using the SIV model have shown that chronic Δ^9 -THC depressed the progression of infection in male macaques (Molina et al. 2011). However, more recent studies from the same laboratory group showed that chronic Δ^9 -THC does not substantially alter the progression of SIV associated disease or viral replication in female macaques (Amedee et al. 2014). The basis for the disagreement in the results with the male and female animals remains uncertain at this time. Several studies have tested the effect of CB2 selective cannabinoids on HIV replication in vitro and have shown that these agonists reduced the replication of HIV in both human T-cells and macrophages (Costantino et al. 2012; Ramirez et al. 2013). Evidence was presented to support a mechanism in the T-cells whereby the CB2 agonist reduced F-actin and blocked viral integration (Costantino et al. 2012). It is interesting that a cannabinoid should be found to interfere with actin polymerization pathways, because, as noted previously in this review, a similar observation has been made for morphine (Ninković and Roy 2012). In an in vivo study, a CB2 selective agonist was found to be protective against HIV encephalitis using a humanized SCID mouse model of intra-cranial infection (Gorantla et al. 2010). The CB2 selective cannabinoid blocked T-cell infiltration into the brain by down-regulating adhesion molecules and altering the blood-brain barrier.

Cocaine has also been investigated in regard to effects on HIV infection and found to potentiate replication in in vitro systems (Bagasra and Pomerantz 1993; Peterson et al. 1992). Cocaine has also been shown to up-regulate DC-SIGN, a molecule on the surface of human dendritic cells that can act as a receptor for HIV (Nair et al. 2005). In addition, it has been reported that mice with severe combined immunodeficiency, that were reconstituted with human leukocytes and infected with HIV, demonstrated enhanced replication of the virus after cocaine treatment (Roth et al. 2002). However, a recent report using the SIV model shows that chronic cocaine administration results in minimal effects on viral replication, neuroinflammation including inflammatory cytokine mediator expression, or neurodegeneration (Weed et al. 2012). A more complete accounting of the impact of cocaine abuse on HIV pathogenesis is clearly warranted.

41.3.4 Summary

The fact that opioids, cannabinoids, and cocaine can alter replication of HIV in cell culture in vitro certainly suggests that the drugs should be able to alter HIV progression in vivo. Isolation of variables in the laboratory permits elimination of confounding factors in epidemiologic studies in humans,

such as poly-drug abuse, and also standardizes drug dosage. Thus, there is considerable evidence from laboratory studies supporting a role for drugs of abuse in potentiating HIV infection. There are, however, some inexplicable contradictions in the literature showing that opioids and cannabinoids in general inhibit immune cell migration, yet seem to potentiate HIV infection in the brain.

41.4 Synopsis

It has been clearly demonstrated that opioids, cannabinoids, and cocaine alter a variety of assays of immune function when added to cells of the immune system in vitro. Receptors and/or mRNA for the receptors for opioids and cannabinoids have been demonstrated in a variety of cells of the immune system. In many cases, especially for the opioids, pharmacological specificity of the action of the drugs has been verified using appropriate antagonists. For the cannabinoids, mice with genetic defects in CB1 or CB2 receptors have been used. These observations provide a biological basis for concluding that drugs of abuse have direct effects on immune cells. In addition, all three drug classes alter immune responses of rodents, and in some cases, humans, when treated in vivo. In vivo mechanisms of action may be harder to determine as the drugs may activate other physiologic systems in the body that may also impinge on immune responsiveness, such as the hypothalamic-pituitary axis and the sympathetic nervous system. Nonetheless, drug abusers suffer the cumulative effects of direct and indirect effects of the drugs on the immune system. Assays of immune function that have been measured include effects on the innate immune system, which encompass effects on neutrophils, macrophages and natural killer cells, and effects on adaptive immunity, which include the humoral and cellular arms of the immune system. Considerable attention has been focused on cytokine and chemokine mediators of immune function that are modulated by the drugs and on their capacity to modulate activation of the various arms of the immune system by polarization of the cytokine profile.

In general, opioids and cannabinoids have been found to be suppressive in a wide variety of assays of immune responsiveness. The literature on cocaine is smaller and less consistent. An extension of these observations is the assessment of effects of the drugs on resistance to infection, a consequence of alterations in immune function. Both opioids and cannabinoids have been shown to sensitize animals to a variety of experimental infections. Interest in the effects of the opioids on HIV progression is sparked by the epidemiological intersection of intravenous drug abuse and incidence of HIV. In vitro studies give robust results showing inhibition of HIV replication in the presence of opioids. Studies with Δ^9 -THC and cocaine, using an immunodeficient mouse strain

repopulated with human lymphoid cells, showed enhanced replication of HIV in the presence of the drugs. The implications of the research are that drug abuse increases vulnerability to infection. Together, the vast majority of the literature suggests substantial effects of drugs of abuse on immune competence in general, resulting in immunosuppression. However, there are several studies showing that opioids increase chemokine production, which would increase inflammation. At present, these aspects of the literature have not been reconciled. Taken as a large overview, the studies reviewed in this chapter reinforce the existence of physiological pathways between the neural and immune systems mediated by opioids and cannabinoids.

41.5 Review Questions

- It is observed that morphine given subcutaneously suppresses responses of spleen cells put into tissue culture with the T-cell mitogen Concanavalin A (Con A).
 - Mice with a disruption of the gene coding the mu opioid receptor (Mu Opioid Receptor knock-out mice), would not show suppression to Con A.*
 - Morphine acts mainly through the kappa opioid receptor.
 - Morphine is mainly metabolized to heroin when it is injected in vivo.
 - Methyl-morphine could not be used to determine if peripheral receptors or brain receptors are involved in the immunosuppression.
 - None of the above.
- In regard to cannabinoids:
 - They are proteins.
 - They exert their effects primarily by interdigitating into cell membranes.
 - There is evidence that they polarize the immune response towards a Th1 type phenotype.
 - There is evidence that they polarize the immune response towards a Th2 type phenotype.*
 - They have no direct effects on cells of the immune system.
- In regard to the immune system, morphine has been shown to:
 - Elevate antibody responses to various antigens.
 - Elevate responses to the B-cell mitogen, lipopolysaccharide (LPS).
 - Elevate delayed-type hypersensitivity (DTH) responses.
 - Increase phagocytosis by macrophages.
 - Depress natural killer (NK) cell activity.*
- Cocaine:
 - Has no effect on the immune system.
 - Exacerbates HIV replication in a mouse/human model of viral replication.*
 - Binds to the delta opioid receptor.
 - Depresses IL-2 production.
 - All of the above.
- In regard to infections and drugs of abuse:
 - Morphine sensitizes mice to infection with *Legionella pneumophila* (Legionnaire's Disease).
 - Δ^9 -THC sensitizes mice to *Salmonella* infection.
 - Morphine and Δ^9 -THC have direct effects on the ability of bacteria to grow in broth cultures.
 - Morphine can affect resistance to infection by altering the activity of phagocytes.*
 - Intravenous drug abusers have a rate of infection the same as the general population.
- Morphine most probably affects the progression of HIV infection by all of the following EXCEPT:
 - Changing the level of chemokine receptors.
 - Changing the level of chemokines.
 - Causing T-cells to undergo uncontrolled cell division.*
 - Mediating heterologous desensitization of chemokine receptors.
 - Altering cytokine levels.
- Which of the following statements is true:
 - Opioids, cannabinoids, and cocaine uniformly suppress the activity of NK cells.
 - The use of N-methylmorphine substantiated the direct effects of opioid-induced NK cell suppression.
 - Mice lacking the μ -opioid receptor do not have suppressed NK cell activity in response to morphine treatment.*
 - Δ^9 -THC prevents NK cell proliferation by inhibiting the secretion of TGF- β
 - Morphine inhibits NK cell activity by inducing endogenous cannabinoid levels.
- Opioids modulate phagocyte activity by:
 - increasing phagocytic uptake of bacteria.
 - decreasing apoptosis of phagocytic cells.
 - enhancing maturation of bone marrow cells into macrophages.
 - decreasing uptake of microbes.*
 - decreasing maturation of lymphocytes in the bone marrow.
- Immune cells treated with morphine:
 - Uniformly have markers of activation.
 - Display altered levels of pro-inflammatory chemokines, but chemokine receptor numbers remained unchanged.
 - Display bi-directional heterologous desensitization between opioid receptors and certain chemokine receptors.*

- (d) Clearly have inhibition of Th2 cytokine responses.
 (e) None of the above
10. Which of the following statements is true:
 (a) Δ^9 -THC induces its effects through both CXCR4 and CCR5.
 (b) *Both Δ^9 -THC and morphine have been shown to induce the expression of pro-inflammatory chemokines, such as MCP-1 and IL-8.*
 (c) Like cannabinoids and morphine, cocaine treatment increases TNF- α and IL-1.
 (d) Cocaine uniformly suppresses cytokine and chemokine production when given in vivo or applied to cells of the immune system in vitro.
 (e) Opioids have no effect on antibody formation.
11. Morphine and/or DAMGO treatment results in decreases in which of the following?
 (a) Apoptosis
 (b) Pro-inflammatory chemokine production
 (c) *Antibody responses*
 (d) TGF- β
 (e) All of the above
12. Inhibition of T cell responses is observed for which of the following drugs of abuse?
 (a) Morphine
 (b) Δ^9 -THC
 (c) Cocaine
 (d) *All of the above*
 (e) None of the above
13. The initial evidence suggesting that opioid receptors are expressed by cells of the immune system was:
 (a) *Results showing impairment of T-cells to rosette to sheep red blood cells in the presence of morphine.*
 (b) studies examining functions of the CB1 and CB2 receptors.
 (c) primate studies examining disease incidence in self administration of heroin
 (d) biochemical analyses of lymph nodes in heroin addicts.
 (e) studies showing increased HIV infection in heroin abusers.
14. All of the following statements are true EXCEPT?
 (a) In vitro studies have shown Δ^9 -THC biases the immune response towards a Th2 cytokine profile.
 (b) *Cocaine administration stimulated production of the anti-inflammatory cytokine IL-10, while simultaneously suppressing IFN γ .*
 (c) Activated human PMNs show enhanced functional activity in response to cocaine.
 (d) The effects of opioids, cannabinoids, and cocaine on immune system function are compounded by the involvement of the HPA axis.
 (e) Chemokine expression is induced by morphine administration.
15. Evaluation of the effects of drugs of abuse can be complicated by a number of factors, including:
 (a) The effects of the sympathetic nervous system on immune cell function.
 (b) The effects of the HPA axis on immune cell function.
 (c) The capacity of cells of the immune system to produce endogenous opioids.
 (d) The production of endogenous cannabinoids in the periphery.
 (e) *All of the above.*
16. The function of G protein-coupled receptors, such as the opioid and cannabinoid receptors, can be regulated by the process of heterologous desensitization. Which of the following statements is true about this regulatory mechanism?
 (a) This process occurs when the activation of one receptor leads to an increased expression of a second receptor.
 (b) This process only occurs between receptors expressed on the surfaces of adjacent cells.
 (c) This process cannot occur between receptors expressed on the same cell.
 (d) *This is a process which appears to involve transphosphorylation of G protein-coupled receptors.*
 (e) All of the above.
17. Both opioids and cannabinoids have been shown to sensitize animals to a variety of experimental infections. The impact of drugs of abuse on resistance of humans to infectious agents can be difficult to evaluate because:
 (a) Drug abuse rarely involves the administration of a single drug, and the effects of poly-drug abuse are poorly understood.
 (b) Drug abusers are exposed more frequently to pathogenic agents than non-abusers.
 (c) A number of additional factors, which are hard to control, impact on measurement of the immune competence of drug abusers, including the dose of the drug and the time since it was last taken.
 (d) The contributions of legal drug use, including nicotine and alcohol, can complicate the effects of illegal drug abuse.
 (e) *All of the above.*
18. All of the following influence the effect of opioids on susceptibility to HIV infection EXCEPT:
 (a) Opioids alter the expression of chemokine receptors that are co-receptors for HIV-1.
 (b) Opioids increase the expression of some chemokines which may promote the attraction of additional susceptible target cells for HIV infection.
 (c) Opioids increase the expression of chemokines which, for an individual cell, may block viral replication by blocking the chemokine coreceptor.

- (d) *Opioids alter the phagocytic activity of neutrophils, and this would be expected to significantly alter the kinetics of the infection.*
- (e) *Opioids would be expected to alter the expression of cytokines that may, in turn, alter the replication rate of the virus in monocytes and T-cells.*

Part III

Therapies and Diagnostics

Kristi M. Anderson and R. Lee Mosley

Abstract

Until the 1990s, progress in developing therapy for neurodegenerative diseases was slow and there were few clinical trials. However, with the advent of animal models and the recent advances in understanding the basic pathophysiological mechanisms underlying the diseases, potential therapies to prevent, delay the onset or slow the progression of neurodegenerative disease are being identified at an ever increasing rate. High throughput technologies are being used to screen large numbers of potential therapeutic agents and new developments in the realms of immune modulation, RNA interference, viral vector delivery of gene products and stem cell therapy hold great promise for the future. There are still many unanswered questions regarding the mechanisms of disease and why beneficial therapy in animal models has not translated well into human clinical trials. Neurodegenerative diseases are rare, and so identifying enough patients to obtain studies with adequate power has been difficult. Novel phase II designs are now being used to screen greater numbers of agents and to better define correct dosing before proceeding to phase III trials. Multicenter phase III trials are being designed with adequate power, and using meaningful validated outcome measures that reduce the high dropout rates of past trials. Agents are now being tested in combination in order to detect possible additive effects. Focus is also being given to the need to better define the best symptomatic therapies in randomized controlled trials. Further research will prompt more targeted therapies that we hope will soon provide truly meaningful breakthroughs for neurodegenerative disorders.

42.1 Introduction

The neurodegenerative disorders, which include amyotrophic lateral sclerosis (ALS), Alzheimer's disease (AD), Parkinson's disease (PD), and Huntington's disease (HD), are clinically heterogeneous. Medications can ameliorate some symptoms, but none reverse the relentless progression of the illnesses. The past several decades have seen dramatic increases in the understanding of the complex pathophysiology

underlying the diseases. Overlapping features at the cellular level provide clues for targets of therapeutic interventions. While the disorders can now be studied using *in vitro* and animal models, the complex biochemistry, pathology and lack of mechanism-based treatments pose a particular challenge. With few unequivocal neuroprotective agents, we await the major breakthrough that will provide truly meaningful clinical improvement. Until then, numerous symptomatic therapies improve the quality of life for those suffering from neurodegenerative diseases. This chapter outlines the current strategies for the use of symptomatic therapies and the development of neuroprotective treatment for neurodegenerative disorders.

42.1.1 Overview of Mechanism

Progressive and premature neuronal cell death is a common feature among the neurodegenerative disorders. ALS involves progressive degeneration of the motor neurons in the brain and spinal cord. AD shows selective neuron degeneration in the hippocampus and cerebral cortex. PD is caused by degeneration of pigmented dopaminergic neurons in the substantia nigra. HD has selective neuron loss in the striatum and cortex. It is increasingly recognized that the clinical syndromes may overlap, with features of two or more disorders co-existing. For instance, ALS and dementia, or ALS, parkinsonism, and dementia may occur together in the same family or in an individual. Similarly, the disorders have common pathological findings at the cellular level. While the mechanisms that lead to neuronal degeneration are still sought, in general, neurodegenerative diseases are thought to be caused by a combination of events associated with factors of age, genetics, and environment; the causality of each varying proportionately (Koo and Kopan 2004; Rowland and Shneider 2001). All cases of HD, but only rare cases of ALS and AD are due to single genetic mutations. In sporadic forms, complex genetic interactions may render an individual susceptible to some as yet unknown environmental exposure, with the combination necessary to initiate the disease. Whatever the cause, be it genetic, environmental or some combination of the two, a cascade of events at the cellular level is set in motion that ultimately results in cell death. Animal models of the genetic forms of the disorders have helped elucidate some of the underlying molecular mechanisms that contribute to neuronal demise. Common processes among the neurodegenerative diseases include oxidative stress, excitotoxic injury, altered metal homeostasis, aberrant protein aggregation, mitochondrial injury, apoptosis, and inflammation (Andersen 2004; Bossy-Wetzel et al. 2004; Ross and Poirier 2004). With better understanding of mechanism(s) of disease

etiology and progression, more effective treatments may follow. Until then, a major goal is to identify therapies that slow the course of the illnesses by targeting cellular changes that occur after the inciting event.

42.1.2 Overview of Animal Models

The inherited forms of neurodegenerative diseases have been utilized in the development of animal models. Rodent models created using transgenic and gene targeting technologies (Deng and Siddique 2000) provide the opportunity to better study disease pathology and screen potential therapeutic agents. The advent of the ALS mouse model is one example of the progress that has resulted from this technology. A mutation in the gene encoding the enzyme copper-zinc superoxide dismutase (SOD1) on chromosome 21 was identified as a causative mutation in one form of familial ALS (Rosen 1993). The first mutant transgenic mouse line was created by over-expressing high levels of mutant SOD 1 (G93A). This mouse developed a phenotypic and pathologic condition similar to human familial and sporadic ALS (Gurney et al. 1994). The murine model of ALS has since been used to screen a variety of therapeutic agents. Riluzole, the only approved agent for ALS, yielded positive results in the model that correspond very closely to the modest benefit in human clinical trials (Gurney et al. 1996, 1998).

Similarly, mouse models have been created for other neurodegenerative diseases. Transgenic mouse models of AD express mutations for the amyloid precursor protein (APP), presenilin genes, or a combination of the two (German and Eisch 2004). Insight into the molecular mechanisms of dopaminergic cell death in PD have come from the study of 6-hydroxydopamine (6-OHDA) and 1-methyl 1-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) animal models (Dawson 2000). Discovery of genes linked to familial PD have also provided the opportunity to generate animal models that better recapitulate the phenotypic and pathologic features of PD. Similarly, animal models have been created for HD through utilization of CAG triplet expansion in the HD gene. Homozygous and heterozygous knockout mice did not produce phenotypic or pathologic features of HD, but transgenic mouse models of HD produced a progressive neurological phenotype that resembles features of HD and has improved the understanding the disease process (Deng and Siddique 2000).

Many of the past and current therapeutic studies have targeted slowing neurodegenerative processes in animal models. While models of human diseases have played an essential role in understanding the mechanisms involved in neurodegeneration and in developing therapeutic strategies, the translation of findings in animal models to human therapeutics

has been fraught with difficulty. Twenty years after the approval of riluzole and following numerous clinical trials based on findings in the model, we still await the second unequivocally positive trial in ALS. This suggests that human disease processes are seemingly more complex than those otherwise transferred to rodents. Murine models may best be used for establishing the scientific justification for testing a potential agent, with the knowledge that findings in the laboratory, as yet, cannot provide certain hope of success in human trials.

42.2 Disease Specific Therapy

In certain disorders, such as AD and PD, neurodegeneration leads to deficiencies in specific neurotransmitters. Therapy has been targeted at replacing or increasing levels of the deficient neurotransmitter in patients. Disease specific therapy that targets neurotransmitter replacement or inhibition of neurotransmitter loss does not alter the underlying progression of neurodegeneration, but may improve symptoms, at least temporarily.

42.2.1 Alzheimer Disease

Changes in the cholinergic system in AD were first studied by Whitehouse *et al.* in 1981, who found atrophy of cholinergic nerve cells in the substantia innominata (Whitehouse *et al.* 1981). It was thought that replacing or increasing acetylcholine in patients with AD could stabilize cholinergic transmission. The cholinergic hypothesis of AD has been the basis of many research efforts and the accumulated evidence has launched the development of a variety of compounds to improve cholinergic neurotransmission (Lancot *et al.* 2003; Scarpini *et al.* 2003). Currently, the cholinergic deficiency is considered to be a secondary event resulting from nerve cell death due to other causes (Albers and Beal 2000).

42.2.2 Cholinesterase Inhibitors

Cholinesterase inhibitors, developed with the goal of stabilizing cholinergic transmission, block the enzyme that degrades acetylcholine in the synaptic cleft and lead to increased levels of acetylcholine in the brain. Three cholinesterase inhibitors currently are available in the United States: donepezil, rivastigmine and galantamine (Table 42.1). Donepezil, a piperidine derivative, is a selective inhibitor of acetylcholinesterase that noncompetitively and reversibly blocks acetylcholinesterase.

Individually, the cholinesterase inhibitors improve memory in patients with AD. Although all three drugs inhibit acetyl-

Table 42.1 Disease specific and neuroprotective therapy in alzheimer disease

Medication	Dosage
<i>Cholinesterase Inhibitor</i>	
Donepezil (Aricept)	5–10 mg QD
Rivastigmine (Exelon)	3–6 mg BID
Galantamine (Razadyne)	8–12 mg BID
<i>NMDA Antagonist</i>	
Memantine (Namenda)	10 mg BID

cholinesterase, they differ in additional mechanisms of action, pharmacokinetics, and side effects (Hogan and Patterson 2002). Both rivastigmine and galantamine have additional mechanisms of action; galantamine may induce a stronger response by acting as an allosterically potentiating ligand of nicotinic acetylcholine receptors, making the remaining nicotinic acetylcholine receptors more sensitive. Additionally, it is believed to increase the presynaptic release of acetylcholine and prolong postsynaptic neurotransmission (Greenblatt *et al.* 1999; Scott and Goa 2000). Rivastigmine, a slow reversible inhibitor of acetylcholinesterase and the only of the three drugs that also inhibits butyrylcholinesterase, may be more useful in later stages of disease when butyrylcholinesterase may provide greater functional importance (Hogan *et al.* 2004). Despite these differences, the primary known differences are the side effect profiles, titration schedules and the dosing regimens (Table 42.1). The most common side effects of treatment with cholinesterase inhibitors are initially gastrointestinal and include nausea, vomiting and diarrhea. Chronic use has been thought to increase the likelihood of gastric acid secretion and possible risk of gastrointestinal bleeding, especially for those with history of peptic ulcer disease or chronic use of non-steroidal anti-inflammatory drugs (NSAIDs). A recent retrospective study of over 97,000 cholinesterase inhibitor users and non-users showed the gastrointestinal bleeding event rate for users was 10.6 events per 1000 person-years compared to 9.6 events per 1000 person-years for non-users and was insignificant as determined by Cox proportional hazards model (Thavorn *et al.* 2014).

A meta-analysis of the efficacy and safety of these agents revealed that despite many clinical studies showing short-term benefit, there is insufficient evidence to conclude long term efficacy (Lancot *et al.* 2003). Head to head studies performed shed some light as to which cholinesterase inhibitor to use as initial therapy for patients with AD. Interpretation of the study results should be made with caution, but the conclusion was that galantamine should be favored over donepezil (Hogan *et al.* 2004). Ultimately, which cholinesterase inhibitor is used as a first-line drug must be made based on a patient by patient basis and many variables taken into account.

Table 42.2 Disease specific therapy in Parkinson' disease

Medication	Dosage
<i>Dopamine Precursor</i> Levodopa	300–3000 mg per day
<i>Dopa decarboxylase inhibitor/</i> <i>Dopamine precursor</i> Carbidopa/Levodopa	25 mg/300 mg–200 mg/2000 mg per day
<i>Dopamine Agonist</i> Bromocriptine Ropinirole Pramipexole Cabergoline Rotigotine transdermal patch	10–30 mg TID 3–8 mg TID 0.5–1.5 mg TID 2–10 mg per day 2–6 mg per day
<i>COMT Inhibitor</i> Entacapone Tolcapone	200–400 TID–6×/day 100–200 TID
<i>NMDA Antagonist/Anticholinergic</i> Amantadine	100–300 per day
<i>Anticholinergic</i> Trihexyphenidyl Benztrapine	2 mg TID–QID 1–4 mg QD–BID
<i>MAO Inhibitor</i> Selegiline	5 mg BID

42.2.3 Parkinson Disease

As in AD, knowledge of the neurotransmitter deficiency underlying PD (*i.e.*, dopamine) has been the basis for the development of therapy. Early studies showed that cerebral dopamine was concentrated in the striatum and that levodopa, the precursor to dopamine, could reverse the akinetic effects of the dopamine-depleting agent reserpine in experimental animals (Carlsson et al. 1957, 1958). Eventually, the identification of striatal dopamine depletion as a key neurochemical finding in parkinsonian brains lead to treatment with levodopa in humans and to the subsequent advent of compounds that mimic the effects of dopamine or prolong its action (Table 42.2).

42.2.3.1 Levodopa

Levodopa is the most effective drug for the symptomatic management of PD. Levodopa, which usually produces an excellent initial response in alleviating the motor symptoms of PD, is particularly effective for bradykinesia and tremor (Fahn 2000). However, side effects such as motor fluctuations and dyskinesias may limit its long-term usefulness for individual patients (Fahn 2000; Jankovic 2000). Up to 50 % of all patients treated for 5 years or more, develop instability in their motor response (Koller et al. 1999; Schrag and Quinn 2000). As a consequence, levodopa is usually given later in PD, particularly in younger patients who may require many years of anti-Parkinson therapy. In this group, dopa-sparing agents (see below) are usually prescribed until symptoms

begin to interfere with independence. Levodopa is often used as the first drug of choice in the elderly for whom low dose monotherapy is preferable to avoid side effects, and who may not be expected to develop motor fluctuations after years of therapy due to already advanced age. Immediate and controlled release preparations of levodopa are available.

Carbidopa, a peripheral aromatic-L-amino-acid decarboxylase (AADC) inhibitor, enhances the therapeutic benefits of levodopa (Opacka-Juffry and Brooks 1995). Levodopa is converted to dopamine by AADC, an enzyme that functions both inside and outside the brain. Peripherally produced dopamine directly stimulates the medullary vomiting center, which is not protected by a blood brain barrier, producing anorexia, nausea and vomiting. Carbidopa in doses less than 150 mg per day does not enter the brain and so blocks only the peripheral metabolism of levodopa by AADC (Cedarbaum et al. 1986). Co-administration of carbidopa and levodopa therefore has two main effects; to reduce levodopa-related gastrointestinal side effects, and ensure the majority of levodopa is converted to dopamine in the brain. Dosages of 75 mg/day of carbidopa are necessary to completely block peripheral AADC activity. Additional doses can be given to those who are particularly sensitive to levodopa-induced nausea. Other major side effects of levodopa therapy include orthostatic hypotension, chorea, dystonia, myoclonus, akathisia and hallucinations. Studies have not yet shown conclusively whether levodopa alters the underlying rate of neurodegeneration (Fahn 2005).

42.2.3.2 Catechol-O-Methyltransferase Inhibitors

Another strategy to enhance dopamine response utilizes the inhibition of catechol-O-methyltransferase (COMT), which metabolizes dopamine once converted from levodopa either within or outside the brain. Agents that block the degradation of dopamine by inhibition of COMT effectively prolong the half-life of dopamine and may increase peak concentration. The two currently available COMT inhibitors, entacapone (Holm and Spencer 1999; Rinne et al. 1998) and tolcapone (Tolcapone Study Group 1999; Kurth and Adler 1998), reduce motor off time when given with levodopa, but the efficacies of the two drugs have not been directly compared. Tolcapone has a theoretical advantage over entacapone in that it inhibits both peripheral and central COMT, and has a longer duration of action necessitating administration only three times per day. However, tolcapone can cause explosive diarrhea and abnormal liver function. Fulminant liver failure has occurred, albeit rarely, and therefore frequent monitoring of liver function is necessary in those prescribed tolcapone (Assal et al. 1998). Entacapone usually does not cause diarrhea or abnormal liver function and can be administered with levodopa up to eight times a day.

42.2.3.3 Dopamine Agonists

Dopamine agonists exert their effect by activating dopamine receptors and bypassing the presynaptic synthesis of dopamine. They are often used as part of a dopa-sparing strategy, in which agonists are prescribed early in PD, postponing the need for levodopa and the motor complications associated with exogenous dopamine administration. Activation of the dopamine-2 (D_2) receptors is important in mediating the motor effects of dopamine agonists, but to achieve optimal physiologic and behavioral responses, both D_1 and D_2 receptors must be stimulated (Brooks 2000).

Bromocriptine was the first dopamine agonist developed to stimulate D_2 receptors and inhibit D_1 receptors (Perachon et al. 1999). Dosage should be increased slowly to prevent orthostatic hypotension and gastrointestinal side effects. Because the compound is an ergot derivative, rare associations with retroperitoneal or pericardial fibrosis, including cardiac valvular disease have been reported (Van Camp et al. 2004).

In 1997, two additional dopamine agonists, ropinirole and pramipexole, were approved. These agents are nonergolines, and therefore may carry a lower risk of ulcerative, vasoconstrictive, or fibrotic complications (Shaunak et al. 1999). Pramipexole has been promoted as a D_3 agonist (Bennett and Piercey 1999), but a study that measured the affinities of bromocriptine, pramipexole, pergolide, and ropinirole for human recombinant dopamine D_1 , D_2 , and D_3 receptors found that all four compounds had high affinity for the D_3 receptor (Perachon et al. 1999). The observation that D_3 receptors are located primarily in the mesolimbic system may explain the possible antidepressant effect of pramipexole and ropinirole (Corrigan et al. 2000), but may also explain the occurrence of hallucinations noted particularly with higher doses of dopamine agonists.

Pramipexole has been shown to be safe and effective as monotherapy early in PD (Parkinson Study Group 1997, 2000) and in mild to moderate PD (Shannon et al. 1997). Ropinirole has also been shown to be effective in early PD (Korczyn et al. 1999; Rascol et al. 1998). In later stages of PD, dopamine agonists are usually prescribed with levodopa to achieve optimal therapeutic effects and to help moderate the motor fluctuations associated with levodopa (Pinter et al. 1999). Possible side effects of all dopamine agonists include nausea, peripheral edema, somnolence, hallucinations, and compulsive behavior (Driver-Dunckley et al. 2003).

Rotigotine, licensed in 1998, is commonly used for the treatment of PD and restless leg syndrome. Rotigotine is also the first transdermal patch for the treatment of PD. After being withdrawn in 2008 for problems with the delivery system, rotigotine was reintroduced in 2012 (Waters 2013). Pilot tests of 24 month duration to evaluate the efficacy and tolerability of newly formulated rotigotine in PD patients proved beneficial. Rotigotine not only improved UPDRS scores, but was well-tolerated and improved patient compliance (Moretti et al. 2014a, b).

42.2.3.4 Anticholinergic Agents

The manipulation of non-dopaminergic neurotransmitters can also be used as disease specific therapy in PD. Anticholinergic agents, one the first effective therapies for PD signs, having been prescribed by Charcot in the 19th Century, are particularly helpful in tremor reduction. The exact mechanism of anticholinergic medications in PD remains unclear. They likely counteract an imbalance between striatal dopamine and acetylcholine that results from degeneration of dopaminergic neurons (Katzenschlager et al. 2003). Medications with anticholinergic properties include amantadine, benztropine and trihexyphenidyl, among others. Amantadine may be the most commonly used anticholinergic medication in PD. In addition to its anticholinergic properties, amantadine promotes the release of dopamine and blocks the N-methyl-D-aspartate (NMDA) receptor, which may relieve levodopa-induced dyskinesias. Benztropine has anticholinergic properties and also blocks the reuptake of dopamine.

A meta-analysis of nine double-blind cross over trials found that anticholinergic therapy is effective as monotherapy or as an adjunct to other anti-Parkinson drugs (Katzenschlager et al. 2003). The most common side effects include dry mouth, constipation, and urinary hesitancy. These agents may occasionally exacerbate narrow angle glaucoma. Neuropsychiatric and cognitive adverse effects limit their use in the elderly.

42.3 Neuroprotective Therapy

A neuroprotective agent alters the underlying pathophysiology of a disease, and therefore delays the onset or slows the progression of neurodegeneration. Much of the current research into the treatment of neurodegenerative diseases focuses on neuroprotective therapy; agents are being tested that impact processes identified at the cellular level.

Glutamate is a major excitatory neurotransmitter in the central nervous system. Theoretically, increased glutamatergic neurotransmission may lead to excitatory neurotoxicity or excitotoxicity. The only two currently approved neuroprotective agents in the United States, riluzole for ALS and memantine for AD, may act to prevent glutamatergic excitotoxicity.

42.3.1 Riluzole

Riluzole, which may block the presynaptic release of glutamate, was initially developed as an anti-epileptic medication. However, due to evidence of excitotoxicity-mediated neurodegeneration in epilepsy and potential excitotoxicity involvement in ALS, riluzole was tested as a neuroprotective agent in the latter. It was approved for use in ALS after two double-blind, placebo-controlled trials showed modest improvement in survival from 3 to 3.25 years (Bensimon et al. 1994; Lacomblez et al. 1996). *Post hoc* analyses

revealed that patients who took riluzole experienced a slight prolongation in the time to progress from mild to severe disability; however, this effect was not apparent to patients, family or physicians. A meta-analysis of four randomized controlled trials indicated that 100 mg/day of riluzole prolongs survival by approximately 2 months (Miller et al. 2002). Nausea, fatigue, vertigo, and somnolence are the most common side effects of riluzole. Serum transaminase elevations may also occur but rarely to levels that are clinically meaningful.

Once riluzole was shown to be effective for ALS, and excitotoxicity was thought to be a component of neurodegeneration in general, studies of riluzole began in PD, HD, and AD. The neuroprotective effects of riluzole have been shown in the 6-OHDA and MPTP models of PD (Barneoud et al. 1996; Benazzouz et al. 1995), and in a small human trial, riluzole reduced levodopa-induced dyskinesias (Merims et al. 1999). In a separate pilot trial, riluzole extended the “on” state compared to placebo, but the difference was not statistically significant. A placebo-controlled trial in patients with HD showed that riluzole ameliorated chorea intensity (Huntington Study Group 2003). Phase III trials for the treatment of Parkinson’s and Huntington’s disease with riluzole failed to show beneficial outcomes and were discontinued (Bensimon et al. 2009; Landwehrmeyer et al. 2007). Large trials with adequate power are still needed to determine whether riluzole is neuroprotective in disorders other than ALS.

42.3.2 Memantine

Memantine, a non-competitive NMDA antagonist, has medium affinity for the phencyclidine binding site of the NMDA receptor. Memantine may block glutamate-mediated excitotoxicity, but leaves the activation of the NMDA receptor during physiological neurotransmission unchanged (Molinuevo et al. 2004). Two randomized placebo-controlled clinical trials showed positive effects in later stages of AD (Reisberg et al. 2003; Tariot et al. 2004). These studies led to the approval of memantine for the treatment of moderate and severe AD. Additional clinical data are needed to determine whether memantine can be used as monotherapy or combination therapy in early AD. Common side effects include headache, dizziness, and confusion. Initial pilot trials have already been conducted in HD and PD (Beister et al. 2004; Merello et al. 1999) and showed that memantine treatment was beneficial and associated with lower axial motor symptoms and dyskinesia scores (Moreau et al. 2013). Phase II/III clinical trials in ALS patients showed memantine was safe and well-tolerated, but did not show any benefits to patients; however, the positive effects of memantine on neuronal survival cannot be entirely ruled out at this time (de Carvalho et al. 2010).

42.3.3 Selegiline

Selegiline (L-deprenyl) is a monoamine oxidase (MAO) inhibitor used in PD. In doses under 10 mg/day, selegiline irreversibly binds MAO-B, preventing the enzyme from degrading dopamine, but does not inhibit MAO-A, thereby avoiding the potential hypertensive crisis, or the “cheese effect”, seen with inhibitors of both MAO-A and MAO-B (Yasuhara et al. 2004). The DATATOP (Deprenyl and Tocopherol Antioxidative Therapy of Parkinsonism) study conducted in 800 patients with early untreated PD assessed the neuroprotective effects of selegiline 10 mg/day, alpha-tocopherol (vitamin E) 2000 IU/day or a combination of the two (NINDS NET-PD Investigators 2006; Parkinson Study Group 1989, 1993, 1996). After follow-up (mean time of 14 ± 6 months), 38.6% (154/399) of selegiline-treated subjects reached the end-point or the time-to-disability requiring levodopa therapy, compared to 55.4% (222/401) subjects who did not receive selegiline. The projected median length of time to reach end-point was 9 months longer in the selegiline-treated group than in the groups treated with placebo or tocopherol alone. However, waning effects of selegiline after the first year coupled with slight, but significant improvement in motor performance after initiation of selegiline have been used as an argument in favor of a predominantly symptomatic, rather than neuroprotective effect. Data from other reports are also conflicting. Several studies suggest that it may exert some sort of protective effect, possibly by a mechanism other than MAO inhibition (Maruyama et al. 1997; Mytilineou et al. 1997, 1998). One study detected no deterioration after washout in *de novo* patients initially treated with selegiline (Palhagen et al. 1998), but most studies have concluded that while selegiline can delay the need for levodopa therapy, this does not translate into meaningful long-term therapeutic benefits (Brannan and Yahr 1995). Furthermore, selegiline does not appear to prevent the development of levodopa-induced motor fluctuations and dyskinesia (Parkinson Study Group 1996). Further research is needed to fully define the mechanism of action of selegiline in PD, and to clarify its role as a putative neuroprotective agent.

42.4 Symptomatic Therapy

Even though neurodegenerative diseases still have no cure, specific symptoms may be amenable to medical treatment (Table 42.3). While few randomized clinical trials of symptomatic therapy have been performed in individual neurodegenerative diseases, off-label use (*i.e.*, the prescription of an agent for a symptom or disease other than the one for which it is approved) is often helpful in improving quality of life for patients.

Table 42.3 Symptomatic therapy in neurodegenerative diseases

Symptom	Management	Dosage
<i>Psychiatric</i>		
Depression	Tricyclic antidepressants	20–100 mg QD
	Mirtazapine	15–30 mg QHS
	Selective serotonin uptake inhibitors (SSRI)	20–100 mg QHS
	Venlafaxine	37.5–75 mg BID-TID
	Bupropion	100 mg TID
Anxiety	SSRI antidepressants	20–100 mg QHS
	Buspirone	10 mg TID
	Mirtazapine	15–30 mg QHS
	Benzodiazepines	0.5–5 mg BID-TID
	Trazadone	50–100 mg BID-TID
Psychosis/ Agitation	Neuroleptics (Haloperidol)	0.5–3 mg QD
	Atypical Neuroleptics (Risperidone, Olanzapine, Quetiapine, Clozaril)	0.25–200 mg per day
	Benzodiazepines	0.5–30 mg per day
	SSRI medications	20–100 mg QD
Irritability/ Aggression	Divalproex sodium	250–2000 mg per day
	Carbamazepine	100–2600 mg per day
	SSRI antidepressants	20–100 mg QD
Pseudobulbar Affect	Tricyclic antidepressants	20–100 mg QHS
	Mirtazapine	15–30 mg QHS
	Venlafaxine	37.5–75 mg BID-TID
	Dextromethorphan/quinidine	30 mg/30 mg BID
	Lithium carbonate	300 mg QD-TID
	SSRI antidepressants	20–100 mg QD
<i>Sialorrhea</i>	Tricyclic antidepressants	20–100 mg QHS
	Atropine sulfate	0.4 mg Q 4–6 h
	Glycopyrrolate	1–2 mg TID
	Hycosamine sulfate	0.125–0.25 mg Q 4 h
	Diphenhydramine	25–50 mg TID
	Scopolamine transdermal patch	1.5 mg applied behind ear Q 72 h
<i>Motor</i>		
Spasticity	Baclofen	10–60 mg TID
	Tizanidine	2–8 mg QID
	Dantrolene	25–100 mg TID
	Benzodiazepines	2–10 mg TID
Cramps	Quinine sulfate	260–325 mg QD
	Vitamin E	400 IU TID
	Phenytoin	300 mg QHS
	Diazepam	2–10 mg TID
Tremor	Dopaminergic medication	300–3000 mg per day
	Amantadine	100–300 mg per day
	Beta blocker	10–30 mg BID-TID
	Primidone	50–250 mg QHS
	Clonazepam	0.5–2 mg QHS
Chorea	Neuroleptics	0.5–100 mg per day
	Atypical neuroleptics	0.5–160 mg per day
	Benzodiazepines	0.5–20 mg per day
	Amantadine	100–300 mg QD

(continued)

Symptom	Management	Dosage
<i>Autonomic</i>		
Orthostatic hypotension	Fludrocortisone	0.1–1 mg QD
	Midodrine	10 mg TID
<i>Gastrointestinal</i>		
Thick phlegm	Guaifenesin	200–400 Q 4 h
	Nebulized acetylcysteine	1 NEB Q 6–8 h
	Nebulized saline	1 NEB Q 4–6 hours
	Beta blocker	10–30 mg TID
Constipation	Increase fluid intake	N/A
	Increase fiber intake	N/A
	Docusate sodium	100 mg QD-BID
	Milk of magnesia	N/A
	Dulcolax	5–15 mg QD
	Lactulose	15–30 mL QD-BID
	Magnesium citrate	120–240 mL PRN
	Polyethylene glycol 3350	17 g QD
<i>Gentourinary</i>		
Urinary urgency	Oxybutynin	2.5–5 mg BID
	Tolterodine	1–2 mg BID
	Amitriptyline	25–75 mg QHS
	Oxytrol patch	3.9 mg QD
Erectile	Sildenafil citrate	50 mg PRN
Dysfunction	Vardenafil	
	Tadalafil	
	Avanafil	
<i>Sleep Disorders</i>		
REM sleep behavior disorder	Clonazepam	0.5–2 mg QHS
Insomnia	SSRI antidepressants	20–100 mg QD
	Tricyclic antidepressants	20–100 mg QHS
	Mirtazapine	15–30 mg QHS
	Zolpidem	5–10 mg QHS
	Eszopiclone	2–3 mg QHS
	Zaleplon	5–10 mg QHS
	Antihistamines	25–50 mg QHS
	Chloral hydrate	500–1000 mg QHS
	Benzodiazepine	2–5 mg QHS

42.4.1 Psychiatric Symptoms

Many patients with neurodegenerative diseases exhibit psychiatric symptoms, including depression and anxiety. Tricyclic antidepressants, such as amitriptyline and nortriptyline, may relieve depression. However, the anticholinergic effects of these medications can lead to confusion and must be used with caution in patients with cognitive compromise and in the elderly. Tricyclic antidepressants with low anticholinergic properties, such as desipramine or nortriptyline, can also be used. In PD, mirtazapine, which has noradrenergic and serotonergic effects, may relieve tremor in addition to reducing depression (Pact and Giduz 1999). While selective

serotonin reuptake inhibitor (SSRI) medications are helpful in the management of depression in all neurodegenerative disorders, they can exacerbate tremor, and sexual dysfunction is a common side effect.

Agitation, which may occur in patients with dementia, can be treated with anti-psychotic agents, mood stabilizing anti-convulsants, trazadone and anxiolytics (Doody et al. 2001). The atypical anti-psychotic medications are the treatment of choice for psychotic symptoms, such as hallucinations or delusions, particularly in those with parkinsonism when dopamine receptor blockage is contraindicated due to the potential to worsen motor symptoms. In these patients, clozapine, which may reduce tremor in addition to its anti-psychotic effects, is particularly effective. However, rare cases of agranulocytosis necessitate weekly blood counts and may limit its utility in PD. Quetiapine may be a next agent of choice due to the apparent fewer adverse motor effects compared to other medications in the class (Ondo et al. 2005). Irritability and aggression can be seen in HD, and less commonly in PD with dementia, AD, or ALS. SSRI medications and anticonvulsants such as valproic acid and carbamazepine can be effective in treating these symptoms.

In ALS, emotional lability or pseudobulbar affect can limit social interactions and quality of life. While no currently FDA approved therapies for pseudobulbar affect are available in ALS, SSRIs, tricyclic antidepressants, and dopaminergic therapy can be beneficial (Gordon and Mitsumoto 2007). One randomized, controlled trial showed that a combination of dextromethorphan and quinidine reduced emotional lability and improved quality of life in ALS (Brooks et al. 2004).

42.4.2 Sialorrhea

Drooling is an embarrassing symptom that is common in both ALS and PD. Anticholinergic medications are often helpful, but the benefits can be self-limiting and may require higher doses after initial improvement. Side effects include constipation, fatigue, and impotence. Urinary retention, blurred vision, tachycardia, orthostatic hypotension, dizziness and confusion may also occur. Drug selection depends on the severity and frequency of drooling. Hycosamine, which has a short half-life, is useful for sialorrhea that is associated with mealtimes or a particular time of the day. Transdermal scopolamine and oral glycopyrrolate provide a more continuous effect (Gordon and Mitsumoto 2007). Botulinum toxin injections have reduced sialorrhea in several small studies reported for both ALS and PD (Bhatia et al. 1999; Bushara 1997; Pal et al. 2000), but need to be used with caution in those with dysphagia. A more recent study showed that PD patients who received botulinum toxin injections into parotid and submandibular glands had significantly improved sialor-

rhea 1 month post-injection compared to placebo controls (Ondo et al. 2004). Additional clinical trials addressing botulinum toxin for the treatment of sialorrhea in ALS and PD patients are underway.

Thick phlegm can also be problematic in ALS. It is exacerbated by inadequate water intake, especially in patients with bulbar weakness, and by use of anticholinergic agents, which reduce serous secretions while sparing mucous secretions. Pharmacologic treatments that loosen phlegm include guaifenesin, nebulized acetylcysteine, nebulized saline, or beta adrenergic receptor blockers such as propranolol (Gordon and Mitsumoto 2007). Patients with a weak cough due to respiratory muscle involvement can use a cough-assist device or in-exsufflator to help clear secretions.

42.4.3 Motor Symptoms

In ALS, spasticity can be disabling. baclofen, a gamma amino butyric acid (GABA) analog, is the treatment of choice for spasticity, although the benefits are often modest. Patients may develop a sense of looseness or weakness, which can be minimized by slow dose titration. Other side effects include dizziness, fatigue and sedation. Intrathecal baclofen can be tried for those with severe or painful spasticity and inadequate response to oral treatment. Alternative medications to treat spasticity include dantrolene, tizanidine, and benzodiazepines. Dantrolene acts by blocking calcium release at the level of the sarcoplasmic reticulum and has the theoretical benefit of reducing excess neural excitation. At higher doses, liver function abnormalities may occur and require periodic monitoring. Tizanidine, an α_2 adrenergic agonist that has proven benefit for spasticity in multiple sclerosis, has similar side effects to baclofen. Benzodiazepines can be effective for spasticity, painful spasm and cramps. However, these medications can produce sedation and respiratory depression in high doses (Gordon and Mitsumoto 2007).

In PD, the most common motor symptoms are tremor, bradykinesia and rigidity. Beta blockers, primidone and clonazepam, can be used to treat postural tremor. Muscle relaxants are occasionally used for painful rigidity. Most of the typical motor symptoms, including rest tremor, respond to disease-specific therapy, at least early in the disease course. Some levodopa-induced motor complications, including chorea, dystonia, myoclonus and akathisia (Fahn 2000), can be reduced by prescribing lower more frequent doses of levodopa or by adding an anti-dyskinesia agent such as amantadine (Luquin et al. 1992).

Huntington's disease can cause chorea, bradykinesia, rigidity, and postural instability, among other motor symptoms. The chorea is often most noticeable and usually responds to treatment with dopamine receptor blocking or dopamine

depleting agents, but only at the expense of worsening bradykinesia. Atypical neuroleptics are also used to treat chorea and some behavioral symptoms. Other medications that are used to treat chorea include benzodiazepines and amantadine. Levodopa is not effective for bradykinesia due to HD because of its potential to worsen chorea and cognitive symptoms.

42.4.4 Autonomic Symptoms

Dysautonomia may produce orthostatic hypotension, sphincter abnormalities and sexual dysfunction. Orthostatic hypotension, particularly problematic in PD and Parkinson-plus syndromes such as multiple system atrophy (MSA), can be treated with salt, fludrocortisone, and midodrine (Jankovic et al. 1993). Fludrocortisone is a corticosteroid, but the exact mechanism on blood pressure is not fully understood. Side effects are similar to other glucocorticoids and mineralocorticoids. Midodrine stimulates $\alpha 1$ adrenergic receptors, but can cause significant hypertension in the supine position. Other common side effects include paresthesias, piloerection, dysuria, and pruritis.

42.4.5 Gastrointestinal Symptoms

Constipation is a common symptom in the neurodegenerative disorders. Inadequate fluid intake, dysphagia, dysautonomia, and immobility all contribute to constipation. Increasing fluid and fiber intake, along with increasing physical activity can help. Use of docusate sodium, milk of magnesia, dulcolax and senna may also improve symptoms. For severe constipation, lactulose, magnesium citrate and enemas can provide relief.

42.4.6 Genitourinary Symptoms

In neurodegenerative disorders, patients often experience urinary urgency, which is thought to be caused by spasm of the urinary sphincter or detrusor muscle. Oxybutynin (Ditropan) and tolterodine (Detrol) are effective for urinary urgency. For ALS patients and some PD patients, swallowing tablets may be difficult due to dysphagia. Extended release oxybutynin allows for infrequent daily dosing and oxytrol patches avoids the oral route of administration.

Sildenafil citrate (Viagra) has been found to be safe and effective for managing erectile dysfunction in PD, but can unmask orthostatic hypotension in patients with MSA (Hussain et al. 2001; Zesiewicz et al. 2000). Sildenafil is also effective for erectile dysfunction in other neurodegenerative disorders, but it should be used cautiously in those with cardiovascular disease.

42.4.7 Sleep Disorders

Sleeplessness in ALS has numerous causes. Respiratory insufficiency, difficulty repositioning in bed, anxiety and depression can all contribute to poor sleep. Treatment of depression with sedating antidepressants such as mirtazapine, tricyclic antidepressants, or trazadone can help promote sleep. Zolpidem, a non-benzodiazepine sleep aid, is effective and carries a low risk of respiratory depression. Other medications that can be helpful include antihistamines, chloral hydrate, and selective use of benzodiazepines (Gordon and Mitsumoto 2007). Non-invasive positive pressure ventilation can help relieve orthopnea in those with respiratory muscle weakness, and special equipment, such as a hospital bed, can reduce nighttime discomfort.

The sleep dysfunction in PD may also be multifactorial, but can also be due to an underlying sleep disorder. Parkinson's disease is commonly associated with rapid eye movement (REM) sleep disorder (Comella et al. 1998), which can be an initial manifestation of the disease. REM sleep disorder, best diagnosed with an overnight sleep study, can be treated with a nighttime benzodiazepine such as clonazepam.

In AD, non-pharmacological approaches to treating insomnia are undertaken first. Techniques include sleep restriction and keeping patients awake during the day as well as providing a cool comfortable quiet sleep environment at night. If pharmacologic management is necessary, sedating antidepressants or zolpidem may be helpful for promoting sleep in AD (Corey-Bloom and Galasko 1995). In those with nighttime confusion or sundowning, a low dose of a sedating atypical antipsychotic medication such as quetiapine can be helpful. Anticholinergic hypnotics should be avoided.

42.5 Current and Future Directions For Neuroprotection

42.5.1 Anti-inflammatory Agents

42.5.1.1 Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Because inflammatory cells surround dying neurons in all neurodegenerative disorders, a recent approach to neuroprotection has been the use of anti-inflammatory agents. Nonsteroidal anti-inflammatory drugs (NSAIDs) reduce inflammation in part by inhibiting one or both of the cyclooxygenase (COX) enzyme isoforms. Inhibition of COX reduces prostaglandin synthesis leading to a general decrease in inflammation. While NSAIDs have demonstrated an ability to provide neuroprotection in animal models, human trials have been less rewarding.

Both celecoxib and rofecoxib, selective COX-2 inhibitors, had positive effects in the SOD1 mouse model of ALS (Drachman et al. 2002; Azari et al. 2005). However, a subsequent randomized controlled trial of celecoxib was reported not to impart a beneficial effect in 300 ALS patients (Cudkowicz et al. 2006). No differences in adverse effects between treated and control groups were detected, and the drug was well-tolerated at a dosage of 800 mg/day for 12 months. This trial had a high dropout rate, which may have impaired the ability of the investigators to detect a small impact of the drug if one existed.

Celecoxib and rofecoxib have also been studied in AD. Randomized double-blind, placebo-controlled trials failed to demonstrate a therapeutic benefit (Aisen et al. 2003). The rofecoxib trial used naproxen as a control; the results were consistent with other studies in which nonselective NSAIDs such as diclofenac, were ineffective in AD (Scharf et al. 1999). Other NSAIDs including ibuprofen, indomethacin, and sulindac sulfide have demonstrated potential efficacy in AD (in't Veld BA et al. 2001; Rogers et al. 1993), but trials failed to show positive effects as a result of NSAID therapy in mild to moderate AD (Pasqualetti et al. 2009; de Jong et al. 2008).

Pioglitazone is a member of the thiazolidinedione class of drugs that acts as an agonist for the nuclear peroxisome proliferator-activated receptor-gamma (PPAR- γ) and is indicated for type 2 diabetes to reduce insulin resistance. Preclinical and early clinical evidence suggested the neuroprotective properties of PPAR- γ agonists PD and neurodegenerative disorders (Nicolakakis et al. 2008; Chaturvedi and Beal 2008; Risner et al. 2006; Ristow 2004; Moreno et al. 2004). Although the neuroprotective mechanisms that PPAR- γ agonists afford have yet to be delineated, they have been shown to inhibit activation of microglia and astrocytes, and inhibit production of pro-inflammatory cytokines and nitric oxide (Storer et al. 2005). In a multi-center, double-blind, placebo-controlled, futility clinical trial of early PD patients, pioglitazone was administered for 44 weeks, but yielded no beneficial changes to UPDRS scores and suggested that pioglitazone failed to affect disease progression compared to placebo controls. (NINDS NET-PD FS-ZONE Investigators 2015).

42.5.2 Immunomodulation

42.5.2.1 Vaccination in ALS

Another approach is to harness the body's own immune system to regulate inflammation. In models of neurodegeneration caused by mechanical or biochemical injury, more neurons survive in the presence of a well-regulated evoked anti-self T cell-mediated response (Moalem et al. 1999). Vaccination can be used to induce nonpathogenic T cell

responses, including the activation of anti-inflammatory Th2 cells, which may migrate to lesion sites where they affect innate immune responses through the release of anti-inflammatory cytokines or by inducing the production of neurotrophic factors. Glatiramer acetate (GA, Copaxone, Cop-1), a random mix of four amino acids in a known molar ratio, was originally designed to mimic myelin basic protein and is now FDA approved for the treatment of multiple sclerosis (MS). Cop-1 can induce a protective T cell-mediated response without risk of causing an autoimmune disease. A study of acute and chronic motor neuron disease in animal models demonstrated that twice the number of motor neurons survived in Cop-1 vaccinated mice than control mice (Angelov et al. 2003). This study also showed that Cop-1 vaccination prolonged life span in SOD1 transgenic mice, although pathological findings were not reported. An initial trial in ALS patients revealed the modality to be safe in this disease (Gordon et al. 2006). ALS patients tolerated two different dosing frequencies in conjunction with riluzole, and patients mounted immune responses similar to those seen in MS patients. Larger trials of efficacy are planned.

42.5.2.2 Immunotherapy in AD

In AD, locally generated complement proteins are activated by extracellular amyloid deposits. Microglia aggregate at these deposition sites, and attack and destroy neuronal extensions. Research has focused on recruiting the immune system to remove beta amyloid (A β) protein deposits. Exogenous antibodies to A β protein selectively bind to senile plaques and cerebral amyloid in vivo, and the amyloid deposition can be ameliorated in A β precursor protein-transgenic mice by active immunization with the A β peptide (Walker et al. 1994). Other studies have confirmed that diverse anti-A β immunization schemes reduce cerebral A β burden and behavior deficits in AD transgenic mice (Dodel et al. 2003; Lemere et al. 2004).

A β immunization was initiated in humans after successful studies in rodents. Phase I studies were completed without major adverse events, and Phase II trials were initiated with AN 1792 (active immunization with A β 42 and QS-21 adjuvant). The trials were interrupted in 2002 because approximately 6% of those vaccinated developed aseptic meningitis (Orgogozo et al. 2003). Data from the incomplete trial suggest that AD patients who mounted a significant antibody response also showed signs of clinical benefit (Hock et al. 2003; Orgogozo et al. 2003). Autopsy findings from three patients who died approximately one year after the first immunization showed evidence of A β clearance (Ferrer et al. 2004; Masliah et al. 2005; Nicoll et al. 2003). However, two of the three brains also showed changes of encephalitis with infiltration of T lymphocytes, white matter lesions invaded by macrophages, and in one case, severe small vessel disease with multiple cortical hemorrhages (Ferrer et al. 2004; Nicoll et al. 2003).

The potential for A β immunization development as a disease modifying treatment in AD depends on whether serious side effects can be effectively controlled. Further studies are needed, especially in aged nonhuman primates, to clearly understand the adverse effects and how to allow for safe application of this therapy to humans (Orgogozo et al. 2003).

Granulocyte-colony stimulating factor (G-CSF) is a protein that induces the production of stem cells and granulocytes within the bone marrow and mobilizes bone marrow elements to the peripheral circulation (Thomas et al. 2002). However, this protocol alters the immune repertoire such that a more suppressive and alloprotective responsiveness is bestowed upon the immune system (Saraceni et al. 2015; Jun et al. 2004). In AD mice, administration of G-CSF diminishes A β deposition and reverses cognitive impairment (Sanchez-Ramos et al. 2009). In a pilot Phase I cross-over trial in 8 AD patients, G-CSF was administered over 5 days and was tolerated without serious events (NCT01617577). While no significant differences in cognitive ADAScog or paired associate learning (PAL) memory tests were detected at 14 week post-administration, total PAL tests of total PAL between G-CSF- and placebo-treated patients.

42.5.2.3 Immunotherapy in Prion Disease

Antibody based immunotherapy has also been evaluated in animal models of prion disease. In vitro assays have demonstrated that antibodies to the cellular prion protein (PrP^C) antagonize the deposition of disease-associated prion protein (PrP^{Sc}) (Sigurdsson et al. 2002). However, the induction of protective antiprion immune responses has been difficult in wild type animals because of tolerance to endogenous PrP^C. Some studies have shown the possibility to overcome this tolerance by inducing immune responses to bacterially expressed recombinant PrP (Heppner et al. 2001). However, developing antibodies that are capable of recognizing native cell surface PrP^C is more difficult (Heppner and Aguzzi 2004). One study demonstrated that anti-PrP antibodies cross-linked with PrP^C when directly injected into the brains of laboratory animals and subsequently provoked neurotoxicity (Solforosi et al. 2004); however, passive immunization studies have proven successful in animals (White et al. 2003). Anti-PrP^C antibodies represent a unique set of compounds that may prove beneficial in treating prion disorders, and could elicit protection through several avenues including reduction of available PrP^C substrates for conversion to PrP^{Sc}, stabilization of the PrP^C molecule to prevent conversion, and possibly prevention of the formation of PrP^{Sc} conversion intermediates (Rovis and Legname 2014).

42.5.2.4 Immunotherapy in Parkinson Disease

In the MPTP animal model of PD, glatiramer acetate (GA, Cop-1) has also been investigated. In that model, Cop-1-immune cells provided significantly more neuroprotection than placebo

(Benner et al. 2004). Mice received adoptive transfers of splenocytes from Cop-1 or ovalbumin immunized mice since MPTP-immunotoxicity precluded active immunization due to lymphotoxicity (Benner et al. 2004). In animals given splenocytes from Cop-1 immunized mice, T cells entered and accumulated in inflamed areas of the CNS. The T cells secreted interleukin-10, an inhibitory Th2 cytokine, which suppressed microglial activation, and also stimulated local expression of astrocyte-associated glial cell line derived neurotrophic factor. This immunization strategy minimized dopamine loss compared to control animals and resulted in significant protection of nigrostriatal neurons. CD4+, but not CD8+ T cells proved to provide neuroprotection in the MPTP model and suggested that regulatory T cells (Tregs) may play a crucial role in neuroprotection (Laurie et al. 2007). Indeed in a series of studies, adoptive transfer of as few as 3.5×10^6 Tregs from naïve animals delivered complete neuroprotection of nigral neurons and up to 90% protection of striatal termini, while concomitantly attenuated microglia-derived neuroinflammation in the MPTP model (Reynolds et al. 2007). Tregs also suppressed microglial activation and oxidative stress induced by stimulation with aggregated α -synuclein (Reynolds et al. 2009a, b). Immunization with nitrated- α -synuclein (N- α -syn) induces N- α -syn specific CD4+ effector T cells (Teffs) which exacerbate neuroinflammation and microglial activation, and increase neurodegeneration in the MPTP model. That Teffs are stimulated by N- α -syn, but not unmodified α -syn suggest the effectively breaking or evading immunological tolerance (Benner et al. 2008). Indeed N- α -syn-specific Th17 effectors were the principal neurotoxic effector cell type associated with a more neurotoxic phenotype. In the presence of these Th17 effectors, CD4+ Tregs counter N- α -syn-specific Teffs and protect dopaminergic neurons better than Tregs acting in the absence of Th17 effectors (Reynolds et al. 2010). These studies suggested that in PD, Teffs are no longer adequately controlled by Treg populations and could drive disease progression over a long period of time. Indeed, observational clinical studies showed that PD patients exhibited greater frequencies of T cells with effector phenotypes compared to age-matched caregivers (Saunders et al. 2012). Moreover, Teff frequencies correlated with increased severity of motor dysfunction as determined by UPDRS part III scores and were associated with diminished Treg function as determined by their ability to inhibit CD3/CD28-stimulated T cell proliferation. Two immune modulating agents, vasoactive intestinal peptide (VIP) and granulocyte-macrophage colony-stimulating factor (GM-CSF, CSF2) known to upregulate Treg function were neuroprotective in the MPTP model (Reynolds et al. 2010; Delgado and Ganea 2003; Kosloski et al. 2013). Using synthetic VIP receptor (VIPR) agonists altered to diminish degradation and increase half-lives, the Treg inducing and neuroprotective capacities were afforded by VIPR2

agonism compared to VIPR1 agonists or scrambled peptides (Olson et al. 2015). Moreover, treatment with VIPR2 agonist yielded CD4+ T cells that expressed a 45-fold increase in GM-CSF gene expression. Together, these studies resulted in the initiation of a double-blind, randomized, placebo-controlled Phase I clinical trial in PD patients treated daily with GM-CSF (sargramostim) at 6 µg/kg or placebo for 8 weeks and is estimated to be completed in 2016 (NCT01882010).

Immunophilin binding proteins are being developed as a potential immune based therapy in PD. Immunophilins, intracellular receptor proteins that bind to the immunosuppressive drugs cyclosporine A, FK506, and rapamycin, are 10–50 fold more abundant in the brain than in the immune system (Guo et al. 2001). The immunophilin ligands combine with immunophilin proteins to suppress the immune system by inhibiting the calcium activated phosphate calcineurin, and some promote nerve growth in vitro and in vivo. GPI 1046 (Guilford Pharmaceutical) and AMG-474-00 or NIL-A (Amgen) are immunophilin ligands that promote neuronal growth without demonstrating immunosuppressive effects (Gold et al. 1998; Steiner et al. 1997). These agents stimulate growth of nigrostriatal dopaminergic neurons spared after MPTP-induced damage to the substantia nigra. Human trials have been completed to determine whether these or other immunophilin ligands will be useful in slowing or reversing PD but results are unavailable.

42.5.3 Anti-apoptotic Therapies

One process associated with neurodegeneration is caspase enzyme-driven apoptosis, and drugs that inhibit the activation of caspase enzymes are being studied as a potential neuroprotective strategy.

42.5.3.1 Minocycline

Minocycline is a tetracycline antibiotic with anti-inflammatory and anti-apoptotic properties. It has been shown to delay disease onset and prolong survival in transgenic ALS mice (Kriz et al. 2002; Zhu et al. 2002). Two early randomized, placebo-controlled trials have been conducted in ALS. The first trial showed that minocycline can be used safely in combination with riluzole. The second trial showed that minocycline was tolerated at doses up to 400 mg/day (Gordon et al. 2004). However, upon completion of phase III, researchers reported that minocycline had a harmful effect on ALS patients (Gordon et al. 2007). The negative effects of minocycline on ALS patients, despite promising phase II results, are not clearly understood at this point.

Markers of apoptosis are also present in PD (Mogi et al. 2000; Tatton 2000). Administration of minocycline to 6-OHDA treated mice inhibits microglial activation, protects

dopaminergic neurons, and reduces markers of apoptosis (He et al. 2001). Minocycline has also been shown to prevent nigrostriatal dopaminergic neurodegeneration in MPTP mice models of PD (Du et al. 2001). Similarly, minocycline delays disease progression in animal models of HD, presumably by inhibiting caspase-1 and caspase-3 mRNA up-regulation and decreasing inducible nitric oxide synthase (iNOS) activity (Chen et al. 2000; Tikka et al. 2001a). In a Phase II NINDS-funded clinical trial of PD patients, treatment with minocycline over 18 months yielded no significant differences in the change of UPDRS scores or in the time to needed symptomatic therapy compared to placebo controls (NINDS NET-PD Investigators 2008).

42.5.3.2 TCH 346 (Omigapil)

TCH 346, which is structurally related to selegiline, binds to glyceraldehyde 3-phosphate dehydrogenase (GAPDH) in a mechanism that may prevent programmed cell death. It slows the degeneration of motor neurons in in vitro models of apoptosis (Carlile et al. 2000), but did not have a significant effect on survival in transgenic mice. Phase II/III trials in patients with ALS revealed no beneficial effects of TCH 346 on disease progression (Miller et al. 2007).

In PD, nuclear translocation of GAPDH in melanized nigral neurons has been interpreted as a marker for apoptosis (Dastoor and Dreyer 2001). After MPTP treatment in animal models, GAPDH is upregulated and undergoes nuclear translocation. TCH 346 has been shown to bind to GAPDH and rescue neurons from cell death in this model (Andringa and Cools 2000). TCH 346 also attenuates MPTP-induced toxicity in primates (Andringa et al. 2003). Clinical trials of TCH 346 in PD yielded similar results to trials in ALS. In a 12–18 month trial of 255 patients, no significant evidence of neuroprotection was seen at any of the doses evaluated (0.5, 2.5, or 10 mg) (Olanow et al. 2006).

42.5.3.3 Mitogen Activated Protein (MAP) Kinase Inhibitors

The cascade of apoptosis may be promoted by mitogen activated protein (MAP) kinase activation. CEP-1347, a small molecule MAP kinase inhibitor that crosses the blood brain barrier is protective in MPTP-treated mice (Saporito et al. 1999). A clinical trial showed good tolerability, no interference with L-DOPA pharmacokinetics, and no symptomatic effects of treatment over a 4-week period (Parkinson Study Group 2004). Phase II trials of CEP1347 were terminated during an interim analysis that demonstrated continuation of the trial would be futile (Parkinson Study Group PRECEPT Investigators 2007). Notably, the doses of CEP1347 used in the trial were selected from preclinical MPTP studies, but whether any of the doses actually inhibited MAP kinase activity in the human brain was not determined (Burke 2007).

42.5.4 Antioxidants

Another proposed mechanism of neuronal death is oxidative stress due to the accumulation of free radicals. Normal and abnormal cellular metabolic processes involving molecular oxygen produce free radicals, which can cause oxidative damage to lipids, proteins and nucleic acids (Andersen 2004).

42.5.4.1 Vitamin E

Alpha tocopherol (vitamin E), a naturally occurring antioxidant, delays disease onset in mutant human SOD1 transgenic mice (Gurney et al. 1996). One epidemiological study suggested that regular intake of vitamin E may reduce the risk of contracting ALS (Ascherio et al. 2005). A randomized, placebo-controlled trial of vitamin E at 500 mg twice daily dosages showed no significant difference in 12-month survival in patients with ALS (Desnuelle et al. 2001). This trial was probably underpowered due to insufficient sample size, and used a non-validated outcome measure, the Norris Scale. Vitamin E has also been studied in combination with other antioxidants. L-methionine, vitamin E, and selenium were studied in ALS in a double-blind placebo-controlled trial of the combinations taken three times a day (Stevic et al. 2001). After 12 months, the treatment group exhibited 80% survival compared to 50% survival in the control group, however, those findings that were not statistically significant (Orrell et al. 2005). Vitamin E was ineffective in slowing progression of PD in the DATATOP trial (Parkinson Study Group 1989).

42.5.4.2 Selegiline

Selegiline (or L-deprenyl) may have anti-oxidant and anti-apoptotic properties in addition to inhibiting MAO, and has been reported to increase SOD activity in the basal ganglia of rats (Knoll 1989). There have been several trials of selegiline 10 mg per day in patients with ALS: a randomized, placebo-controlled, double-blind trial (Lange et al. 1998), and a placebo-controlled crossover trial (Mitchell et al. 1995). Neither showed improvement in functional or subjective rating scales, but both trials were underpowered due to insufficient sample size and so may be considered inconclusive. In clinical trials with PD patients, treatment with selegiline was found to have beneficial effects during the first 12 months of treatment with delayed onset of disability that required L-DOPA therapy and improved motor function clinical scores (Parkinson Study Group 1989, 1993). The drug upregulates anti-oxidant enzymes such as SOD and catalase, affects pro-inflammatory mediators such as INF- γ , TNF- α , and IL-1 β , and increases trophic factors (Kitani et al. 2002).

42.5.4.3 N-acetylcysteine

N-acetylcysteine is a precursor of glutathione and a natural intracellular antioxidant. In a randomized, placebo-controlled trial in patients with ALS, 35 patients (65%) given 50 mg/kg of

N-acetylcysteine by daily subcutaneous infusion and 30 patients (54%) given placebo were still alive at 12 months, a difference that was not statistically significant (Louwerse et al. 1995). In a small clinical trial, patients with PD or Gaucher disease and healthy controls treated with N-acetylcysteine showed increased blood redox ratios and levels of brain glutathione by 7-T magnetic resonance spectroscopy (MRS) (Holmay et al. 2013).

42.5.4.4 Coenzyme Q10 (CoQ10)

CoQ10 is an essential cofactor of the mitochondrial electron transport chain, and may act as an antioxidant. It has been shown to have neuroprotective effects in models of ALS, PD and HD (Beal 2002). An open label escalation trial in ALS was completed in 2004 with dosages up to 3000 mg per day well-tolerated (Ferrante et al. 2005). An NINDS-funded randomized controlled phase II trial of CoQ10 showed insufficient improvement to justify a larger phase III trial (Kaufmann et al. 2009).

A phase II trial has also been completed in PD (Shults et al. 2002). Over a period of 16 months, CoQ10 was safe and well tolerated at doses up to 1200 mg/day. Trends toward less disability occurred in treated patients and the benefits were greater in those receiving the highest dosage. Phase III trials aimed at examining whether CoQ10 could be used to slow disease progression in early PD verified that safe and well-tolerated, however no evidence of clinical benefit was detected (Parkinson Study Group QEI et al. 2014).

42.5.4.5 AEOL 10150

AEOL 10150 (manganese (III) meso-tetrakis (di-N-ethylimidazole) porphyrin) is a compound that can catalytically decompose biological oxidants such as peroxynitrite via its ability to cycle between MN (III) and MN (IV) states. Several investigators have reported the presence of nitrotyrosine in affected tissue in motor neuron disease; however, no cause and effect relation between protein nitration and neuronal death has been established (Crow et al. 2005). AEOL 10150 prolonged survival in the SOD1 ALS model when administered at disease onset (Zoccolella et al. 2009). Phase I trials of AEOL 10150 showed that a single injection was safe and well-tolerated in 25 patients with ALS (Zoccolella et al. 2009). Using the SOD1 mouse model of ALS, researchers have described AEOL 10150 as one of the most promising drugs for preventative and therapeutic trials in patients with ALS (Benatar 2007), however no current clinical trials using AEOL 10150 are in progress.

42.5.5 Trophic Factors

42.5.5.1 Insulin-Like Growth Factor (IGF-1)

Nerve growth factors promote neuronal sprouting in vitro, and reduce nerve cell death in vivo. Viral delivery of IGF-1 was shown to prolong survival and delay the onset of disease

in the ALS mouse model (Kaspar et al. 2003). Human trials of viral vector delivery are planned, but the safety of the modality must be shown before the FDA will allow trials to proceed. In two randomized controlled trials of IGF-1 in ALs, one showed slowed progression of functional impairment using an non-validated outcome measure (Lai et al. 1997), the other showed no significant change using the same outcome tests (Borasio et al. 1998). In a phase III trial of ALS patients, twice daily subcutaneous injections of IGF-1 for 2 years were found to provide no significant effect on muscle effect, clinical score, or tracheostomy-free survival (Sorenson et al. 2008). In a small clinical trial of ALS patients, high dose of IGF-1 (3 µg/kg) given intrathecally every 2 weeks for 40 weeks slowed decline of motor functions for some clinical signs, and afforded a modest, but significant beneficial effect without serious adverse effects (Nagano et al. 2005).

In animal studies, IGF-1. N-terminal tripeptide of IGF-1 was peripherally administered to 6-OHDA mouse models of PD and results indicated that administration after the onset of nigrostriatal dopamine depletion improved long-term parkinsonian motor deficits; however IGF-1 administration did not prevent the loss of tyrosine hydroxylase in the substantia nigra pars compacta or the striatum (Krishnamurthi et al. 2004). In human studies of drug-naïve PD patients, increased IGF-1 serum concentrations were associated with better clinical scores of movement and cognitive function, while poorer scores were associated with lower serum IGF-1 levels (Pellecchia et al. 2014; Picillo et al. 2013). Human trials of IGF-1 have yet to be conducted in PD.

42.5.5.2 Vascular Endothelial Growth Factor (VEGF)

Vascular endothelial growth factor (VEGF) is an angiogenic factor, shown important in tumor biology and recently has been implicated in neurodegeneration and therapies (Jin et al. 2000). Moreover, increasing evidence points to the involvement of other members of the VEGF family including, VEGF-B, VEGF-C, VEGF-D, and placental growth factor-2 (PLGF2) on a variety of neuronal cell types (Carmeliet and Ruiz de Almodovar 2013). Researchers have shown that reduced VEGF in persons carry a higher risk of ALS, and targeting the VEGF promoter region in transgenic mice causes an ALS-like syndrome (Storkebaum et al. 2005). Also, intramuscular delivery of VEGF to mSOD1 mice delays onset and prolongs survival. In a clinical study of AD patients, elevated levels of VEGF in CSF was found to be associated with positive clinical outcomes (Hohman et al. 2015). In the 6-OHDA mouse model of PD, VEGF promoted neuroprotection by activating glial proliferation and promoting angiogenesis (Yasuhara et al. 2004). Human trials will likely be initiated in the future, once optimal dosing and route of administration have been established.

42.5.5.3 Brain Derived Growth Factor (BDNF)

Brain derived neurotrophic factor (BDNF) has been shown to have a positive effect in preclinical models of neurodegeneration and psychiatric disorders (Nagahara and Tuszynski 2011). It prolonged survival, protected against glutamate neurotoxicity, and slowed disease progression in the wobbler mouse, an early model of ALS. In an early study with ALS patients, systemic administration of BDNF failed to show benefit for survival, but patients with early respiratory impairment showed significant benefit (BDNF Study Group 1999). Attempts to increase motor neuron exposure by intrathecal administration of BDNF showed no improvement in autonomic or motor function (Ochs et al. 2000; Beck et al. 2005). Regardless of delivery route, the failure of BDNF to reach the appropriate motor neuron targets is a consistent issue (Nagahara and Tuszynski 2011; Ankeny et al. 2001; Pardridge et al. 1998).

BDNF was also evaluated in the rat 6-OHDA model of PD, and was compared to glial cell line derived neurotrophic factor (GDNF). Results of the study showed that GDNF was more effective than BDNF in the model, but that there were no significant benefits from either of these neurotrophic factors (Sun et al. 2005).

In animal models of AD, BDNF has been shown to reverse age-associated changes in neurons, reduce neuronal death, and improve learning and memory, but did not change amyloid plaque density (Blurton-Jones et al. 2009; Nagahara et al. 2009).

42.5.5.4 Ciliary Neurotrophic Factor (CNTF)

Ciliary neurotrophic factor (CNTF) was shown to protect wobbler mice, to be required for preservation of adult motor neurons in knockout mice, and to reduce immunoreactivity in the spinal cord of ALS patients. This drug advanced as far as Phase III clinical trials, however, no significant difference in survival was observed between CNTF and placebo groups (ALS CNTF Treatment Study Group 1996; Hurko and Walsh 2000).

CNTF has also been investigated in mouse models of PD. Although CNTF had potent neurotrophic effects for injured adult rat dopaminergic substantia nigra neurons, it did not prevent the disappearance of the transmitter synthesizing enzyme tyrosine hydroxylase (Hagg and Varon 1993).

42.5.5.5 Glial Derived Neurotrophic Factor (GDNF)

GDNF has been a particularly promising approach to neuroprotection in ALS and PD (Gash et al. 1998; Lapchak 1998). GDNF enhances survival of the midbrain dopaminergic neurons in vitro and rescues degenerating neurons in vivo (Tseng et al. 1997). Intracerebroventricular (ICV) administration of GDNF in monkeys ameliorated parkinsonism and produced 20% enlargement of nigral neurons accompanied by increased fiber density (Gash et al. 1998). A GDNF-levodopa

combination reportedly reduced levodopa side effects in experimental monkeys (Miyoshi et al. 1997). A pilot trial administering GDNF ICV to humans with moderately advanced PD was abandoned because of lack of efficacy and the frequent occurrence of nausea, anorexia, tingling, hallucinations and depression (Nutt et al. 2003). Autopsy of one case showed no evidence of significant trophic effects on nigrostriatal neurons (Kordower et al. 1999). In another Phase 1 trial of PD patients, GDNF was administered into the putamen for 1–2 years with no serious side effects and improvement of motor scores and daily living activities (Gill et al. 2003; Patel et al. 2005). In a randomized controlled clinical trial, recombinant human GDNF (liatermin) was administered by intraputamenal infusion (Lang et al. 2006). Treatment resulted in increased ^{18}F -DOPA uptake, but did not improve motor scores, and was terminated due to safety concerns in preclinical trials, device-related serious events, and production of neutralizing antibodies to GDNF in several patients. Subsequent MRI analyses yielded no significant cerebellar differences between pre- and post-treatment examination of the patients (Chebrolu et al. 2006).

GDNF shows protective capability in axotomized motor neurons (Gimenez et al. 2011; Buj-Bello et al. 1995) and in preclinical models of ALS (Park et al. 2009; Suzuki et al. 2007; Li et al. 2007; Mohajeri et al. 1999). Human pluripotent stem cells engineered to produce GDNF and acquired under cGMP protocols have been used in preclinical models with the intent to use in ALS patients in the future (Gowing et al. 2014; Shelley et al. 2014).

Laboratory studies are now testing lentoviral and AAV vectors to deliver GDNF to the striatum of monkeys with MPTP-induced parkinsonism. One study demonstrated reversal of functional deficits, extensive and long term GDNF expression, augmentation of dopaminergic function, and prevention of nigrostriatal degeneration (Kordower et al. 2000; Kells et al. 2012; Bartus et al. 2011; Richardson et al. 2011). A Phase I clinical trial (NCT01621581) in PD patients testing the safety and efficacy of surgically implanted AAV2-GDNF is currently underway. The new delivery system provides a hopeful therapeutic strategy for PD, and has also been beneficial in the SOD1 model of ALS (Lu et al. 2003; Wang et al. 2002).

42.5.6 Antiglutamatergic Agents

42.5.6.1 Gabapentin

Gabapentin, an antiepileptic agent, may reduce glutamate release and thereby, reduce excitotoxicity. Gabapentin showed a small but significant effect on survival in SOD1 transgenic mice (Gurney et al. 1996). An early phase clinical trial in ALS showed a non-significant slower rate of decline in arm strength due to gabapentin (Miller et al. 1996a). A phase III study using a higher dose revealed no change in strength and a more rapid

rate of decline of the forced vital capacity (Miller et al. 2001), exemplifying the need to better define dose in early phase trials before preceding to definitive trials.

42.5.6.2 Topiramate

Topiramate reduces glutamate release from neurons and antagonizes activation of the alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor, a glutamatergic excitatory amino acid receptor. A double-blind, placebo-controlled trial conducted in 296 ALS patients over 12 months showed a faster rate of decline in arm strength and no effect on survival from topiramate (Cudkowicz et al. 2003). This trial had a large dropout rate and proceeded to a phase III trial without first exploring the effects of topiramate in the SOD model.

Topiramate was recently studied in the marmoset model of PD (Silverdale et al. 2005). Overactive AMPA receptor-mediated transmission may be involved in the pathogenesis of levodopa-induced dyskinesias. Topiramate significantly reduced levodopa-induced dyskinesias without affecting the antiparkinsonian action of levodopa. Further studies are needed to better elucidate the potential benefits of topiramate in PD.

42.5.6.3 Lamotrigine

Lamotrigine is another glutamate release inhibitor that inhibits voltage-sensitive sodium channels and stabilizes neuronal membranes, thus has been studied as a candidate neuroprotecting agent in neurodegenerative diseases. In ALS, 300 mg of lamotrigine per day had no effect when compared to placebo in a small number of patients (Ryberg et al. 2003). Lamotrigine also failed to show symptomatic benefit in patients with PD (Shinotoh et al. 1997), but neither study had adequate power to truly assess efficacy (Braga et al. 2002).

42.5.6.4 Ceftriaxone

Ceftriaxone was selected from the recent NIH-supported high throughput screening initiative in ALS. Approximately 1050 FDA approved drugs, for which the safety and toxicity are already known, were screened using in vitro assay systems (cell survival, cytochrome C release, protein aggregates, etc.). Positive results or “hits” were then tested in the transgenic model. Ceftriaxone was shown to increase glutamate transporter activity and prolong motor neuron survival. Ceftriaxone is a third generation cephalosporin that also protects against SOD toxicity, radiation induced neurodegeneration in in vitro models (Tikka et al. 2001b), and has the ability to cross the blood brain barrier. Phase I/II clinical trials in ALS patients testing the pharmacokinetics, tolerability, and safety of ceftriaxone showed the drug was well-tolerated at optimal dosing levels (Berry et al. 2013; Zhao et al. 2014). A Phase III trial (NCT00349622) was continued using two doses of ceftriaxone or placebo administered over

12 months and has been completed, however statistical analyses and publication of primary and secondary outcomes are pending.

42.5.6.5 Talampanel

Talampanel, an AMPA antagonist with antilglutamatergic activity, is also being evaluated in neurodegeneration. Talampanel has been shown to be neuroprotective after traumatic brain injury in rats (Belayev et al. 2001), and AMPA receptor antagonists have been shown to prolong survival in the transgenic mouse model of ALS (Van Damme et al. 2005). Phase II clinical trial of talampanel in ALS patients was well-tolerated, but did not show significant results in primary outcome measures; however, the rate of decline was slowed in isometric arm strength, timed hand movements and scores in ALS Functional Rating Scale (ALSFRS) (Pascuzzi et al. 2010). An extended clinical trial (NCT00982150) was terminated. Several Phase II trials of talampanel for PD have been completed, but results are unavailable.

42.5.6.6 Remacemide

Remacemide as an anticonvulsant and NMDA antagonist has been studied in PD and some models. It enhanced the effects of levodopa in parkinsonian rats and monkeys (Greenamyre et al. 1994). A randomized, controlled trial of remacemide in 279 patients with PD and motor fluctuations showed trends towards improvement of "on" time, but no evidence of neuroprotection (Shoulson et al. 2001). In a small HD trial, remacemide tended to alleviate chorea, but failed to slow functional decline (Huntington Study Group 2001). Later examination of those data suggested that after adjusting for age, longer CAG repeats were associated with greater clinical progression and may confound the results in clinical trials (Ravina et al. 2008).

42.5.7 Stem Cell Transplant Therapy

Advances in stem cell therapy have received a great deal of press in recent years. The science provides hope for potential therapeutic interventions in neurodegenerative diseases, but it is in its early stages and the mechanisms that control stem cell proliferation, differentiation into specific cells and optimal functional recovery are needed. With public expectations, patients will likely search for non-orthodox and unproven sources of treatment for which the internet provides a plethora of pages extolling the promise of stem cells, and various forms of stem cell therapy in a variety of countries. The administration of stem cells in an uncontrolled manner and without long-term follow-up by medical protocols that permit rational scientific conclusions remain an issue with some commercial ventures. Moreover, ethical concerns have clouded the collection and use of human fetal

tissue as sources of stem cells for transplantation; however the use of other sources as stem cells and tightly controlled programming protocols provide substantial advances in the possible use of neuronal replacement therapy (Lindvall 2015; Castorina et al. 2015; Haidet-Phillips and Maragakis 2015; Diaz et al. 2015; Tong et al. 2015).

42.5.7.1 Stem Cell and Gene Therapy and Parkinson Disease

The loss of specific dopaminergic neurons in PD makes the prospect of replacing missing or damaged cells a potential therapy. Recent double-blind, placebo-controlled trials of primary human embryonic dopaminergic tissue used functional neuroimaging and neuropathological investigations to demonstrate integration of transplanted dopaminergic neurons in host striatum (Freed et al. 2001; Olanow et al. 1996). However, only subpopulations of PD patients displayed significant benefits, and some patients developed uncontrollable side effects due to excess dopamine production (Freed et al. 2001; Olanow et al. 2003). Postmortem analysis at 18 months post-transplantation, showed robust engraftment of the tissues and seemingly no adverse effects of transplantation on the tissues (Kordower et al. 2008). Later autopsies of 8 patients demonstrated long-term survival of the grafts; however, long term benefits were limited in scope. Postmortem analysis showed that host factors of PD also affected the neurons from transplanted tissues as well as the transplant recipients (Li et al. 2008; Kordower et al. 2008; Mendez et al. 2008). Three patients showed typical PD neuropathology with α -synuclein inclusions from long-term transplants, but no Lewy pathology was evident from patients that succumbed up to 4 years after transplantation. Increased Lewy pathology was noted with increasing age of the grafts. Additionally, Lewy pathology was noted to be associated more with those patients with long-term transplants that had received tissue fragments rather than cell suspensions.

Retinal pigmented epithelia (RPE) are dopaminergic support cells in the neural retina. RPE cells on gelatin beads, also called Spheramine, produce levodopa (Watts et al. 2003). An open label clinical trial of transplantation of Spheramine was conducted in 6 patients with PD and implantation therapy was deemed safe and well tolerated at 6 months post-implantation (Bakay et al. 2004). However a larger double-blind, placebo-controlled trial in advanced PD showed no anti-parkinsonian benefits compared to control surgery (Gross et al. 2011). In another clinical trial, human RPE cells from 10–20 week postmortem tissues were cultured and unilaterally transplanted into the postcommissural putamen of 12 PD patients (Yin et al. 2012). The surgery was well-tolerated and 11/12 patients showed improved UPDRS scores at 3 months which peaked at 12 months and declined over the next 24 months. PET analysis detected trends of increased DA release during the first 6 months.

The activity of both GABA efferents to the subthalamic nucleus and its targets within the basal ganglia are affected in PD. Glutamic acid decarboxylase (GAD) is the rate-limiting enzyme for GABA production and thus gene therapy consisting of GAD gene insertion may serve as an alternative PD treatment strategy (LeWitt et al. 2011). In patients who received the bilateral delivery of AAV2-GAD, there was a greater decrease in their UPDRS scores correlating with an improvement in motor control compared to patients who received sham surgery. The efficacy of GAD gene therapy supports its further investigation as a PD therapy and also shows promise for gene therapy in other neurodegenerative and neurological disorders (LeWitt et al. 2011).

42.5.7.2 Stem Cell Therapy and Huntington Disease

In animal models of HD, transplanted striatal cells survive, grow, and establish afferent and efferent connections (Freeman et al. 2000). One open label human trial indicated that grafts may have restored function (Hauser et al. 2002). Recipients showed cognitive and motor improvements that were associated with reductions in striatal and cortical hypometabolism. The success of grafting may be sensitive to the age of the donor and to the degree of neuronal loss in the patient.

In HD rodent models, mesenchymal and adipose derived stem cells have been shown to improve HD pathology through the secretion of neurotrophic factors and reduction in proinflammatory cytokines. Further studies will be required prior to the use of stem cell transplants in clinical trials, however studies-to-date suggest that stem cell therapy has great potential to effectively treat HD (Maucksch et al. 2013).

42.5.7.3 Stem Cell Therapy and Amyotrophic Lateral Sclerosis

Stem cell therapy poses a greater challenge in ALS than in other neurodegenerative diseases because of the length of motor axons and growing evidence that neurodegeneration in ALS may be mediated by neuronal and glial influences. Late stage fetal cortical neurons have been shown to replace apoptotic neurons when grafted into adult mouse neocortex, to receive afferents from host brain, and to project to the contralateral hemisphere (Fricker-Gates et al. 2002). Fetal motor neurons grafted to the adult rat spinal cord lacking motor neurons migrate to the ventral horn and make functional connections with skeletal muscle (Clowry et al. 1991). Whether these neurons are integrated into neuronal circuits is unclear. It is also unknown if similar neuronal replacement could work in the brains of individuals with ALS. A series of Phase 1 clinical trials using bone marrow-derived mesenchymal stem cells (MSCs) were injected into the spinal cord of ALS patients and followed for various lengths time (Mazzini et al. 2003, 2006, 2008, 2010, 2012). The trials demonstrated that

intraspinal injection of MSCs was generally safe, and beneficial trends included slowing the rate of decline of the forced vital capacity and of the ALS-FRS score. However, neither graft survival nor transplant growth could be confirmed. Several other trials have reported that MSC transplantation in ALS patients is well-tolerated (Feldman et al. 2014; Garcia Santos et al. 2013; Riley et al. 2012; Blanquer et al. 2012; Glass et al. 2012; Karussis et al. 2010; Deda et al. 2009; Oh et al. 2015), but only a few studies yielded significantly positive outcomes for patients (Karussis et al. 2010; Oh et al. 2015). Using a spinal cord-derived neural stem cell line, NSI-566 (Glass et al. 2012; Riley et al. 2012) implanted into spinal cords of ALS patients, a Phase II trial showed the maximum dose of 16 million cells was well-tolerated and at 9 months post implant, 47 % (7/15) patients responded to the treatment as measured by non-declining slope of ALSFRS scores, increased grip strength, and retention of lung function.

42.5.7.4 Stem Cell Therapy and Alzheimer's Disease

Preclinical studies in animal models of AD have shown that stem cells, including embryonic stem cells, iPSCs, MSCs, and adipose-derived stem cells (ADSCs) have the capacity to model familial AD (if derived from AD patients); improve memory, cognitive, and locomotor functions; remove A β plaques from hippocampal tissues; reduce A β deposits by induction of M2-like microglia; support and enhance autophagy; and improve acetylcholine levels (Salem et al. 2014; Shin et al. 2014; Ma et al. 2013; Yang et al. 2013; Park et al. 2013; Darlington et al. 2013; Yagi et al. 2011; Lee et al. 2009; Tang et al. 2008; Amemori et al. 2015). Several clinical trials using stem cells in AD patients have been initiated or completed, but results have not yet been posted (NCT01297218, NCT01547689, NCT02054208, and NCT02600130).

42.6 Others

42.6.1 Amyotrophic Lateral Sclerosis

42.6.1.1 Calcium Channel Blockers

Calcium channel blockers antagonize excitatory amino acid receptor activation. A randomized, double-blind, placebo controlled, crossover study of nimodipine was conducted in patients with ALS (Miller et al. 1996b). There was no significant difference in the rate of decline of pulmonary function or limb strength with treatment compared to placebo and the authors concluded that nimodipine was ineffective in slowing the progress of ALS.

The efficacy of verapamil, a calcium channel blocker, was studied in a clinical trial in which the treatment of phase was compared to a natural history phase (Miller et al. 1996c).

During months 1–3, patients were not given drug and the natural history of their progression was measured. Following the month 3 visit, verapamil was started at 40 mg and titrated to a daily dose of 240 mg per day. The decline in forced vital capacity and limb strength were not significantly different between the treatment phase and natural history phase.

42.6.1.2 Creatine

A key pathological feature in the animal model of ALS is abnormality of the mitochondria (Wong et al. 1995). Creatine, which acts as a mitochondrial energy buffer and may also have anti-oxidant properties, provided a dose dependent improvement in survival in the transgenic SOD1-G93A mouse (Klivenyi et al. 1999). A subsequent randomized placebo-controlled trial using 5 g per day showed no significant benefit in survival (Groeneveld et al. 2003). This trial broke new ground in several ways. First, the investigators used a sequential analysis plan, so that the trial was stopped once the null hypothesis could no longer be rejected, saving 18 months over a fixed duration trial. Second, the dropout rate was nearly zero, because the investigators made home visits when necessary to obtain data from patients no longer able to travel to the centers. A second double-blind, placebo-controlled trial of 5 g per days also did not show a benefit (Shefner et al. 2004), but this trial likely had inadequate power due to small numbers of patients enrolled. Neither trial may have been dosed adequately.

42.6.1.3 Sodium Phenylbutyrate

Transcriptional dysregulation may contribute to the pathogenesis of neurodegeneration (Gonzalez de Aguilar et al. 2000). Sodium phenylbutyrate, a histone deacetylase inhibitor (HDAC inhibitor), regulates transcription and has provided improvement in survival, body weight and motor performance in the SOD mouse model (Ryu et al. 2005). The safety and tolerability of sodium phenylbutyrate has been evaluated in a trial funded by the Veterans Administration and the Muscular Dystrophy Association and shown that the lowest dose was therapeutically efficient in improving histone acetylation levels (Cudkowicz et al. 2009).

42.6.1.4 SOD-1 Clearing Agents

Motor neurons may have a high threshold to activation of the heat shock protein pathway, which is involved in protein repair. Arimoclomol, an inducer of heat shock proteins, delays disease progression and improves survival in the murine model (Kieran et al. 2004). In safety trials, arimoclomol was shown to be well tolerated and safe at up to 300 mg/day in ALS patients (Cudkowicz et al. 2008). Additional phase II/III clinical trials are underway.

An FDA-approved drug for malaria treatment, pyrimethamine (Daraprim) is showing promise in ALS treatment. Pyrimethamine reduces SOD1 levels in cultured cells, mice,

and ALS patients (Pandya et al. 2013; Lange et al. 2013). Another SOD-1 clearing agent, edaravone, was shown to effectively slow symptom progression in mSOD1-G93A mice but further characterization of edaravone is necessary (Pandya et al. 2013).

42.6.1.5 Ribonucleic Acid Interference

Mutant gene expression leading to neurodegeneration might be reduced by gene silencing techniques. RNA interference (RNAi) molecules have been generated that target the SOD1 gene and reduce its expression. RNAi has prolonged survival in the SOD1 model (Ralph et al. 2005; Raoul et al. 2005). The technology will only apply to the 2–5% of patients whose ALS is due to mutations in the gene encoding SOD1, and so obtaining adequate numbers of patients to conduct clinical trials may be difficult.

42.6.1.6 Olesoxime

mSOD1 aggregation in the mitochondria is linked with spinal cord-specific dysfunction of mitochondria and may play a role in the pathogenesis of ALS. Neuroprotection could therefore be achieved using compounds that target mitochondria (Pandya et al. 2013). Olesoxime (TRO-19622 or mitotarget) has been shown to be protective in in vivo and in vitro models of ALS. In mSOD1-G93A mice, olesoxime increased lifespan by delaying disease onset rather than slowing disease progression (Pandya et al. 2013; Bordet et al. 2007).

42.6.1.7 Combination Therapy

Because of the complexity of the mechanisms underlying neurodegeneration, testing combinations of agents that target different processes could theoretically be more beneficial than individual agents alone. The combinations of minocycline and creatine, and celecoxib and creatine showed additive effects in the SOD1 model (Klivenyi et al. 2004; Zhang et al. 2003). Phase II/III clinical trial have been completed and results are pending (Gordon et al. 2004).

42.6.2 Alzheimer Disease

42.6.2.1 Statins

Statins, used predominantly in the treatment of hypercholesterolemia, act by inhibiting 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, which regulates the synthesis of cholesterol. Statins are also agonists of peroxisome proliferator activated receptors (PPARs), which are part of the nuclear receptor superfamily and when activated, can suppress transcription of pro-inflammatory genes (Chinetti et al. 2000). In vitro and in vivo studies have shown that a decrease in serum cholesterol inhibits the production of beta amyloid and plaque (Fassbender et al. 2001; Simons

et al. 1998). A randomized, controlled trial evaluating the efficacy of simvastatin on disease progression in patients with AD provided conflicting results. Overall, the plasma levels of beta amyloid protein remained relatively unchanged after 6 months of treatment, but those with better cognitive function demonstrated a greater reduction in beta amyloid protein levels than patients with more severe dementia (Simons et al. 2002). The mechanism of how lowering cholesterol affects beta amyloid production is still unclear; studies have demonstrated that statins do not alter beta amyloid morphology (Hoglund et al. 2004). It may be that the neuroprotective properties of statins are due to antioxidant and anti-inflammatory effects.

42.6.2.2 Secretase Inhibitors

Beta amyloid peptide is cleaved from the beta amyloid precursor protein by the beta secretase (or beta amyloid cleaving enzyme, BACE) and gamma secretase enzymes (Cummings 2004). Experimental studies in animal models have shown that secretase inhibition lowers the amount of beta amyloid protein in the brain and can reduce the formation of beta amyloid protein aggregates (Dewachter and Van Leuven 2002). While BACE and gamma secretase are viable therapeutic targets, they have thus far been refractory to drug development. Gamma secretase inhibitors diminish beta amyloid protein load in the brain, but also cleave other proteins essential for signaling in cellular proliferation. Gamma secretase is essential for embryogenesis and gamma secretase knockout mice are not viable (Dewachter and Van Leuven 2002). Until these limitations can be overcome, the potential for gamma secretase inhibitors for AD therapy is restricted.

BACE is another therapeutic target. One study showed that raising BACE expression increased plaque load in beta amyloid precursor protein-transgenic mice (Willem et al. 2004). However, the development of pharmacological inhibitors of BACE has been challenging due to its large catalytic site, which does not bind small molecules effectively.

42.6.3 Huntington Disease

42.6.3.1 Sodium Phenylbutyrate

Impaired gene transcription is thought to be a key event in the cascade that leads to neurodegeneration in HD. Mutant huntington can bind to histone acetyltransferase, reducing histone acetylation and ultimately suppressing gene transcription. HDAC inhibitors act to relax the DNA conformation and facilitate transcription by keeping DNA acetylated. HDAC inhibitors may also be effective in preventing sequestration of certain transcription factors by mutant huntington during the process of aggregation (Ferrante et al. 2003). Sodium phenylbutyrate was tested in the R6/2 mouse model

of HD and was shown to significantly increase survival, improve motor function and minimize brain atrophy (Gardian et al. 2005). An initial dose-finding study of sodium phenylbutyrate in humans was conducted and found to be safe and well-tolerated but no further clinical trials were completed (Hogarth et al. 2007).

42.6.3.2 Ethyl-EPA

Ethyl-EPA (ethyl-eicopentaenoate) is a semisynthetic, highly purified derivative of the n-3-fatty acid EPA. Ethyl-EPA acts to preserve mitochondrial function by targeting peroxisome proliferator activated receptors. Ethyl-EPA reduces loss of neuronal function by inhibiting caspase activation and apoptosis, and by reducing mitochondrial damage in models of neurodegeneration (Van Raamsdonk et al. 2005). A randomized, double-blind, placebo-controlled trial of ethyl-EPA was conducted in patients with HD. This study showed that there was no benefit in the intent to treat cohort of patients with HD. However, exploratory analysis revealed that a significantly higher number of patients in the cohort treated with ethyl-EPA showed stable or improved motor function (Puri et al. 2005). Phase III clinical trials of ethyl-EPA on HD patients revealed no benefit in total motor score change, function, cognition, or global impression compared to control patients (Huntington Study Group TREND-HD Investigators 2008).

42.6.4 Parkinson Disease

42.6.4.1 Creatine

Administration of MPTP produces parkinsonism in experimental animals by a mechanism involving impaired energy production. MPTP is converted to 1-methyl-4-phenylpyridinium (MPP+), which blocks complex I of the electron transport chain. Supplementation with creatine, a substrate for creatine kinase, may increase phosphocreatine and cyclophosphocreatine levels, buffer against ATP depletion and exert neuroprotective effects. Oral supplementation of creatine produced significant protection against MPTP-induced dopamine depletion in mice (Matthews et al. 1999). Based on these results, a randomized, double-blind, futility clinical trial of creatine was conducted in 2006 (NINDS NET-PD Investigators 2006). The study found that creatine and separately, minocycline, could not be rejected as futile and that they should be considered for phase III clinical trials to determine whether they alter the long-term progression of Parkinson disease. The trial was terminated early after showing treatment with creatine for at least 5 years did not improve clinical outcomes. Thus the findings did not support the use of creatine in patients with Parkinson's disease (Kieburtz et al. 2015).

42.7 Review Questions/Problems

- Which one of these medications for Alzheimer's disease is NOT a cholinesterase inhibitor?
 - galantamine
 - rivastigmine
 - tacrine
 - memantine*
- Amantadine is a useful medication in the treatment of dyskinesias in Parkinson Disease. What side effect limits its use in the elderly?
 - diarrhea
 - sialorrhea
 - dyskinesias
 - neuropsychiatric and cognitive effects*
- Which is the only FDA approved medication for amyotrophic lateral sclerosis?
 - memantine
 - lamotrigine
 - riluzole*
 - coenzyme Q10
- Memantine is approved for use in which disease?
 - moderate to severe Huntington disease
 - early stages of Huntington disease
 - moderate to severe Alzheimer disease*
 - early stages of Alzheimer disease
- In ALS patients, sialorrhea can be a major symptom as bulbar weakness worsens. Which of these medications is ideal for a patient with swallowing difficulty?
 - amitriptyline
 - scopolamine*
 - diphenhydramine
 - glycopyrrolate
- Which one of these medications are used to treat chorea in Huntington disease?
 - risperidone*
 - levodopa
 - fluoxetine
 - bupropion
- Proposed mechanisms in neurodegenerative diseases include all of the following EXCEPT:
 - oxidative stress
 - apoptosis
 - inflammation
 - excess GABA*
- Which of these medications currently being investigated in neurodegenerative diseases have anti-apoptotic properties?
 - remacemide
 - minocycline*
 - insulin growth factor
 - ceftriaxone

Acknowledgements We gratefully acknowledge the work of Jinsy A. Andrews, MD, MSc and Paul H. Gordon, MD, PhD, FAAN for their authoritative input and work as authors of the first edition version of this chapter.

Abstract

Substantial progress has been made over the past 25 years in terms of understanding the underlying pathophysiology, developing diagnostic and monitoring tools, and, most importantly, in the treatment of Multiple Sclerosis (MS) and its symptoms. Clinical trials have contributed greatly to this progress, as both successes and failures have helped understand that MS is far more complex than was initially appreciated. The spectrum of clinical phenotypes was thought to be an expression of varying severity of the disease rather than of different pathophysiological processes. Generally, treatment was reserved for later stages of the disease, when accrual of disability was well underway.

Keywords

Experimental allergic encephalomyelitis • Gadolinium • Glatiramer acetate • IFNBeta-1a • IFNBeta-1b • Mitoxantrone • Natalizumab • Neuromyelitis optica • Sclerosis

43.1 Introduction

Multiple Sclerosis (MS) is the most common disease of the central nervous system (CNS) to cause disability in young adults. It is an immune-mediated inflammatory disease of the brain and spinal cord that typically presents in the second or third decade of life and affects women about two times more often than men (Noseworthy et al. 2000). The most common clinical presentation, representing approximately 85–90 % of cases, is of relapsing-remitting disease (RRMS) characterized by episodes of discrete neurological symptoms that resolve fully or with some residual deficit. The very first clinical episode is termed clinically isolated syndrome (CIS). Over time, the frequency of relapses decreases and, in the majority

of patients, slowly progressive accumulation of disability ensues; this stage of the illness is termed secondary progressive MS (SPMS). Approximately 10–15 % of people with MS present with slowly progressive disease from the onset (primary progressive MS or PPMS) (Miller and Leary 2007). Additionally, a progressive-relapsing (PRMS) course, described as progressive disease from onset with superimposed acute relapses, has inconsistently been referred to as a distinct presentation in the literature. These four phenotypes, based on description of clinical course alone, were first formally proposed in 1996 (Lublin and Reingold 1996) and have represented the basis for categorization of MS for research and clinical management purposes.

At the cellular level, a prominent role of T cells in the immune mediated injury in MS has long been recognized. It is now clear that in addition to T cells, B cells are also important players. A role of innate immunity is increasingly appreciated with macrophage and microglia acting as antigen presenting cells, contributing to oligodendrocyte injury and creating a chronic, diffusely inflammatory environment (Moore et al. 2015). Histopathological studies have shown that distinct immune-mediated pathways may lead to acute demyelination in individual patients (Lassmann et al. 2001)

and that mechanisms driving immune-mediated injury may change over time, with shifts between predominantly adaptive immune responses to innate immunity over the natural course of the disease (van Horssen et al. 2012) and possibly compartmentalization of the immune response in later stages of the disease (Lassmann et al. 2012).

Pathologic changes are appreciated throughout the white matter such that MS can no longer be considered simply a focal or multifocal disease; and lesions are not restricted to white matter, but occur throughout the CNS parenchyma, including cerebral cortex and deep gray matter (Dutta and Trapp 2014).

Moreover, it is now clear that in parallel to immune-mediated injury, a neurodegenerative process is already evident in the earliest stages of the disease with extensive neuroaxonal degeneration (Trapp et al. 1999). Neurodegenerative features increase over the course of the disease, predominating in later phases, and are now recognized to be the primary mechanism leading to accrual of irreversible disability over time. The relationship between inflammation and neurodegeneration remains unclear, however at least in the earliest stages of the disease it is thought that axonal damage is a direct result of the acute inflammatory lesion.

As a result of an improved understanding of the disease, increasingly more potent and targeted immunotherapies have been developed together with a paradigm shift toward treating MS in its earliest stages in an attempt to arrest or slow the process before irreversible injury occurs. To this end, MRI has been instrumental, permitting to satisfy diagnostic criteria of dissemination in time and space (denoting multifocal, recurring bouts of inflammation; McDonald diagnostic criteria) already at the time of first clinical presentation (CIS) (Polman et al. 2011). Recently, the classification of clinical phenotypes of MS originally proposed in 1996 (Lublin and Reingold 1996) was revised (Lublin et al. 2014). The new schema, which takes into account both inflammatory and neurodegenerative contributions, is more complex but more accurately reflects current understanding of underlying biology of the disease. Grouping of patient cohorts based on biologically meaningful differences is expected to enhance the ability of clinical trials in MS to further advance our understanding of this disease.

Immune abnormalities in cerebrospinal fluid (CSF) have been extensively studied in multiple sclerosis. The presence of oligoclonal bands in CSF are often used as evidence of polyclonal B cell activation and as a supportive criteria for diagnosis of Primary progressive MS (Polman et al. 2011). It is noted that while FDA-approved therapies are able to suppress relapses and contrast enhancing lesions by MRI, most do not have any effect on the oligoclonal bands, likely due to the lack of any effect on long-lived plasma cells. CSF cytokine abnormalities and markers of neuronal injury may

on the other hand have potential role as biomarkers for monitoring disease progression and effects of treatment, (Komori et al. 2015) but to date have not entered clinical practice.

43.2 FDA-Approved Disease Modifying Therapies (DMT)

The armamentarium available for treatment of MS has grown rapidly over the past two decades. The first medications to be FDA-approved were interferon β -1b in 1993, followed in 1996 by glatiramer acetate. Since that time, a total of 10 additional drug products, as well as a generic formulation of glatiramer acetate, have been approved (Fig. 43.1; Tables 43.1 and 43.2). The use of MRI in monitoring clinical trials in MS was transformative. The ability to quantify contrast enhancing lesions and accumulation of new lesions was far superior to the clinical scales and lead to the identification of drugs that could modify the course of RRMS. All the approved medications target and suppress the active inflammation that underlies clinical relapses and contrast enhancement detected by MRI. None of these medications have proven effective in arresting the more gradual accumulation of disability occurring in progressive forms of MS.

43.3 Trials in Progressive MS

Indeed, the failures of these medications in progressive forms of MS have been instrumental in revealing the distinct nature of the inflammatory and neurodegenerative processes in this disease. This was first recognized in the collective experiences of trials of interferon β , in which it quickly became clear that patients beginning treatment later in the course of their illness did not gain the same benefits as those who began treatment early. While trials in SPMS consistently showed reductions in relapse rate and accumulation of new MRI lesions, time to disability progression (assessed by EDSS) was not impacted (Secondary Progressive Efficacy Clinical Trial of Recombinant Interferon-Beta-1a in 2001; Cohen et al. 2002; Andersen et al. 2004; Kappos et al. 2004; Panitch et al. 2004; Bates 2011).

Similar results have been replicated even with the most effective anti-inflammatory agents available. Coles et al. (2006) reported a cohort of 36 patients with SPMS treated with alemtuzumab, who were subsequently followed longitudinally for 14 years. At study entry, mean disease duration was 11 years; EDSS was 6.5; and patients had an average of 0.7 relapses per year. Alemtuzumab led to reduction in annualized relapse rate (ARR) to 0.02 and a 90 % decrease in new lesion formation by MRI. Despite this, the EDSS continued to worsen, on average by 0.2 points per year with associated brain atrophy by MRI. At a follow up 7 years later, continued

Monitoring	Hepatic panel and CBC baseline, month 3, month 6 then yearly				None		As for other IFN formulations

brain atrophy had occurred despite stable T2 lesion load, again noted at follow-up 14 years post treatment, by when median EDSS had increased to 7.5 (Hill-Cawthorne et al. 2012). Subjects with the highest T2 lesion load at baseline were noted to have progressed the most during the observation period (Coles et al. 2006). This study suggested that while progression may occur through non-inflammatory mechanisms, accrual of disability may somehow depend upon earlier inflammatory injury (Jones and Coles 2014).

Early trials of hematopoietic stem cell transplantation (HSCT) were conducted in patients with progressive forms of MS, often in patients with significant disability. These studies too showed that despite aggressive immunosuppression, disability continued to progress, consistent with non-inflammatory factors underlying progressive neurodegeneration. Long-term follow-up showed that patients who did the best were those who had active CNS inflammation before HSCT (Fassas and Mancardi 2008).

Table 43.2 FDA approved disease modifying therapies for MS

	Mitoxatrone	Natalizumab	Fingolimod	Teriflunomide	Dimethyl fumarate	Alemtuzumab
Brand	Novantrone	Tysabri	Gilenya	Aubagio	Tecfidera	Lemtrada
Pivotal trials		AFFIRM, SENTINEL	FREEDOMS I, FREEDOMS II, TRANSFORMS	TEMPO, TOWER	DEFINE, CONFIRM	CARE-MS I, CARE-MS II
Year approved	2000	2004, 2006	2010	2012	2013	Under review
Dosing	Every 3 months	Monthly IV	Daily PO	Daily PO	BID PO	Annual course IV
Reduction RR (%)	67	68	54	31	44–50	55 (naïve) 49 (treated)
MRI (%)	84	92	82	57	74–90	>90
Adverse reactions	Blue-green discoloration of urine and sclera. Myelosuppression. Hepatotoxicity. Congestive heart failure	Headache. Gastrointestinal distress. Hypersensitivity reactions. Hepatotoxicity	Headache. Diarrhea. Hepatotoxicity. Bradycardia with first dose. Macular edema	Hair thinning. Diarrhea. Nausea. Hepatotoxicity. Renal toxicity. Peripheral neuropathy. Leukopenia. Hypertension	Flushing. Gastrointestinal distress. Hepatotoxicity. Lymphopenia. Hypersensitivity	Rash. Headache. Fever. Thyroid dysfunction. Infusion reactions. HSV reactivation
Recommended monitoring	CBC and LFT baseline and prior to each dose	CBC and LFT baseline and Q6 months	CBC baseline and every 6 months	UPT	CBC and LFT baseline and every 6 months	Baseline and monthly CBC (platelets). Serum creatinine and UA at baseline and then monthly
	Echocardiogram baseline and prior to each dose; yearly following discontinuation	JCV baseline and every 6 months	Baseline VZV titer	LFT baseline monthly in 6 months — 1st year, then Q6 month		Baseline and Q3 months TFT
	UPT before each dose	In JCVAb + subjects, MRI brain Q 3–6 months	Ophtho exam baseline and month 3 (continued in patients with DM or uveitis)	Baseline TB test		Monitor lab work for 48 months after last dose
			Baseline ECG; 6 h monitoring with first dose			Baseline and yearly skin exams

The best candidates for HSCT have since been determined to be young patients with short disease duration, in RRMS phase (Krasulova et al. 2010) and with active inflammation by MRI (Fassas et al. 2011).

Thus, clinical trial experience has strengthened the notion that progressive neurodegeneration in MS is not directly driven by active inflammation. It is however important to note that while progressive forms of MS have significantly less prominent inflammatory infiltrates compared to RRMS, histopathology clearly shows that adaptive and innate immune mechanisms do persist (Bruck et al. 2002; Kutzelnigg and Lassmann 2014). Whether neurodegeneration is truly an independent process or whether lack of efficacy of anti-inflammatory strategies might be due to qualitative differences in this smoldering inflammation or to its compartmentalization behind an intact barrier, is not yet fully clear.

43.4 Clinically Isolated Syndrome and Radiologically Isolated Syndrome

A duality of MS pathophysiology is now widely accepted and has reshaped management and research in this disease. It has led to the notion of a window of therapeutic opportunity for immunotherapies early in MS; to the development of diagnostic criteria permitting earlier and earlier diagnosis (Polman et al. 2011); and to a focus on CIS clinical trials. Several clinical trials have demonstrated the benefit of initiating DMT after the very first clinical manifestations of MS (Jacobs et al. 2000; Comi et al. 2001, 2009; Kappos et al. 2009) leading to delay in conversion to clinically definite MS, as defined by occurrence of relapse. As a result, in the United States, first-line injectables are approved for use in this setting (Sellner et al. 2010).

How early to initiate treatment remains a dilemma. As MRI has become more commonplace, the incidental identification of patients meeting radiological criteria for MS, despite no clinical symptoms, has been described with prevalence estimated to be between 0.06 and 0.7 % of the general population. Cohorts of these patients have been followed longitudinally and it has been seen that approximately one-third go on to develop neurological symptoms over a follow-up period of 2–5 years (Granberg et al. 2013).

How to manage these patients clinically has not yet been studied in the controlled trial setting and different approaches have been proposed ranging from doing nothing unless the patient becomes symptomatic; intermittently following the patient clinically and radiologically; to the initiation of off-label treatment. Since in the individual patient the clinical relevance of these MRI findings long term is uncertain, and due to the potential impact of DMT both in terms of risk and cost, this latter approach cannot be advocated until studies demonstrate benefit.

43.5 Treatment Strategies: Escalation vs. Induction

The currently available DMTs differ in terms of mechanism of action of immunomodulation, efficacy, side effects and risk profile. Additionally, factors such as route and frequency of administration, general tolerability as well as type of monitoring required are important factors for patient acceptability and adherence. Very few head-to-head comparison studies have been carried out and unfortunately, there is still little data on which to construct a rational framework for optimal therapeutic management.

Most common treatment is initiated with a moderately effective, low risk agent following which patients are monitored for evidence of clinical and radiological disease activity. Often patients can remain stable long-term on such a regimen. A decision to switch therapy is based on determination of treatment failure. There are no specific criteria to define treatment failure, but generally this can be due to insufficient suppression of disease activity or due to inability of the patient to comply with the treatment regimen.

Adherence to DMTs has been reported to be about 60 %, (Treadaway et al. 2009) which is comparable to self-administration of treatments in other chronic illnesses (Brandes et al. 2013). This is often due to unrealistic expectations of treatment effects, such as expectation of resolution of established neurological deficits, or because patients are not adequately educated about possible adverse reactions of therapy. To improve adherence, identification of goals of therapy as well as education and assistance with management of side effects are of great importance. Generally switching therapy before 6 months due to poor tolerability should be discouraged as this improves over time.

Switching therapy in this paradigm can occur as a treatment “escalation,” when a therapy with greater efficacy is initiated, or as a “lateral switch” to a drug with comparable efficacy but different mechanism of action. One such treatment algorithm is provided in Fig. 43.2.

An alternative treatment strategy is that of aggressive induction therapy to suppress all inflammatory activity and possibly “reset” the immune repertoire, followed by long-term maintenance therapy. At this time, there are no studies supporting this strategy as effective for improving long-term outcomes. With the wider use of powerful immunosuppressive strategies, such as alemtuzumab and HSCT, the value of such a treatment strategy will be evaluated.

In the future, development of pathway-specific biomarkers may lead to a new era of personalized medicine with the ability to identify optimal treatment strategies based on biological patterns.

Fig. 43.2 Treatment Algorithm. RIS: current evidence does not support initiation of therapy but rather to wait and/or actively follow patients closely for development of symptoms. CIS: evidence suggests that initiating DMT can delay conversion to clinically definite MS; first line injectable therapies can be pursued or patients can be followed clinically off therapy. MS: first-line therapy should be initiated, typically with medications having moderate efficacy and good safety profile. For patients with high inflammatory disease burden, consideration can be given to directly initiating therapies with greater efficacy albeit

greater risk profile. JCV Ab status can guide decision. Treatment failure should prompt change in therapy. If this is due to suboptimal treatment response, either lateral switch to another first line agent or treatment escalation to class of drug with greater efficacy albeit greater risk profile can be pursued. If this is due to poor tolerability, it is reasonable to try lateral switch first. JCV Ab status and patient preference can help guide decision. At any stage of disease course, participation in Clinical trials is an option. Off label therapies should be reserved for clinical trial setting and/or for patients who have failed approved treatments

43.6 The DMTS

43.6.1 First-Line Injectable Therapies

Interferon- β (1b, 1a, peginterferon β -1a)

First formulation, interferon β -1b SQ QOD approved in 1993.

43.6.1.1 Pregnancy Category C

43.6.1.2 Background

The failure of interferon gamma ($\text{IFN}\gamma$) as a therapeutic (Panitch et al. 1987) and the observation that it provoked exacerbations led to the investigation $\text{IFN}\beta$ for the treatment of MS as it was a known inhibitor of $\text{IFN}\gamma$. Interferons are naturally occurring proteins that mediate antiviral, anti-proliferative and immunomodulatory cellular response to various stimuli; exactly which of these effects are relevant for the efficacy of this class of medications in MS is not entirely clear.

43.6.1.3 Mechanism of Action

Interferons have pleiotropic biological effects. Immunomodulatory effects believed to be important for therapeutic efficacy include up-regulation of anti-inflammatory cytokines (IL-4, IL-10, IL-27) and down-regulation of pro-inflammatory cytokines (IL-2, IL-12, $\text{IFN}\gamma$, $\text{TNF}\alpha$); inhibition of T cell adhesion and migration across the blood-brain barrier; induction of T-regulatory cells; and reduction in T cell activation (Dhib-Jalbut and Marks 2010).

43.6.1.4 Formulations

Several formulations are available including $\text{IFN}\beta$ 1a administered by intramuscular injection; $\text{IFN}\beta$ 1a administered by subcutaneous injection; $\text{IFN}\beta$ 1b administered by subcutaneous injection; and peginterferon β -1a, which is interferon β -1a conjugated to a methoxy-polyethylene glycol (PEG molecule). This latter modification renders the drug more stable, permitting a less frequent dosing schedule of every 2 weeks.

43.6.1.5 Efficacy

Interferon β_1b subcutaneous, interferon β_1a subcutaneous and interferon β_1a intramuscular preparations have been shown to decrease the relative risk of annualized relapse rate by 34 % (The IFNB Multiple Sclerosis Study Group 1993), 33 % (Ebers 1998) and 18 % (Jacobs et al. 1996) respectively as compared to placebo, while reduction of gadolinium enhancing lesions was 83 %, 88 %, and 50 % respectively. These studies suggest a dose response with this class of drugs.

The phase III ADVANCE study (Calabresi et al. 2014) demonstrated comparable efficacy of pegylated interferon to unconjugated formulations, with a reduction in adjusted annualized relapse rate of 36 % as compared to placebo and an 86 % reduction in gadolinium enhancing lesions. The major advantage of the pegylated drug is the less frequent dosing, thereby improving tolerability, as well as possibly a lower incidence of neutralizing antibodies (Hu et al. 2012; Craddock and Markovic-Plese 2015).

It is worth noting that IFNB formulations are not effective for neuromyelitis optica (Tanaka et al. 2009) and may even lead to exacerbation of disease (Shimizu et al. 2010; Uzawa et al. 2010). Such paradoxical reactions should prompt reconsideration of the MS diagnosis.

43.6.1.6 Side Effects

The most frequent side effects, shared by all the interferon formulations, include flu-like symptoms, which occur in up to 75 % of patients (Moses and Brandes 2008).

Flu-like side effects, including fever, chills, myalgias, arthralgias and headache, usually begin within a few hours of administration and improve within 24 h. Typically these side effects lessen over time, with most patients noting improvement within weeks—3 months of initiation of therapy. It has been noted that low body weight and female gender are associated with greater risk of these side effects (Moses and Brandes 2008).

Strategies to mitigate flu-like side effects include beginning dosing with reduced dose (one-quarter to half dose) and titrating up slowly every 2–4 weeks. Premedication with nonsteroidal analgesics, to be taken at the time of injection and then as needed over the subsequent 24 h, is helpful. Timing of dose administration to best suit a patient's lifestyle, (i.e.—dosing in the evening such that symptoms occur during sleep or if sleep is disrupted, dosing earlier in day).

For patients experiencing significant flu-like symptoms, low dose prednisone (30 mg PO for the first 2 weeks, tapered over 2 weeks) or alternatively 10 mg given at time of injection and then every 4–6 h for the subsequent 12 h can be considered. Pentoxifylline 800 mg given twice daily as an anti-inflammatory drug that blocks cytokine production has also been shown to be of benefit and could be considered if other strategies do not work (Brandes et al. 2009).

Some degree of injection site reaction can occur in as many as 86–92 % of patients. These are most common with subcutaneous administration and vary greatly in terms of severity, with skin necrosis representing the most severe manifestation. This latter has been reported in up to 3–4 % of patients receiving subcutaneous injections (Moses and Brandes 2008).

Injection technique is critical for mitigating these reactions. Keeping the site clean; rotating sites and avoiding sites that develop worse reactions; icing skin or using a topical anesthetic cream before injecting; warming the syringe or vial in one's hand prior to injecting can reduce pain; and use of autoinjectors can all be helpful strategies. Typically injection site reactions lessen over the first 56 months of treatment.

Laboratory abnormalities, including hepatic enzyme elevations and lowered white blood cell counts occur in almost 40 % of patients. The majority of patients with mild elevations ($<2.5 \times \text{ULN}$) will return to normal range despite continued treatment with IFN. Greater elevations ($2.5\text{--}5 \times \text{ULN}$) should prompt lowering or suspension of dosing and close monitoring; once values return to normal range, re-challenge can be considered. Greater than $5 \times \text{ULN}$ should prompt discontinuation of treatment and diagnostic work-up. All patients should be counseled to limit exposure to common hepatotoxins, including alcohol and acetaminophen. IFN-induced leukopenia does not typically improve with dose reduction and usually fails re-challenge.

Transient, subclinical thyroid dysfunction and autoimmunity has been reported in post-marketing surveillance.

A higher incidence of depression, already more common in MS than the general population, is associated with IFN treatment (40 % in IFN-treated patients compared to 21 % in GA-treated patients). Mood should be monitored and treated as appropriate (Patten et al. 2003).

Headache is reported with IFN treatment, either together with flu-like symptoms or independently—and can be managed with triptans as needed.

43.6.1.7 Monitoring

It is recommended that white blood cell counts and hepatic enzymes at baseline and again 1, 3, and 6 months after initiating treatment, with yearly checks thereafter as long as values are stable.

43.6.1.8 Special Considerations: Neutralizing Antibodies (NAbs)

Up to 45 % of patients receiving treatment with preparations of interferon beta will develop NABs. These typically develop within 2 years, most often in the first 4–6 months, of initiating treatment. In some patients this may be associated with treatment failure, as defined by persistent clinical and/or MRI disease activity. IFNB1b preparations are more immunogenic

than IFN β 1a preparations, with intramuscular IFN β 1a having the lowest incidence of NABs. This latter may be due both to formulation, dosing and to route of administration. Reported frequencies of neutralizing antibodies are 2–6 % for IFN β 1a given intramuscularly; 12–28 % for IFN β 1a given subcutaneously and 28–47 % for IFN β 1b when given subcutaneously (Bertolotto et al. 2014). Increased likelihood of development of NABs may be related to the presence of antigen presenting cells such as the Langerhans cells in the skin. Of note, NABs cross react with other formulations; therefore switching to a different formulation is not beneficial.

Concomitant autoimmune diseases:

IFN β is ineffective and can even worsen diseases where the Th17 immune response is prominent such as neuromyelitis optica, systemic lupus erythematosus, rheumatoid arthritis and ulcerative colitis (Axtell et al. 2011). Hence patients should be screened for other autoimmune diseases and IFN β should be avoided if other autoimmune diseases are concomitantly present.

43.6.2 Glatiramer Acetate

Approved in 1996

43.6.2.1 Pregnancy Category B

43.6.2.2 Background

The discovery of glatiramer acetate was fortuitous. In the production of synthetic polypeptides with amino-acid composition similar to MBP with the intent of creating encephalitogenic mixtures for generating EAE, some of the copolymers were found to protect mice from disease. Cop 1, randomly composed of L-alanine, L-lysine, L-glutamic acid and L-tyrosine in a molar ratio of 4.2:3.4: 1.4:1.0 was the most effective in ameliorating EAE and was ultimately developed as a disease modifying agent (Teitelbaum et al. 1971).

43.6.2.3 Mechanism of Action

The therapeutic effects of GA are complex and not completely understood.

Most studies indicate the principle mechanism of GA is to shift the peripheral T cell response from a predominant pro-inflammatory Th1 to anti-inflammatory Th2 pattern. Additionally, GA-induced CD4 and CD8 regulatory immune cells are thought to enter the CNS and mediate *in situ* anti-inflammatory cytokine shifts and bystander immunomodulation (Arnon and Aharoni 2004; Aharoni 2014).

43.6.2.4 Formulations and Dosing Regimens

In 2014, a modified dosing regimen of 40 mg three times weekly was approved providing an alternative to the previous 20 mg daily SQ regimen. A generic formulation was approved in 2015.

43.6.2.5 Efficacy

Glatiramer acetate SQ daily led to a 29 % reduction in relapse rate compared to placebo (Johnson et al. 1995). The alternative thrice weekly dosing regimen was found to be at least as effective, with a reduction in relapse rate of 34 % (Khan et al. 2013). A reduction in gadolinium enhancing lesions of 35 % (Comi et al. 2001) and 44.8 % (Khan et al. 2013) respectively.

43.6.2.6 Side Effects

Glatiramer acetate is generally well tolerated with injection site reactions (in up to 73 % of patients) being the most common side effect. This latter can be associated with development of lipatrophy. Strategies for mitigating injection site reactions are analogous to those employed for IFN β formulations.

Another adverse reaction, unique to GA, is an immediate post-injection reaction, characterized by flushing, chest pain, palpitations and anxiety that can last a few minutes or more than an hour, and then spontaneously resolves. This reaction was reported to have occurred in 15 % of subjects at least once during a 2–3 year period (Johnson et al. 1995). While this reaction can be dramatic and sometimes mistaken for angina, it very rarely re-occurs and does not require discontinuation of the medication or adjustment of dosage. The exact etiology of the chest pain is unclear but does not appear to be of cardiac origin.

Asymptomatic lymphadenopathy is also associated with GA treatment and can occur in up to 30 %.

43.6.2.7 Monitoring

None

43.6.3 Oral Therapies

Fingolimod

Approved in 2010

43.6.3.1 Pregnancy Category C

43.6.3.2 Background and Mechanism of Action

Fingolimod was the first oral therapy to be FDA-approved for the treatment of MS. Its development was the result of rational drug design targeting the S1P receptor on lymphocytes, thus preventing their egress from secondary lymph organs and reducing the number of circulating lymphocytes. The drug affects naïve and central memory T cells, while sparing effector memory T cells (Chun and Hartung 2010); this may explain the relatively low incidence of opportunistic infections.

43.6.3.3 Efficacy

In registration trials, fingolimod demonstrated approximately 50 % relative reduction in ARR compared to placebo and reduction of gadolinium contrast enhancing lesions by about 82 % (Kappos et al. 2010; Calabresi et al. 2014).

43.6.3.4 Side Effects

The most common side effect reported is liver enzyme elevation in approximately 10 % of treated patients and leading to discontinuation of treatment in 3.8 %; upon discontinuation of treatment values returned within normal range in the majority of patients within a few months.

Reduction in lymphocyte counts by 73 % compared to baseline is observed within 1 month of treatment initiation, typically remaining stable thereafter. Up to 18 % of subjects develop more profound lymphopenia, with absolute lymphocyte counts below 200 (Kappos et al. 2014a).

Transient bradycardia and atrio-ventricular block following first dose administration and resolving by 1 month after treatment initiation is reported to occur in 0.5 % of subjects. Due to this effect, use of this drug is contraindicated in patients with CAD, heart failure, Mobitz type II 2nd degree or 3rd degree AV blocks; prolonged QT interval or patients being treated with Class Ia or Class III antiarrhythmic drugs (Wingerchuk and Carter 2014).

Macular edema was reported in 0.4 % of patients included in the registration trials. In the majority this developed within the first 6 months of treatment and resolved with discontinuation of treatment, and patients with history of uveitis were at increased risk for developing this adverse reaction.

Blood pressure elevations occur in approximately one third of subjects, with systolic over 160 mmHg and/or diastolic above 100 mmHg in about 9 %.

There appears to be a specific predisposition to herpes infections in patients treated with fingolimod, with overall incidence of about 11 %. To date, 6 serious infections have been reported, including 3 fatal cases, including disseminated zoster and herpes virus type-1 encephalitis (Kappos et al. 2014a); these were reported both at the higher dose (1.25 mg) explored in the registration trials as well as the lower (0.5 mg) FDA-approved dose.

PML has been reported to date in 2 patients treated with fingolimod (for 8 months and 4 years, respectively) in whom no other risk factor or drug exposure was recognized (FDA safety communications, Novartis safety communications).

43.6.3.5 Monitoring

EKG at baseline; 6 h cardiac monitoring with first dose administration. Ophtho exam at baseline and 3 months; people with DM or history of uveitis, require continued yearly monitoring. CBC at baseline and every 6 months.

43.6.4 Teriflunomide

Approved in 2012

43.6.4.1 Pregnancy Category X

43.6.4.2 Background

Teriflunomide is the principal active metabolite of leflunomide, which was approved for treatment of rheumatoid arthritis in 1998.

43.6.4.3 Mechanism of Action

Teriflunomide has a cytostatic effect on rapidly dividing T and B lymphocytes mediated by its inhibition of *de novo* pyrimidine synthesis.

43.6.4.4 Efficacy

Compared to the other DMTs, teriflunomide has relatively modest efficacy with a 31 % relative risk reduction in annualized relapse rate compared to placebo (O'Connor et al. 2011); 36 % reduction in TOWER (Confavreux et al. 2014) and a reduction of gadolinium enhancing lesions by 80 % (O'Connor et al. 2011).

43.6.4.5 Side Effects

Elevated liver enzymes occurs in about 12–14 % of patients, with elevations greater than 3×ULN in about 6 %. Current monitoring recommendations as well as black box warning for hepatotoxicity are based on the experience with leflunomide. Self-limited, mild to moderate diarrhea and/or nausea are reported in approximately 15 % of patients. Hair loss or thinning occurs in approximately 10–13 % of patients; this typically improves within 6 months and is reported to lead to treatment discontinuation in less than 1.5 % of patients. Leucopenia with decrease of about 15 % occurring in the first 6 weeks of treatment. Cases of tuberculosis were observed during clinical studies with teriflunomide, prompting recommendation perform tuberculin skin test prior to initiation of therapy. Increased blood pressure with frank hypertension in approximately 3–4 %. Peripheral neuropathy is a rare adverse reaction, occurring in about 1–2 % of patients. Based on animal studies, there is risk of teratogenicity and fetal death.

43.6.4.6 Special Considerations: Pregnancy

Teriflunomide is the only immunomodulatory drug used to treat MS shown to have a teratogenic effect. Moreover, since there is potential risk of male-mediated embryo-fetal toxicity, and therefore reliable contraception should be used by both females and males being treated with teriflunomide.

The half life of teriflunomide is 18–19 days and it can take months or up to 2 years to completely eliminate the drug (Wingerchuk and Carter 2014). For females or males desiring pregnancy, current recommendations are to discontinue treatment and undergo procedure for accelerated elimination with cholestyramine or activated charcoal; these regimens lead to 98 % decrease in teriflunomide plasma concentrations

at the end of 11 days. Following this procedure, verification that plasma concentrations are less than 0.02 mg/L is advised as this is expected to have minimal risk (package insert).

43.6.4.7 Monitoring

Complete blood cell count at baseline and at 6 months.

Liver enzymes monthly for the first 6 months—1 year.

TB screen and UPT before treatment initiation.

43.6.5 Dimethyl Fumarate

Approved in 2013

43.6.5.1 Pregnancy Category C

43.6.5.2 Background

Dimethyl fumarate (DMF) is a small molecule derived from fumaric acid. It was initially proposed as a therapeutic for psoriasis in the 1950s based on the notion that this disease was due to abnormal citric acid cycle. While this rationale did not prove to be correct, a combination of ester derivatives of fumaric acid including DMF did ultimately prove effective for the treatment of psoriasis and in 1994 this treatment strategy was approved for use in Europe (Bomprezzi 2015).

43.6.5.3 Mechanism of Action

While the precise mechanism of immunomodulation is incompletely understood, it appears that DMF promotes pleiotropic anti-inflammatory and cytoprotective activities mediated by activation of the NRF2 pathway.

43.6.5.4 Efficacy

The phase III trials DEFINE (Gold et al. 2012) and CONFIRM (Fox et al. 2012) demonstrated a relative reduction of the annualized relapse rate of 50 and 44 % compared to placebo.

43.6.5.5 Side Effects

The most common side effects experienced with this agent include flushing (40 %), gastrointestinal distress (diarrhea, abdominal pain; approximately 20 %), lymphopenia, and elevated liver enzymes (2 %).

Flushing and gastrointestinal symptoms typically decreases over time and can be mitigated by taking doses with food. Flushing can be further managed with ASA or anti-histamine, while gastrointestinal symptoms can be managed with H2 blockers and proton-pump inhibitors.

Lymphopenia is well described in patients treated with fumaric acid derivatives. The experience with DMF in MS is that mean lymphocyte counts drop 30 % during first year of treatment and then plateau. Severe, persistent lymphopenia has developed in about 2 % of patients; this was usually evident

already in the first year of treatment and persisted if treatment continued. Counts increased, although not back to baseline, within ~4 weeks after discontinuation (Tecfidera package insert December 2014).

PML has been reported in patients treated with fumaric acid derivatives for the treatment of psoriasis who experienced prolonged, severe lymphopenia with absolute lymph counts less than 500/mL. It is important to note that this has also been reported in patients in absence of severe lymphopenia (Nieuwkamp et al. 2015; Mrowietz and Reich 2013). As of April 2015, a single patient with MS and treated with DMF has been reported to have developed PML; similar to the previous experience in psoriasis, this patient had presented severe, persistent lymphocytopenia for 3.5 years (Rosenkranz et al. 2015).

43.6.5.6 Monitoring

It is recommended to monitor blood work, including CBC and hepatic panel, at baseline and then every 6 months. Treatment should be discontinued in people with absolute lymph counts below 500.

43.6.6 Intravenous Infusions

Mitoxantrone

Approved in 2000 for the treatment of worsening relapsing remitting, progressive-relapsing, secondary progressive MS.

43.6.6.1 Pregnancy Category D

43.6.6.2 Background

Mitoxantrone is a synthetic anthracenedione agent originally developed for treatment of cancer.

43.6.6.3 Mechanism of Action

It interacts with topoisomerase-2 and interferes with DNA synthesis and repair; as such, it is a potent immunosuppressant due to its effects on rapidly proliferating immune cells including macrophage, T cells and B cells. Mitoxantrone is the only disease modifying therapy approved for the treatment of secondary progressive multiple sclerosis.

43.6.6.4 Efficacy

Mitoxantrone led to a 67 % reduction in annualized relapse rate compared to placebo (Hartung et al. 2002) and an 84 % reduction in gadolinium enhancing lesions compared to methylprednisolone (Edan et al. 1997).

43.6.6.5 Side Effects

Treatment with mitoxantrone is associated with risk of irreversible congestive cardiomyopathy. Cumulative dose is the primary risk factor for cardiotoxicity. Cardiac evaluation

must be performed prior to initiation of treatment and before administration of each dose. Significant decrease of left ventricular ejection fraction or in patients with LVEF <50 % are contraindications for use. Lifetime cumulative dose must be limited to 140 mg/m² due to increased risk of cardiomyopathy above these thresholds (Marriott et al. 2010; Rivera et al. 2013). Cardiotoxicity may develop years after stopping treatment; it is thus recommended that patients undergo yearly quantitative LVEF evaluation to monitor for this delayed toxicity.

Risk of leukemia has been variably reported; taken together the incidence is estimated to be approximately 0.81 %. This too can be a delayed complication, occurring even years after discontinuing dosing (Marriott et al. 2010). Persistent amenorrhea is estimated at approximately 22 % (Rivera et al. 2013).

Additional side effects include severe local tissue damage with extravasation, temporary blue-green discoloration of urine and sclera, and myelosuppression. Mitoxantrone should not be administered in patients with ANC less than 1500 cells/mm³ and due to hepatic clearance, should not be administered in patients with abnormal liver function.

43.6.6.6 Monitoring

Evaluation of LVEF at baseline, prior to each dose and yearly after stopping treatment. CBC and LFT every 3 months prior to dosing.

43.6.7 Natalizumab

Approved 2003; suspended 2005; re-introduced 2006.

43.6.7.1 Pregnancy Category C

43.6.7.2 Background

Rational drug design targeting α 4-integrin, cell-adhesion molecule that mediates homing of immune cells to the central nervous system (Drews 2006).

43.6.7.3 Mechanism of Action

Natalizumab blocks α 4-integrin on lymphocytes, thus reducing trafficking of lymphocytes into the CNS.

43.6.7.4 Clinical Efficacy

The pivotal trials of natalizumab demonstrated a 68 % reduction of relapse rate compared to placebo, with a 92 % reduction of gadolinium enhancing lesions and 83 % reduction of new or enlarging T2 lesions (Polman et al. 2006).

43.6.7.5 Side Effects

The most common side effects include headache, infusion reactions and hepatic toxicity.

A rarer but potentially fatal side effect of natalizumab that has greatly influenced the use of this drug is progressive multifocal leucoencephalopathy (PML). Natalizumab was first approved in 2003. Following the development of PML in two subjects enrolled in the Phase III SENTINEL trial and a subject who had been treated with natalizumab for Crohn's disease, the drug was withdrawn from the market. In 2006, it was reintroduced in the United States under a restricted distribution program called the TOUCH Prescribing Program.

Risk stratification for PML of patients being treated with natalizumab can guide management. Several risk factors for the development of PML have been identified, including latent JCV infection, duration of treatment with natalizumab and history of previous treatment with immunosuppressive therapies. Current risk stratification, based on long-term follow-up of patients enrolled in clinical trials as well as post-marketing surveillance, takes into account these three variables.

JC virus infection status can be measured by serum anti-JCV Ab, a surrogate marker of JCV exposure. The risk of PML in subjects who are JCV Ab negative and who have never received prior immunosuppressive therapy is negligible and estimated to be 1:10,000.

In subjects who are JCV Ab positive, there is an overall 10-fold increase in risk for development of PML (1:1000). In subjects with greater than 2 years treatment duration, this increases to 4.6 in patients without prior immunosuppressive therapy and to 11.1 per 1000 for those with history of prior immunosuppressive therapy.

Recently it has been proposed that determination of JCV Ab titer, measured as the JCV Ab Index (determined based on reference quality control standards), can help further stratify JCV Ab positive patients. Titers below 1.5 were shown to be associated with risk of PML of 0.1 per 1000 during the first 2 years of therapy. For patients treated longer than 24 months, this risk reached 1.3 per 1000. For patients with index >1.5, the risk of PML was 1 per 1000 during the first 2 years of treatment, and reached 8.5 per 1000 for longer duration (Plavina et al. 2014). For patients who had received prior immunosuppressive therapy, the index did not predict risk. Based on these findings, current recommendations are that before initiating treatment with natalizumab, patients should undergo JCV Ab testing with index determination. Current understanding of risk of development of PML based on infection status and duration of treatment is summarized in Fig. 43.3.

Although longitudinal measurements of JCV Ab have demonstrated these values to be stable over an 18 month period in the majority of individuals (Plavina et al. 2014), the risk of exposure to JCV is recognized to be continuous over time with a seroconversion rate of about 1–2 % per year (Wingerchuk and Carter 2014).

Therefore JCV status needs to be monitored every 6 months in order to reassess risk. Close clinical and MRI

Fig. 43.3 JCV infection status and risk for development of PML

JCV Ab	Prior IS	JCV Ab Index	0-24 months	>24 months
+	-	<0.9	0.1:1,000	0.1:1,000
		0.9 - 1.5	0.1:1,000	1.3:1,000
		>1.5	1:1,000	8.6:1,000
-	+		1.6:1,000	11.1:1,000
			0.1:1,000	

monitoring, especially after the first 2 years of treatment, must be performed. New onset of clinical symptoms—especially if represented by symptoms such as aphasia, seizures, apraxia or visual symptoms which are highly suspicious of PML—must prompt discontinuation of treatment and diagnostic work up. Of note, since diagnosis of PML can occur following discontinuation of natalizumab, it is recommended that close monitoring continue for 6 months following discontinuation of treatment.

The typical clinical presentation of PML is of subacutely progressive neurological symptoms in the setting of immunosuppressed state. In such a patient, MRI can be helpful in identifying lesions suggestive of PML, characterized by T2W hyperintense white matter lesions at the gray-white junction or in the brainstem or cerebellum, with or without contrast-enhancement. The diagnosis is confirmed based on JCV PCR in CSF. In subjects with typical clinical presentation and characteristic MRI but negative CSF JCV PCR, in whom alternative diagnoses have been discarded, brain biopsy for histology and in situ hybridization can confirm PML. Plasma exchange has been shown to accelerate the removal of natalizumab from circulation (Khatri et al. 2009); therefore this is the recommended course of action should a diagnosis of PML be confirmed. Of note, following rapid removal of natalizumab, PML-related immune reconstitution inflammatory syndrome can develop, which in itself can be potentially life-threatening (Carruthers and Berger 2014).

43.6.7.6 Monitoring

Anti-JC virus antibody before initiation of treatment and then every 6 months thereafter.

CBC and hepatic enzymes and baseline and then every 6 months. For JCV Ab+ subjects, MRI of the brain every 3–6 months for PML surveillance; in such patients, it is recommended to limit treatment to 24 months.

43.6.8 Alemtuzumab

Approved 2014

43.6.8.1 Pregnancy Category C

43.6.8.2 Background

Alemtuzumab originated as the rat monoclonal directed against human CD52 known as Campath-1 (derived from the Pathology department of Cambridge University). It was subsequently developed as a T cell depleting agent as part of conditioning regimen in HSCT and as a therapeutic for lymphoproliferative disease (Hale et al. 1998).

43.6.8.3 Mechanism of Action

CD52 is a cell surface glycoprotein present on all T and B cells, monocytes and eosinophils; targeting this receptor leads to rapid and long-lasting depletion of peripheral lymphocytes. The rate of reconstitution of the immune cell compartments depends on the cell type, with B cells recovering quickly, while CD4 and CD8 T cell lymphopenia lasts 35 and 20 months respectively. It is generally believed that lymphopenia alone cannot account for the efficacy of this drug in suppressing inflammatory activity. Supported by the observation that reconstituting immune compartments are represented by

mature naïve cells dominating over memory cells, some resetting of the immune repertoire may contribute to the long-lasting benefits (Craddock and Markovic-Plese 2015).

43.6.8.4 Efficacy

The two pivotal trials showed that compared to IFN β 1a, there was a 55% and 49% reduction in ARR in CARE-MS I and CARE-MS II respectively (Cohen et al. 2012; Coles et al. 2012).

43.6.8.5 Side Effects

Almetuzumab causes infusion reactions in approximately 92% of patients; these can be serious in 3%. It is recommended to premedicate with 1000 mg methylprednisolone or equivalent prior to infusion and for the first 3 days of each treatment course. Premedication with antihistamine and/or antipyretics can also be considered. Infusion reactions can be delayed, and subjects must be observed for at least 2 h following each infusion.

An increased risk of malignancies, most commonly including thyroid cancer (0.3%), melanoma (0.3%), is recognized.

Increased risk of HSV infection, most commonly localized manifestations, usually in the first month after therapy; it is recommended to administer anti-viral prophylaxis to be continued for 2 months following treatment or until CD4 lymphocyte counts are $\geq 200/\mu\text{L}$. Test for VZV antibodies and consider vaccination for Ab negative subjects prior to initiating treatment.

Secondary autoimmunity is the most common serious side effect, most commonly manifesting as autoimmune thyroid disease (34%). Idiopathic autoimmune thrombocytopenic purpura (ITP) is reported in about 2%; and glomerular nephropathies occurred in 0.3%. All secondary autoimmune syndromes have been reported to develop even years after the last dose, and therefore patients and physicians should remain vigilant. The increased incidence of autoimmune diseases may be due to the effect of the drug on regulatory T cells; alternatively it has been attributed to homeostatic expansion of residual self-reactive clones (Zwang and Turka 2014).

Lymphopenia is a direct pharmacodynamics consequence of treatment with alemtuzumab, with absolute lymphocyte counts reaching a nadir at about 1 month post-infusion. Counts reach lower limits of normal in 40% of patients by 6 months, and in 80% by about 12 months.

UPT should be checked prior to dosing and effective contraception is recommended for 4 months following a course of treatment.

43.6.8.6 Special Considerations

Oral prophylaxis for HSV is recommended for 28 days upon initiation of treatment. Vaccination schedules must be completed 6 weeks prior to dosing. No live vaccines should be administered following dosing.

43.6.8.7 Monitoring

All monitoring to be continued until 48 months following last dose. CBC at baseline and then monthly thereafter. Serum creatinine at baseline and monthly thereafter. Urinalysis at baseline and monthly thereafter. TFTs at baseline and every 3 months thereafter. Yearly skin exams to monitor for melanoma.

43.7 Immunosuppressive Therapies in MS

Before the advent of FDA approved immunomodulatory therapies immunosuppressive therapies were the mainstay of treatment of MS, and continue to be used in patients with aggressive or refractory course of disease. A summary of evidence supporting use of these agents follows.

43.7.1 Cyclophosphamide

Cyclophosphamide is an alkylating agent that binds to DNA and disrupts cell replication. It targets rapidly proliferating cells, including immune cells, acting as a general immunosuppressant. Several studies have been conducted with the first being an open label study in 32 patients with chronic progressive MS (Hommes 1975), which showed benefit especially in patients with shorter disease duration. Subsequent studies have shown that cyclophosphamide is effective as add-on rescue therapy to IFN β 1a leading to a 45% reduction in relapse rate and 82% reduction in contrast enhancing lesions as compared to IFN β 1a alone (Smith et al. 2005). Similar efficacy was reported in an open label studies (Gonsette et al. 1977; Reggio et al. 2005).

More recently, renewed attention has been given to its use in treatment of refractory pediatric MS and one retrospective study in 17 children has suggested (Makhani et al. 2009) that this was safe and effective.

43.7.2 Methotrexate

Oral immunosuppressant inhibits dihydrofolate reductase, essential for purine and thymidylate synthesis and cell proliferation and growth. A few studies have suggested a trend toward clinical benefit in chronic progressive MS (Goodkin et al. 1995) and in RRMS (Currier et al. 1993). On the other hand, no benefit was found in a trial of methotrexate as add-on therapy to IFN β 1a (Cohen et al. 2009). Generally, systematic reviews have thus concluded there is a limited role of methotrexate for the treatment of MS (Gray et al. 2004). More recently a retrospective case series was reported suggesting benefit of intrathecal methotrexate in SPMS (Sadiq et al. 2010), however this has not been replicated.

43.7.3 Azathioprine

Steroid sparing purine analog that targets rapidly proliferating cells through inhibition of purine synthesis. A large RCT was done on 354 patients and showed a trend toward beneficial effect on some clinical outcome measures. Since then, several RCT studies have been performed which suggest modest relative risk reduction in relapse rate (20 %). More recently, a non-inferiority trial suggests that it may be at least as effective in reducing relapses and new brain lesions and interferon β formulations (Massacesi et al. 2014).

43.7.4 Mycophenolate Mofetil

Inhibitor of inosine 5'-monophosphate dehydrogenase type II, resulting in interruption of purine biosynthesis within activated T and B lymphocytes and macrophages. Limited data exists, with the largest RCT investigating MMF as monotherapy was conducted in 35 RRMS with trend toward benefit in the primary MRI outcomes (Frohman et al. 2010). A recent retrospective study in 344 patients treated with MMF suggested significant reduction in ARR by 68 % (Michel et al. 2014).

43.7.5 Cyclosporine

Selective and reversible inhibitory effect on T cells via block of calcineurin and thus downstream transcription of IL-2 and related cytokines.

A few clinical trials of cyclosporine in MS were pursued in the late 1980s/early 1990s. One study showed a 50 % reduction in relapse rate and delay to first relapse in RRMS subset. The authors concluded however that the adverse event profile, and specifically nephrotoxicity, outweighed benefits (Rudge et al. 1989).

In one of the first sizable (547 patients with progressive MS) double-blind, placebo controlled studies in MS, cyclosporine was found to satisfy one of its three efficacy criteria (delayed time to becoming wheelchair bound), failing however to show an effect on time to sustained progression or time to dependency in ADL. In this study, adverse reactions contributed to a 44 % drop out rate (The Multiple Sclerosis Study Group and Wolinsky 1990).

43.8 Emerging Experimental Therapeutic Strategies

43.8.1 Daclizumab

Daclizumab is a monoclonal antibody directed against the alpha chain of the high affinity IL-2 receptor. A newer formulation, daclizumab high-yield process, differs in glyco-

sylation and likely results in decreased antibody-dependent cellular toxicity.

The rationale for exploring daclizumab in MS was the proposed blockade of CD25+ T cells, based on the concept that MS is a CD4 mediated disease. Indeed a decrease by about 25 % of this T cell population is observed, however this does not fully account for therapeutic effects seen. Interestingly, patients treated with daclizumab were found to have a seven to eightfold expansion of immune regulatory CD56^{bright}NK cells in the blood and CSF (Bielekova et al. 2006). This expansion appears to correlate with clinical response. Other mechanisms have been described including blockade of cross-presentation of IL-2 by dendritic cells to T cells (Wuest et al. 2011) and a reduction of lymphoid inducer cells (Perry et al. 2012).

Two phase II double-blind RCT in RRMS, the CHOICE study using daclizumab as add-on therapy to IFN (Wynn et al. 2010) and the SELECT study who received daclizumab high-yield process as monotherapy.

These studies showed a 95 % reduction in relapse rate and 78 % reduction in contrast enhancing lesions compared to placebo; (Gold et al. 2013) and a 70 % reduction in CEL and 43 % decrease in relapse rate in the high dose group compared to IFN β (Wynn et al. 2010). The Phase III study DECIDE was completed in 2014.

43.8.2 Anti-B Cell Strategies: Rituximab, Ocrelizumab, Ofatumumab

CSF oligoclonal bands have been recognized as one of the most consistent findings in MS patients since the 1970s (Laterre et al. 1970; Link and Muller 1971). Traditionally however CNS immunoglobulins, including OCB, have been considered an epiphenomena and a significant role of B cells to CNS injury in MS was not fully recognized until more recently. In addition to producing antibodies, B cells act as antigen-presenting cells and contribute to the cytokine milieu. Antibody deposition is seen in acute demyelinating lesions (Breij et al. 2008) and more recently, ectopic lymphoid follicles containing B cells have been recognized in the meninges of patients with chronic MS and are associated with greater disease severity (Serafini et al. 2004).

Targeting B cells as a strategy for the treatment of MS was initially undertaken based on the observation in EAE models that B-cell deficient mice leads to characteristic lack of demyelination (Svensson et al. 2002). This was interpreted to suggest that demyelination required the presence of pathogenic T cells as well as presence of autoantibodies.

Rituximab is a chimeric monoclonal antibody, first approved for treatment of non-Hodgkin's lymphoma in 1997. In a phase II study in RRMS, (Hauser et al. 2008) rituximab led to a rapid and significant reduction of CEL and ARR. The rapid response implied this effect was not due to

reduction of autoantibodies but more likely to be a direct effect on the B cells themselves.

Ocrelizumab is a recombinant humanized monoclonal antibody, expected to be better tolerated than rituximab. In a phase 2 study, the number of CEL was reduced by 89 % and 96 % with reduction in ARR by 80 % and 73 % respectively in the high and low dose arms, as compared to control arms (Kappos et al. 2011). Phase III trials are underway.

Ofatumumab is a humanized antibody that binds to a different region of CD20. Its slower rate of dissociation provides for improved complement-dependent cytotoxicity (Sorensen et al. 2014). Ofatumumab was explored in a phase 2 study where it was found to suppress gadolinium enhancing lesions by more than 99 % as compared to placebo.

43.8.3 Vitamin D

Vitamin D deficiency as an explanation of the geographic distribution of MS has generated much interest. The Nurse's Health Study and the Nurses' Health Study II (Munger et al. 2004) showed that those taking supplements with Vit D (>400 IU/day) had less chance of developing MS. This protective role of vitamin D was supported by a retrospective study looking at vitamin D levels in previously stored blood samples (Munger et al. 2006).

A pilot study in 15 patients with RRMS treated with calcitriol, with primary outcome of safety, suggested a decreased MRI and clinical activity compared to baseline pre-treatment (Wingerchuk et al. 2005). Similarly, a phase I/II RCT in 50 MS also showed trend in reduction in ARR (Burton et al. 2010) while another phase II RCT demonstrated no benefit on relapse rate (Shaygannejad et al. 2012). Further studies to define a possible role in protecting or reducing risk of relapse or MRI activity are underway (Bhargava et al. 2014).

43.8.4 Estriol

Pregnancy, especially in the last trimester, is associated with a significant reduction in relapse rate in patients with MS and estriol is considered the sex hormone most likely mediating these effects. A small phase II study with crossover design of estriol showed a decrease in the number of CEL by 82 % (Sicotte et al. 2002). In 2014, a Phase II RCT of estriol as add-on to glatiramer acetate was completed.

43.8.5 Laquinimod

Laquinimod is a derivative of linomide, an anti-inflammatory agent shown to be effective for MS but found to have cardiopulmonary toxicity that precluded further development as a

therapeutic. Laquinimod is thought to exert its anti-inflammatory effects via suppression of the NF-kappa signaling pathway. Two phase III trials have been completed to date. ALLEGRO demonstrated a modest reduction in annualized relapse rate compared to placebo (Comi et al. 2012) while BRAVO did not show a significant reduction in relapse rate (Vollmer et al. 2014). A third phase III study exploring a higher dosing is underway.

43.8.6 Hematopoietic Stem Cell Transplantation

Autologous hematopoietic stem cell transplantation (HSCT) has been pursued for the treatment of autoimmune disease as a way to repair, rather than suppress, the immune system (Atkins and Freedman 2013). Efficacy of this approach is attributed not simply to the profound immunosuppression used in the conditioning regimen, but to the subsequent immune reconstitution with a renewed self-tolerant, T cell repertoire. New thymic outputs with reduced numbers of proinflammatory effector T cells and increased numbers of regulatory cells are also thought to contribute to the resetting of the immune system (Muraro 2015).

More than 800 cases of MS have been treated with HSCT in recent years (Mancardi et al. 2015); a wide variety of protocols have been used, which together with differences in patient cohorts and outcome assessments, leads to difficulty in comparing results. Recently two larger prospective studies have been reported that begin to better define a viable future role for HSCT in the treatment of MS.

HALT-MS is an on-going, open label phase II study of high-dose immunosuppressive therapy and HSCT with a planned 5-year follow-up after transplantation. Twenty-five patients with RRMS were enrolled. The 3-year interim analysis was completed and event free survival (defined as death or evidence of MS disease activity or progression of disability) was reported to be 82.8 % at 2 years and 78.4 % at 3 years following HSCT (Nash et al. 2015). This is a striking result when compared to the AFFIRM study in which only 37 % of patients treated with natalizumab had no radiologic or clinical activity after 2 years (Havrdova et al. 2009) or CARE-MSII in which only 32 % of patients treated with alemtuzumab had no radiologic or clinical activity after 2 years (Coles et al. 2012).

Mancardi et al. (2015) reported the results of the first RCT comparing intermediate intensity conditioning (BEAM) followed by HSCT to BEAM followed by treatment with mitoxantrone (ASTIMS). This led to complete suppression of gadolinium enhancing lesions compared to 56 % of subjects in the control arm, and a reduction in relapse rate by about 30 % as compared to mitoxantrone, sustained at 4 years despite only symptomatic therapy.

For both these studies, reported AEs were expected and reversible, occurring early after high dose immunochemotherapy with no early treatment-related mortality.

The possibility of pursuing less intense non-myeloablative conditioning regimen holds appeal for anticipated reduced morbidity compared to myeloablative regimens. A large case series of 121 patients treated with non-myeloablative conditioning regimen demonstrated that 50 % and 64 % of patients had sustained improvement in EDSS scores at 2 and 4 years respectively, relapse free survival of 89 % at 2 years and 87 % at 4 years as well as significant reduction in gadolinium enhancing lesions sustained at 5 years post transplant (Burt et al. 2015). A phase III study in RRMS with evidence of active inflammation using non-myeloablative conditioning regimen is underway (NCT00273364).

43.9 Clinical Trial Failures

Clinical trials can fail for a variety of reasons, including flawed trial design or inadequate dosing or route of administration, but also as a result of fundamental gaps in our understanding of the pathophysiology of a disease, despite apparently rational considerations. As with any experiment, trial failures represent opportunities to revise and correct our disease model. This is especially true when unexpected worsening of disease occurs as a result of interventions.

Unexpected adverse reactions and/or unexpectedly severe adverse reactions can sometimes lead to an interventional strategy being abandoned. One such example is that of cladribine. This is an adenosine deaminase-resistant purine nucleoside, demonstrated promising efficacy in 2 phase III studies, with a relative risk of ARR reduction of 54.5 % and 57.6 % and reduction in gadolinium-enhancing lesions by 87.9 % and 85.7 % at high and low dose respectively compared to placebo (Cook et al. 2011) and delay in conversion to CDMS (Leist et al. 2014). Its concerning safety profile, including risk of malignancy, myelosuppression, opportunistic infections arrested further development of this drug as a therapeutic.

43.10 Drugs That Made MS Worse

43.10.1 IFN γ

In 1987 an open label study of 2 doses of interferon γ was undertaken based on previous benefit seen in studies using interferon α and β (Jacobs et al. 1981, 1986; Knobler et al. 1984). Seven out of 18 subjects developed clinical exacerbations, which was significantly greater than expected based on pretreatment rate. This was attributed to a direct effect of increasing HLA class II expression on immune cells. This study marked the beginning of an effort to identify therapeutics that could block IFN γ , including IFN α and β .

43.10.2 PDE Inhibitors

Rolipram is a selective cyclic nucleotide phosphodiesterase inhibitor that targets PDE-4, the predominant isozyme present in inflammatory cells. Inhibition of PDE-4 leads to an increase of intracellular cAMP levels and can thereby modulate immune functions such as T cell activation and cytokine secretion. In vitro and in EAE models, rolipram reduced production of TNF α by activated T cells. PDE-4 inhibitors were effective in several models of EAE (Sommer et al. 1995, 1997).

An open-label Phase I-II study was terminated early after enrolling only 8 patients, due to poor tolerability and increased number of contrast enhancing lesions in 5/8 patients (225 % increase, $p=0.052$). No clinical deterioration was associated with this MRI activity and pharmacologic activity of rolipram was as predicted with inhibition of Th1 and Th17 cell function (Bielekova et al. 2009). The authors concluded that factors other than simplistic Th1/Th2 balance, including possibly effects on regulatory cell populations, might need to be considered.

Ibudilast is a non-selective PDE-inhibitor, shown to shift in vitro (Yoshimura et al. 1998) and in vivo (Feng et al. 2004) cytokine profile from Th1 to Th2, and specifically to reduce TNF- α production by immune cells including microglia. A Phase II RCT in 297 patients showed no benefit on rate of newly active lesions or on relapses (Barkhof et al. 2010). PDE inhibitors are no longer being pursued as anti-inflammatory agents in MS, but still hold interest as early data has suggested a possible neuroprotective role, yet to be confirmed (Fox 2010).

43.10.3 TNF Inhibitors

TNF is an important pro-inflammatory cytokine and there is evidence that it contributes to tissue injury in MS: TNF is found in active demyelinating lesions; has a direct toxic effect against oligodendrocytes in vitro; patients with MS have elevated TNF levels in serum and CSF and TNF production is increased prior to and during clinical exacerbations. TNF inhibitors have been very effective in the treatment of chronic inflammatory diseases, including RA and spondyloarthropathies (Kaltsonoudis et al. 2014).

Based on this rationale, the TNF inhibitor infliximab was studied in a small open label phase I study of 2 patients with rapidly progressive MS. Both patients developed an increase in number of gadolinium enhancing lesions by MRI associated with laboratory biomarkers indicating increase of active inflammation (IgG Index and CSF pleocytosis) (van Oosten et al. 1998).

Subsequently a phase II placebo controlled study in 168 patients with lenercept, a soluble TNF receptor fusion protein, was pursued. This study was terminated due to an unex-

pected 68 % increase in relapse rate in the lenercept treatment arms compared to the placebo arm. This effect was evident already in the first month of treatment, and was associated with a dose-dependent decrease in time to first exacerbation was seen (1999).

A paradoxical role of TNF in MS is further supported by an unexpectedly high occurrence of CNS demyelinating disease has been described in anti-TNF-treated individuals, with a prevalence of about 0.05 and 0.2 % (Ramos-Casals et al. 2010). The relatively low rate of this adverse outcome has been interpreted as an unmasking of underlying predisposition to demyelinating disease rather than a direct causal effect.

More recently, an MS-associated splice variant of TNFR1 was described; this mutated protein is secreted rather membrane bound and is capable of neutralizing circulating TNF, thereby acting as an endogenous TNF inhibitor (Gregory et al. 2012). Additional effects of the mutated protein leading to enhanced production of TNF-driven pro-inflammatory activity has also been described and may further contribute to MS disease susceptibility (Ottoboni et al. 2013).

TNF has thus emerged as a pleiotropic factor that acts in a complex network, with pro-inflammatory and anti-inflammatory effects. The net effect of modulation of this cytokine likely depends on the environment in which it is found and possibly genetic susceptibility.

43.10.3.1 APL

Altered peptide ligands are short peptides with amino-acid substitutions in key T-cell contact positions that can block specific T cell responses to the native antigen by displacing it or by inducing regulatory T cell populations (Bielekova and Martin 2001).

Two phase II studies were conducted using identical APL MBP₈₃₋₉₉ (Kappos et al. 2000; Bielekova and Martin 2001). Both studies were terminated early due to poor tolerance of the intervention, mainly related to hypersensitivity reactions. While neither trial demonstrated statistically significant difference between treated and untreated patients (Kappos et al. 2000) or baseline vs. treatment (Bielekova and Martin 2001), Bielekova *et al.* reported a higher than expected incidence of relapses, seen in 3 out of the 8 enrolled subjects, associated increase in gadolinium enhancing lesions. In 2 of these 3 patients, the exacerbations were directly linked to APL-induced 1000-fold expansion of MBP₈₃₋₉₉-specific T cells in peripheral blood and CSF. This was taken to support the encephalitogenic potential of MBP-specific T cells in MS.

43.10.4 Atacicept

Atacicept is a recombinant fusion protein, made of the extracellular ligand-binding portion of the human TACI receptor linked to a recombinant Fc domain of human immunoglobulin

G. It binds and blocks the activity of two B cell growth factors: B cell activating factor (BAFF) and a proliferation-inducing ligand (APRIL). Both factors are essential for B cell differentiation, maturation and survival. Atacicept targets mature B cells (antigen-driven B cell responses) and plasma cells and late stages of B-cell development while sparing B cell progenitors and memory cells.

ATAMS (Kappos et al. 2014b) a 36-week placebo-controlled phase II study of atacicept in RRMS was terminated early due to more than doubling of relapse rate in all doses of study drug explored and associated dose-dependent decrease in time to first relapse. Over the subsequent 60-week safety follow-up, relapse rate returned to pre-treatment baseline in parallel with B cells counts and Ig concentrations returning toward pre-dose values, suggesting biological relevance of these pharmacological effects. The concurrent phase II study of atacicept in optic neuritis (ATON) was terminated early based on the ATAMS results. Although difficult to draw conclusions since very few patients completed the study, a higher proportion of patients converting to clinically definite MS was observed in the atacicept arm compared to placebo (35.3 % vs. 17.6 %) (Sergott et al. 2015).

Different explanations have been proposed for these unexpected effects, including the decrease in immunoglobulin levels precluding non-specific occupation of Fc receptors on antigen-presenting cells and/or disruption of the balance between effector and regulatory B cells (Luhder and Gold 2014).

This study, similarly to both the lenercept and daclizumab experiences, demonstrates that the net effect of specific interventions in this complex network of checks and balances can lead to unpredictable outcomes. In order to benefit and advance understanding of immune-physiology and pathophysiology, to be gained both from negative and positive studies alike, clinical trials must include measures of biological activity of study interventions.

43.11 Drugs That Cause CNS Demyelination

43.11.1 Fludarabine

Fludarabine is a purine nucleoside (Warrell and Berman 1986) used to treat myeloproliferative malignancies and as immunosuppression prior to BMT.

At doses higher than 100 mg/m² fludarabine has been described to cause a delayed, progressive demyelinating encephalopathy in approximately 36 % of subjects within 6–8 weeks of treatment; this has limited the use of this otherwise well-tolerated chemotherapeutic agent (Spriggs et al. 1986; Chun et al. 1991). This effect is dose-dependent, such that at lower doses (<25 mg/m²) neurotoxicity occurred in 0.2 % (Chun et al. 1986).

Clinically patients most often present with visual deficits. Neuropathology of autopsy cases has shown leukoencephalopathy with predominant involvement of occipital and parietal lobes, with vacuolization, demyelination, PAS-positive macrophage infiltration and axonal loss (Ding et al. 2008).

More recently ocular toxicity, specifically characterized by retinal ganglion and bipolar cell loss, optic nerve atrophy and macrophage infiltration has been described (Ding et al. 2008; Bishop et al. 2010); ocular toxicity is not be limited to high dose therapy.

It has been suggested neurological complications caused by fludarabine may be due to specific, direct toxic effect on susceptible neural progenitor cells and non-dividing myelinating oligodendrocytes in regions with greatest metabolic activity. (Ding et al. 2008; Hafner et al. 2014).

43.12 Opportunistic Infections in Patients with MS Due to Immunomodulatory Therapy

43.12.1 Progressive Multifocal Leukoencephalopathy

43.12.1.1 Therapies Implicated

PML is caused by a ubiquitous polyomavirus, JC virus. Immunomodulatory therapies associated with an increased risk of PML include natalizumab, rituximab, and efalizumab (Nath and Berger 2012). Mycophenolate mofetil also carries a black box warning for PML. Any broadly immunosuppressive therapy may be associated with PML, but separating the contribution of the immune abnormality of the underlying disease from the therapy may be difficult.

43.12.1.2 Treatment

The only unequivocal improvement in outcome attends restoration of immune function. Therefore, removing the offending agent is critically important aim of therapy is to restore immune function (Fox 2011).

43.12.1.3 Withdrawal of Immunomodulatory Therapy

Discontinuation of the drug may be sufficient for drugs with a short half life.

Removal of the drug by plasmapheresis (PLEX) may be needed. To date, PLEX has only been demonstrated to effectively remove natalizumab and the effects on the immune system of some monoclonal antibody therapies, such as, rituximab, do not lend themselves to rapid reversal. Serum natalizumab concentrations are reduced by a mean of 92 % from baseline to 1 week after three PLEX sessions ($p < 0.001$). Although average alpha4-integrin saturation was not reduced after PLEX because it was tightly bound to the lymphocytes,

it was reduced to less than 50 % when natalizumab concentrations were below 1 ug/mL. PBMC trans migratory capacity increased 2.2-fold after PLEX ($p < 0.006$) suggesting partial functional recovery (Khatri et al. 2009).

Immune restoration is the cornerstone of treatment of PML; however, the inflammatory response associated with it may result in IRIS. This has been observed in the majority of patients with treated for natalizumab associated PML and may be fatal. Early treatment with high dose steroids (1 g methyl prednisone/day for 5 days) is necessary followed by a slow oral taper over 2 months as evidenced by analysis of retrospective studies (Tan et al. 2011).

43.12.1.4 Antiviral Therapies

Although several agents have been demonstrated to suppress JC virus replication in vivo, such as, cytosine arabinoside, camptothecin, mefloquine (Brickelmaier et al. 2009) and, in some but not all studies, cidofovir (Andrei et al. 1997; Hou and Major 1998). A carefully designed clinical trial of cytosine arabinoside for HIV-associated PML showed no benefit (Hall et al. 1998). Observational trials have failed to show any benefit of cidofovir in HIV-associated PML (Gasnault et al. 2001; Marra et al. 2002). Similarly, a trial of mefloquine that used CSF JC virus copy numbers as its primary endpoint failed to show an effect of the drug.

43.12.2 Herpes Simplex Virus-1 (HSV-1) Encephalitis

43.12.2.1 Therapies Implicated

There have been isolated cases reported with natalizumab and fingolimod.

43.12.2.2 Treatment

National guidelines for treatment of viral encephalitis were established for the United Kingdom (Solomon et al. 2012). This consensus statement recommended that all patients undergo neuroimaging studies prior to cerebrospinal fluid evaluation. The etiological diagnosis is best made by polymerase chain reaction for the viral genome. While they suggested that there was no role for a brain biopsy in the initial assessment of patients with suspected HSV encephalitis; it may be useful in patients with suspected HSV encephalitis who are CSF PCR negative and deteriorating despite acyclovir to confirm the diagnosis or to identify alternative disorders.

43.12.2.3 Acyclovir

Standard dosage: 10 mg/kg IV (over 1 h) given every 8 h; MAX 20 mg/kg every 8 h. Duration of treatment in the original randomized trials of aciclovir for HSV encephalitis was 10 days. However, clinical relapse after 10 days treatment

are known to occur (Dennett et al. 1996). As a consequence most clinicians now use at least 14–21 days intravenous treatment in confirmed cases. Some advocate repeating a CSF examination at 14–21 days, and continuing treatment until the CSF is negative of virus by PCR (Solomon et al. 2012). A prolonged duration of therapy may be more important in the immunosuppressed patients.

43.12.3 Varicella Zoster Virus Infection

43.12.3.1 Therapies Implicated

In immunosuppressed patients, single or multidematomal eruptions of shingles may occur. Unusual presentations may include a CNS or retinal vasculitis with infarcts in the absence of a rash. Rarely, it may cause acute encephalitis without a vasculitis or a rash (De Broucker et al. 2012). In United States, three drugs have been approved for treatment which includes acyclovir, valacyclovir and famciclovir. In Europe, brivudin is also approved for treatment. All CNS complications should be treated with IV acyclovir while shingles can be treated with oral valacyclovir or famciclovir.

43.12.3.2 Famciclovir

Standard dosage: Shingles: 500 mg orally every 8 h for 7–10 days. Dosage needs to be adjusted in patients with renal insufficiency.

43.12.3.3 Special Consideration

Famciclovir is a prodrug that gets metabolized to penciclovir which is the active form of the drug.

43.13 Review Questions

Your brother had some “double” vision problems lately and has felt very tired. Your family physician sent him to a neurologist who scheduled several tests. On follow up, the neurologist says that your brother has optic neuritis that may potentially be associated with multiple sclerosis. The neurologist also recommends that your brother consider beginning an interferon β therapy.

1. What clinical data would support initiating IFN β therapy even before a definitive diagnosis of MS?
2. What clinical information, in association with verification of the clinical symptoms of optic neuritis and fatigue would be sufficient to verify that the diagnosis is definitive MS using the revised MacDonald criteria?
3. Your brother has received information on the two FDA approved IFN β -1a products. What are the differences in dose, dosing schedule, potential for side effects and efficacy for the two products?

4. Over the next year, your brother has 2 more episodes that include problems with walking and numbness in his right hand. Are any other criteria necessary for a definitive diagnosis of MS by the revised McDonald criteria?
5. What would you expect an MRI to show if your brother truly has MS?
6. Your brother has been on IFN β -1a IM therapy for 9 months and is still complaining of flu like symptoms and muscular aches and pain following each injection. What other therapeutic option(s) does he have?
7. How has the diagnosis of MS changed your brother's life expectancy?
8. Your brother has just had a major relapse that has left him unable to walk. What is the standard therapy for this type of acute relapse and what is the postulated mechanism of action?
9. If the previous scenario had been your sister rather than your brother, would the prognosis have been different?
10. Your brother continues to progress rapidly with no apparent remission even on standard immunotherapy for RR-MS. What therapy is FDA approved for rapidly progressing MS?

43.14 Answers

1. The CHAMPS study showed that patients who were started on Avonex with your brother's symptoms had a 1% risk of meeting criteria for definitive MS in 18 months compared to a 16% risk for those who did not begin therapy.
2. The presence of lesions on a brain MRI with and without gadolinium (Gd) to evaluate for the presence of recent and evolving plaques CSF and EMG data are often also used to verify MS.
3. The two FDA approved IFN β -1a products are Avonex® (Biogen-Idex) which is the lowest total weekly dose available at 33mcg IFN β -1a to be injected intramuscularly (IM) once a week and Rebif® (Serono) which is available in doses of 22 mcg and 44 mcg for subcutaneous (SQ) injection three times weekly. Both reduce MS relapses significantly. Both have similar side effect profiles. The lower dose may cause fewer side effects but there is also some evidence that the lower the dose the less effective in reducing relapses.
4. If an MRI confirms the presence of active lesions, and your brother has clinical verification of at least 2 episodes separated by time in at least two different sites. MacDonald criteria are met.
5. There should be evidence of lesions within the brain or spinal cord as a result of the recent exacerbations. Since they are relatively recent, one would expect Gd to infil-

trate the brain parenchyma through breaches in the cerebrovascular endothelium.

6. There are several options that should be discussed with his neurologist. He could first try pre-medicating with an over the counter NSAID before his weekly injection. Ibuprofen and naproxen are effective in alleviating some flu like symptoms in some patient. If that is not effective, there is also evidence that oral corticosteroids taken in conjunction with the IFN β injection will decrease the inflammatory side effects. The other possibility is to change to a non IFN β therapy. Glatiramer acetate (Copaxone[®]) has a similar efficacy profile without the flu like side effects.
7. Prior to approval of the current therapies, life expectancy from MS was only decreased by 2–3 years. Since the longest any approved therapy has been available is approximately 10 years, there is no additional information available. In general with all things considered, his expectancy should not be significantly different that yours.
8. The standard of therapy is a Methyl prednisolone (Solu-Medrol[™]) with IV treatment for 3–5 days at 500–1000 mg/day. There is no evidence that steroids reduce the relapse rate but they are effective in treating the acute inflammation.
9. Men often have a more aggressive and progressive MS than women. With frequent clinical and MRI monitoring to determine if the current therapy is adequate, his prognosis should be better than if he were diagnosed 10 years ago.
10. The only FDA approved therapy is mitoxantrone (Novantron[®]) with a recommended dosage for treatment of multiple sclerosis at 5–12 mg/mL IV every 3 months. Acute side effects of mitoxantrone include nausea and alopecia. Because of cumulative cardiotoxicity, the drug can be used for only 2–3 years (or for a cumulative dose of 120–140 mg per m²).

Abstract

HIV-associated neurocognitive disorders follows viral invasion of the central nervous system and can lead to impairments in memory, problem solving, behavior and decision making capabilities. Disease is divided into asymptomatic neurocognitive impairment, mild neurocognitive disorder and HIV-associated dementia. In an advent of combination antiretroviral therapy disease severity has been attenuated with mild dysfunction becoming the prominent feature. Also operative has been the emergence of confounders and comorbid conditions that may cause cognitive impairments and behavioral deficits such as depression, liver disease, drug toxicities and nutrition. This chapter serves to review the virologic and immune disease parameters, disease diagnosis, antiretroviral and adjunctive therapeutic considerations to combat disease.

Keywords

Antiretroviral therapies • HIV-associated neurocognitive disorders • HIV-replication • Neuroimaging

44.1 Introduction: HIV-Associated Neurocognitive Disorders (HAND)

According to recent estimates, over 35 million people are currently living with HIV-1 worldwide (WHO 2014). Estimates for the lifetime prevalence for neurologic consequences of HIV involving the central nervous system (CNS) and peripheral nervous system (PNS) are between 40 and 70 % of HIV-infected individuals (McArthur et al. 2005; Simioni et al. 2010). With ART treatment, the rates of opportunistic infections of the CNS and PNS have been reduced

(Mamidi et al. 2002; Habata et al. 1999; Roulet 1999), however the prevalence of neurological disorders directly caused by HIV have increased (Antinori et al. 2007). HIV infection can directly cause peripheral neuropathy, vacuolar myelopathies, and HAND even in immune-competent hosts (Childs et al. 1999; McArthur et al. 2003, 2005; Antinori et al. 2007).

HIV-Associated Neurocognitive Disorders (HAND) encompass a spectrum of cognitive impairment with sub-syndromes of varying severity. These include asymptomatic neurocognitive impairment (ANI), mild neurocognitive disorder (MND), and HIV-associated dementia (HAD), which are characterized by cognitive, motor, and behavioral abnormalities (Kaul et al. 2005) and are classified by patient neuropsychological test performance and neurological and behavioral functioning (Table 44.1) (Antinori et al. 2007). HIV-associated asymptomatic neurocognitive impairment (ANI) is the least severe form of HAND and includes individuals with only mild cognitive impairment in neuropsychological testing and without functional impairment in daily activities. In HIV-associated MND, individuals have a higher level of cognitive impairment, which interferes with

Table 44.1 Diagnostic criteria of HAND

HAND diagnosis	Functional status	Neuropsychological testing criteria
Asymptomatic neurocognitive impairment (ANI)	Mild cognitive impairment with no effect on ADLs	Below 1 SD in ≥ 2 of 5–7 domains
Minor neurocognitive deficit (MND)	Mild cognitive impairment with impact on ADLs	Below 1 SD in ≥ 2 of 5–7 domains
HIV-associated dementia (HAD)	Marked cognitive impairment with marked impact on ADLs	Below 2 SD in ≥ 2 of 5–7 domains

ADLs activities of daily living, SD standard deviation

daily functioning, as determined by self-reporting or by observation of others. HAD, the most devastating form of HAND has been considered a late complication of HIV infection, often in the setting of uncontrolled viremia and severely depleted CD4+ T-cell counts. In HAD, cognitive impairment is associated with marked interference with day-to-day functioning and HAD is considered a significant independent risk factor for death due to AIDS (Liner et al. 2008).

44.1.1 Role of HIV Replication in HAND

HIV enters the CNS compartment early in the course of infection and yet not all HIV+ individuals go on to develop HAND. Understanding how HIV replicates in the CNS compartment, the role of ART in suppressing the CNS reservoir and the circumstances that promote neurocognitive deficits are necessary for developing effective therapeutics. Recent studies confirm early entry (within weeks of systemic infection) of HIV into the CNS, and these studies have also confirmed a predominance of T lymphocyte-tropic R5 HIV strains in the CSF of newly-infected individuals, with a later increase in the prevalence of macrophage-tropic R5 variants (Sturdevant et al. 2015). These findings suggest infiltration of HIV-infected T lymphocytes into the CNS early after initial infection and throughout the course of later infection, with adaptation of virus to replication in brain macrophages in at least some individuals (Sturdevant et al. 2015). Predicting which infected individuals are at high risk for developing HAND based upon early entry events remains uncertain, but certainly worthy of intensive study.

HIV infection in the CNS can be clinically silent throughout the infection course, as is evident by the number of HIV+ patients lacking neurocognitive deficits. However, even those who are virally suppressed by ART are at risk for developing HAND, and this risk is most strongly linked to the individual's historic CD4 T lymphocyte nadir (Ellis et al. 2011). A recent study examined the prevalence of neurocognitive deficits in patients with undetectable serum HIV RNA over a median time of 48 months. Within this cohort, 27% had cognitive complaints and within this group, HAND was diagnosed in 84% (ANI 24%, MND 52% and HAD 8%). Of the 73% of patients without cognitive complaints, an additional 64% were found to have HAND on formal neuropsychological

testing (ANI 60%, MND 4% and HAD 0%) (Simioni et al. 2010). Furthermore, data suggest that neurological injury can progress even while patients are on virally suppressive ART. A recent review summarizes studies that demonstrate significantly elevated CSF neurofilament light-chain (NFL, a specific biomarker of neuronal injury) not only in ART-naïve individuals but also in individuals on suppressive ART, in comparison with age-matched HIV-negative controls (Jessen Krut et al. 2014). Additional evidence indicates that neuronal damage affected prior to initiation of ART is not fully reversible (Tozzi et al. 2007). In a cohort of individuals with AIDS, 21% of those who had undetectable blood and CSF HIV RNA progressed to HAD (Sevigny et al. 2007). And initiation of neuronal damage and clinically evident HAND can occur before AIDS criteria are met, as is evident by a prospective study that identified HAND in 8–34% of aviremic patients who had no comorbidities and with a CD4 nadir of greater than 200 cells/ μ L (Cysique et al. 2006). As such, HAND cannot be mediated simply by uncontrolled HIV replication in the CNS compartment and the neuropathogenesis of this syndrome must take into account accumulating neuronal damage even in the absence of clinically detectable HIV replication. These new insights underscore the need for adjunctive neuroprotective therapies, as there are no current therapies for improving neurologic outcomes other than ART, which targets only viral replication (Sacktor et al. 2002; Antinori et al. 2007; Brew 2004).

44.2 The Role of Neuroimaging in the Diagnosis of HAND

Apart from neuropsychological testing, which assesses current HAND symptoms and signs; there is limited evidence to support predictive usefulness of either serum or CNS biomarkers in detecting the risk for development of HAND. The most promising biomarker, which has only been validated for CSF, is neurofilament light-chain (NFL). This is a marker for axonal injury but it is not specific to HIV-induced injury (Gisslen et al. 2007, 2009). Neuroimaging has been investigated for the diagnosis and staging of HAND, and for monitoring the CNS response to therapy. Additionally, neuroimaging has been utilized in assessing for other causes of neurocognitive dysfunction in HIV+ patients, including

CNS lymphoma, PML, cerebral toxoplasmosis and other opportunistic infections that have distinct abnormalities.

Throughout the course of HAND, cerebral atrophy is greater than predicted by age, although cerebral atrophy is not a specific to HIV infection alone, as it can occur with associated nutritional deficiency or drug and alcohol abuse. However, characteristic magnetic resonance imaging (MRI) signal changes due to HIV are often observed both within subcortical (basal ganglia) and cortical (frontal grey/white matter and posterior grey matter) compared to HIV-controls (Aylward et al. 1995). A newer MRI study has revealed loss of structural integrity and micro-edema in the global white and cortical gray matter, as well as in the thalamus and basal ganglia in MND patients compared to controls (Granziera et al. 2013). Multiple regression analysis showed a significant interaction of subcortical nuclei changes and executive indices in HIV+ patients with MND, suggesting that multi-contrast MRI at high field strength may be able to differentiate ART-treated HIV+ patients with mild neurocognitive deficits from those without (Granziera et al. 2013).

Functional MRI (fMRI) is used to examine the hemodynamic response related to neural activity, and impairment of normal recruitment of brain regions suggests brain dysfunction. Using this technique, it has been shown that HIV+ individuals have greater parietal activation for a simple attention task and greater frontal and parietal activation during more complex tasks (Chang et al. 2001). This is believed to represent evidence of modulation of neural circuits during HIV infection and greater use of brain reserve in order to meet cognitive demand. A recent meta-analysis of fMRI studies examining the fronto-striatal-parietal network revealed functional differences in the left inferior frontal gyrus and caudate nucleus and this dysfunction was qualitatively related to neurocognitive impairment (Plessis et al. 2014). Additionally, baseline functional connections may be compromised in HAND, in a similar way to those seen in normal aging (Thomas et al. 2013). With future studies, fMRI may be able to better characterize the networks involved in the cognitive decline during HIV infection and could then be utilized to monitor progression and efficacy of therapeutics.

MR Spectroscopy (MRS) adds additional information to traditional MRI by determining the relative concentrations of target brain metabolites. *N*-acetyl-aspartate (neuronal marker), choline (marker of cellular proliferation and inflammation), creatinine (brain metabolism and reference marker) and myoinositol (marker of gliosis) are the most commonly measured. Early after seroconversion, MRS metabolites are altered (Lentz et al. 2011) with neuroimaging alterations correlating with inflammation and neuronal injury (Valcour et al. 2012; Sailasuta et al. 2012). HIV+ patients with chronic infection have reduced levels of *N*-acetyl-aspartate (NAA) and increased choline and myoinositol (Harezlak et al. 2014; Paul et al. 2008; Yiannoutsos et al. 2008). However, many of

these same alterations are seen with aging, making it a more relevant examination for younger HIV-infected individuals.

Fluorodeoxyglucose-positive emission topography (FDG-PET) imaging is used to measure metabolic activity in neurons. Studies have identified two unique metabolic signatures in HIV infection. First, there is evidence of a hypermetabolic state, especially prominent in the striatum, which appears to be specific for HIV infection and CNS involvement, even in the setting of normal neuropsychological performance testing. This has been seen as evidence of abnormal functional connectivity within subcortical areas in the setting of HIV infection (von Giesen et al. 2000). Secondly, in chronic infection, there is generalized hypometabolism in cortical and subcortical regions, which correlate with, age, extent of cerebral atrophy and neurocognitive status (Rottenberg et al. 1996). A transition from a hypermetabolic state to a hypometabolic one in subcortical regions was associated with the development of functional deficits and progression to HAD (von Giesen et al. 2000). Even in the ART era there are subtle FDG-PET changes that have been observed, with at least half of virologically suppressed HIV+ individuals on ART having evidence of hypometabolism in the mesial frontal lobes (Andersen et al. 2006). Interestingly, a significant age effect has been demonstrated in frontal brain regions suggesting a synergistic interaction between aging and HIV (Towgood et al. 2013). As neuroimaging techniques continue to advance, it is hoped that they can be used to diagnose HAND, characterize its severity and evaluate the efficacy of novel therapeutic candidates in longitudinal studies.

44.3 HAND in the Era of Antiretroviral Therapy (ART)

The largest and most comprehensive cross-sectional study examining the prevalence of cognitive impairment in HIV+ infection is the CNS HIV Antiretroviral Therapy Effects Research (CHARTER) cohort study. Cognitive impairment was found in 814 (52%) of 1555 HIV seropositive patients attending treatment centers in the United States and reflects all causes of impaired cognitive function in HIV+ individuals (Heaton et al. 2010). While the most severe form of cognitive impairment, HAD, was rare, the milder categories of ANI and MND remained common even in those receiving ART and with minimal comorbidities.

44.3.1 The Effectiveness of ART in HAND

Since the introduction of ART, there has been a profound reduction in the incidence of HAD from approximately 20% in the pre-ART era to a current prevalence of between 2 and 5% (Heaton et al. 2010). This reduction due to ART represents

Fig. 44.1 Prevalence of HIV-associated neurocognitive disorders in the USA after introduction of ART in patients without confounding comorbidities (CHARTER study, $n=1316$) (Heaton et al. 2010). *NCN* neurocognitive normal, *ANI* asymptomatic neurocognitive impairment, *MND* mild neurocognitive impairment, *HAD* HIV-associated dementia

the only consistent therapeutic treatment success for HAND patients to date. However, the prevalence of MND and ANI has increased in the ART era (reviewed in Nightingale et al. (2014)). While estimates of the prevalence of HAND vary, it is evident that HIV-associated neurocognitive impairment does persist, even in those with virologic suppression on ART. In the CHARTER cohort study, prevalence estimates were 33% for ANI, 12% for MND, and 2% for HAD (Heaton et al. 2010) (Fig. 44.1).

Failure of consistent suppression of viral replication with ART could contribute to HAND persistence. With ART treatment, many patients have shown durable and complete suppression of HIV replication as determined by plasma viral RNA quantification, although a surprisingly high overall rate of HIV ‘blipping’ (defined as spontaneous expression of viral RNA copies (plasma, CSF)) in individuals on ART with sustained antecedent undetectable VLs with return to undetectable levels (Grennan et al. 2012) of up to 25% has been reported. This suggests that ART efficacy in maintaining consistent viral suppression has been overestimated, and that viral ‘blipping’ in ART-treated patients might represent a risk factor for HAND (Chen et al. 2014).

An additional concern for patients who are now being maintained on ART for decades is the possibility of ART neurotoxicity. Long-term treatment with ART has been demonstrated to have a range of systemic side effects including hepatic steatosis, peripheral neuropathy, cardiomyopathy, pancreatitis, ototoxicity, retinal lesions and lipodystrophy. Complete suppression of HIV replication in the CNS reservoir has been limited, in part due to the poor blood–brain barrier penetrance of ART. As new compounds, regimens and methods are developed to increase the penetrance of antiretroviral compounds, consideration will have to be given to the possibility of direct neurotoxicity by these compounds.

There is known to be substantial variation in the toxicity of various NRTIs in different tissue types and thus far, relatively little is known about the possibility of antiretroviral toxicity within the CNS compartment. In vitro work has demonstrated that several of the first line antiretroviral agents cause direct neurotoxicity when used at concentrations seen in the CSF of patients on ART (Robertson et al. 2012). Further work is needed to determine if ART causes a similar effect in the CNS of patients on long-term ART and if and how boosting CNS penetrance of these antiretrovirals alters neuronal function and cognition.

44.3.2 ART Treatment Strategies

While ART has significantly decreased the incidence of HAD, presumably by lowering systemic and CNS viral loads, more recent efforts have focused on improving the penetration of ART past the blood brain barrier. In theory, improved penetration or retention of bioavailable ART drugs in the CNS would slow HAND progression by decreasing CNS viral replication and reducing concomitant release of neurotoxins from infected and activated macrophages/microglia and immune activated astrocytes (Letendre et al. 2008; Ellis et al. 2007; Spitznberger et al. 2007). However, clinical trials have been unable to reduce the incidence or progression of HAND in patients treated with ART regimens with high CNS penetrance efficacy (CPE) (Reviewed in Nightingale et al. (2014)). Additionally, there is some evidence to suggest that increasing ART penetrance into the CNS may be detrimental. A 2009 study by Marra *et al.* suggested that ART regimens with strong CNS penetration and reduced CSF viral loads were associated with poorer neurocognitive outcomes (Marra et al. 2009). While further clinical studies are needed, this study highlights the importance of considering drug toxicity when promoting ART in the CNS. More recently, it has been proposed that choosing ART regimens based upon their efficacy in reducing HIV replication in monocyte and macrophage lineages may be more efficacious in targeting HAND pathogenesis (Shikuma et al. 2012). Effective therapies for HAND will likely require combination therapy that not only targets viral replication in the relevant cell populations in the CNS, but also addresses the indirect pathways known to contribute to HIV-associated neurodegeneration.

44.3.3 Viral ‘Blipping’ in ART-Treated Patients

Further research is underway to examine the relationship between CSF viral replication in systemically controlled HIV+ patients maintained on ART and its potential link to HAND. The term “viral blipping” has been applied to the observation that HIV RNA has been intermittently detected

at low-levels when assayed in the serum and/or CSF of HIV+ patients maintained on therapeutic ART. Up to 25 % of ART treated individuals may show non-sustained viral blipping in the plasma and it has been estimated that 10–30 % of patients who have clinical suppression of HIV replication by serum measurements have detectable CSF HIV RNA (Grennan et al. 2012). This suggests that ART, while extremely effective, cannot currently eliminate all viral replication and that the CNS can be a privileged reservoir that should be considered independently of the systemic compartment (Eden et al. 2010).

The role of viral blipping remains undetermined, as does its potential link to neuroinflammation pathways and development of HAND. A recent study has proposed that plasma HIV blipping contributes to immune activation, as measured by increased T cell activation. HIV+ patients on ART were characterized as blippers (having a one time viral load between 50 and 1000 copies/mL following at least 180 days of undetectable VL) or non-blippers. Patients with plasma viral blips showed increased T-cell activation compared to those without blips (Zoufaly et al. 2014). While this study was assaying peripheral markers of immune activation, it suggests that a similar mechanism may be occurring in the CNS within HIV-infected monocytes/macrophages and that this may contribute to neurocognitive deficits and disease progression. In a small study of 11 patients by Canestri et al., CSF samples of HIV-suppressed individuals with neurologic symptoms were collected and monitored for viral blipping. Of these 11 patients, 10 had evidence of pleocytosis in their CSF, suggesting an association between CSF blipping and inflammation in the CSF (Canestri et al. 2010). Additionally, ART resistance mutations were found in seven of eight CSF specimens supporting the theory that blipping is associated with increased duration of ART and the emergence of ART resistance (Eden et al. 2010; Pozniak et al. 2009). As these patients did not undergo neuropsychological testing, the link between viral blipping in the CNS, neuroinflammation and presence of HAND remains speculative.

The presence of these viral blips have been controversial with suggestion that they could promote changes in immune responses for better control of HIV infection while an opposing hypothesis states that they predict an increased risk of virological failure. In a retrospective analysis of an ART interruption study, it was found that individuals with plasma blips (termed episodes of intermittent viremia) above 200 copies/mL had lower CD4+ T cell counts and higher activation markers while receiving ART. After ART interruption, these individuals had a significantly higher viral rebound despite having a greater specific immune response against HIV. Of note, most of these differences disappeared when smaller blips of 20–200 copies/mL were included (Castro et al. 2013). Taken together, this study provides evidence that blipping can drive immune activation and also that the

magnitude of the blip can determine future virological failure. Given the prevalence of viral blipping and ongoing evidence of neuroinflammation in HIV+ individuals on ART, it is unlikely that ART will ever be a monotherapy for HAND, and as such, development of adjunctive therapeutics will be necessary to mitigate cognitive sequelae of HIV infection.

44.4 Proposed Adjunctive Therapies in HAND

Initially, known therapeutics for other neurodegenerative and neuropsychiatric disorders were trialed in HAND. Specifically, medications with FDA approval for use in Alzheimer's and Parkinson's disease have been examined. Mood stabilizers, antidepressant medications and antioxidants have also been investigated.

44.4.1 Therapies Applied to Other Neurodegenerative Diseases and HAND

Noted clinical similarities between the neurodegeneration seen as a consequence of HIV infection and other neurodegenerative diseases such as Alzheimer's and Parkinson's has prompted investigation into the currently approved neuroprotective therapies in the treatment of HAND (Table 44.2). Memantine (Namenda) is approved in the treatment for Alzheimer's disease and acts as a non-competitive NMDA receptor antagonist. In vitro and in vivo animal studies have shown that memantine inhibits gp120 and Tat-induced neurotoxicity (Nath et al. 2000a; Anderson et al. 2004; Toggas et al. 1996) and in a SIV-infected macaque model, increases levels of brain-derived neurotrophic factor (BDNF) and conserves dopamine function (Meisner et al. 2008). A short term clinical trial in HAND patients demonstrated that memantine improved neuronal metabolism, indicative of neuroprotection, but did not cause significant neurocognitive improvement (Schifitto et al. 2007a). A longer-term follow up study in this patient cohort failed to reveal a clinically demonstrable neurological benefit (Zhao et al. 2010).

Selegiline (Deprenyl), a monoamine oxidase B (MAO-B) inhibitor used in the treatment of early-stage Parkinson's disease, is proposed to act as a neuroprotectant by reducing the antioxidant burden of the cell (Magyar and Szende 2004). However, recent studies have shown neither a reduction in biomarkers of oxidative stress nor evidence of cognitive improvement with short-term (24 weeks) transdermal selegiline (Schifitto et al. 2007b, 2009a). Rivastigmine, an acetylcholinesterase inhibitor approved for Alzheimer's and Parkinson's disease, was examined in a 20 week, placebo controlled crossover study in aviremic HIV patients with HAND. While there was no change in the primary outcome

Table 44.2 Proposed therapeutics for HAND

Generic (Brand) name	Molecular target	Proposed effects	References
Memantine (Namenda)	NMDA receptor antagonist	Increases BDNF levels, conserves dopamine function, inhibits gp120 and Tat-induced neurotoxicity, improves neuronal metabolism, short-term treatment provided no neurocognitive improvement	Meisner et al. (2008), Nath et al. (2000b), Toggas et al. (1996), Anderson et al. (2004), Schifitto et al. (2007a) and Zhao et al. (2010)
Selegiline (Deprenyl)	MAO-B Inhibitor	Proposed to reduce antioxidant burden of cell, may improve psychomotor speed, no clinical evidence of cognitive improvement over 24 week treatment	Sacktor et al. (2000), Magyar and Szende (2004), Schifitto et al. (2009a) and Schifitto et al. (2007b)
Rivastigmine (Exelon)	Acetylcholinesterase inhibitor	Proposed to increase acetylcholine levels in the CNS. Improved processing speed and possible effect on executive functioning after 20 week treatment	Simioni et al. (2013)
Sodium valproate (Depakote) and lithium	GSK-3 β inhibitor	Reduces neurotoxicity, improved neuropsychological performance	Ances et al. (2008), Tong et al. (2001), Dou et al. (2003), Everall et al. (2002), Schifitto et al. (2006), Letendre et al. (2006) and Schifitto et al. (2009b)
SSRIs: Citalopram (Celexa), Paroxetine (Paxil)	Serotonin transporter	May decrease HIV viral levels in CSF, improved adherence to ART	Ances et al. (2008) and Letendre et al. (2007)
Minocycline	5-lipoxygenase and others	Decreases CCL2 levels in CSF, suppresses HIV replication and inhibits secretion of TNF- α , IFN- γ and IL-2 by lymphocytes	Copeland and Brooks (2010), Colovic and Caccia (2003), Si et al. (2004), Zink et al. (2005) and Szeto et al. (2010)

of cognition, processing speed improved and there was a possible, albeit non-significant effect, on executive functioning (Simioni et al. 2013). While memantine, selegiline and rivastigmine have shown some limited effectiveness, they are clearly not suitable monotherapies for HAND. In addition to using such drugs prior to neurocognitive decline, effective neuroprotective therapies will likely have to be used in combination with ART and over the duration of viral infection to provide maximal clinical benefit.

44.4.2 Therapies Applied to Neuropsychiatric Disorders and HAND

In addition to therapies for neurodegenerative diseases, compounds in clinical use for neuropsychiatric disorders are also under investigation in HAND (Table 44.2) (Ances et al. 2008). Sodium valproate (VPA) and lithium are approved for treatment of bipolar disorder and related mood disorders, and both inhibit glycogen synthase kinase-3 β and provide neuroprotection against HIV-induced toxicity in vitro and in mouse models of HIV encephalitis (Tong et al. 2001; Dou et al. 2003; Everall et al. 2002). Several small pilot studies have demonstrated improved neuropsychological performance in HAND patients following short-term VPA or lithium therapy (Schifitto et al. 2006, 2009b; Letendre et al. 2006). Additional studies using selective serotonin reuptake inhibitors (SSRIs), including citalopram and paroxetine are also under consideration as adjunctive therapies for HAND (Ances et al. 2008; Letendre et al. 2007). SSRIs were predicted

to directly decrease levels of HIV replication, although clinical trials have not yet found a significant improvement when an SSRI is used as an adjunctive therapy (Benton et al. 2010; Horberg et al. 2008). However, using an SSRI or other antidepressant medication in order to treat clinical depression in HIV+ individuals increases ART compliance and thereby improves virologic control, immune status, and would be predicted to improve cognitive functioning (Horberg et al. 2008).

44.4.3 Other Tested Therapies for HAND

Other adjunctive therapies for HAND are focused on targeting inflammation cascades that contribute to neurotoxicity. Minocycline is a broad-spectrum tetracycline antimicrobial that is capable of efficiently crossing the blood–brain barrier and suppressing HIV replication in microglia, macrophages and lymphocytes; the cell types mediating the neuropathogenesis of HAND (Colovic and Caccia 2003; Si et al. 2004; Zink et al. 2005; Szeto et al. 2010). In addition, minocycline has anti-inflammatory and antioxidative properties and can inhibit the secretion of the inflammatory cytokines including TNF- α , IFN- γ , and IL-2 by lymphocytes (Szeto et al. 2010). Experimental studies using SIV-infected macaques demonstrated that minocycline decreased CSF levels of CCL2, a marker of CNS inflammation, and decreased the severity of encephalitis (Zink et al. 2005). However, a 24-week clinical trial in which 73 ART-naïve, HIV+ patients were treated with minocycline demonstrated no improvement in cognitive functioning (Nakasujja et al. 2013). However, analysis of

CSF from a subset of patients demonstrated a significant reduction in lipid markers of oxidative stress (ceramides) in those who were treated, suggesting that a longer minocycline treatment period should be considered (Sacktor et al. 2014).

44.5 Current Therapeutic Considerations

Several new antiretroviral therapies, including integrase inhibitors and virus entry inhibitors, are now available clinically and are being investigated as therapeutics in HAND. Other active therapeutic considerations include inflammation, the immune response and oxidative stress.

44.5.1 Modified ART Regimens: Integrase Inhibitors

There are several novel ART-based therapeutic regimens and treatment strategies that are under current investigation for HAND. Raltegravir (Isentress), an integrase inhibitor, is being investigated as a potential neuroprotectant when used as part of intensification therapy in individuals with suppressed viral loads on ART. Theoretically, raltegravir when added to traditional ART regimens would reduce infection of healthy cells from chronic and latently infected cells replicating virus at low levels. In a small clinical trial (NCT00672932), raltegravir was added to home ART regimens for a 12-week period of time and CSF markers of immune activation and inflammation (neopterin) and blood CD8+ T cell activation (co-expression of surface CD38 and HLA-DR) was assessed. There was no significant difference observed in these domains after 12-weeks of intensification therapy with raltegravir (Dahl et al. 2011). A clinical trial was terminated due to inability to successfully recruit patients (NCT01448486) and as such, no clinical data linking raltegravir intensification therapy with neurocognitive performance is available.

44.5.2 Modified ART Regimens: Chemokine Receptor Blockade

The monocyte-derived brain macrophage and infiltrating T lymphocytes have each been proposed as potential HIV brain reservoirs, and as such each could be considered a critical target for novel therapeutics in HAND (Sturdevant et al. 2015). Accordingly, maraviroc (Selzentry) a CCR5 receptor antagonist and entry inhibitor is under active investigation. In a single arm, open-labeled trial, maraviroc was used in intensification therapy in 15 HIV+ individuals who had undetectable plasma VL and detectable monocyte HIV DNA (>10 copies/10⁶ cells). After 24 weeks of treatment, there was a
